We dedicate this book to Dr. Darcy Umphred, who has inspired generations of physical and occupational therapists to ask brave questions, to trust in the wisdom of patients, and to value acts of kindness both large and small. The work completed for this seventh edition is an expression of the gratitude we feel for Darcy's devotion to the rehabilitation professions. The host of esteemed colleagues who have contributed their knowledge to this edition is a testimony to Darcy's legacy in the neurologic rehabilitation community.

RTL, SRG, MQ

Personally, to me this book has signified love, dedication, commitment, perseverance, resilience, grit, kindness, and understanding—all of which I have learned from my mother. I dedicate this book and all that it stands for to her.

RTL

I would like to dedicate the work on this book to my husband, Mario, and to our children young and old. The gratitude I have for your love and support was the purest motivation, from beginning to end. To Davis Reina-Guerra, when you went away to college, you gave up your bedroom for my office and shared with me your passion for neuroscience—sparking my own, again. Thank you for lending me your keen student's eye and perspective during the editing process.

SRG

To Diana and Eric, for all the times you've both supported me to pursue my passions of learning and for joining me in all my adventures. To Mom and Dad, for instilling a love for reading, grit, and kindness. This is for you. For all my students and UNTHSC colleagues who continue to push me to be a better teacher, leader, and human being: I'm up for the challenge.

MQ

Over the last 60 years, tremendous changes have occurred in the educational level and research within the professions of physical and occupational therapy. This book has evolved over my lifetime as a physical therapist and movement specialist. In the early 1970's colleagues followed approaches and philosophies developed by master clinicians for treating patients with movement disorders caused by central nervous system (CNS) pathology. Those approaches evolved because master clinicians were experts in analyzing movement and how patients responded to those interventions. Those colleagues analyzed abnormal patterns while their patients tried to perform functional movements. With their understanding of normal movement, they identified what components needed to be corrected and identified ways for those individuals to learn or relearn those functional movements. None of those master clinicians developed those approaches based on neuroscience but instead on movement analysis.

In the 1970's I started developing a model that integrated all the techniques. That model was based on a huge number of types of movement problems presented, such as instability of the scapula, poor postural tone or co-activation of the trunk, lack of neck stability, abnormal extensor or flexor tone in the leg, lack of adequate range or power problems, and others. Also, I tried to analyze how those movements changed in various spatial and functional positions. That model was based on the integration of three very different conceptual frameworks. One was based on the science or current research on the brain, which is and will always be constantly changing but continues to explain why specific movement problems develop given the trauma to specific areas of the brain. The second focused on how and why human movement develops from birth and over the life span. It isn't the position a child uses to develop motor control but how and why the brain uses those patterns to advance motor control and learning to gain upright posture or to regain that function if lost. The third aspect had to do with both the individual patient's internal and external environment as well as that of the clinicians. How the variance in both clinician and patient affected the learning environment and the motivation of the patient to participate is critical.

Empowering colleagues to become critical visual observers of patient movements and behavior in spite of any medical diagnosis seems to be the role of therapists if we are truly movement specialists and are the best professionals to create an environment of learning that

empowers the patient to take control over their own motor system and thus their quality of life.

The first edition of the book was published in 1985. Each edition thereafter has always taken a problem-solving approach to movement dysfunction based on observations following neurological problems. From my experience in the last 60 years, I knew there was something special about the brain's ability to learn in spite of trauma. In the 90's, the term neuroplasticity became common. We all learned that in spite of disease or trauma, individuals can learn to move again. This textbook never has been a cookbook for the treatment of any movement problem associated with brain dysfunction but always has tried to identify environments or potential maps for both the clinician and the patient to analyze the movement dysfunctions presented. Although the available science or research of the time, no matter the edition, has always been integrated into the discussion, that research can only provide recommendations of types of evaluations to use for specific movement problems and various treatment approaches or ideas that have the potential of improving function. The analysis needs to be done by the movement specialist.

Science, research, and clinical strategies today should always be used to help colleagues select best tools and treatment approaches, but we must remember that science is always evolving and will never give us only one answer to a clinical problem. The answer to the clinical problem is within the patient and not the research. We need to continue to develop a movement-based conceptual framework that classifies and identifies variance in normal movement across the lifespan and then analyze what components are missing or substituting in abnormal movements. We need to stop relating our research to specific disease and pathology of the brain and analyze the dysfunction in relation to the area of the brain from which that movement problem arises. We have always been hands-on clinicians. If we ever give up (1) using our hands to feel the problems, (2) analyzing the functional movement problem with our eyes, and (3) interacting with the patient as a whole person and what motivates them, we certainly won't truly be movement specialists. We have the potential to truly become those specialists if we can move away from a medical model of disease/pathology and into a movement classification model that embraces all movement dysfunctions no matter the age or medical diagnosis of the patient.

Darcy A. Umphred

OVERVIEW OF THE SEVENTH EDITION

The seventh edition of the *Umphred's Neurological Rehabilitation* textbook contains several significant changes, but the overlying foundational principle remains the same—that clinicians must have a thorough understanding of the patient/client as a total human being to provide the best care that optimizes the person's health and well-being. We continue to use and expand the clinical problem-solving, diagnosis-prognosis approach that this book has taken since its inception. This book orients the student and clinician to the roles that multiple systems within and outside the human body play in the causation, progression, and recovery process of a variety of common neurological problems. Another objective is to orient the reader to a theoretical framework that uses strategies for **enhancing functional movement, enlarging the individual's repertoire for movement alternatives, and creating an environment that empowers the person to achieve the highest levels of activity, participation, and quality of life.**

Methods of examination, evaluation, prognosis, and intervention must incorporate all aspects of the client's nervous system and consider the influences of the external environment on those individuals. In the clinical management of persons with neurological dysfunctions, it is important to highlight the importance of a team approach in the physical rehabilitation of these individuals.

As to be expected, the foundations for contemporary clinical practice in neurological rehabilitation continue to be in a constant state of evolution, and this book has clearly articulated that evolution throughout its seven editions. This book emphasizes evidence-based clinical practice and guides clinicians to generate new hypotheses when there is an absence of clear evidence to guide practice. It is for that reason that this edition has retained information of conventional approaches that remain commonly used by therapists in the world today.

This book is divided into three sections. Section I provides the foundational knowledge necessary to understand and implement a problem-solving approach to for clinical care across the span of human life. The basic knowledge of the function of the human body in disease and repair is constantly expanding and often is changing in content, theory, and clinical focus. This section reflects that change in both philosophy and scientific research. This section has been designed to weave together the issues and concepts related to evaluation and intervention with components of central nervous system (CNS) function to consider a holistic approach to each patient/client's needs. This section delineates the conceptual areas that permit the reader to synthesize all aspects of the problem-solving process in the care of a client.

Section II is composed of chapters that deal with specific clinical problems, beginning with pediatric conditions, progressing through neurological problems common in adults, and ending with aging with chronic impairments. In Section II, each author follows the same problem-solving format to enable the reader either to focus more easily on one specific neurological problem or to address the problem from a broader perspective that includes life impact. The multiple authors of this book use various cognitive strategies and methods of addressing specific neurological deficits. The seventh edition of the text now contains separate and expanded chapters on Balance

Dysfunctions and Vestibular Dysfunctions. This edition also contains a new chapter on Concussion Management in response to the emerging body of knowledge related to the examination and physical rehabilitation management of this condition.

A range of strategies for examining clinical problems is presented to facilitate the reader's ability to identify variations in problem-solving methods. Many of the strategies used by one author may apply to situations presented by other authors. Just as clinicians tend to adapt learning methods to solve specific problems for their patients/clients, readers are encouraged to use flexibility in selecting treatment interventions with which they feel comfortable and to be creative when implementing any therapeutic plan. Chapters in Section II also include methods of examination and evaluation for various neurological clinical problems using reliable and valid outcome measures. The identification of impairments in body structures and functions, activity-based functional limitations, factors that create restrictions in participation and affect health quality of life, significant outcome measurement tools in neurologic examination, and patient empowerment are critical aspects of each clinical chapter's diagnostic process.

Section III of the text focuses on clinical topics that can be applied to any one of the clinical problems discussed in Section II, such as pharmacology and cardiopulmonary management in neurorehabilitation. Chapters have been updated to reflect changes in the focus of therapy as it continues to evolve as an emerging flexible paradigm within a multiple systems approach. Two additional chapters that were added in the sixth edition were further enhanced in this edition: (1) the chapter on current technology in rehabilitation that discusses the current technology being used to inform the physical rehabilitation management of individuals with neurologic dysfunctions, and (2) the chapter on the use of medical imaging in neurorehabilitation.

We conclude the overview of this text by recognizing the immense contribution of Dr. Darcy Umphred and her significant influence in shaping the foundations for practice in neurological rehabilitation. A majority of the authors in the sixth edition have agreed to update their chapters for this new edition "one last time for Darcy," with many bringing with them new co-authors with the intent of passing on the torch for the succeeding editions. Taking over a textbook that has been exceptionally successful and transformative for the past several decades is an absolutely a daunting task, and the one main reason for this edition's editors and authors in continuing the book is to keep Darcy's voice, vision, and perspective alive for the next generations of students and clinicians. Those of us who have had the honor and privilege of knowing Darcy will forever have the "Darcy" in us—always seeing the patient as a whole person, recognizing the immense effect of the limbic system in movement, constantly striving to give the best care for each patient, and empowering them to take ownership for their health and well-being. We encourage the reader to learn from the concepts presented in the text and more importantly, to understand Darcy's clinical pearls that have been incorporated in each of the chapters.

NEUROLOGICAL REHABILITATION

Foundations of Clinical Practice

Rolando T. Lazaro, Myla U. Quiben, and Sandra G. Reina-Guerra

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Analyze the concepts of a systems model and discuss how cognitive, affective, sensory, and motor subsystems influence normal and abnormal function of the nervous system.
2. Use an efficient and effective physical therapy diagnostic process that is centered on the patient/client management model.
3. Apply the International Classification of Functioning, Disability and Health (ICF) to the clinical management of patients/clients with neuromuscular dysfunction.
4. Discuss the evolution of enablement, health classification models, neurological therapeutic approaches, and health care environments in the United States and worldwide.
5. Discuss the interactions and importance of the patient, therapist, and environment in the clinical triad and the generation of movement.
6. Consider how varying aspects of the clinical therapeutic environment can affect learning, motivation, practice, and ultimate outcomes for patient/client.
7. Define, discuss, and give examples of a holistic model of health care.
8. Describe the relevance of the movement system to the practice of physical therapy.

patient/client management model

WHAT ARE THE FOUNDATIONS OF CLINICAL PRACTICE IN NEUROLOGICAL REHABILITATION?

The foundations of physical¹ (PT) and occupational² (OT) therapy practice are continuously being retooled. Even at the writing of this edition, professional leaders are still working to refine the *identity* of their respective professions to clarify the core knowledge and skills a therapist should possess. This clarification is necessary to justify consumer access to therapy services, to improve entry-level professional education, and to convey to society the professions' commitment to improve health, function, and quality of life for all. Both professions face the challenges of the current health care climate, which demands therapeutic care models that are efficient, cost-effective, and result in measurable outcomes.³ In the particular branch of neurological rehabilitation, practitioners must be skilled not only in the choice and application of system-specific interventions but also in their understanding of the patient's/client's function in all aspects, including the central nervous system (CNS) as a movement control center. In this chapter, five foundational elements will be discussed: the complexity of the CNS; professional

roles in rehabilitation for the patient with neurological conditions; the movement system and the PT's identity; models and constructs for the different elements of the patient care management cycle and the practitioner-patient partnership.

COMPLEXITY OF THE NERVOUS SYSTEM AS A CONTROL CENTER

The concept of the CNS as a control center is based on a therapist's observations and understanding of the sensory-motor performance patterns that are reflective of that system. This understanding requires an in-depth background in neuroanatomy, neurophysiology, motor control, motor learning, and neuroplasticity, and gives the therapist the basis for clinical application and treatment. Understanding the intricacies and complex relationships of these neuromechanisms provides therapists with direction as to when, why, and in what order to use clinical interventions. Motor behaviors emerge based on maturation, potential, and degeneration of the CNS. Each movement behavior observed, sequenced, and integrated as part of the intervention strategies should be interpreted according to neurophysiological and

neuroanatomical principles, as well as the principles of learning and neuroplasticity. As science moves toward a greater understanding of the neuromechanisms by which behaviors occur, therapists will be in a better position to establish efficacy of intervention. Unfortunately, our observation of behavior is ahead of our understanding of the intricate mechanisms of the CNS that create it. Thus the future will continue to expand the reliability and validity of therapeutic interventions designed to modify functional movement patterns as we better understand the neuromechanisms responsible for the change. First, therapists need to determine what interventions are effective within a clinical environment. Then the efficacy of specific treatment variables can be studied and more clearly identified. The rationale for the use of certain treatment techniques will likely change over time as we better understand the CNS.

PROFESSIONAL ROLES IN NEUROLOGICAL REHABILITATION

Identity, Efficacy, and Advocacy

The rich history of neurological rehabilitation was built upon the foundation of master clinicians who developed unique models of therapeutic interventions through well-honed observations of human movement and how impairments in the neuromusculoskeletal system alter motor behavior and functional mobility. These approaches include those developed by Ayers (sensory integration), Bobaths (Neuro Developmental Treatment [NDT]), Brunnstrom (movement therapy approach), Feldenkrais (Functional Integration and Awareness Through Movement), Knott and Voss (Proprioceptive Neuromuscular Facilitation [PNF]), and Rood (Rood's sensorimotor approach), among others. These were the first behaviorally based models introduced within the health care delivery system, and they have been used by practitioners within the professions of physical and OT since the middle of the 20th century. These individuals, as master clinicians, tried to explain what they were doing and why their respective approaches worked using the available science of the time. From their teachings, various philosophical models evolved. These isolated models of therapeutic intervention were based on successful treatment procedures as identified through observation and described and demonstrated by the teachers of those approaches. In the decades that followed, content related to these techniques has been taught as individual units; many continuing education courses still teach these specific techniques individually. The general model of health care delivery under which these approaches were used was the allopathic model, which began with physician-diagnosed disease and pathology. Various models of health care delivery will be discussed in later sections of this chapter.

In a broader sense, the roles of PTs and OTs in neurological rehabilitation have moved beyond impairment-based interventions. Because a specific treatment has a potential effect on multiple body systems and interactions with the unique characteristics of each patient/patient clinical problem, establishing efficacy for interventions is extremely difficult. The rationale often used to explain the effectiveness of interventions was based on an understanding of the nervous system as described in the 1940s, 1950s, and 1960s. That understanding has dramatically changed; although this does not negate the potential usefulness of any treatment intervention, it does create a dilemma regarding efficacy of practice.

Efficacy has been defined as the “ability of an intervention to produce the desired beneficial effect in expert hands and under ideal circumstances.”⁴ When any model of health care delivery is considered, the question the therapist must ask is “Which model will provide the most

efficacious care?” Therapists are not responsible for the diagnosis of a pathological disease, but they are in a position of responsibility to examine body systems for existing impairments, to analyze movement, and to determine appropriate interventions for activity-based functional problems. Some differences in this responsibility may exist between practice settings. In selecting the most appropriate examination tools, the therapist must consider several issues independently or in combination: existing levels of evidence, applicability to the setting and population, practicality, availability of norms, and a test's clinical properties.

Within some hospital-based systems, therapists may be expected to use specific tools that are considered a standard of care for that facility, regardless of the applicability and evidence. In some hospitals and rehabilitation settings, a clinical pathway may be used that defines the roles and responsibilities of each person on a multidisciplinary team of medical professionals that may limit the decision making process. The therapist is strongly encouraged to use existing evidence, to consider all the issues related to selecting the most appropriate tests and measures, and to reflect on their own professional values during the decision making process.

Regardless of which clinical setting or role the therapist plays, it is always the responsibility of the therapist to be sure that the plan of care meets the needs of the patient/client, challenges the patient/client to progress appropriately, and renders successful outcomes. If the needs of the particular patient/client do not match the progression of the pathway, it is the therapist's responsibility to recommend a change in the patient's/client's plan of care. Efficacy does not come because one is *taught* that an examination tool or intervention procedure is efficacious; it comes from the judicious use of tools to establish impairments, activity limitations, and participation restrictions, to identify movement diagnoses, to create functional improvements, and to improve quality of life in individuals who come to us for therapy. When a holistic view of the patient/client is the foundation in therapy, it is apparent that outcome tools are not yet available to simultaneously measure the interactions of all body systems, making it difficult to apply models that purport to balance quality and cost of care. We must guard against the tendency to default to a narrow bank of “efficacious” interventions and measurement tools, and to the exclusion of techniques that have clinical effectiveness.

Evidence-based practice is basic to the care process.⁵⁻⁷ Therapists should always be able to defend their choice and use of intervention approaches; this becomes even more relevant as the cost of health care rises. Clinicians need to identify which of their therapeutic interventions have demonstrated positive outcomes for particular clinical problems or patient populations and which have not.⁸ Those that remain in question may still be judged as useful. The basis for that judgment may be a patient satisfaction, an outcome that has become a critical variable for many areas in health care delivery^{9,10} with a growing body of supportive evidence.¹¹⁻¹⁵ A discussion of patient satisfaction will be expanded in following section on the patient-practitioner relationship.

The potential for OTs and PTs to become primary providers of health care in the 21st century is becoming a greater reality (e.g., within the military system as well as in some large health maintenance organizations [HMOs]).¹⁶⁻²¹ The role a therapist in the future will play as that primary provider will depend on that clinician's ability to screen for disease and pathological conditions and to examine and evaluate clinical signs that will lead to diagnoses and prognoses that fall inside and outside of the scope of practice. These clinicians must also select appropriate interventions that will lead to the most efficacious, cost-effective treatment.

The foundation of neurological clinical practice is expanding for both the professions of OT and PT. In recent years, OTs are advocating for practice and policy changes to address the negative effects of

fragmented health care²² on patients/clients. Examples of these issues as identified in professional OT literature are (1) inconsistent patient/client access to care based on region of the country and type of insurance, (2) poor information hand-off between practitioners and clinician-patient, and (3) lack of transition services to bridge patient/client needs between home and work environment. In response, a key action of the OT profession is to advocate for practitioners in their discipline to seek credentialing as Certified Care Managers (CCMs). As described by Robinson and colleagues (2016) “occupational therapists have the training and skills to understand the complexity of medical issues and care, and the ways complex conditions disrupt everyday functioning.”²²

Relevant to both OTs and PTs in neurological rehabilitation settings is clear *communication* in multidisciplinary teams, which is paramount to patient safety and service delivery efficacy. Improvements in patient safety have been closely tied to interprofessional practice and clinician education.

To conclude this section’s highlights on professional identity, efficacy, and advocacy, the reader should refer to the sections in this chapter on *the movement system* and *movement system diagnosis*—two rapidly evolving topics in the profession that will most assuredly shape the future of the doctoring profession in the United States.

THE PRESENT AND OUR FUTURE: THE MOVEMENT SYSTEM AND THE PHYSICAL THERAPIST’S IDENTITY

Movement has long been implied as the core of PT practice for more than 40 years; however, the concept of movement as a physiological system surfaced more recently. Many leaders in the profession have alluded to a professional identity with a component of movement as central the profession.

In 1975, Helen Hislop, PT, PhD, FAPTA, one of the founding leaders in PT, called attention to the profession’s identity crisis and proposed pathokinesiology as defining science of PT during the profession’s 1975 prestigious lectureship, the Mary McMillan lecture.²³ Florence Kendall, PT, FAPTA, in the 1980 McMillan lecture,²⁴ pointed out the distinction of PTs beyond procedures or modalities. She associated many medical specialties with specific body systems and proposed the musculoskeletal system, being the linked most to movement, as the PT’s focus.²⁴ The American Physical Therapy Association (APTA) House of Delegates in 1983 adopted a definition of PT that identified the diagnosis and treatment of human movement dysfunction as the primary focus of PT patient management. In 1990, with input from Kendall and another leader in the profession, Scott Irwin, the movement system was defined in Steadman’s Medical Dictionary as a physiological system that functions to produce motion as a whole or of its body parts.^{25,26} Years later, Shirley Sahrman, PT, PHD, FAPTA, in her 1998 McMillan lecture, challenged the profession in defining its identity and to further develop the concept of movement as a physiological system.²⁵ Only at a later time did the concept gain ground again when Dr. Cynthia Coffin-Zadai, in the John Maley Lecture in 2004, discussed the human movement system, the complexity of the diagnostic process related to movement, and called for advancing diagnostic classification categories.²⁷ Two years later, the Diagnosis Dialog, a series of conferences to discuss diagnosis in PT, was convened by Barbara Norton, PT, PhD, FAPTA, and continued for the next 10 years.²⁸

Clearly, evolving discussions on movement as the profession’s focus have been occurring for many years, and attempts to organize and get consensus on the body of knowledge has been challenging. Agreement on defining, describing, organizing, and labeling concepts of movement as the profession’s “system” has proven to be daunting. Consider

that PTs—clinicians, educators, and researchers—come from multiple philosophies in examination and intervention approaches, in addition to varied frameworks of clinical decision making and practice. The lack of professional consensus on the language and definitions related to movement, and the complexity of the diagnostic process on labeling movement dysfunction, have limited the profession from establishing a unique and singular statement on who and what PTs do. The lack of professional identity has been a dialogue extending many years, even if there seems to be unanimous agreement across many PTs that we are “movement experts.”

Finally, after many years of discussion and debate on movement, in 2013 the House of Delegates of the APTA adopted a vision that highlighted and asserted that movement is an integral part of the PT profession. The vision states, “The physical therapy profession will transform society by optimizing movement to improve health and participation in life.”²⁹ With this vision came guiding principles to communicate how the profession and society will look when the vision is achieved. The first principle, on Identity,²⁹ articulates that the movement system will be the core of PT practice, education, and research.

One of the first steps undertaken to meet this vision was the development of a definition of the movement system to standardize the framework and language. In 2015 the APTA released its definition along with a description of the relationship of the movement system to PT practice.³⁰ The movement system is defined as a “collection of systems (cardiovascular, pulmonary, endocrine, integumentary, nervous, and musculoskeletal) that interact to move the body or its body parts.”³⁰ (Fig. 1.1).

The Identity statement reiterates the long-standing discussion on the PT identity associated with the movement system. The new vision and Identity statement linked the profession to a system of the body, a feature that has long been associated with established professions but has been missing in PT. Discussions that began more than 40 years ago are currently coming into fruition with defining the PT’s role in health care as experts in the movement system.

Shortly then, the House of Delegates adopted the position, the Management of the Movement System, in which APTA endorses the development of diagnostic labels and/or classification systems that

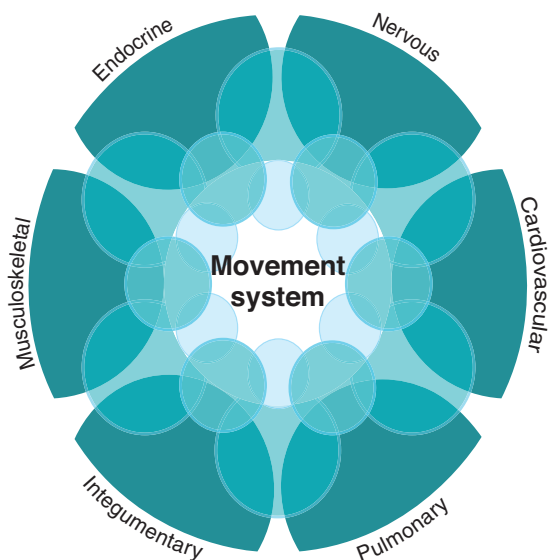

Fig. 1.1 The American Physical Therapy Association Movement System. (Reprinted from <http://www.apta.org>, with permission of the American Physical Therapy Association. © 2019 American Physical Therapy Association. All rights reserved.)

reflect and contribute to the PT's ability to properly and effectively manage disorders of the movement system.³⁰ The formation of the APTA Movement System Task Force, along with the position statement, iterates commitment to moving the profession towards the movement system as the profession's core and identity.

In 2016, APTA held the Movement System Summit, with more than 100 PT clinicians, educators, researchers, and leaders, with the goals of describing the implications of using movement system diagnostic labels and developing an action plan to integrate movement system concepts into practice, education, and research.³¹ Participants' tasks included identifying activities or tasks that are essential to a movement system examination and criteria for diagnostic labels specific to the movement system. Recommendations from the Summit and the APTA Task Force were forwarded to the APTA Board of Directors for review and action.

In 2018 the APTA Movement System Task Force assembled two work groups to move forward with an action plan item from the Summit to "promote the development, implementation and dissemination of diagnostic classification systems/labels that adhere to the established and validated criteria."³² As of spring of 2019, templates developed from the two work groups, the Movement System Diagnosis Work Group and the Task Analysis Work Group, are currently under review of the APTA Board of Directors for consideration. Over the next several years, the integration of the movement system is expected to continue as the profession debates and discusses strategies to infuse the movement system into practice, education, and research.

With many systems interacting to produce movement, so must the PT consider all of the systems contributing to movement. An individual moves the way they do because of many contributing factors—it is the therapists' task to determine which system contributes most to movement dysfunction and eventually prioritize which impairments need to be addressed. Therapists who focus on the movement system must consider the effects of all the components involved rather than examining a specific part of the anatomical system affected by a lesion.

The Guide to Physical Therapist Practice³³ (*The Guide*) describes examination as a comprehensive screening and specific testing process comprised by the patient history, systems review, and tests and measures of body structure and function, activities, and participation. It is during the examination leading to the evaluation that the therapist develops a hypothesis of the possible impairments that cause movement dysfunction based on the information from the history, results of the systems review and standardized tests, and movement analysis. However, the movement observation as envisioned to assist the choice of outcome measures and the diagnosis specific to the movement system is not explicitly identified in *The Guide* as a component of the patient/client management (PCM) model, nor is it a standard component clearly documented as part of clinical examination.

The Academy of Neurologic Physical Therapy (ANPT) Movement System Task Force posits that movement observation and analysis is central to the process of assigning a movement system diagnosis.³⁴ While the diagnostic process is a common in clinical practice, a clear, straight-forward movement observation and analysis of tasks or activities are not typically included in practice³⁴ or in documentation. The ANPT Task Force further acknowledged the absence of validated tools that accurately identify movement system dysfunction and recommend the development of a systematic process of observation and analysis. To date, the recommendation is to have the patient/client perform key tasks methodically and to observe performance that will provide insight on potential impairments that contribute to movement dysfunction. The core tasks recommended for movement observation include sitting, standing, sit-to-stand and stand-to-sit, step up and down, and reach, grasp, and manipulation. Hedman et al, 2018.³⁴

These tasks are likely to change or to be added onto with further discussions regarding what activities/tasks at the minimum should be observed to provide the most insight on movement dysfunction, impairments that contribute to it, and lead to a diagnosis. Currently, there are no standardized methods on the performance of recommended tasks across patient populations. The ANPT Task Force has formed two subgroups, one that specifically is developing diagnostic labels for individuals with postural control dysfunction and the other is developing methods for task analysis that will lead to standardized movement observation. Over time, these diagnostic labels and movement observation procedures will be validated and refined for clinical use.

Movement System Diagnosis: What Is This?

The PCM model identifies a PT diagnosis determined after the evaluation process. A movement system diagnosis is determined after a consideration of all possible sources of movement dysfunction (Fig. 1.2), along with pertinent information from the patient history, systems review, and results of tests and outcome measures from the examination. Prior PT-related diagnostic labels were typically based on pathoanatomical models in which the diagnosis process focused on identification of pathology or anatomical causes that produced movement dysfunction.^{35,36} In contrast to medical diagnoses or pathoanatomical-based diagnosis, movement system diagnostic labels are envisioned to be based on clear description of clusters or patterns of movement observations and associated examination findings that have a greater potential drive interventions.^{34,35} Movement system diagnoses are envisioned to help identify targeted interventions that address specific movement patterns or impairments that limit the ability to function or participate in the environment. Examples of diagnostic labels specific to the movement system have been published^{37,38}; however, these have not been validated through rigorous research nor are they universally used in clinical practice.

The ANPT Task Force recommended characteristics for the development of clinically meaningful movement system diagnosis. These include: a theoretical framework grounded on movement science, an emphasis on movement observation and analysis of core standardized tasks central to the examination, a cluster of movement observation and examination findings across tasks and health conditions, and non-ambiguous labels that are descriptive, unique, and applicable across health conditions.³⁴

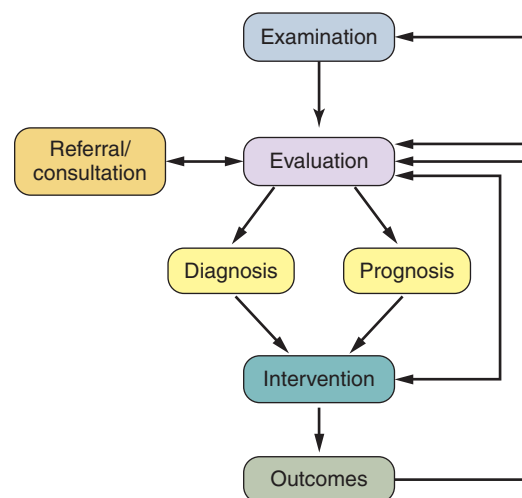

Fig. 1.2 The Process of Physical Therapist Patient and Client Management. (Reprinted from <http://www.apta.org>, with permission of the American Physical Therapy Association. © 2019 American Physical Therapy Association. All rights reserved.)

To date, activities are occurring across the profession at the APTA and its component levels to promote and develop the transition to the movement system throughout the profession. There is much work to do to integrate the movement system across practice, education, and research. Initial steps include the development of standardized movement observation and analysis that will inform therapists' clinical decision making leading to diagnostic labels. Movement system diagnoses, once developed, will need to be validated and examined for clinical utility. Academic curricula based on the movement system and movement system diagnosis will need to permeate entry-level education and diffuse to both academic and clinical faculty. Similarly, research on the clinical utility, validity, and predictability of diagnostic labels will be necessary as PTs characterize diagnoses of the movement system and associate these diagnoses first and foremost with PT. The transition will likely be lengthy and challenging, and universal professional acceptance will be dependent on the entire profession embracing the concepts of the movement system and claiming it as the profession's identity.

MODELS AND CONSTRUCTS FOR THE DIFFERENT ELEMENTS OF THE PATIENT CARE MANAGEMENT CYCLE

Therapeutic Models of Neurological Rehabilitation: What Are “Models” of Intervention? How Are They Useful?

In the development of a prescriptive therapy plan, the therapist's clinical decision making is informed by knowledge of the patient's health condition, the function of all the body systems, and the relationship to activity limitations and/or inability or difficulty in participating in functional tasks and activities. Therapists are also responsible for analyzing the interactions of all other systems and how they compensate for or are affected by the original medical problem. To accomplish these tasks, therapists use a variety of *models* in the patient/client care management cycle. Models of practice serve as road maps for foundation for clinical outcomes. They are also used to create a common language for health professionals. Practice models that focus on disablement—what the patient/client cannot do—were used by clinicians early on. As the practices evolved, clinicians realized the power of recognizing what the patient can do enhances their ability to improve their activity and participation.

To understand how and why disablement, enablement, and health classification models have become the accepted models used by PTs and OTs, it is important for the reader to review the evolution of health care within our culture. The dominant model of health care in Western society began with the allopathic model, and even nowadays it forms the conceptual basis for health care in industrialized countries.³⁹ The allopathic model assumes that illness has an organic base that can be traced to discrete molecular elements. The origin of disease is found at the molecular level of the individual's tissue. The first step toward alleviating the disease is to identify the pathogen that has invaded the tissue and, after proper identification, apply appropriate treatment techniques including surgery, drugs, and other proven methods.

It is implicit in the allopathic model that licensed physicians have the sole responsibility for the identification of the cause of the illness and for the judgment as to what constitutes appropriate treatment. PTs and OTs have never been responsible for the medical diagnosis or treatment of diseases or pathological conditions but rather are responsible for providing therapeutic interventions to help patients achieve their desired quality of life. Improvements in movement function and task participation can be achieved, even when the patient/client disease

or pathology is chronic and unchanged; thus the evolution to more holistic models of diagnosis and health classifications.

A holistic model (*holos*, from the Greek, meaning “whole”), also known as the biopsychosocial model of health care, seeks⁴⁰ to involve the patient/client in the process and take the mystery out of health care for the consumer. It acknowledges that multiple factors are operating in disease, trauma, and aging and that there are many interactions among those factors. An expanded biopsychosocial model includes emotional, environmental, political, economic, psychological, and cultural factors as influences on the individual's potential to maintain health, to regain health after insult, or to maintain a quality of health in spite of existing disease or illness. Measures of success in health care delivery have shifted from the traditional standard of whether the person lives or dies to the assessment of the extent of the person's quality of life and ability to participate in life after some neurological insult. Moreover, “quality of life” or living implies more than physical health. It implies that the individual is mentally and emotionally healthy as well. It takes all dimensions of a person's being into consideration regarding health. From the beginning, even Hippocrates emphasized treatment of the person as a whole, and the influence of society and of the environment on health.

An approach that takes this holistic perspective centers its philosophy on the patient/client as an individual.⁴¹ The individual with this orientation is less likely to have the physician look only for the chemical basis of his or her difficulty and ignore the psychological factors that may be present. Similarly, the importance of focusing on an individual's strengths while helping to eliminate impairments, and activity limitations in spite of existing disease or pathological conditions, plays a critical role in this model. This influences the roles PTs and OTs will play in the future of health care delivery and will continue to inspire expanded practice in these professions.⁴²

Since 2001, when 191 member states of the World Health Organization adopted the International Classification of Functioning, Disability and Health (WHO-ICF), the degree and quality human function has been the focus and framework for population health research and health policy actions. Application of this model is reshaping PT and OT professional education and clinical practice, including diagnosis, prognosis, outcomes measurement, and multidisciplinary patient management. The ICF model evolved from a linear disablement model to a progressive model that encompasses more than disease, impairments, and disablement. It includes personal and environmental factors that contribute to the health condition and overall well-being of individuals. The ICF model is considered an enablement model as it not only considers dysfunctions, but helps practitioners and researchers to understand and use an individual's abilities in the clinical presentation. The ICF recognizes disability not only as a medical or biological dysfunction but as a result of multiple overlapping factors including the impact of the environment on the functioning of individuals and populations. The ICF model is presented in Fig. 1.3.

It is easy to integrate the ICF model into behavioral models for the examination, evaluation, diagnosis, prognosis, and intervention of individuals with neurological system pathologies (Fig. 1.4). Whether an individual's activity limitations, impairments, and strengths lead to a restriction in the ability to participate in life activities, the perception of poor health or restriction in the ability to adapt and adjust to the new health condition will determine the eventual quality of life of the person and the amount of empowerment or control he or she will have over daily life. The importance of the unique qualities of each person and the influence of the inherent environment helped to drive changes in world health models. The ICF is widely accepted and used by therapists throughout the world.⁵

Conceptual Frameworks for Patient/ Client Care Management: Who Needs to Use a Framework?

A patient/client care management framework is useful to convey the timing and relevance of each step and process that takes place between the

patient/client and clinician. The structure of a framework provides an account of each task and responsibility a therapist fulfills in the course of a documented episode of care. A framework model can provide a sequential, developmental pathway, by which students can develop

problem-solving strategies. Thus frameworks are beneficial for both the seasoned practitioner, new program graduate, and student. An example of a widely used framework in PT is the PCM model, as described in *The Guide*.³³ The PCM model⁵ identifies the process used in PT to manage the patient and make clinical decisions. The six distinct elements are critical in clinical reasoning and decision making in neurology PT: examination, evaluation, diagnosis, prognosis, intervention, and outcomes. The PCM model is presented in Fig. 1.2.

PATIENT-CLIENT MANAGEMENT: EXAMINATION

The examination, the required first step for all patients/clients, is a comprehensive screening and specific testing process. Three components comprise the examination: patient/client history, systems review, and tests and measures of body structure and function, activities, and participation. During this initial step, the therapist develops a hypothesis of the possible impairments that cause movement dysfunction. The information from the history, results of the systems review, and tests provide the foundation to hypothesize the underlying cause/s of impairments that contribute to activity limitations and participation restrictions.

Medical Screening by the Therapist

Therapists must be able to screen patients/clients for signs of disease and pathological conditions.¹⁹ This screening process is used to determine whether the individual shows signs and symptoms that are outside a therapist's scope of practice and therefore should be referred to another practitioner such as a physician. If the signs and symptoms both fall within the clinician's scope of practice and overlap with that of other disciplines, the therapist must refer and decide (1) to treat to prevent problems until the other practitioner's treatment can be performed, (2) to manage the limitations in activity and participation in spite of the pathological process, or (3) to manage functional loss and impairments that may correct the pathological cause. In some cases, the overlap with other disciplines may not necessitate an immediate referral, but interactions among the professionals managing the patient/client care must be made when needed to ensure the best outcome from intervention. However, when the information obtained by the therapist indicates a possible immediate and life-threatening condition, the therapist must act accordingly by referring the patient/client to a physician or medical emergency responders.

Examination With a Movement System Framework

Critical to the examination with a movement system framework is identifying the movements that are atypical. This observation of movement includes identification of the individual's movement abilities and limitations during performance of activities or tasks. Several strategies to observe and analyze movement exist along with their own definitions; explicit examination of movement dysfunction occurs variably across settings and among clinicians. Although many clinicians examine movement to some degree, no standardized approach to movement observation and analysis currently exists and consistent terminology to describe movement dysfunction is lacking.

As researchers continue to unravel the mysteries of brain function and learning, their understanding of how children and adults initially learn or relearn after neurological insult is often explained with new and possibly conflicting theories. Behavioral responses observed as functional patterns of movement, whether performed by a child, adolescent, young adult, or older person, are still visually identified by a therapist, family member, or innocent observer as either normal or abnormal.

Human beings exhibit certain movement patterns that may vary in tonal characteristics, amplitude, aspects of the specific movement sequences, and even the sequential nature of development. The range of acceptable behavior does have limitations, and variations beyond those boundaries are recognizable by most people. A 5-year-old child may ask why another child walks on his or her toes with the legs stuck together. If questioned, that same 5-year-old child may have the ability to break down the specific aspects of the movement that seem unacceptable even from a child's lens. From birth, a sighted individual observes human movement and after numerous observations over time will begin to see patterns that may be perceived as normal. Although variability in human movement exists, most everyday human movement patterns have a range of "normal," and therefore many elements are predictable, such as appearance of developmental milestones in children, and the variety of ways a person performs a sit-to-stand. This concept does provide flexibility in analysis of normal movement and its development. Some children choose creeping as a primary mode of horizontal movement, whereas others may scoot. Both forms of movement are normal for a young child. In both cases, each child would have had to develop normal postural function in the head and trunk to carry out the activity in a normal fashion. Thus, for the child to develop the specific functional motor behavior, the various components or systems involved in the integrated execution of the act would require modulation in a plan of action. Because the action must be carried out in a variety of environmental contexts, the child would need the opportunity to practice in those contexts, identify errors, self-correct to regulate existing plans, and refine for skill development. Thus each movement has a variety of complex systems interactions, which when summated are expressed by means of the motor neuron pool to striated muscle tissue function. The specifics of that function, whether fine or gross motor control, or full-body or limb-specific movement, still reflect the totality of the interaction of those systems. No matter the age of the individual, the motor response still reflects that interaction, and the behavior can be identified as normal and functional; functional but limited in adaptability; or dysfunctional and abnormal. Therapists must be able to (1) organize observational skills for any movement pattern, (2) identify components of the movement, (3) identify missing or abnormal movement patterns, and (4) select and administer interventions to incorporate the missing strategies or normalize the missing components.

The concept of the CNS as a control center is based on a therapist's observations and understanding of the sensory-motor performance patterns that are reflective of that system. This understanding requires an in-depth background in neuroanatomy, neurophysiology, motor control, motor learning, and neuroplasticity and gives the therapist the basis for clinical application and treatment. Understanding the intricacies and complex relationships of these neuromechanisms provides therapists with direction as to when, why, and in what order to use clinical treatment techniques. Motor behaviors emerge based on maturation, potential, and degeneration of the CNS. Each movement behavior observed, sequenced, and integrated as part of the intervention strategies should be interpreted according to neurophysiological and neuroanatomical principles, as well as the principles of learning and neuroplasticity. As science moves toward a greater understanding of the neuromechanisms by which behaviors occur, therapists will be in a better position to establish efficacy of intervention. The rationale for the use of certain treatment techniques will likely change over time as we better understand the CNS.

One can be confident that no infant will be born, jump out of the womb, walk over to the physician, and shake hands or say "hi" to mom

and dad before learning to roll or control posture of the trunk and head. Instead, typical motor development requires new motor plans that lead to the infant's ability to achieve functional movement through motor learning. These new motor programs will be modified and reintegrated along with other programs to develop normal motor control in more complex patterns and environments because of neuroplasticity. Each pattern and the advancement from one pattern to another require time and repetition for mastery.

Two important aspects of the clinical problem-solving process emerge when observing movement. First, the examination of motor function is based on the interaction of all components of the movement system and the cognitive and affective influences, as stated previously. Second, as part of the diagnostic process, the therapist needs to recognize which aspects of the movement are deficient, absent, inaccurate, or inappropriate when cross-referenced with the desired movement outcome. Some patients/clients may not have had the opportunity to experience the desired skill because of a congenitally defective nervous system, whereas others may have lost the skill as a result of changes within the CNS or disuse. In either case the normal accepted patterns and variability remain the same.

Specific activity limitations and the impairments within the body systems that affect the individual's ability to control quiet postures or dynamic movement in any activity become a focus in the diagnostic process. The functional loss itself may or may not reflect specific diseases or pathological conditions within the CNS but does reflect specific impairments within that person's body.

Following the examination, a therapist must draw conclusions regarding those examination results and their interactions. That interpretation leads to a PT diagnosis. The interpretation of the examination results and their interaction with the therapist's and patient's/client's desired outcomes within a defined time period, the available resources, and the individual's potential lead to the prognosis. Selection of the best and most efficient resources to achieve the desired outcome will lead to establishment of the treatment intervention plan.

PATIENT-CLIENT MANAGEMENT: EVALUATION AND DIAGNOSIS

The evaluation refers to the synthesis of the findings from the examination components with the goal of establishing a diagnosis and prognosis. The interpretation of results and resulting clinical judgments guide the plan of care and interventions.

Diagnosis is a conclusion drawn regarding specific diseases and pathological processes within the human body; when made by a physician it is considered a medical diagnosis. Diagnosis made by a PT is a conclusion drawn regarding the status of body systems, activity and participation, and their interactions considering the patient's/client's personal factors and the environment. In consideration of each of these elements of examination subcomponents, the relative contribution to an overall movement disorder is determined. PTs use recognized movement problems to establish problem lists and intervention sequences. Using functional behavioral models such as the ICF model, clinicians are becoming comfortable with the *identification of body system problems (impairments)*, *activity limitations (functional limitations)*, and *participation restrictions*, and the conceptual understanding that a diagnosis²⁸ of a *movement system* dysfunction is very different from that made by a physician.

Differential Diagnosis Within a Therapist's Scope of Practice

Once a clinician determines that the patient's/client's need for service falls within his or her respective scope of practice, then the examination

continues and results in the development of a PT diagnosis, prognosis, and plan of care. The use of the ICF model will help the therapist to best capture the patient's/client's abilities, impairments, activity limitations, and participation restrictions, and the personal and environmental (contextual) factors that may influence progress. The information can then be used to determine the patient's/client's goals, address the individual's needs, and optimize function and quality of life. The patient's/client's functional goals and expectations may include activities of daily living, job skills, recreation and leisure activities, or the skills required for performance of typical societal roles. Each of these goals are associated with examination tools that can result in realistic, objective, measurable outcomes.

Two important clinical components affect the accuracy of the PT diagnosis and prognosis. First, the clinician must establish accurate, nonbiased results. This fact seems obvious, but with the pressures of third-party payers, family members, and other care providers and the desire to have the patient improve, it is easy to submit to drawing a conclusion based on *desired* outcomes rather than facing what is truly present and realistic. The second factor deals with the honesty of the interaction between the therapist and the patient/client. This "bonding" is critical for obtaining accurate examination results. Safety, trust, and acceptance of the patient as a human being play key roles in therapeutic outcomes and thus in efficacy of practice.⁴³⁻⁴⁶

The specific cognitive process used by therapists before formulation of a PT diagnosis might be conceptualized as a nine-step process. As the therapist enters into the clinical environment of the patient/client, he or she starts collecting data that might be relevant to the analysis of the clinical problem (step 1). This includes information obtained through observation, history taking, chart review, and interviews. The therapist must take that array of divergent information and determine what data are relevant to the case while disregarding what may be irrelevant information (step 2). This body of knowledge is then differentiated into various body systems that might be affected by the identified problems. If a specific system does not seem to be affected, then it can be eliminated, at least temporarily, from the diagnostic process (step 3). In general, administration of self-report measures and performance-based testing will provide an overview of the strengths and limitations of the individual in terms of function (step 4). After performing examination procedures and observing patterns of movement and specific normal and abnormal responses, the therapist once again diverges his or her thought processes back to separate large body systems to classify problems in the appropriate system (step 5). The therapist further subdivides these large systems into their components to assess specific subsystem deficits and strengths (step 6). This will allow the therapist to categorize objective measurements of impairments that are recognized as deficits within subsystems. Clusters of specific signs and symptoms will emerge that will help to direct the clinicians to a therapy diagnosis. Once the therapist has obtained these clusters of symptoms within specific subsystems, two additional convergent steps need to be completed. First, the presence and lack of impairments and how those impairments interact to cause dysfunction in a major body system are determined (step 7). Second, how those impairments affect the interaction of the major system with other major body systems is determined (step 8). These first eight steps tell the therapist exactly why the individual has difficulty performing specific functional activities. The problem list that incorporates the severity of impairments that have interacted to cause loss of function gives the clinician the therapy diagnosis. The number and extent of impairments along with an understanding of the cause of loss of function will lead the therapist to establishment of various prognoses and identification of optimal intervention strategies.

The last step (step 9) requires the therapist to diverge his or her thought processes back to the patient's/client's total environment to determine the accuracy of the diagnosis, prognosis, and selected treatment interventions as they interact with the individual as a whole. This is the "putting them all together" step where the clinician synthesizes all the information and makes sure that the individual is front and center in the process. Although some completion of this diagnostic process may occur within minutes after a patient/client and therapist begin their interactions, the process is continual, and at any time a therapist may need to go back to previous steps to obtain and analyze new and relevant information.

PATIENT/CLIENT MANAGEMENT: PROGNOSIS

*The Guide*³³ defines prognosis as the determined, predicted outcome of improved movement function. Intermediate levels of improvement and the optimal level of function are included in the prediction. Documentation of prognosis also requires prediction of the amount of time to reach each level within a course of PT.

How Long Will It Take to Get From Point A to Point B?

If a patient/client has a variety of impairments, activity limitations, and participation restrictions, then a variety of appropriate prognoses may be formulated. These prognoses could be used to speculate the amount of time or number of treatments it will take to get from the existing activity limitations and participation restrictions (point A) to the desired outcomes (point B). The intended outcomes provide information on whether the intervention will (1) improve activity through changes, adaptations, and learning within the patient as an organism or (2) improve function through compensation and modification of the external environment. Once the PT diagnosis has been established, a clinician must consider many factors when making a prognosis. Some factors are related to the internal environment of the patient/client, such as number and extent of impairments, level of physical conditioning or deconditioning, the ability and motivation to learn, participate, and change, and the neurological disease or condition that led to the existing problems. The patient's/client's support systems have a dramatic impact on prognosis. Cultural and ethnic pressures, financial support to promote independence, availability of appropriate skilled professional services, prescribed medications, and the interaction of all of these factors need to be considered. Specific environmental factors such as belief in health care and agreement about who has the responsibility for healing can create tremendous conflict among current health care delivery systems, the patient/client, the family, and the clinician.^{44,47,48} In the ICF model, all of these variables influence the prognosis and must be considered in the patient/client management model.

Once a prognosis has been established, the therapist's next step is to identify the intervention strategies that will guide the patient/client to the desired outcome within the time period identified.

PATIENT/CLIENT MANAGEMENT: INTERVENTIONS

*The Guide*³³ defines interventions as any purposeful interaction to produce changes in a patient's/client's condition. Interventions should be consistent with the patient's diagnosis and prognosis and may also include interactions with others directly involved in the individual's care. Therefore, within this definition, an intervention includes direct, hands-on movement guidance, verbal instructions, and family education. Chapter 8 of this text describes interventions for patient's with neurological movement disorders. Foundationally, however, therapeutic interventions are based on knowledge of

the movement system and the interactions of the patient-provider relationship.

Most treatment interventions used for patients/clients with CNS pathology incorporate principles of neuroplasticity, adaptation, motor control, and motor learning in various environmental contexts. Thus the consideration of the basic science of central and peripheral nervous system function and a behavioral analysis of movement must be included in any conceptual model used as a foundation for the entire diagnostic process.

The established plan of care determines the interventions and the method toward the achievement of the agreed-on outcome goals. The therapist, in collaboration with the patient/client, can choose from restrictive and nonrestrictive treatment environments and interventions to best achieve identified goals. The recognition and value of a holistic approach to illness are receiving increasing attention in society. Interventions designed to improve both the emotional and physical needs of patients/clients during illness has been recognized and advocated as a way to help individuals regain some control over their lives. Currently, the task of PTs and OTs is to empower the patient/client to be more responsible for their own health, in addition to the health and well-being of the community. This means that the consumer must play a critical role in the decision making process within the entire health care delivery system, including optimizing adherence to prescribed interventions.⁴⁹ The current increasing limitations placed on the delivery of medical care forces the patient/client to be more responsible for their health. Levin⁵⁰ points out that there is a lot that patients can do for themselves. Most people can assume responsibility to care for minor health problems. The opioid epidemic has forced our medical system to look at other options for managing pain. The use of nonpharmaceutical methods (e.g., hypnosis, biofeedback, meditation, and acupuncture) to control pain is becoming common practice.

The available choices of interventions will depend on the therapist's skill, the level of function and ability of the individual to control his or her own neuromuscular system, and treatment tools and strategies that are available in the clinic. Yet, freedom within that established environment must exist if learning by the patient/client is to occur.

PATIENT/CLIENT MANAGEMENT: OUTCOMES

Although patient/client satisfaction is a critical variable within the ICF model, there are always problems with satisfaction and outcomes versus identification of specific measurable variables within the CNS that are affecting outcomes. One reason for the problem of integrating patient satisfaction with PT and OT services within a neurorehabilitation environment is the large discrepancy between the variables we can measure and the variables within the environment that are affecting performance. For example, a neurosurgeon once asked the question to one of the editors, "Do you know how to prove the theories of intervention you are teaching?" The answer was, "Yes, all I need are two dynamic PET units that can be worn on both the patient's and the therapist's heads while performing therapeutic interventions. I also need a computer that will simultaneously correlate all synaptic interactions between the therapist and the patient to prove the therapeutic effect." The physician said, "We don't have those tools!" The response was, "You did not ask me if the research tools were available, only if I know how to obtain an efficacious result." Thus the creativity of the therapist will always bring the professions to new visions of reality. That reality, when proven to be efficacious, assists in validating the accepted interventions used by the professional. Therapists have a responsibility to provide evidence-based informed practice

to the scientific community, but more important, also to the patient/client. Therapeutic discovery usually precedes validation through scientific research. This discovery leads the way to, first, effective interventions, followed by efficacious care. If research and efficacious care always have to come before the application of therapeutic procedures, nothing new will evolve because discovery of care is most often, if not always, found in the clinic during interaction with a patient. Thus the range of therapeutic applications will become severely limited and the evolution of neurological care stopped if that discovery is ignored because there is no efficacy as defined by current research models. However, performing interventions because the approaches “have been typically done in the past” could be wasteful and irresponsible.

A therapist, through professional education, efficacy of preexisting clinical pathways, and clinical experience, can generally identify the most effective interventions and the most expedient way to guide a patient/client toward the desired outcome. However, the patient/client response to intervention is not always immediate or complete and may not lead the individual in the most direct path to the desired outcome. For example, if a therapist and patient/client are working on coming to standing patterns and the patient/client begins to fall, the therapist would need to guide the patient/client back into the desired movement patterns and not allow the fall. In that way the patient/client is working on the identified outcome. Falling as a functional activity should be taught as a different intervention and would be considered part of a different clinical map. The degree to which the therapist needs to control the response of the patient/client will determine the extent to which the intervention would be considered contrived. Contrived interventions can, in time, lead to functional independence of the patient, but as long as the therapist needs to control the environment, functional independence has not been achieved.

Patient and Provider Relationship Is a Determinant of Outcomes

There are many ways to get to a desired outcome. Involving the patient/client in the goal setting and intervention planning process will lead to the best results. These interactions require the patient/client to trust the therapist as a guide and teacher. The patient/client-provider relationship includes concepts of the learning environment.

Learning Environment

The learning environment may be the critical factor in the success or failure of therapeutic interventions. The therapist, patient/client, and the environment formulate and maintain this environment. To comprehend the dynamics of the learning environment and function with optimal success, the clinician must do the following:

- Develop the learning process and provide an environment that promotes learning.
- Investigate the use of sensory input and motor output systems, feedforward and feedback mechanisms, and cognitive processing as means for higher-order learning.
- Use the principles and theories of motor control, motor learning, and neuroplasticity to facilitate learning and carryover of treatment into real-life environments.
- Obtain knowledge of both the patient's and the provider's learning styles. If these learning styles are not compatible, then the clinician is obligated to teach using the patient's preferred style.
- Attend to the sensory-motor, cognitive, and affective aspects of each patient/client, regardless of the clinical emphasis at any given time.

There are four distinct and interactive components of the learning environment: the internal and external environments of the patient, and the internal and external environments of the clinician (Fig. 1.5).

Patient's/Client's Internal Environment

A critical component of the ability to learn is the patient's/client's *internal environment*. When a lesion occurs within a body system, it directly and indirectly affects the entire internal environment. If the lesion occurs before initial learning, then habilitation must take place. These individuals may possess a genetic predisposition for a specific learning style, even though one has not yet been established. The therapist should test the inexperienced CNS by creating experiences in various contexts that require a variety of types of higher-order processing to discover optimal methods of learning that best suit the CNS of the individual. Then the therapist can use those methods in treatment. If previous learning has occurred, then the therapist needs to know what those are and whether they have been affected by the neurological insult so that proper rehabilitation can be instituted.⁵¹

One way to determine preferential learning styles is by taking a thorough history. Leisure activities and job choices often give clues to learning styles. For example, a patient/client who loved to take car engines apart or build model ships demonstrates a preference for the visual-kinesthetic learning style, whereas a patient/client whose preference for pure enjoyment was sitting in a chair and reading a book demonstrates a probable preference toward verbal learning. Again, this does not mean that the patients/clients in the examples mentioned could not selectively use all methods, but it does illustrate the issue of preference. Both the position of the lesion and the preferential learning style can play key roles in matching the learner with a particular treatment environment and identifying potential for recovery of function. For example, if a patient/client has had a massive insult to the left temporal lobe and before the trauma showed poor ability in using the right parieto-occipital lobe, then spatial or verbal strategies may be ineffective in the relearning process. However, an individual with the same lesion who had high-level right parieto-occipital function before the insult will probably learn at a much faster rate if visual-kinesthetic strategies are used to promote learning.

Patient's/Client's External Environment

The patient's/client's *external environment* is the second critical component.⁵² All external stimuli—noise, lighting, temperature, touch, humidity, and smell—can modulate the individual's responses. External inputs can invoke either negative or positive influences on internal mechanisms and alter the patient's/client's ability to manipulate the world. Therefore a therapist should make every effort to be aware of

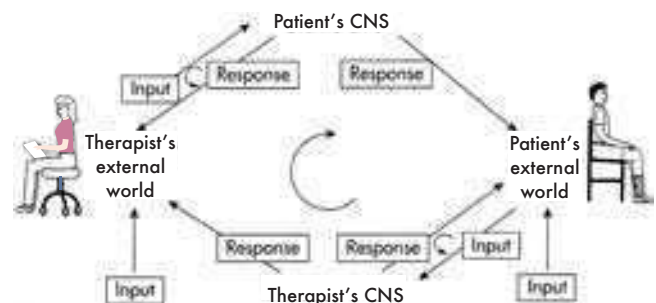

Fig. 1.5 Clinical Learning Environment. CNS, Central nervous system.

what externally is influencing the patient/client.^{53–56} Any behavioral change displayed by the patient/client, such as a change in mood or attitude, or a change in muscle tone could serve as an indicator to the therapist that an environmental effect may have occurred.

Clinician's Internal Environment

The third critical component is the *internal environment of the clinician*.⁵⁷ The clinician should be aware of personal internal factors that can influence patient responses. Everyone has preferential styles of teaching and learning, yet many of us may be unaware of what they are and how they affect our outlook on life and interactions with other people.

Clinician's External Environment

The fourth component of the learning environment is the *clinician's external environment*. It is generally expected that personal life should never affect professional work. However, to accept this assumption may be to deny that emotions affect behavioral patterns. Response patterns can vary without cognitive awareness when an individual is emotionally upset or under stress. Each individual is unique. Therefore it is difficult to analyze the specifics related to each individual's learning environment. However, six basic learning principles have been established that are relevant to both the patient and the clinician in any learning environment.^{58–60} Box 1.1 presents the six principles of the learning experience.

Although all six learning principles seem simple, their application within the clinical setting is not always as obvious. *Principles 1 and 2* are intricately linked with the appropriateness and difficulty of tasks presented to patients/clients. If a patient/client is asked to perform a task that requires a sequence of movements be performed (e.g., moving from supine to sitting, dressing, or maneuvering a wheelchair), to succeed, the patient must be able to plan the entire task and modulate all motor control during the sequence of the entire activity. If steps are not mastered, if sequencing is inappropriate or absent, or if motor control systems are not modulated accurately, dependence on the clinician to solve the problem is reinforced. Clinicians must differentiate missing components (impairments) from functioning systems and create an environment that encourages and allows the CNS to adapt and learn ways to regain that control. The clinician must also facilitate the patient's/client's ability to intrinsically self-correct during practice. This assumes that the patient is able to recognize the error to make the correction. Errors that lead to learning are encouraged, but errors that always lead to failure do not help the patient to learn avenues of adaptation.

The level of difficulty or challenge of the task can be intricately linked with success. Changing the level of difficulty of a task is used to tease out specific impairments or as a progression of activity. The greater the task difficulty or complexity, the greater the challenge and consequently the greater the satisfaction if success is achieved. On the other hand, failed performance on a very difficult challenge can be demoralizing for the patient.

There is a subtle interplay among degree of difficulty, challenge, and success. Selecting tasks that are age appropriate, clinically relevant, and goal related is a challenge to the therapist. For the patient/client to be successful, the therapist must be a creative problem-solver and knowledgeable about the patient's needs, abilities, and goals. If the tasks are too simple or if the patient considers them unimportant, boredom will ensue, and progress may not be achieved. If the tasks are too difficult, the patient may feel defeated and may turn away from

BOX 1.1 Six Principles of the Learning Experience

1. Individuals need to be able to solve problems and practice those solutions as motor programs if independence in daily living is desired. This requires the use of intrinsic feedback systems to modulate feedforward motor plans as well as correct existing plans.
2. The possibility of success must exist in all functional tasks, regardless of the level of challenge to the patient.
3. An individual will revert to safer or more familiar motor programs or ways to solve problems and succeed at functional tasks when task demands are new, difficult, or unfamiliar.
4. The learning effect occurs in multiple areas of the central nervous system (CNS) simultaneously when teaching and learning are focused within one area of the CNS.
5. Motivation is necessary to drive the individual to try to experience what would be considered unknown. Simultaneously, success at the activity is critical to keep the individual motivated to continue to practice.
6. Clinicians need to be able to analyze an activity as a whole, determine its component parts, and use problem-solving strategies to design effective individualized treatment programs. At the same time, if independence in living skills is an objective, the therapist needs to teach the patient those problem-solving strategies rather than teaching the solution to the problem.

them. In such cases, a child tends to withdraw physically, whereas an adult usually avoids the problem. This avoidance can be manifested in different ways—being late to therapy, having to leave early, or always needing to go to the bathroom are all avoidance behaviors that may be linked to inappropriate tasks.

The *third learning principle* describes a behavior inherent in all people: reversal. When confronted by a problem, individuals revert to patterns that produce feelings of comfort and competence when solving the problem. In Fig. 1.6, a 2-year-old child is confronted with just such a conflict. The bridge he wants to cross is unstable. The main goal is to cross the bridge in a manner that the patient thinks will result in the highest probability of success. Therefore the child reverts to previous movement that has proven to be successful—scooting. As the child gains confidence, he sequences from scooting to four-point bunny hopping, then creeping, on to cruising, and finally to reciprocal walking. Although reverting to more familiar or comfortable ways of solving problems is normal, it becomes problematic if used for a prolonged period of time. For example, if a patient/client with residual hemiplegia has spent a week modifying and controlling a hypertonic upper extremity pattern during a simple task and is now confronted with a more difficult problem, the hypertonia within the limb will most likely return with the added complexity of the task. The pattern or plan for standing is different from that for walking, and the emotional implications of walking are very high. The clinician should anticipate the possibility of the patient/client returning to a more stereotypical pattern. This possibility must also be explained to the patient/client. Anticipating that less efficient patterns will usually return as the tasks demanded increase in complexity, the clinician can attempt to modify the unwanted responses and let the patient/client know that the response is actually normal given the CNS dysfunction, but that movement can be changed and normalized with practice. The key to comprehension of this concept is not the behavior itself; instead, it is the attitude of a therapist toward a new

Fig. 1.6 Reverting to more comfortable behavior patterns when confronted with a problem. **(A)** Scooting. **(B)** Bunny hopping. **(C)** Creeping. **(D)** Cruising. **(E)** Walking.

task presented to the patient/client. If the clinician expects the patient to be successful, the patient/client will also expect success. If failure occurs, both parties will be disappointed, and a potentially negative clinical situation will be created; however, if the patient/client succeeds, both will have expected the result and their attitude

will be neither excited nor depressed. On the other hand, a clinician who expects the patient/client to revert to an old behavior can prepare the patient/client. If the individual reverts, neither party will be disappointed; but if no reversion occurs, both will be excited, pleased, and encouraged by the higher functional skill. By

understanding the concept, the clinician can maintain a very positive clinical environment without the constant negative interference of perceived failure when a patient/client does revert.

The *fourth learning principle* deals with the totality of the patient/client. Whether the area of emphasis is motor performance, emotional balance, or perceptual integration, all areas interact and influence movement. Therefore understanding and respect for all factors are important if optimal patient function is a primary objective. This does not suggest that therapists should address each aspect of personality; however, integration of the patient's/client's physical, mental, and spiritual areas should be a responsibility of the staff. Awareness of possible adverse effects of one learned behavior on other CNS functions can help to avoid potential problems. For example, if working on lower extremity patterns creates extreme upper extremity hypertonicity through associated patterns, the clinician is not dealing with the patient/client as a whole.

The unknown creates fear and curiosity for most individuals, and the *fifth learning principle* points out that for most patients/clients the unknown is all encompassing, whatever the degree of prior learning. For a patient whose only difficulty is a flaccid upper extremity, functional activities such as toileting, dressing, or eating will be troublesome. Motivation is a critical factor for success. Maintaining motivation to try while ensuring a high degree of success is an important teaching strategy that tends to encourage present and future learning.

An additional comment regarding patients/clients who lack motivation should be made. If a patient chooses to be totally dependent and has no need to become independent, then participation with tasks will likely be minimal. For example, Mr. Salas, a 63-year-old bank president with a wife, 4 children, and 10 grandchildren, survives an operable brain tumor with residual right hemiparesis and minimal cognitive-affective deficits. The patient's work history indicates that he was highly success oriented. Unknown to most persons is that for 63 years Mr. Salas desired to be a passive-dependent person, but circumstances never allowed him to manifest those behaviors. With the neurological insult, he is in a position to actualize his needs. Until the patient desires to improve, therapy will probably be ineffective; thus motivating the patient becomes critical. This might be accomplished in a variety of ways. Knowing that Mr. Salas values privacy, especially with respect to hygiene, that he thoroughly enjoys dancing and birdwatching in the forest, and that he ascribes importance to being accepted in social situations, such as cocktail parties, helps the therapist to create a learning environment that motivates this patient toward independence. Being independent in hygiene requires certain combinations of motor actions, including sitting, balance, and transfer skills. Being able to birdwatch deep in an unpopulated forest requires ambulation skills, tolerance of the upright position for extended periods of time, and endurance. Being socially accepted depends to a large extent not only on grooming but on normal movement patterns, especially in the upper extremity and trunk. Creating a therapeutic environment that stresses independence in the three goals identified by the patient will simultaneously create further independence in other areas. Whether the patient decides to return to banking and other activities in conflict with his personality will need to be addressed later. Another way to motivate Mr. Salas is to place him in an environment in which he is not satisfied, such as a nursing home or his own home with an assistant rather than his wife to help him with his needs. Dissatisfaction with the current external environment will generally motivate an individual to change or may trigger depressive symptoms. Obviously, creating a positive environment for change versus a negative one would be the method of choice.

The *sixth learning principle* has been discussed in earlier sections. To be a successful teacher of motor skills and to assist the

patient in recovery of function, the clinician should be able to break more complex motor plans and functional tasks into smaller component parts. These parts can then be taught successfully and then integrated back into the whole activity for optimal learning to occur. The therapist should always strive to allow each patient/client to solve movement problems and develop strategies for reaching the outcome goals, rather than producing the desired outcome for or with the patient.

Many additional learning principles from the fields of education, development, and psychology can be used to explain the behavioral responses seen in our patients/clients. It is not expected that all therapists will intuitively or automatically know how to create an environment conducive to helping the patient achieve optimal potential. Yet all can become better at creating a beneficial learning environment by understanding how people learn. The critical importance of being honest and accurate with prognosis and how that will ultimately affect function outcomes, participation in life, and quality of life cannot be overemphasized.⁶¹

The principles presented in this chapter deliver a strong message: individuals need to solve problems, and most want to solve the problem given a chance that the solution will be successful. Unless the task fits the individual's current capability, adaptation using whatever is available will become the consensus that drives the motor performance through the CNS. Learning is taking place in all aspects of life, and the patient/client must ultimately take responsibility for the means to solve the problem.⁶²

CONCLUSION

The roles of PTs and OTs have evolved over the past several decades to include benefits to the patient for overall health, wellness, and disease/injury prevention. Medical screening and early detection of neurological problems should facilitate early referral of the consumer to a medical practitioner. Similarly, patients/clients may reenter PT or OT after a neurological insult as someone who has a chronic movement dysfunction or degenerative condition that may be getting worse and who needs some instruction to regain motor function.

Neurological rehabilitation will continue to take place in a constantly changing health care environment and ever-evolving delivery system. The balance between visionary and pragmatist must be maintained by the practitioner. By the end of the 21st century, neurological rehabilitation will have evolved into a new shape and form, will take place within a very different health system, and will involve the patient as the center of the dynamic exchange among wellness, disease, function, and empowerment.

We are getting closer to fully defining who we are and our distinct roles and responsibilities in the health care environment. It is also a time of distinct challenges with changes and uncertainties will most likely affect health care delivery. Increased globalization means that these changes and challenges will not be confined to one area but can potentially change the world. The seventh edition of this text also reminds us that regardless of these changes, there are foundations of our neurological rehabilitation practice that remain constant. Although the PCM process is changing, we recognize the importance of a more universal language and process. Such processes should (1) inform data gathering for the purpose of identifying a movement, function, and participation deficit, (2) guide the design of a plan of care, (3) prognosticate the likelihood of success following targeted interventions, and (4) assess outcomes following therapeutic intervention. We recognize that the unique relationship of the therapist and the patient/client in the therapeutic process has evolved into a partnership, with a set of negotiated, collaborated, and shared therapeutic goals. We reiterate the importance of the

therapeutic environment to success in therapy. Finally, we highlight the value of learning in the healing and recovery process.

ACKNOWLEDGMENT

All the present authors and editors would like to express their deepest gratitude to Dr. Darcy A. Umphred and Dr. Margaret L. Roller who helped develop this chapter in the previous editions of the text.

Abstract: This chapter provides the clinician the foundational concepts for clinical practice in neurological rehabilitation. In this chapter, five foundational elements will be discussed: the complexity of the central nervous system; professional roles in rehabilitation for the patient with neurological conditions; the movement system and the physical therapist's identity; models and constructs for the different

elements of the patient care management cycle and the practitioner-patient partnership.

Keywords: clinical problem solving; patient/client management model; International Classification of Functioning, Disability and Health (ICF) learning environment movement system

Movement Analysis Across the Life-Span

Dale Scalise-Smith and Darcy A. Umphred

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Comprehend the complexity and interlocking nature of human development over a lifetime.
2. Differentiate traditional theories of development from contemporary theories.
3. Analyze the differences among various subsystems within the human organism.
4. Identify elements of physiological changes over a lifetime.
5. Analyze normal movement strategies and identify subsystems' responsibility for success of a motor task.
6. Identify normal changes in motor strategies over a lifetime and synthesize differences between normal movement patterns and pathological movement problems across the life cycle.

KEY TERMS

abnormal movement strategies

developmental theory

neuroconstructivism

nonlinear dynamics

normal movement strategies

stages of motor development

systems theory

As physical and occupational therapists assume greater roles in primary care of patients/clients, they recognize the importance of a multifactorial approach. To competently evaluate functional movement across the life-span, clinicians must possess knowledge and skills in the development of skilled, refined movement across domains. Only then will therapists be prepared to perform the necessary evaluative and diagnostic testing and effectively develop and implement plans of care aimed at minimizing impairments, maintaining or regaining functional skills, and improving quality of life.

Throughout much of the 20th century, developmental researchers were heavily focused on skill acquisition from infancy through early childhood.¹⁻³ In the 1970s, as research paradigms directed at motor development and motor learning evolved, it became evident that changes in motor skills were not limited to childhood but occurred throughout the life-span. Consequently, the concept of life-span development came to incorporate the prenatal period through older adulthood.

During infancy (birth to 1 year) and childhood (1 to 10 years) acquisition of motor skills coupled with cognitive and perceptual development are the primary foci of developmental researchers and clinicians. As the young child transitions to adolescence (11 to 19 years) and has the opportunity to experience motor behaviors across different environmental contexts, more complex behaviors emerge. Adulthood (20 to 59 years) signals a period when skills are refined and motor behaviors mature. Only through practice and repetition are skills attained and retained. Individuals who continue to use motor learning strategies into late adulthood (60 years through death) often

report more successful aging than those who do not engage in such motor skills.⁴⁻⁶

Identifying mechanisms that enable individuals to be successful in acquisition and retention of functional motor behaviors is critical to examining variables that alter or impair these same behaviors in other individuals. Kandel and colleagues⁷ suggested that “the task of neural science is to understand the mental processes by which we perceive, act, learn, and remember” (p. 3). This view supports the interactive and collaborative nature of intrinsic and extrinsic systems to accomplish motor learning tasks.

Given the interactive nature of different subsystems, it would seem most effective for clinicians to recognize the need for implementing a multidimensional approach when devising intervention programs. To discuss the interactive nature of these issues, this chapter will (1) briefly provide a historical perspective of theories of motor development, (2) discuss domains (cognition, memory, perception, and so on) associated with life-span motor development from prenatal development through older adulthood, (3) discuss the impact of various body systems on motor skill acquisition, retention, or deterioration, and (4) describe behavioral changes that may positively or negatively influence motor performance across the life course.

With the focus of this book on neurological rehabilitation, it is imperative to incorporate the complex and interactive nature of the physiological, cognitive, and perceptual systems. Although readers can read about movement development across the life-span, it will not integrate into clinical practice until the therapist understands movements of the patient and how those movements reflect the summation of systems

interacting to allow that individual to express movement, whether that be as a functional task, a written script, or the use of verbal language. Without that link between identified movement and motor control expressing that movement, often the therapist misses critical clues to the analysis of the central nervous system (CNS) of the patient and how best to provide an environment that provides the opportunity for that individual to improve functional skills and quality of life. For that reason, figures have been inserted to help the reader understand the differences among movement patterns across the life-span.

THEORIES OF DEVELOPMENT

Development is often portrayed as a series of stages through which an infant progresses with a fixed order to the sequence.⁸ A developmental theory may be characterized as a systematic statement of principles and generalizations that provides a coherent framework for studying development. Historically, development was thought to be linear, occurring in an invariant sequence and resulting in behavioral changes that are direct reflections of the maturation of anatomical and physiological systems.^{9,10} Development is generally examined in terms of quantitative and qualitative change. Although it is universally accepted that acquisition of developmental skills is not reversible, the underlying principles surrounding the emergence of these behaviors has evolved over the past 50 to 75 years.

Early developmental theorists used neuromaturational models of CNS organization as the framework for conceptualizing development.^{1,2} These researchers provided elaborate descriptions of posture acquisition and a blueprint delineating skill development. Research focused on the emergence of cognitive and affective behaviors and ignored the processes and mechanisms involved in acquiring motor skills.¹¹ Several investigators attributed developmental changes to intrinsic variables such as maturation of the CNS, whereas others associated changes with extrinsic variables involving the environment.^{1,2,12,13}

During the 1930s and 1940s, Arnold Gesell and Myrtle McGraw led a cadre of avant-garde researchers exploring the field of infant motor development. Gesell¹⁴ described the normative time frame for when behaviors emerge, and McGraw² examined the underlying mechanisms responsible for the emergence of these behaviors. The underlying premise, the foundation for their elaborate descriptions of motor development, was based on maturational processes in the CNS.

Gesell, a pioneer in developmental research, was a proponent of the theory that nature drives development.¹⁵ He proposed that growth is a process so complicated and so sensitive that intrinsic factors are solely responsible for influencing development. He used the evolutionary thinking of Darwin and Coghill to explain changes in motor behaviors. Coghill,¹⁶ in his work with salamander embryos, reported that motor behaviors, like swimming, emerge in an orderly sequence as connections of specific neural structures appear. Coghill concluded from his observations of emergence of behaviors in the salamanders that human infant motor behaviors appear in a predictable sequence and at predictable chronological ages.

With Coghill's research as the foundation for his thinking, Gesell embraced the concept of a hierarchical organization of the CNS. He believed that the emergence of motor behaviors was contingent on maturation in the CNS and concluded that only after the emergence of higher-level neural structures would complex motor behaviors appear. Within this constrained theoretical perspective, extrinsic or environmental stimuli, human or otherwise, were thought to have little impact on the appearance of motor behaviors. Gesell concluded that infant development is preprogrammed and linear, emerging at predetermined stages or periods in time.¹⁵ Perhaps his greatest contribution to

motor development was the conceptualization of milestones as markers to evaluate infant behavior.

Although McGraw was a proponent of ontogenic development as one variable influencing motor development, she did not believe, as Gesell did, that it was the sole determinant.¹⁷ Rather, McGraw attempted to explain the emergence of motor behaviors through environmental influences as well as CNS maturation.² She examined the temporal and qualitative aspects of motor skill acquisition through her study of Jimmy and Johnny,¹⁸ a study of twin brothers in which one twin was provided an exercise program, whereas no intervention was afforded the other twin. She found temporal and qualitative differences in the boys' acquisition of motor skills and attributed differences in acquisition of these behaviors to disparities in practice opportunities.

McGraw believed that the acquisition of the movement (process) is as important as when (chronological time frame) the behavior is acquired (the outcome). She further elaborated that, within the constraints imposed by the developing CNS, a rich and challenging environment can and does facilitate temporal efficiency in acquisition of motor behaviors. And finally, she proposed that practicing motor skills influences emergence of the same behavior.

Sufficient evidence exists to support the premise that although some predetermined processes occur at relatively similar points in development, not all motor behaviors emerge at the same biological, chronological, or psychological age in every individual. Although motor milestones provide information regarding outcome, no information can be derived about the process of attaining motor skills from those specific milestones. Perhaps a more realistic explanation may be that emergence of new skills occurs out of a need to solve specific problems within the environment. Working within this context, it is evident that traditional theories of development and maturation fail to adequately encapsulate the innate variability in human development.^{11,12}

Within the last few decades, researchers employed more contemporary theories of development when designing studies involving infants and young children.¹⁹⁻²¹ These investigators examined the process of skill acquisition rather than using traditional methods that assess outcome as a measure of motor development.²²

Although early pioneers in developmental research described development as linear, uniform, and sequential, Thelen and Smith²³ depict development as "messy," "fluid," context-sensitive, and nonlinear. Linear and nonlinear dynamics are derived from mathematics. Linear dynamics is described by the proportional relationship of the initial condition to the outcome, whereas no such proportional relationship exists in nonlinear dynamics. Nonlinearity is used to describe complex systems, in this case biological or more specifically human systems.²⁴ Within these complex systems exists a level of unpredictability, given the interactive and interdependent nature of biological systems.

Thelen and Smith²³ suggested that, although traditional theories of development support the premise that behaviors emerge in accordance with a relatively fixed temporal sequence, an organism may exhibit "precocious" abilities when the context is altered and the behavior emerges earlier than expected. These authors stated that immature systems exhibit behaviors that are variable and easily disrupted. Although development of some organisms in a controlled laboratory environment may reflect more traditional perceptions of development, outside, in a more naturalistic environment, development is more likely to be flexible, fluid, and tentative. Thelen and Smith also found that factors most likely to have an impact on performance are the "immediacy of the situation" and the "task at hand" rather than "rules" of the performance. Given this perspective, Thelen and Smith²³

identified six goals as essential to developmental theory. These goals are as follows:

1. To understand the origins of novelty.
2. To reconcile global regularities with local variability, complexity, and context-specificity.
3. To integrate developmental data at many levels of explanation.
4. To improve a biologically plausible yet nonreductionist account of the development of behavior.
5. To understand how local processes lead to global outcomes.
6. To establish a theoretical basis for generating and interpreting empirical research (p. xviii).²³

Thelen and Smith urged developmental researchers to devise paradigms that attempt to explain development in terms of diversity, flexibility, asynchrony, and “the ability of even young organisms to reorganize their behavior around context and task” (p. 18).²³

Contemporary theorists inferred that developmental changes are nonlinear and emergent and may be the result of the interactive effects of intrinsic and extrinsic variables. This divergence from traditional thinking compelled avant-garde scholars to propose new theories.^{23,25,26} Investigators described behaviors as complex, interactive, cooperative, and reflects an ability to organize and regroup around task and context, rather than conforming to a rigid structure and rule-driven hierarchy, as many earlier cognitive researchers believed.^{23,26} Contemporary theorists exploit technology to derive a model to explain variability and flexibility in developing, mature, and aging populations.²⁶

GENERAL SYSTEMS THEORY

Systems theory, first described by von Bertalanffy in 1936, was not discussed in great detail until 1948. In 1954 von Bertalanffy and colleagues from three other professions met to discuss systems movement.²⁸ Theorists then applied systems theory to a variety of human and nonhuman systems. As theorists became acquainted with systems theory, they became more receptive to alternate theoretical proposals of growth and development in living organisms.

Systems theory may be applied as a transdisciplinary model examining relationships of structures as a whole.²⁸ “The notion of a system may be seen as simply a more self-conscious and generic term for the dynamic interrelatedness of components”²⁸; von Bertalanffy proposed this theory to more adequately describe biological systems, investigate principles common to all complex organisms, and develop models that can be used to describe them.²⁸

Principles that embody general systems theory include nonsummative wholeness, self-regulation, equifinality, and self-organization.²⁸ Contrary to systems theory in disciplines such as traditional physics, in which systems are said to be *closed*, von Bertalanffy suggested that biological systems are open and modifiable and that changes in the system are the result of the dynamic interplay among elements of the system.²⁸

Embedded in the general systems theory is nonlinear dynamics, a concept in which behaviors are not described as the sum of their parts. Thus within a nonlinear model, a mathematical model is derived.^{26,29} Characterized within this model is the notion that systems may change in a sudden, discontinuous fashion. During development a small increase or decrease in one parameter leads to changes in the behavior. This abrupt change, identified as a bifurcation, causes the system to move out of its previous state and toward a new state of being.

Throughout development, periods of rapid differentiation or change occur when an organism is most easily altered or modified. These periods were identified by Scott³⁰ as “critical periods.” Physiological systems are most vulnerable during these periods and may be seriously affected by both intrinsic and extrinsic factors acting on the system. These periods occur at different times for different body

systems. Understanding systems theory and the concept of critical periods is crucial to all aspects of motor development.

As scientists began to revisit theories of motor development, they discarded some of the traditional theories and embraced contemporary concepts of nonlinear dynamics.^{26,27,29} Proponents of nonlinear dynamics contend that modifications in motor behaviors are the result of dynamic interactions among the musculoskeletal, peripheral and central neuromuscular, cardiovascular and pulmonary, and cognitive and emotional systems.²⁸ These interactive, multidimensional elements are vulnerable to changes in organizational and behavioral abilities (system) over time.^{30,31} Some theorists propose that as skills are acquired and organizational or behavioral changes occur, the system is driven to identify the most efficient and effective strategy to produce motor behavior(s).^{30,31} Yet others purport that variability implies that typical healthy individuals may use a variety of strategies to produce the same behavioral outcome and that variability is an indication of the individuals’ flexibility in responding to unpredictable perturbations.^{26,32} Implicit in nonlinear dynamics is the concept of critical periods in development.^{30–33} Investigators suggested that interventions imposed during a critical period may more easily positively or negatively modify the behavior. Recognizing the crucial role systems theory and critical periods play in development is essential to comprehending how developmental skills emerge. The multifactorial nature of nonlinear dynamics illustrates the complexity of development and the difficulty in identifying the appropriate variables that influence motor skill development.

With use of concepts previously described, it is reasonable to expect that a small change in any subsystem may result in a large change in a motor behavior. This is evident in work by Thelen and colleagues examining stepping in infants 8 weeks of age.^{31,34–36} They reported that introducing a small change in one element of the system, identified as a small weight applied to an infant’s leg, resulted in the infant being unable to step. The authors deduced that small changes in one subsystem, in this case the musculoskeletal system, may result in a change in the outcome. Additionally, adverse events during vulnerable periods of childhood can negatively impact the immune system leading to inflammatory responses that negatively impact health and risk for chronic disease and cognitive deficits in adulthood.³⁷ This lends support to the hypothesis that modifying one aspect of a multicomponent system, especially during a critical period, may cause the system to evolve into an entirely new behavior.

Periods of rapid differentiation, although often observed during early life, have also been observed across the life-span. Changes in anthropometric measures, such as weight gain during pregnancy, influence coordination between limbs and cause emergence of a different gait pattern. Changes in one system, in this case the endocrine system, result in increased ligamentous laxity at the pelvis and also contribute to gait alterations.

Menopause may be another critical period. During menopause, decreases in hormone production are thought to lead to osteoporosis and cardiac disease.³⁸ Examples described previously provide evidence across the life-span that the dynamic interplay within a system and among systems may significantly influence emergence and disappearance of behaviors.

Although research in the beginning of the 20th century was heavily focused on development of the very young, studies during the latter part of the century were directed toward research on aging. Technological advances in medicine have dramatically increased life expectancies. During the 20th century, the number of individuals in the United States older than 65 years old grew from 3 million to 35 million.³⁹ Perhaps the most significant statistic is that the oldest old grew from 100,000 in 1900 to 4.2 million in 2000.³⁹ By 2011 the Baby Boomer

generation began turning 65 years old, and the number of older individuals will increase sharply between 2010 and 2030.³⁹ By 2030, Americans over the age of 65 years will represent nearly 20% of the population, and by 2050 the number of individuals over the age of 85 years is predicted to grow to 21 million in the United States and 400 million worldwide.^{5,39} Given this incredible demographic transformation and that current policymakers are, in large part, the generation directly affected by these statistics, a significant paradigm shift in funded research has evolved over the past quarter century. “As such, aging and death are inseparable partners to growth and development” (p. 32).⁴⁰ Recognizing that a critical mass of Americans are entering older adulthood, terminology that operationally defines and is then applied consistently when referring to the aging population or an individual is imperative.

Biological and Chronological Age

Age can be described in terms of chronological age and biological age.⁴¹ Chronological age is the period of time that a person has been alive, beginning at birth. In infants it is measured in days, weeks, or months, whereas in adults it is expressed in terms of years and at times decades.

Although chronological age is measured in terms of temporal sequencing, biological age is related more to functioning and physiological aging of organ systems.⁴² For example, a triathlete may have biologically younger cardiovascular and pulmonary systems than same-age peers who do not perform high-level aerobic activities. Another example might be a child who underwent precocious puberty. Precocious puberty, identified as puberty earlier than 8 years of age in girls and 9.5 years in boys, results in acceleration in a biological system before same-chronological-age peers.⁴³ Physiological changes include elevated hormonal levels, which would then stimulate development of breast tissue and early menstruation in girls. Changes in the musculoskeletal system include early closure of the epiphyseal plates, resulting in significantly smaller stature. Conversely, these young women’s reproductive cycles are significantly skewed. Women would also have menopause and aging issues associated with hormonal changes earlier than other women of the same chronological age. Although no consistent method has been established for measuring biological age, there is general agreement that a wide variability of biological aging exists and that a number of factors contribute to accelerated or decelerated biological aging.

Aging

“Aging refers to the time-sequential deterioration that occurs in most animals including weakness, increased susceptibility to disease and adverse environmental conditions, loss of mobility and agility, and age-related physiological changes” (p. 9).⁴⁴ Goldsmith’s description of aging is typically viewed as an inevitable fact of life. This perspective evolved as technological advances and new evidence emerged indicating that age-related changes are more medically treatable than previously thought.^{41,44,45} Scientists are hesitant to attribute a decline in functional movement in older adults to a decline in physiological systems or to diminished opportunities for practice or conditioning.⁴ Rowe and Kahn reported that “with advancing age the relative contribution of genetic factors decreases and [of] the nongenetic factors increases” (p. 446).⁴ Age-related factors that are modifiable may be used to identify individuals who may or may not age successfully. For instance, lifestyle choices, including diet, physical activity, and other health habits, and behavioral and social factors have a potent effect and accelerate or decelerate aging. Evidence to support this was initially derived from a 10-year study conducted by Rowe and Kahn.⁴⁶ The

authors identified three critical factors that contribute to aging successfully: avoidance and absence of disease, maintaining cognitive and physical functioning, and “sustained engagement in life.”⁴⁶ Recently researchers suggested that Rowe and Kahn’s classification of successful aging is too restrictive and may lead to classifying individuals with relatively minor health problems as unhealthy.⁴⁷ McLaughlin and colleagues⁴⁸ suggested that a critical variable in defining successful aging is first identifying what the goal is for measuring successful aging. Building on Rowe and Kahn’s conceptual model of successful aging, recently researchers suggested shifting the focus from older adulthood to a life course approach.^{47,49} The life course approach is a more holistic model focused on “aging well” and promoting healthy lifestyle choices for both physical and mental well-being across the lifespan, well before older adulthood.⁴⁹ Aging, a complex and dynamic phenomenon, is impacted by temporal modulation between and within systems/subsystems. Only then can researchers determine how best to define and measure successful aging. Although controversy exists regarding defining successful aging, factors that contribute to successful aging hinge on higher levels of physical activity, increased social interactions, and positive perception of health. Factors thought to negatively impact successful aging include smoking, chronic diseases (arthritis, diabetes), and impaired cognition.^{50,51} Consequently, developing a healthy lifestyle early in life may be critical to maintaining good health and may play a significant role in successful aging.^{5,6} Moving away from a deficit model, researchers are now conceptualizing aging as a lifelong process influenced by development, lifestyle choices, social relationships, health, and experiences influencing aging from a physical and behavioral perspective.^{5,47,49,52,53}

Factors associated with aging are generally identified as either age related or age dependent. Age-dependent changes within organ systems are observed in individuals at a similar age, whereas age-related changes may be accelerated or decelerated in same-age individuals on the basis of intrinsic or extrinsic factors related to lifestyle. Just as variables associated with lifestyle (extrinsic factors) influence aging, genetics (intrinsic factors) also play a significant role. From a genetic perspective, structural and functional changes are generally thought to be a consequence of aging and are therefore predictable and consistent across physiological systems.⁶ Variables thought to influence the genetic potential for longevity include environmental factors such as toxins, radiation, and oxygen free radicals. Free radicals are highly reactive molecules produced as cells turn food and oxygen into energy.^{52,54} In summary, the use of biological age rather than chronological age may be a more accurate reflection of an individual’s true age.

Theories of Aging

Throughout the 20th century, the average life expectancy of individuals living in the United States increased. The second half of the 20th century signaled a shift in the focus of human development research, from infant and child development to older adult development.

Scientists view aging as a progressive accumulation of changes over time that increases the probability of disease and death.⁵⁵ Given that portrayal of aging, researchers have proposed myriad hypotheses regarding aging. Aging theories evolved because there is no single factor or mechanism responsible for physiological aging.⁴¹ Biological aging theories, similar to developmental theories, are attributed to complex, underlying mechanisms.^{41,44,45,56} Although theorists attempt to classify aging theories, these theories are rarely mutually exclusive. Some theories were formulated around control of physiological functioning, others around cellular changes, and still others around genetic causes.

Neuroendocrine theory is based on the premise that hormones play a significant role in aging.^{45,49} Hormones are vital to repairing and regulating bodily functions. Hormone production decreases significantly during aging and limits the body's ability to repair and regulate itself as effectively. Although hormonal decline is one plausible explanation for age-related changes, it does not account for all changes. Harman⁵⁷ proposed the free radical theory on the basis of his investigations that examined the effects of radioactive materials on human tissue.⁵⁷

Harman reported that when human tissue is exposed to radiation, a byproduct is formed. He identified the byproduct, an unstable compound, as a free radical. Over time, human tissue with free radicals showed evidence of biological defects consistent with accelerated aging. Harman postulated that accumulation of free radicals in human tissue may also occur as a part of the normal aging process. This became known as the free radical theory of aging.⁵⁷⁻⁵⁹

Free radicals are highly reactive molecules that damage proteins, lipids, and deoxyribonucleic acid (DNA). In some instances, free radicals combine with enzymes and turn into water and a harmless form of oxygen that moves harmlessly through the cells.⁵⁸ In other instances the oxygen binds with intrinsic or extrinsic sources that influence the aging process.

Scientists have suggested several different ways that free radicals influence aging through intrinsic and extrinsic mechanisms.^{58,59} An example of an intrinsic mechanism would be chronic infections that extend phagocytic activity and expose tissues to oxidants, creating cumulative oxidative changes in collagen and elastin. Extrinsic sources of free radicals include environmental toxins—for example, industrial waste and cigarette smoke.

Human exposure to intrinsic and extrinsic free radicals causes large numbers of reactive oxygen molecules to interact with DNA, leading to mutations thought to be the cause of a variety of diseases, including cancer, atherosclerosis, amyloidosis, age-related immune deficiency, senile dementia, and hypertension. Although some scientists suggest that aging has many factors that can accelerate or decelerate the process, other scientists suggest a much simpler, preprogrammed theory, known as the Hayflick limit.^{41,58-60}

Hayflick and Moorhead^{60,61} proposed that there is a finite number of times that a normal cell is capable of dividing. Current thinking is that cells are capable of dividing up to 50 times. Cell division is recognized as one way in which cells age and, after attaining the maximum number of divisions, finally die.

The factor thought to limit a cell's ability to divide infinitely is the presence of telomeres. Telomeres are minute units at the end of the DNA chain.⁶⁰ Each time a cell divides a small amount of the telomere is used in the process. Eventually, when cells have exhausted the supply of telomeres available, the cell is unable to divide and cell death ensues.

Telomerase, a substance that can lengthen telomeres, is available in human cells. Typically, telomerase is switched off in all cells except the reproductive cells. The availability of telomerase in reproductive cells allows for many more divisions than previously observed in the Hayflick limit. In addition to the presence of telomerase in reproductive cells, scientists have also discovered that telomerase remains active in cancer cells. Both reproductive and cancer cells divide well beyond the 50-division limit. Consequently, scientists are now working toward activating telomerase in all cells to slow or stop aging. If scientists are successful in activating telomerase in other cells, it may stimulate skin cell regrowth for burn patients and cure diseases that result from failure of aging cells to divide, as in macular degeneration or Hutchinson-Guilford progeria syndrome.^{62,63} The downside of this is that scientists may have a difficult time controlling the telomerase and in fact may see

more uncontrolled cell growth—cancer—one of the greatest threats to prolonged existence.

Although many aging theories are directed at mechanisms that negatively influence aging, other theories are focused on factors that have a positive impact on aging processes. One such process is the caloric restriction theory.^{57,59,60,64} Liang and colleagues,⁶⁴ with use of several genetic mouse models, investigated the impact of dietary control on the life-span. The authors reported that the mice did, in fact, have their life-spans extended when their dietary intake was controlled. Although these findings are potentially significant, given the small sample size and model examined, these data were not generalizable to all species. The researchers suggested that these preliminary data provide a foundation for scientists to examine whether dietary control will extend the life-span in humans as it did in the mouse models.

Sleimen-Malkoun and colleagues proposed a framework that aging is “driven by complexity changes and dedifferentiation within and between the different functional subsystems.”⁶⁵ Additionally, they suggested that their view diverged from a more traditional perspective and suggested that if we better understand how different subsystems interact and how the interactions change as a consequence of the adaptive processes across the life-span, we might develop a model that promotes healthy, active, and successful aging.

Although a large body of literature exists examining the underlying mechanisms associated with aging, it seems inconceivable that any one mechanism is responsible for age-related changes. More likely is that aging may be attributed to multiple factors, including lifestyle choices, in combination with the physiological and environmental factors.⁶⁶

Belsky and colleagues conducted longitudinal research examining aging of adults in their third and fourth decades of life.⁵ They found participants with accelerated aging were less physically able, had cognitive changes, were less healthy, and physically appeared older.

In summary, current research is challenging more traditional perspectives on aging. Rather than focusing on declining motor behaviors in older adults attributable to declining physiological systems, decreased practice or conditioning, or decreased ability to perform skilled behaviors,⁶⁷⁻⁷⁰ researchers are suggesting that promoting health and well-being across the life-span might mitigate decline in older adults.^{5,6,37,47,49} This suggests that physical or occupational therapy intervention may provide adults with strategies to positively impact performance over the life course, with a focus on promoting successful aging and maintaining skills.

The exogenous and endogenous variables across the life course are thought to be interrelated and provide an expansive description of the deleterious changes at the cellular, organ, and system level that accompany both aging and many age-associated diseases. The accumulation of damage is in DNA, proteins, membranes, and organelles, as well as the formation of insoluble protein aggregates. Many organ systems, such as the cardiovascular system, the brain, and the eye, are not programmed for indefinite survival. Consequently, the inability to maintain the integrity of tissues and organs is the end result of the multidimensional aspect of aging.

PHYSIOLOGICAL CHANGES IN BODY SYSTEMS ACROSS THE LIFE-SPAN

Organ systems undergo critical physiological changes across the life-span. These alterations are observed most often during periods of rapid differentiation. Applying concepts of dynamic systems theory to life-span development may help to explain how small changes in biological systems have a significant impact on the individual as a whole.

Examining interactions among variables within different body systems may provide insight into when one system may play a greater or lesser role in acquisition, retention, or deterioration of functional motor behaviors. The next section will examine how different systems develop and their contribution to functional movement.

Musculoskeletal System

Structural and functional adaptations in the musculoskeletal system are evident across the life-span. The musculoskeletal system provides a structural framework for the body to move and serves as protection for the internal organs.

Skeletal muscle tissue first appears during the fifth week of embryonic development and continues to develop into adulthood.^{60,71} During this early period of embryonic development, the differentiation of musculoskeletal system is rapid: during the fifth week of embryonic life the limb buds appear, by the seventh week muscle tissue is present in the limbs, and limb movements emerge as early as the eighth week of prenatal life.^{42,72,73}

Whereas many of the structural aspects of the musculoskeletal system are formed prenatally, muscle and bone continue to grow into adulthood. Motor skill acquisition involves considerable variability among young children from age 5 months through 3 years. During this time, the rate of growth of muscle tissue is reportedly two times faster than that of bone.⁷⁴

Structural and functional differences in the musculoskeletal system of a child versus an adult are attributed to the presence and predominance of muscle fiber types. For example, infant muscles are composed predominantly of type I (slow-twitch) fibers, whereas adult muscles contain types I and II (fast-twitch) fibers. Behaviorally, infant movements are characterized predominantly by postural movements. The capacity to produce a greater repertoire of movements, including rapid or ballistic movements, emerges later in development.

Distinct differences also exist in temporal differentiation of the muscular systems of males and females of the same chronological age. Through adolescence, boys show evidence of a significantly greater increase in fiber size compared with girls.⁷⁵ In addition, differences exist in the age at which the number of muscle fibers dramatically increases. Girls reportedly have a steady increase in the muscle fibers from 3.5 to 10 years of age. In contrast, boys have two periods of rapid differentiation in the number of muscle fibers. The first period occurs from birth until 2 years of age and the second from ages 10 to 16 years.⁷⁵ Although the pace slows considerably, muscle fiber development continues in men and women well into middle adulthood.

Age-related changes evident in the musculoskeletal system include decreased fiber size, loss of muscle mass, denervation of muscle fibers, decline of total muscle fiber number, and decreased quantity of fast-twitch fibers.^{76–79} Muscle mass peaks in the third decade of life and then begins to decline with approximately 10% lost by the fifth decade and 20% to 40% decrease between the seventh and eighth decades.^{80–82} Muscle force production likewise decreases at a rate of about 30% between 60 and 90 years of age. Additional musculoskeletal changes documented in older adults include decreased tensile strength in bone, reduced joint flexibility, and limited speed of movement. Decreased muscle mass in a person older than 60 years may be attributed to decreased size, fewer type II muscle fibers, and an increase in fat infiltration into the muscle tissue.^{83,84} Clinically these factors manifest as reduced muscle force production during high-velocity movements.

Currently, scientists are examining the premise that, as an individual ages, muscular changes are more likely attributable to decreased motor activity levels and are age related rather than being solely age dependent.^{78,83} Acknowledging that investigators had previously found that muscle power deteriorates more quickly with age, scientists set out

to measure training effects in older adults.^{69,85} These investigators concluded that with training older adults were capable of improving strength, power, and endurance. Modifying musculoskeletal tissue may take longer in older adults and requires that other body systems are capable of modifying performance levels to adjust to the increased demands of the musculoskeletal system.⁸⁶ The skeletal system, similar to the muscular system, experiences periods of growth, stability, and degeneration. The immature skeletal system is composed primarily of preosseous cartilage and physes (growth plates).⁸⁷ More simply, bone in infants and young children is flexible, porous (lower mineral count), and strong with a thick periosteum.^{87,88} Given these properties of immature bone, a child is less likely to have a fracture because the periosteum is strong and consequently the bones absorb more energy before the break point is reached. In addition, if a fracture does occur, healing is usually quicker because callus is formed faster and in greater amounts in children than in adults.

A primary difference between the child's and the adult's skeletal system is the presence of the growth plate complex in children. Whereas primary ossification occurs prenatally, secondary ossification is not complete until the child reaches skeletal maturity, generally at age 14 years in girls and 16 years in boys.^{88,89}

Even after bones have attained their full length, they continue to grow on the surface. This is termed *appositional growth* and continues throughout most of life. During childhood and adolescence, new bone growth exceeds bone resorption and bone density increases. Until age 30 years, bone density increases in most individuals, and bone growth and reabsorption remain stable through middle adulthood. Later in adulthood, resorption exceeds new bone growth and bone density declines.⁹⁰

Women exhibit more loss of bone mass than men do.⁹¹ Decreased bone density in women is generally attributed to differences in the types and levels of hormones present. Although the difference is most significant during menopause, premenopausal women still lose bone density at a higher rate than their male peers do.

Osteopenia is the presence of a less-than-normal amount of bone and, if not treated, may result in osteoporosis. Progressive loss of bone density, observed into older adulthood, is commonly identified as osteoporosis. Osteoporosis is more common in women than in men and is a major cause of fractures and postural changes in both sexes.⁹²

Overall, much of the growth in the musculoskeletal system is related to demands placed on the system. Intrinsic and extrinsic forces imposed on the musculoskeletal systems of typically and atypically developing children may lead to structural and functional differences in their respective skeletal structures. Consequently, temporal sequencing, acquisition, and characteristics of motor behaviors emerge differently in typically and atypically developing children. Similarly, age-related changes in older adulthood may be accelerated in direct proportion to decreased levels of activity.⁹³ Older adults who maintain more active lifestyles and place greater physical demands on their musculoskeletal systems are more likely to have an improved bone density and muscle mass than their peers who are not as active.⁹⁴

Sarcopenia, the age-related loss of muscle mass, and dynapenia, the loss of muscle strength, each contribute to changes in power and function.^{76,81,95} Researchers examining sarcopenia in older adults reported that men are affected more by sarcopenia than women.^{83,96} In fact, men with sarcopenia manifest four times the rate of activity limitations than do men with a normal muscle mass. Additionally, research suggests that while there is a relationship between changes in muscle mass and strength, they are not necessarily proportional, as many neuromuscular factors contribute to force production.^{80,76} Therefore, it is important to differentiate between sarcopenia and dynapenia and to examine the interactive effects, as these might be

more sensitive indicators of muscle function than strength or mass alone.⁹⁷

Reid and colleagues suggested that changes in neuromuscular activation changes may precede changes in muscle mass or strength and may be the initial mechanism that influences muscle power loss as a consequence of aging.⁹⁸ Investigators noted increased adipose tissue in skeletal muscle of older adults impacting the older adult's muscle power and performance.^{98,99} The increase in fat in muscle tissue is now recognized as myosteatosis. JafariNasabian and colleagues⁸¹ proposed a similar term for changes in bone-osteosteatosis described as the process where adipose tissue infiltrates into the bone marrow. Examining bone, muscle, and fat changes across the life course and evaluating how these changes impact functional performance, mobility, and risk for falls and fractures is important to planning and implementing therapeutic interventions in older adults.⁸¹

While sarcopenia, osteopenia/porosis, and obesity are recognized and exist as unique entities, the presence of the triad is now characterized as osteosarcopenic obesity syndrome.⁸¹ Increased body fat is redistributed to muscle and bone as well as abdominal and visceral organs as a consequence of aging. Osteosarcopenic obesity syndrome is composed of two newly recognized components that might exist independently or as components of the syndrome: osteopenic/osteoporotic obesity and sarcopenic obesity.⁸¹

Finally, while it may take longer for older individuals to regain strength or flexibility than a young adult or child, musculoskeletal tissue is modifiable throughout life.⁹⁵ Modifying the strength and flexibility of an older adult requires that other bodily systems be capable of modifying performance levels to meet the increased needs of the musculoskeletal system. Therapeutic interventions focused on reversing the physiological changes in bone and muscle may improve musculoskeletal health, functional performance, and quality of life in older adults. Recognizing the interconnections between bone, muscle, and fat, therapeutic approaches should focus efforts on all of these tissues to maximize the impact.⁹⁹

Although strength is critical to musculoskeletal function, flexibility is equally as important. Flexibility incorporates joint motion and the extensibility of the tissues that cross the joint. The degree of flexibility changes across the life-span as a direct result of aging and activity level.¹² Changes in flexibility are evident throughout life: limited at birth, increasing until the individual approaches adolescence, and then gradually decreasing. Exceptions may be seen in athletes, dancers, and other individuals involved in activities that incorporate flexibility training. Loss of flexibility as a consequence of age may have a negative impact on functional independence in older adults. Flexibility is thought to be directly proportional to the amount, frequency, and variability of motor activities performed. As activity increases, so does flexibility. Conversely, as individuals exhibit decreased levels of motor activity, often associated with age, flexibility decreases.⁹⁰

By age 70 years, flexibility is thought to have decreased by 25% to 30%.⁷⁹ Although this was purported to be age dependent, it may be more likely that it is age related.⁷⁸ Regularly performing exercise directed toward improving strength and flexibility can reverse the effects of inactivity for most individuals, even those older than 90 years of age.^{76,78,93} As scientists continue to examine functional changes across different systems as a consequence of age, physical and occupational therapists must educate individuals regarding the importance of embracing a physically active lifestyle and methods to enhance quality of life at each stage in an individual's life. Although all systems contribute to an individual's health and wellness across the life-span, the cardiovascular and pulmonary systems play a key role (see Chapter 29).

Cardiovascular and Pulmonary Systems

The cardiovascular system is composed of the heart, lungs, and associated vascular complex. It is responsible for pumping blood through the coronary, pulmonary, cerebral, and systemic circulations, with the goal of perfusing all bodily tissues for the delivery of oxygen and vital nutrients and picking up waste products for elimination. The pulmonary system is responsible for oxygen transport, gas exchange, and removal of airborne pollutants that may enter during respiration (see Chapter 29).

The interdependent nature of the cardiovascular and pulmonary systems is evident in the fact that, each minute, all of the body's blood travels through the lungs before being returned to the left side of the heart for ejection into the systemic circulation.¹⁰⁰ Because of this relationship, changes in heart function can dramatically affect lung function, and vice versa. In addition, these two systems are connected as part of a larger closed pressure-volume loop through the peripheral circulatory structures. Likewise, any alteration in the function of the peripheral vessels will affect both the heart and lungs, and vice versa.

The function and homeostasis of the cardiovascular, pulmonary, and peripheral vascular systems are influenced by both internal and external forces.¹⁰⁰ Internal mechanisms of control are based on the autonomic nervous system, the relative health of the anatomic structures involved, the growth and development of the structures, and the behavioral and emotional adaptations of a particular individual. All those internal mechanisms are subject to changes with growth and development, aging, lifestyle choices, and the unique life experiences of an individual. Growth and development primarily affect the physics of the system by altering volumes, lengths, smooth and myocardial muscular tension, and physiological capacitance within the system to support the growing body. Numerous effects of aging have an impact on the adaptability of the system. Behavioral and emotional responses influence both autonomic and volitional cardiovascular and pulmonary reactions to stress. External forces include movement, environment, and activity level, which alter the gravitational forces on the closed pressure-volume system. An increased activity level causes exercise stress, which requires an altered demand for oxygen and nutrients to the structures providing the work. Finally, emotional stress needs to be considered as an external factor. Behavioral responses to stress can affect functional movement and cause maladaptive coping mechanisms on any or all systems. As with anything, the age, cognitive status, and relative health of an individual will dictate the potential success of these endeavors.

Because oxygen transport and exchange are the primary requirements for sustaining life, efforts toward maximizing the efficiency of the cardiovascular and pulmonary systems represent a fundamental component of therapeutic practice. It is critical that no matter where a patient falls in the life-span, strategies for screening, prevention, and rehabilitation of the cardiovascular and pulmonary systems be incorporated into a comprehensive plan to promote optimal mobility, function, and independence.¹⁰¹ It is essential for therapists to keep in mind that all interventions have a direct or indirect impact on these systems and that it is their responsibility to monitor and manage those responses to maintain safety.

A detailed understanding of the anatomy of the heart, lungs, and vessels, as well as the physiology and interrelationship of the organs involved, is essential to the practice of both physical and occupational therapy. Refer to Chapter 29 for additional information. For pediatric therapists, the added knowledge of normal growth and development of these structures is critical.

From weeks 3 to 8 of fetal life, the cardiac structures are formed.^{71,72,102} All other structures of the cardiovascular system are fully developed and functional shortly after birth. Although the left and

right ventricles are of similar size at birth, by 2 months of age the muscle wall of the left ventricle is thicker than that of the right ventricle.¹⁰³ This is attributable to the fact that the left ventricle is responsible for pumping blood to the whole body, requiring a higher internal pressure and contractile force, whereas the right ventricle is responsible for pumping blood only to the lungs, a relatively low-pressure function in a healthy individual.

It bears mentioning that the heart's function begets structure. Therefore if function becomes impaired, the structure is likely to adaptively change. For example, if the resistance in the vascular system from the right ventricle to the lungs becomes increased, the right ventricle must pump harder, with a greater volume of blood, to overcome the resistance.¹⁰⁴ Over time, this will increase the size of the ventricular walls because the myocardium is muscular tissue that is as equally capable of hypertrophy as skeletal muscle tissue.

Structurally, the heart doubles in size by year 1, and its size increases fourfold by year 5. Many of the changes associated with size are complete by the time the child has reached maturity. Recall that cardiac output (CO) is equal to stroke volume times heart rate. As the size of the heart increases (increasing the volume capacity for each stroke), the heartbeat decreases and the blood pressure increases.¹⁰⁵ Heart rate in a newborn infant is generally 120 to 200 beats per minute (bpm), 80 bpm by 6 years of age, and 70 bpm by 10 years of age.^{103,106} Systolic blood pressure (defined as maximal pressure on the artery during left ventricular contraction or systole) is 40 to 75 mm Hg at birth and increases to 95 mm Hg by 5 years of age.¹⁰³ Blood pressure continues to rise into adolescence. The capacity to maintain exercise for longer periods and greater intensities increases through early childhood. Although cardiovascular disease is generally associated with adults, children as young as 5 years of age may show signs of or be at risk for cardiovascular disease if they do not engage in regular aerobic activity.^{103,107}

Development of the pulmonary system occurs late in prenatal and early postnatal life.¹⁰⁶ As the lungs increase in size, tripling in weight during year 1, the capacity and efficiency increase while the respiratory rate decreases.¹⁰⁶ Physiological performance of the cardiovascular and pulmonary systems improves in response to growth and development. Although the vital capacity of a 5-year-old child is 20% of an adult's, this is not usually a limiting factor during exercise.¹⁰⁵ Overall, aerobic capacity increases during childhood and is slightly higher in boys than in girls. The overall work capacity of children increases most dramatically from 6 through 12 years of age.¹⁰⁵ Peak oxygen consumption is achieved early in adulthood and changes in direct relation to activity levels. Lungs of an average adult at rest take in about 250 mL of oxygen every minute and excrete about 200 mL of carbon dioxide.¹⁰⁸ As activity levels change across the life course, so do the structural and functional capacities of the cardiovascular and pulmonary systems.

Many of these changes are a result of changes in the elasticity of the tissues, efficiency of the structures, and ability to increase workload. CO decreases approximately 0.7% per year after age 20 years so that by age 75 years the CO is 3.5 L/min, down from 5 L/min at age 20 years.¹⁰⁸ Functional changes include a decrease in the overall maximum heart rate from 200+ bpm through young adulthood to 170 bpm by age 65 years.¹⁰³ Older adults typically have less elastic vessels, with increased resistance to the blood volume. Consequently, older adults reach peak CO at lower levels than do younger individuals. These cardiovascular changes may be compounded by inactivity, resulting in decreased capacity to perform activities that raise metabolic demands and increase the requirement for oxygen transport.¹⁰⁹

Cardiovascular health also plays a significant role in the health of the brain, in particular white matter.¹¹⁰ As individuals age, cardiovascular health changes leading to hypertension and elevated resting heart rate

are related to white matter health and the associated macro- and micro-structural changes. Pulse pressure, defined as the difference between a person's systolic and diastolic blood pressure, is recognized as a good indicator of cardiovascular and white matter health in older adults. That is, higher systolic and lower diastolic blood pressures may indicate increased arterial stiffness and reduced vessel compliance. Additionally, body mass index (BMI) also impacts cardiovascular and white matter health. As BMI increases, white matter health decreases, suggesting that changes in cardiovascular and white matter health are possible by controlling BMI through lifestyle changes such as nutrition and exercise.¹¹⁰

Throughout life, performance of motor activities and activities of daily living (ADLs) is highly dependent on the integrity of an individual's cardiopulmonary and cardiovascular systems. Introduction of aerobic activities during early childhood has implications for improved health and wellness across the life-span.⁵ Although aging has a negative impact on performance and efficiency of the cardiovascular and pulmonary systems, aerobic exercise has a positive impact on these systems. Howden and colleagues¹¹¹ examined changes in cardiac stiffness and maximum oxygen uptake in healthy sedentary middle-aged adults participating in a 2-year intensive exercise program. They suggested that maintaining a regular exercise training program may reduce cardiac stiffness and improve the overall health of the cardiovascular system. These findings are consistent with the work of other researchers examining the impact of aerobic activity on body systems.¹¹² Aerobic exercise improves the elasticity of blood vessels, enhances cardiac contractility, and improves the oxygenation to different organs. Changes in the cardiovascular and pulmonary systems have a significant impact on the overall health of other systems and consequently on body functioning. Information from these systems, including blood pressure and oxygen saturation rates, is communicated through the nervous system. The nervous system, in turn, regulates responses of the cardiovascular and pulmonary systems through the autonomic nervous system.

Neurological System

The nervous system encompasses the CNS and the peripheral nervous system (PNS). The CNS includes the brain and spinal cord, and it is responsible for all bodily functions. The PNS includes both the autonomic and the somatic nerves and is responsible for transporting impulses to and from the CNS.⁵ The capacity for humans to produce behaviors far beyond those of other animals is directly related to the complex abilities of the CNS and interneuronal communications.

Over the past three decades, technological advances have enabled neuroscientists to dramatically improve their understanding of the molecular changes in the nervous system over time.¹¹³ Development of the CNS is coordinated through intrinsic influences involving the temporal and spatial coordination of synaptic connections with genetic processes, along with extrinsic or environmental factors. Initially, development of the CNS is dependent on precise connections formed between specific types of nerve cells and begins with the recruitment of cells that form the neural plate, which gives rise to the neural tube, and then differentiation of regions of the brain begins.^{5,114} Changes in the nervous system are predicated on critical periods, or times when different regions of the brain are sensitive to change, and occur across the life-span.^{5,30,115,116}

Each region of the brain is thought to undergo critical or sensitive periods at different ages. One of the most critical periods in development of the CNS occurs from birth through 1 year of age. During this period, when the system is most vulnerable to change, intrinsic and extrinsic variables may influence the nervous system structurally and functionally. In late adulthood, gray matter is thought to be vulnerable to

the effects of aging, with the frontal and temporal regions most susceptible to age-related changes.^{116,117}

Differentiation of cells in the nervous system begins during the embryonic period and continues throughout adulthood.^{5,113} Development of the nervous system during embryonic life involves the overproduction of glial cells and neurons that, after they are no longer useful, die. Additional developmental changes noted in the nervous system include increased myelination within the brain and an increase in neuronal size.⁷¹ Much of the growth may be attributed to these changes in the nervous system and may account for the development of the infant's brain, which increases to one half the size of the adult brain during the first year of life. Neural development, particularly in the cerebral cortex, documented early in development, may emerge out of environmental demands and the need to solve problems (tasks). Consequently, experiences can alter neural networks, and more complex experiences lead to increasing complexity of the neural structures.¹¹⁸ As individuals age, brain weight and volume decreases.^{116,119} Brain volume decreases an average of 0.2% to 0.5% per year.¹¹⁶ Atrophy, noted in both gray and white matter, is not thought to be equally distributed, with upwards of 15% to 20% decrease in white matter.^{52,116,119}

Whereas researchers long supported the premise that decline of the nervous system begins generally after age 30 years, more recent studies indicate that adults, even older adults, can form new neural connections and grow new neurons as an outgrowth of learning and training.^{113,115,120} Before the work of Eriksson and colleagues, researchers and clinicians believed that structural changes in older adults, such as decreased numbers of corticospinal fibers, intracortical inhibition, and neuronal degradation in centers in the CNS, particularly the cerebellum and basal ganglia, were inevitable.¹²³ In contrast, more recent research challenged traditional constructs that the only possible changes in the adult human brain were the result of negative changes caused by aging or pathology.¹²² Instead these researchers reported that the brain retains a level of neuroplasticity and is capable of changing into late adulthood. Employing strategies that promote neuroplasticity may provide more positive and cost-effective experiences and reduce the rate of cognitive decline in older adults.^{115,116} They suggested a direct relationship exists between learning a novel task, juggling, and structural changes in the gray matter.¹²² The authors caution that these structural changes were task specific and limited to the training period. Reexamination of magnetic resonance imaging (MRI) scans, after 3 months of no training, demonstrated that subjects no longer displayed the same structural changes as during juggler training.

Loss of neurons in the centers controlling sensory information, long-term memory, abstract reasoning, and coordination of sensorimotor information negatively affects function.¹¹⁶ For some individuals this may not have significant implications. For others, CNS changes create serious functional losses. Alterations in the CNS, including altered neural control and decreased efficiency in temporal sequencing of muscle synergies, may play a role in postural instability and impaired sensation.^{52,77,116} Although the CNS, similar to other bodily systems, may have the capacity to compensate for some age-related changes, the degree of compensation may be modulated by the complexity of the task and continuation of "practice" over time. Although some investigators have reported that neuromuscular systems in older adults may not be as flexible as systems in younger adults, new studies examining changes in mature and aging systems are still in the early stages. Neuromuscular systems in older adults may not be as capable of rapidly reorganizing muscle synergies to produce variable functional responses.¹²¹ The researchers did say that this may be related not solely to the aging neurological system but to other factors including experience, cardiovascular and musculoskeletal fitness, and current

level of functional independence. Other scientists suggested an alternative view that repetition of motor activities may stimulate new growth in dendrites located proximal to neurons previously lost.^{52,77} Implicit in performance of many functional activities is cognition. If changes in cognition coexist with changes in other systems, it may be difficult to accurately interpret the underlying causes.

Cognitive System

Cognition may be defined as awareness, perception, reasoning, and judgment.¹²³ Cognitive development involves processes of perception, action, attention, problem solving, memory, and mental imagery. Action, from the perspective of physical or occupational therapy, may be referred to as *functional movement(s)* and incorporates all the processes described previously to successfully perform a specific task.

Jean Piaget, one of the most recognized scientists in developmental psychology of the 20th century, was particularly intrigued with how biological systems affect what individuals "know."^{123,124} He observed interactions among children of different ages and hypothesized that younger children's thought processes were different from those of older children as evidenced through the differences in responses between them to the same questions.

Piaget proposed that cognitive development moved in a linear, stagelike progression, each stage of which involves radically different schemes.¹²⁴ He suggested four stages of cognitive development, identified as sensorimotor state (infancy), preoperational (toddler and early childhood), concrete operational (childhood and early adolescence), and formal operational (adolescence and adulthood).¹²³ He proposed that (1) sensorimotor behaviors stimulate cognitive development and (2) problem solving as a measure of cognition enables infants and young children to identify and modify motor behaviors.

Piaget's theory of cognitive development focused around how humans adapt within the environment and how these adaptations or behaviors are controlled.¹²⁴ He postulated that behavioral control is mediated through schemas or plans, generated centrally. These schemas provide a representation of the world in an effort to formulate an action plan. At birth, infants' earliest schemas are organized around reflexive behaviors that are modified as the infant adapts to the affordances and constraints of the environment.

Piaget suggested that adaptations occur through two processes: assimilation and accommodation.¹²⁴ He defines *assimilation* as a process of altering the environment around cognitive structures. An example of assimilation is when an infant, initially breast-fed, is transitioned to bottle feeding. *Accommodation* refers to changes of the cognitive structures to meet changing demands of the environment. Accommodation may be involved when an infant transitions from nutritive sucking (breast or bottle) to nonnutritive sucking (pacifier).

Much of Piaget's work was based on descriptive case studies. Although some aspects of his theory were supported by subsequent studies, other aspects of his work have not been shown to have empirical evidence. The inconsistencies of research findings examining Piaget's stages of development may be indicative of the dynamic and nonlinear nature of development and, more specifically, cognition.

Rather than postulating that infants are reflexive beings with little or no volitional movements early on, it may be more appropriate to view infants as competent beings with volitional and complex behaviors present at birth.¹²⁵ Brazelton reported that a newborn infant turns toward the mother's voice rather than toward an unfamiliar voice. In addition, research conducted by Meltzoff and Moore¹²⁶ provides evidence supporting the complex nature of infant behavior. They found that infants as young as 2 to 3 weeks of age can imitate facial gestures performed by adults. Their work was supported by subsequent studies performed by independent investigators using different procedures

and in different environments.¹²⁷ These findings, contrary to Piaget's proposal that infants were not capable of imitative behaviors until 1 year of age, provided scientists with a new perspective on infant behavior.

Contemporary researchers approach developmental theory from a dynamic and nonlinear model.^{23,114,118,128} Over the past 10 years, advances in technology (e.g., diagnostic imaging, functional magnetic resonance imaging [fMRI], magnetoencephalography [MEG], event-related potentials [ERPs]) have dramatically improved the ability to document change within the developing brain.¹¹⁴ These technological advances coupled with developmental paradigm shifts and computer modeling have led developmentalists to propose new theoretical frameworks to explain cognitive development. One model, called *neuroconstructivism*, incorporates intrinsic constraints and abilities of the CNS at the most basic cellular level with extrinsic influences involving environmental experiences and interactions.^{114,118} Fundamental to the neuroconstructivist theory is the principle of context dependence, in which representations emerge in direct response to the structural changes in the cognitive system. Embedded within neuroconstructivism is the concept of the infant as interactive, in contrast to more traditional developmentalists' perception of the infant as passive. Experiences that individual infants engage in vary through processes involving competition and cooperation. The processes employed during development may result in differing pathways or trajectories of development through which the outcome or behavior is realized. Despite the variability in the individual developmental trajectories, the behavioral outcome is often similar.

This model is purportedly applicable to typical and atypical development as well as mature and aging systems. In contrast, whereas the processes and interactions among multiple interactive constraints (biological and environmental) may be similar in typical and atypically developing systems, the constraints may differ. Hence the outcome or emergent behavior may be different.

Current theories lend support to the concept that the cognitive system integrates multimodal input to process, interpret, store, and retrieve information as a mechanism for information processing and problem solving.¹²³ Changes in cognition, defined as relatively permanent changes in behavior, cannot be measured directly but rather must be inferred from changes observed across multiple systems.

As the ability of infants to act on the environment develops, their ability to accurately detect and process relevant information becomes more efficient, lending support to the interdependence of the motor, cognitive, and perceptual systems.

Information processing, defined as the ability to understand human thinking, is a critical factor that must be examined within the cognitive system. Initially, infants and young children cannot recognize relevant cues or chunk information for storage. As children's developing systems become more adept at integrating information from multiple systems and more efficient at processing information, they begin to process relevant information more effectively. Consequently, infants and young children may not use or interpret information as efficiently as older children.

The integrative nature of movement, cognition, and perception is evident in developmental psychology literature.¹²⁹ Given that these domains are interrelated, one area cannot be examined in isolation of other interrelated systems. Acquisition of motor skills is the primary mechanism for evaluating cognition and perception in prelinguistic children. In addition, as individuals grow older, changes in any system may influence functional movement. Finally, when examining functional movements, therapists must always consider the individual's cognitive and perceptual abilities.

As higher-level cognitive processing skills become apparent, the child can accurately identify relevant cues, filter irrelevant cues, and

process information more efficiently. One such higher-level cognitive processing skill is executive functioning. Adolescence signals a period during which executive functioning begins to mature.¹³⁰ This period may be characterized as critical in CNS development. During this critical period, production of mature, adult-like decisions requires selective attention and increased integration of information via the prefrontal cortex (PFC). During the maturation process, adolescents may exhibit inconsistent decision making, resulting in less-than-optimal outcomes. By young adulthood, as the individual approaches maturity, optimal executive decision making becomes more consistent.

Human systems are continuously pelted with sensory information through some or all of the sensory modalities. At any one time, more sensory information is available than can possibly be processed. Consequently, the individual must learn to select information relevant to the task and chunk the information for processing.

Another example of the multidimensional processes involved in higher order tasks such as functional movement is found in a study conducted by Hazlett and Woldorff.¹³¹ They proposed that implicit in motor tasks are concepts of cognition including attention, perception, and information processes. This multimethodological approach examined (1) the influence of attention on sensory and perceptual processing, (2) the executive control of attention by higher centers of the brain, and (3) the processes underlying multisensory integration and the mechanisms by which attention interacts with such integration processes.¹³¹ Processing information acquired from different sensory systems may be directly related to changes to the respective sensory system.

Throughout the life-span, physical growth and development of many systems have an impact on the acquisition and performance of motor skills. Changes in one system and the interactive effects on all other systems can lead to deleterious changes in motor performance as a whole.

Changes in cognitive function in older adults are variable. Examining micro- and macro-level changes is critical to understanding the relationship between structural and behavioral changes.

Consequences of aging include slowed information processing and increased time necessary to perform motor skills.¹¹⁹ Even though learning may take more time in older adults, once a behavior is learned, retention is similar to that of younger individuals. Of significance for older adults is delayed performance of long-standing tasks, such as driving a car, which may have serious consequences for the driver, passengers, or others in the immediate vicinity of the vehicle. Delays in processing and task execution pose risks to the older person or individuals with CNS deficits and may affect the individual's level of independence and quality of life.¹³² These changes are directly related to state-imposed mandatory driving tests for older adults.¹¹⁹

Researchers have suggested that some individuals with higher cognitive reserve, attributed to higher educational level and socioeconomic status among other factors, have better compensation and neural plasticity in the face of neural insults, and clinicians should employ strategies to maintain cognitive functioning and/or slow cognitive decline.^{115,116} With technological advances introduced over the past three decades, clinicians and researchers are better able to measure structural changes influencing aging.¹³³ Researchers suggested that the brain and nervous system in older adults, similar to young children, may also be vulnerable to even small changes.¹¹⁶ Consequently, examining structural and functional changes will be important to better differentiate factors influencing changes.¹¹⁷ The relationship between cognitive function, brain integrity, compensation, and plasticity are central to a better understanding of normal and impaired cognitive processing in older adults.¹¹⁵

Evidence is mounting in support of the premise that physical exercise has a positive effect on the rate of cognitive aging and cognitive

performance,^{134–138} suggesting that the impact of these normal aging responses can be reduced through structured physical activities. Exercise provides benefits to overall functioning with little cost or side effects. Hence future efforts should focus on delineating the most effective types of exercise programs, frequency, and duration that yield the best outcomes. Recently, evidence emerged supporting the positive impact of social and leisure activities on maintaining cognitive performance in mid-life and older adults.^{47,138,139}

Physical and occupational therapists have expertise and would serve as key contributors in developing best practices for exercising with older adults. Therapists are well positioned to work with patients in identifying physical activities that they previously or currently enjoy and find ways to modify the activities to the patients' abilities, as a means of encouraging increased levels of physical activity. Finally, group exercises may be a means to integrate social and leisure activities with exercise to improve participation and benefits to patients.

While older adults experience deterioration in the processing and retrieval of information, the extent of the decline is not consistently predictable. Cognitive deficits most frequently observed in older adults include word retrieval, recall, dual-task execution, and activities involving rapid processing or working memory.

Memory

Memory can be broken down to three types: working, declarative, and procedural. Working memory, short-term memory, is the equivalent of the RAM of a computer.¹²³ This is the mechanism that enables a child who does not appear to be attending to what the parent is saying to repeat what the parent has just said. Given the temporary nature of this memory, no space in the hippocampus or amygdala is required. Working memory may in fact be more of a cortical phenomenon. Declarative memory is what is typically envisioned when we think of intermediate or long-term memory. Declarative memory is the area where long-term information about everything an individual has ever learned or information acquired is stored, including facts, figures, and names.¹²³ An example of declarative memory is a second-grade teacher recalling the name of a student she had in her class 15 years previously. Declarative memory is analogous to the hard drive in the computer. The third type of memory is procedural memory. Procedural memory involves all motor activities, actions, habits, or skills that are learned through repetition in motor practice.¹²³ Examples of procedural memory include walking, playing an instrument, and driving a car.

Different structures in the brain are involved in declarative and procedural memory. Declarative memory involves the hippocampus and other medial-temporal lobe structures, and procedural memory involves interconnected brain structures in frontal/basal-ganglia circuits, including frontal premotor and related regions.¹⁴⁰ Declarative memory is able to rapidly acquire new knowledge from a single experience/exposure.^{140,141} While new knowledge acquired through declarative memory can be implicit and explicit, long-term explicit knowledge is thought to solely be acquired through declarative memory. A variety of factors are thought to influence declarative memory including age, sex, sleep, and stress.¹⁴⁰

Rovee-Collier and colleagues^{142–144} have conducted numerous studies related to memory retention in prelinguistic children. Evidence exists to support the premise that infants as young as 2 to 3 months of age are capable of identifying relevant cues and chunking this information for later retrieval. One caveat is that retrieval of such information is possible only when the specifics of the behavior are retained. Infant memories are tightly linked to the specific information related to the task, environment, and stimulus. Consequently, a slight change in any of these three components may result in an inability to retrieve information from infant memory. Retention of information is directly

proportional to the infant's age. As an infant grows older, the period for which information is retained increases.

While declarative memory continues to develop through childhood into young adulthood, procedural memory matures in childhood and is thought to influence some aspects of language.¹⁴⁵ As children grow older, they develop more effective and efficient strategies to retain information. During adolescence the brain enters a plastic period, particularly in the frontal lobes. Neuronal connections that control sleeping and eating habits; regulate motor behavior; and modulate impulses, decision making, memory, and other high-level cognitive functions change significantly during adolescence. Given the plasticity of the adolescent's brain, it is highly probable that environmental stimuli influence intrinsic changes in the adolescent's CNS.

Across the life-span, some aspects of cognition seem to be impaired or changed before others. One area most susceptible to age-associated changes is the PFC. This particular area of the brain is where information critical to executive function, attention, and working memory is stored.¹⁴⁶ Although memory is one component of cognition that is generally acknowledged to deteriorate as an individual moves toward older adulthood, not all aspects of memory are affected at the same time or in the same way. Additionally, older adults are thought to compensate for changes in memory by keeping lists and writing things down.¹¹⁹ Using these strategies, performance of older adults may be better than younger adults depending solely on memory.

Episodic memory is reportedly the first to be impaired, then working memory (short-term memory).¹⁴⁶ Episodic memory is thought to begin declining in the fifth decade.¹¹⁶ Implicit memory and semantic memory remain intact for a much longer period of time. Little information is available about procedural memory, memory of how to perform tasks. Researchers have suggested that an older adult's declarative memory is also affected by normal and neuro-pathological aging.^{45,146} These investigators suggested that although older adults with deterioration in declarative memory are able to perform tasks, the individual is unable to retain information and consequently unable to learn tasks.⁴⁵ Many factors negatively or positively influence memory, including the nature of encoding or processing that information, such as the source of the material or time of day material is presented.¹⁴⁶

Although evidence exists that many aspects of memory decline with age, recent evidence supports the premise that variables other than encoding and retrieving information may have a significant impact on memory and remembering in older adults.^{116,147,148} Researchers at the University of Kuopio examined memory in older persons and focused on neuropsychological processes as a method for evaluating memory and other functions of the frontal lobe.¹⁴⁸ The investigators reported that elderly subjects with subsequent degradation of the frontal lobe had memory loss. These researchers suggested that some aspects of memory loss could be staved off through memory-sharpening activities and games, limitation of alcohol consumption, and participation in activities designed to retain details of skills and tasks. Combining physical and cognitive activities in a training program were also found to improve performance in executive functioning (attention and working memory), episodic memory, and processing speed of older adults for at least 1-year following physical-cognitive training.¹³⁶

May and colleagues¹⁴⁷ examined the role of emotion in memory tasks for older adults and found that older adults seem to be motivated to remember information that is emotionally relevant and meaningful. These findings lend support to yet another system, the emotional system, and its impact on an older adult's memory and task performance.

Emotional System

Although current literature examines the emotional development of children, evidence documenting how emotions are mediated, at a neurobiological level, are still emerging.¹⁴⁹ Emotion is modulated through the amygdala and measured through neuroimaging techniques including positron emission technology (PET) and fMRI scans. The amygdala appears to undergo changes throughout infancy and childhood into adolescence, increasing in volume until age 4 in females and age 18 in males.¹⁴⁹ In addition to the amygdala, the PFC plays an important role in emotional regulation, particularly in early childhood, and decreases in adolescence into early adulthood. If the connection between the amygdala and the PFC is weak, the ability to modulate emotional responsivity may be negatively impacted. Parental control appears to be an important factor in emotional regulation. The better input of parental control on emotion during sensitive periods in development, the better the individual's self-regulatory capacity later in life.

Zinck and Newen¹⁵⁰ proposed a classification of emotion that might provide a clearer understanding of responses within and between individuals and factors that affect emotion. The authors characterized emotion into four categories based on when the emotions appear developmentally. Emotion is characterized as a means of communicating state, expectations, and reactions of an individual.¹⁵⁰ Emotions are “interpersonal/interactive” behaviors that enable the individual to communicate to the world. The four categories are pre-emotions, basic emotions, primary cognitive emotions, and secondary cognitive emotions. Pre-emotions and basic emotions function as basic mental representations, whereas primary cognitive and secondary cognitive emotions are categorized as cognitive attitudes.

Pre-emotions are characterized as innate behaviors, present at birth, nonspecific, nonintentional, and used for communication to others about the state of the infant.¹⁵⁰ Pre-emotions are identified as comfort and distress. These responses may be positive or negative responses depending on the situations. Pre-emotions are the most fundamental sensations followed by basic emotions.

Basic emotions and developmental timing of basic emotions include joy at 2 to 3 months, anger at 3 to 4 months, sadness at 3 to 7 months, and fear at 7 to 9 months. These emotions are said to emerge in the absence of conscious processing of stimuli. These responses are shared by other mammals, and do not involve complex cognitive processing. These behaviors lead to faster and more stereotypic responses.¹⁵⁰

Primary cognitive emotions are characterized as basic emotions with more specificity, in addition to a cognitive component. Primary cognitive emotions are highly dependent on the individual's cognitive development as well as cultural variations and socialization.

Secondary cognitive emotions are depicted as complex constructs that involve social relations, with consideration for expectations of the future. Consequently, secondary cognitive emotions are highly dependent on personal experiences and culture. The authors provide an example of how one situation—high performance in academics—would be perceived by different cultures. Whereas a child from one culture might receive praise for and exhibit pride in high academic performance, a child from another culture could have such performance deemphasized and display shame. In addition to cognition, secondary cognitive emotions incorporate social constructs of family, culture, previous experiences, and environment in formulating complex responses.¹⁵¹ These responses are cumulative, using previous experiences to render new responses.

Examination of emotion in adults often involves a retrospective analysis of the behavior over a specified period of time. Although the focus of the research may be directed toward emotion, memory cannot

be disentangled from the emotion. With regard to aging in older adults, researchers generally have reported that emotions—in particular, negative emotions—diminish later in life. Some researchers have suggested that diminished negative emotions may be attributed to decreased functioning in the amygdala.¹⁵² Still other investigators have suggested that, rather, a decline in the functioning of the amygdala and decreased ability to recall negative experiences may be attributed to the socioemotional selectivity theory (SST).¹⁵³ The SST involves prioritization of memories and which temporal boundaries play a role in prioritization. Specifically, older adults do not perceive negative emotions as a priority; hence older adults are more likely to process positive emotions than negative.

Problems in normal emotional development are documented in the literature, focused on childhood and adulthood emotional problems stemming from either pathological conditions or environmental conditions during childhood.^{154–159} Within the literature, the reader can find discussions of emotional intelligence in adults and how emotional skills such as empathy or cultural sensitivity might be taught.^{160–166} Specific aspects of an emotion or mood change and how that might assist or hinder an individual within a psychosocial environment can be located,^{167–170} but the integration of the entire emotional system and its normal changes throughout life require additional study. Future research directed toward aging and emotion has potential to broaden the theoretical perspective by examining emotional experiences in an ecological context.^{171,172} In addition, identifying, measuring, and analyzing variables that appear to make a difference in social and professional success will be a central focus of future studies.¹⁷³ (See Chapter 4 on the limbic system and its influence on motor control and Chapter 5 on psychosocial adaptation and adjustment for additional information.)

Language

Consistent with all areas of development, acquisition of language, receptive and expressive, is measured quantitatively and qualitatively. Critical to the acquisition of receptive and expressive language is sensory, cognitive, perceptual, and motor development in the infant and child. Researchers have found evidence that language development emerges through nonverbal gestures or “signs”^{174–178} and is evident as early as 6 months of age.^{177,178} As the number of nonverbal gestures increases, verbal communication reportedly emerges earlier than in infants who do not use nonverbal gestures.^{175,177,178} “Gestures thus serve as a signal that a child will soon be ready to begin producing multi-word sentences.”¹⁷⁹ Having a large number of gestures at 18 months of age positively affects later language development and is the foundation for later linguistic abilities.¹⁷⁶

Imitation, such as “mama” or “dada,” is often the first form of verbal communication, progressing to spontaneous single-word utterances. Infants produce their first spoken single-word utterances as early as 12 to 15 months of age.¹⁸⁰ During this time the child's brain is undergoing rapid differentiation in Broca's area; at the same time, motoric ability to communicate verbally is emerging. Consequently, it is evident that intrinsic (neurodevelopmental) constraints and extrinsic (environmental) factors affect the emergence of receptive and expressive language. Investigators examining utterances in children and adults reported that utterances produced by children do not approximate those of adults until 14 years of age.^{181,182} Recently researchers reported that, consistent with findings of earlier investigators, articulatory movement speed increases from birth to adulthood.¹⁸² Throughout childhood, as language acquisition emerges, children become more sophisticated in communicating and more fully integrate information from intrinsic and extrinsic sources to produce more complex utterances.¹⁸⁰

Maner and colleagues¹⁸¹ reported that children exhibited increased variability when a five-word sentence was embedded in longer sentences than when the child spoke only the five-word sentence. These findings led the investigators to infer that a relationship existed between language processing and movement in young children.¹⁸³ In addition, adults reportedly modified the five-word sentence when it was embedded in the longer sentence, but 5-year-olds did not modify the utterance. Sadagopan and Smith¹⁸⁴ replicated the work of Maner and colleagues¹⁸¹ and found that children aged 5 to 16 years exhibited more variability when the five-word sentence was embedded in a more complex sentence compared with when the five-word sentence was spoken in isolation. Young adults (21 to 22 years old) reportedly did not exhibit this same variability. In addition, investigators reported that the duration of the simple and complex utterances differed between children and adults. Unlike the youngest children (5 and 7 years), duration of the utterances decreased in adults. This finding provided evidence for the investigators' theory that adults altered or shortened the complex utterances, given the shorter duration taken to utter the complex sentence. Whereas earlier researchers reported that both adults and children decrease their rate of speech during complex sentences,¹⁸⁵ more recently investigators suggested that adults may increase their rate of speech production. Sadagopan and Smith¹⁸⁴ reported that although both children and adults slow the rate of speech production, children exhibited a much slower rate than adults in producing complex sentences. Hence investigators concluded that whereas adults' rate of speech production did explain some of the difference in utterance duration for the simple and complex sentences, it did not fully explain the differences. This led investigators to suggest that differences in utterance duration may be attributed to both faster rate of speech and altered or shortened complex sentences containing the simple five-word phrase.

Researchers focused on expressive language in adults reported that older adults speech patterns demonstrate more interrupted speech than younger adults and used nonnormative language that might be attributed to increased word-finding difficulties.¹⁸⁶ Speech in adults (65 to 85 years) resembled that of children (<11 years of age).¹⁸⁷ While older adults had more instances of nonnormative word use than younger adults, the words used were often characterized as more optimal than younger adults. Perhaps some of these expressive language changes noted in older adults are related to the high incidence of hearing loss.¹⁸⁷ Older adults experience decreased perception of high-frequency sounds and dynamic range. Researchers used fMRI to document regions activated when examining aspects of expressive language and found that different regions were activated in older adults. Changes in physical and physiological structures as well as decreased motor control in older adults and children may be factors impacting similar language challenges. The dynamic nature of language is grounded in the constructs of dynamical systems theory involving intrinsic and extrinsic mechanisms. These mechanisms evolve over time and are highly sensitive to changes within and between systems.

Perceptual System

As researchers continue to examine the interactive and interdependent roles of body systems, the perceptual system must not be omitted. Perception, yet another process important to performance of functional movements, involves acquisition, interpretation, selection, and organization of sensory information. Perception is the very essence of the interaction between organism and environment. Every movement gives rise to perceptual information and in turn guides the organism to adapt movements accordingly.^{12,188}

Initially perception revolves around the infant's visual exploration of people, objects, and environmental activities. Infants are capable, at

birth, of visually exploring their environment, people, and objects.¹²⁴ Investigators have suggested that infants use information acquired through visual exploration to develop new methods of exploring and discovering cues about the environment such as depth, distance, surface definition, and dimensionality of objects.¹⁸⁹

A second phase of perceptual exploration emerges as an infant's exploratory behaviors transition to functional movements such as reaching and kicking. Through these exploratory behaviors emerge additional mechanisms for acquiring information about the environment.^{6,188} Throughout development, active exploration enhances perceptual information through each new encounter and enables the infant to recognize distinctive features and similar characteristics that allow the infant to differentiate between objects. The information generated from exploration provides new input to many subsystems, in particular the sensory, motor, and cognitive systems that enable the individual to gain new knowledge about the environment and the action.

Development of the infant's perceptual system is dependent on acquiring new information about the affordances of the task that may influence performance of the action. As the infant develops the capacity for independent mobility, the expanse of the environment increases, as do the opportunities to integrate prior knowledge with newly acquired information to discover uncharted surroundings. This again supports the interactive and interdependent nature of systems throughout development. As maturation progresses, infants develop the ability to evaluate information acquired from various systems and to make decisions about the optimal strategy for successfully navigating over or around a surface. With maturation, successful navigation of new environments depends on opportunities for exploration that may involve other processes in addition to motor processes. An example of this may be seen in a person trying to locate a building in an unfamiliar city. Adults typically use maps as a visual representation of the surroundings that allow them to find the location. Infants and young children are most accurate in locating desired targets through active exploration. This allows the child to acquire spatial information critical to locating the destination at a future time.

If perception is the process of integrating and organizing intrinsic and extrinsic input, then changes in sensory systems as a consequence of aging are certain to affect perception.¹⁹⁰ The visual perceptual processing system is most often identified as altered in older adults. Specifically, researchers have reported that although older adults are capable of discriminating between variation in depth perception in a manner similar to that of younger adults, they are less able to discriminate between three-dimensional shapes of objects.¹⁹¹ Clearly the perceptual system is closely associated with many other body systems, and therefore age-related or age-associated structural and functional changes in associated systems will affect the perceptual system.¹⁹² Older adults secure input from multiple areas/systems to address issues associated with cognitive and perceptual changes. This suggests that increasing visual challenges increases the need for compensatory activity. Age-related changes in the visual acuity necessitate use of assistive devices such as glasses.

In addition, May and colleagues¹⁴⁷ found that older adults placed less emphasis on perceptual aspects of an event than they did on the emotional components when encoding information. They suggested that older adults may find emotional information to be more meaningful than perceptual information and may retain more elaborate, detailed processing of emotional data than perceptual information.

Decreased processing speed is well documented in older adults and directly impacts visual perceptual abilities.¹⁹³ Physical activity is one factor that positively impacts age-related perceptual decline. The structural and functional changes associated with physical activity are

thought to delay the onset of degenerative changes in the brain. Findings continue to build supporting the premise that older adults participating in physical activities have maintained visuospatial skills and related cognitive functions.^{193,194}

MOTOR DEVELOPMENT

Movement is the primary mechanism by which prelinguistic children communicate with their environment. That said, it is no wonder that development of motor skills is greatest during the first 2 years of life. Motor development may be defined as the acquisition, refinement, and integration of biomechanical principles of movement in an effort to achieve a motor behavior that is proficient.¹³

Early developmental researchers referred to infants as *reactive*, inferring that, early on, infants are responsive to stimuli rather than capable of initiating functional movements. Young infants were characterized as “reflexive” beings producing stereotypic primitive and postural responses to stimuli. Emergence of these reflexive motor behaviors was based on traditional models of CNS organization and motor development theories. Traditional theories of human development emerged from animal models and studies involving spontaneously aborted fetuses.^{16,195} Traditionally, sucking and stepping behaviors were examples of developmental reflexes. By definition, a reflex is a consistent response to a consistent stimulus. By use of traditional models of CNS organization, developmental reflexes, present at birth, become integrated as higher centers assume control over lower centers and then volitional movements begin to emerge.

Over the past two to three decades, advances in technology have enabled scientists to gain more insight into fetal and infant motor abilities. More recently, research has generated evidence that behaviors emerge out of a need to solve a problem in the environment rather than solely as a result of maturation in the CNS.¹⁹⁶ Given this evidence supporting the premise that newborn infants are capable of producing complex volitional movements, previous views of the infant as passive and “reflexive” are no longer accurate. In addition, continuing to refer to early infant motor behaviors as “reflexes” may also not accurately reflect the behavior. A reflex is defined as a consistent response given in response to a consistent stimulus. Perhaps use of the term *innate motor behaviors* to reflect behaviors that are present at birth may be more appropriate. See Fig. 2.1A–C, for a visual explanation of how the complexity of the stepping reaction of a newborn infant and the learned programming for upright posture and balance, including biomechanical range and force production, will lead to the integration of stepping in standing. Similarly, as an individual ages loss of some of the postural power, effectiveness of balance reactions, and fear can create a potentially dangerous environment for an elderly person (see Fig. 2.1D–E). Likewise, an individual with an abnormal or inefficient stepping pattern (see Fig. 2.1F) should automatically stand out to a therapist analyzing movement dysfunction. If a clinician does not have a clear picture in his or her mind of the movement pattern desired, then easily or quickly identifying the system or subsystem motor impairments seen in a patient’s movement dysfunction may be outside a therapist’s analytical repertoire.

Contemporary research refutes the assertion that infants are reactive organisms.^{114,118} In contrast, contemporary studies purport that infants are competent and capable of producing complex interactive behaviors at birth.^{124,197} Additional support for the complex nature of a newborn infant is evident in the infant’s ability to discriminate and turn toward his or her mother’s voice rather than toward the voice of an adult with whom the infant is unfamiliar.

Evidence from studies examining motor development indicate that motor behaviors do not always emerge in a linear and predictable

sequence, nor do all individuals achieve the same skills at the same chronological age.^{10,197} Rather, emergence of motor behaviors in an alternate sequence may be attributed to the intrinsic and extrinsic constraints that contribute to motor development in a nonlinear fashion and is not necessarily indicative of atypical development. Fig. 2.2A is an example of a child who had a very large head at birth. His head circumference was in the 99.9th percentile and remained so for the first 3 years of his life. His Apgar score at birth was 10, or normal. He was slow in rolling over and coming to sit and spent much of his time playing with his hands and feet and visually exploring the environment. Fig. 2.2B and C illustrate that his focus was on fine motor development throughout his first year, especially when he was placed in a vertical position. He loved to play catch when placed in a sitting position and accurately propelled the ball toward a partner when playing by age 1 year. His early gross motor development was within the normal range but below the mean. He started independently walking at age 14 months and began running on the same day. Fig. 2.2D–F illustrate that once he gained control over the heavy weight of his head, he quickly caught up in gross motor skill. And, like any child, he has taken full advantage of his environment to play and learn.

Over the past several decades the incidence of obesity in children and adolescents has increased dramatically.¹⁹⁸ The incidence of obesity has increased in all age groups and sexes, and currently 20% of all children are classified as obese, with a prevalence greater among children who are African American or Hispanic. With the increase in overweight and obese children, the Centers for Disease Control and Prevention (CDC) defined the terms overweight (>85% BMI) and obesity class I–III. One of the most striking increases of obesity in an age group was noted in children aged 2 to 5 years. Obesity is said to be one of the greatest threats to public health.^{199–201} Several factors are thought to impact the increase in obesity including SES, nutrition, participation in organized sports, access to safe walkable environments, as well as screen device use.^{200,201} The use of screen devices include television (TV), smartphones, tablets, computers, and video-gaming systems place children at risk for obesity associated with decreased physical activity, sleep deprivation, and increased intake of sugary drinks and foods.²⁰⁰ While adolescents are recognized as high-end users of screen devices, it is estimated that up to 50% of 3-year-olds have a tablet. Children with obesity are at increased risk for asthma, sleep apnea, musculoskeletal problems, precocious maturation, polycystic ovarian syndrome, and hepatic steatosis. Children may also have mental health issues directly related to their weight issues, including low self-esteem, depression, decreased quality of life, and bullying. Children with obesity are five times more likely to have obesity as adults than individuals not obese as children. Estimates of previous research indicate that 64% of preadolescent children and 80% of adolescent children with obesity have obesity as adults.²⁰¹ Obesity in childhood that continues into adulthood places an individual at higher risk for chronic diseases associated with obesity including hypertension, hyperlipidemia, type II diabetes, and cardiovascular disease.²⁰² Given the relationship between obesity and physical activity, obesity may play a role in an individual’s motor performance.

Motor performance, measured both qualitatively and quantitatively, is highly dependent on the task, the environment, and the individual. Changes in motor performance emerge in accordance with age-dependent changes, within different systems, and with respect to environmental affordances and constraints. As skills emerge in speech, language, and cognition, other previously achieved skills may “regress.” In reality, acquisition of a new skill requires more attention than the previously attained skills; consequently, the infant or child’s attention is divided between the tasks. Lindenberger and colleagues^{203–205} conducted studies investigating life-span changes in resource allocation

Fig. 2.1 Development and Integration of Stepping, Upright Vertical Posture, and Vertical Balance Reaction. **(A)** Automatic stepping in a newborn infant. **(B)** Early cruising or side-stepping using multiple points of support. **(C)** Early bipedal independent stepping. **(D)** 90-year-old patient stepping. **(E)** 78-year-old patient with falling problems. **(F)** Abnormal stepping after traumatic brain injury.

during multitask activities. The researchers found that for young children certain tasks require more attention and attempting to perform such a task in conjunction with a task requiring less attention causes deterioration in performance of both tasks. Hence deterioration of a previously attained skill is more likely a result of attentional demands of young children performing high-attention tasks rather than a true “regression” of the skill. This progression is illustrated by a child confronted with a new environment, who will seem as if he or she has regressed in motor performance while confronting and solving a task-specific challenge—for example, crossing over a suspension bridge that moves from side to side is compliant to body weight and creates a perceptual challenge from the visual surround. Once the child understands the task, his attention is directed toward developing effective strategies to solve a problem and successfully perform the motor

behavior of crossing the bridge. Stability or consistency in performing a skilled movement is achieved by self-organization through practice and repetition.²³ Performance of skilled movements, such as those observed in athletes, is measured not only on the consistency in performing the task but also on the skilled performance of the task under variable conditions.²³ Conversely, decreased frequency in performing a motor skill as an effect of age may result in a less rich repertoire of normal variability and may be a contributing factor to a decline in motor skills.³² Just as motor skills emerge from a multifactorial interweaving of maturation and experience, deterioration in motor performance may be attributable to alterations in various systems that occur as part of the aging process. Emergence of motor behaviors is never the same for any two individuals, nor does decline in functional motor behaviors follow the same time line. Fig. 2.3 illustrates how standing

Fig. 2.2 Head size can affect when a child initiates independent movement activities and whether he or she develops gross or fine motor skills. **(A)** A 2-month-old being fed (note large head). **(B)** Child at 5 months old placed in sitting has overcome delayed head control in vertical. **(C)** By 9 months old, the child has gained normal head control as well as fine motor skills. **(D)** Head control in horizontal crawling. **(E)** Child running at 2 years of age. **(F)** Normal head control on slide. By 1 year of age, head size is no longer a variable.

patterns will change with practice, be maintained as long as practice continues, become extremely efficient within a specific environmental context, or become deficient after CNS injury.

Prenatal (0 to 40 Weeks' Gestation) Development

Motor behaviors emerge early in embryonic life. By the tenth week of fetal life the variety of observed movements increases, as does the frequency of the movements. Complex movements are present by gestational age (GA) 12 weeks, and goal-directed movements may be seen as early as GA 13 weeks. Facial movements, including sucking, swallowing, and yawning, are evident in the second and third trimesters. The fetal activity level increases so that by week 14 GA, periods of quiet (no activity) are only 5 to 6 minutes in duration. Investigators have documented 15 fetal movements visible by 15 weeks of age.²⁰⁶ After initial observation of a motor behavior, it remains part of the fetal repertoire. Pooh and Ogura's²⁰⁶ research lends support to the premise that before delivery fetuses are in fact capable of producing complex motor behaviors.

The dynamic nature of birth and the associated change from the intrauterine to the extrauterine environment alter the production of movements previously observed in fetal life.⁷³ As the newborn infant adapts to the forces in the extrauterine environment, motor behaviors emerge. These complex behaviors lend additional evidence to the premise that at birth infants are competent beings.

The extrauterine environment poses many challenges for the newborn infant. Consequently, fetal behaviors observed by ultrasonography may not be evident postnatally until the infant learns to adapt to the new environment by modifying movements to accommodate to the new forces imposed by gravity. Newborn infants must learn to use

new strategies to generate functional motor behaviors, given the different environmental constraints.

Infancy (Birth to 12 Months)

As alluded to earlier, newborn infants possess a rich array of motor behaviors. During the first year of life, motor behaviors are the primary mechanism for learning. Every movement is a new and unique opportunity to gain knowledge about the environment. During each movement, new information is gathered in an effort to solve environmental problems, and as a result this motor planning fosters cognitive development. Similarly, each movement provides feedback that intrinsically enables the infant to modify movements in accordance with changes in the environment, the skill, or growth parameters.²⁰⁷ This interdependence between perception and motor behaviors allows one domain to facilitate acquisition of skills in the other domain in a reciprocal fashion.

Given the capabilities of a newborn infant, many behaviors previously identified as reflexes are in fact functional motor behaviors that the infant is capable of modifying. Evidence that one such behavior, sucking, is not a reflex was supported by studies examining sucking rates when stimuli were varied.^{208,209} Researchers reported that the sucking response varied depending on the level of hunger or environmental stimuli. In addition, when the stimulus is introduced after feeding, after the infant is satiated, the stimulus may produce no response or a diminished response, thus refuting the idea that sucking is reflexive.

Consequently, rather than refer to these behaviors as *developmental reflexes*, it seems more accurate to refer to such motor behaviors, evident at birth, as *innate motor behaviors*. Innate motor behaviors are,

Fig. 2.3 Standing as a functional activity will become procedural with practice and be maintained over a lifetime as long as impairments do not preclude practice or injury to the central nervous system (CNS). **(A)** Early standing. **(B)** Relaxed standing as adults. **(C)** Standing on uneven surfaces. **(D)** Procedural standing during a functional activity. **(E)** Advanced skill in standing as ballet dancer. **(F)** Maintained functional standing in healthy 83-year-old elderly couple. **(G)** Elderly man developing verticality impairment. **(H)** Subtle abnormal standing after head injury. **(I)** Multiple subsystem problems in standing after CNS injury.

in essence, functional behaviors present at birth that are modifiable given alterations in feedback from intrinsic or extrinsic mechanisms.

Additional evidence exists to refute the concept that other motor behaviors are reflexes. Stepping is one such behavior. Thelen and Fisher^{20,34,35} conducted a series of experiments examining the stepping reflex in young infants. Early developmentalists hypothesized that stepping reflexes, present at birth, became integrated and then later emerged as a volitionally controlled movement. Thelen and Fisher^{20,35} found that when one variable, weight, was altered, infants mimicked “integration” or emergence of the behavior. Young infants who were stepping had weights added to their lower extremities, to simulate weight gain over the first few months. These infants stopped stepping. Similarly, infants who did not step were submersed in chest-deep water, simulating less weight in the lower extremities, and stepping appeared. Obviously, the presence and absence of this behavior was mediated by weight gain in the lower extremities and not by CNS control as early developmental researchers had postulated. Consequently, upright mobility emerges when the infant is able to garner the force production in the lower extremities to modulate stepping. This is just one example of the significance of one system on another and the interdependent nature of body systems. Recognizing the interdependence of systems may provide one explanation for the presence or absence of motor behaviors at any given time. These concepts have been transferred into the therapeutic practice environment when working with individuals who cannot generate enough force to produce the movement given the body size or cannot produce the postural stability to reinforce the stepping pattern or one of a variety of other motor components that support normal upright stepping or walking. (See Chapter 3 for theories of motor control and learning, Chapter 8 for therapeutic approaches to assist a patient with learning or relearning motor control, and Chapter 38, which introduces emerging practices to bridge the gap between normal human movement development and technologies.)

At birth, an infant is capable of turning toward the sound of her or his mother’s voice and visually focusing on objects 8 to 12 inches from the face.¹²⁴ These behaviors are apparent when the infant’s head is supported, given that at birth the newborn infant does not have the neck strength to maintain head control against gravity. Similarly, auditory and visual stimuli continue to bombard the infant and challenge the motor system, fostering the need to attain head control.

Infant motor behaviors during the first 3 months of life are focused on acquisition of head control in all planes of movement. Once the infant has achieved head control in the supine and prone positions, the complexity of the tasks increases exponentially on the basis of the new challenges and stimuli presented to the infant. For example, while in the prone position an infant may reach for an object out of reach and then roll to attain the desired object. Improvements in visual acuity enable an infant to visually track people and objects at greater distances while challenging the infant to seek out the stimuli.

By age 3 to 4 months, as the infant is able to maintain head control in the upright position for longer periods, coordinated eye-hand activities begin to emerge. Acquisition of manipulative skills involves perception and lends support for the coupling of developing cognitive, sensory, and motor systems.^{25,188} Bushnell and Boudreau⁸ added that if the infant is unable to achieve a motor skill and this skill is coupled with a sensory or cognitive task, that task may not be attained. Bushnell and Boudreau’s⁸ research focused on the role of motor development in achieving skills in other domains.

Reaching is one such task that the researchers suggest may serve to promote skills in cognitive and sensory domains. Initial reaching activities enable the infant to gain information relevant to depth perception, and coupling this information then allows the infant to modulate parameters associated with reaching. For example, the infant

Fig. 2.4 Reaching Activity. **(A)** Error in reaching leads to learning, and **(B)** reaching becomes accurate during a complex motor task.

must learn to vary the distance moved and force necessary to attain an object given a series of opportunities. Infant grasping and reaching may initially seem inefficient, but with practice under varying situations, efficiency and accuracy improve across multiple domains with varying rates. Fig. 2.4 illustrates both the error that provides feedback and the success during complex movement patterns after practice.

As infants develop an upright sitting posture, they use their upper extremities for support. Sitting, a functional motor behavior, is tightly linked to the performance of most ADLs and occupational and leisure-time activities. Fig. 2.5 depicts development of functional sitting over a lifetime. A delay in attaining independent sitting may directly affect upper extremity control, alter attainment of skills in other domains, and ultimately affect an individual’s level of functional independence.

As upright trunk posture is attained and independent sitting emerges, usually by 6 months of age, and infants then begin to explore using their manipulative skills. Manipulative skills are composed of reaching and grasping behaviors. Upper-extremity interlimb coordination bimanual and unimanual tasks include retrieving objects

(placed within reach); holding two objects, one in each hand; using two hands to hold an object (bottle); and holding a toy in one hand while retrieving another object with the free hand.²¹⁰

During the second half of year 1, the infant is focused on mobility, initially prone (rolling, crawling), then creeping on all fours, and then upright (cruising and ambulation). Adolph and Berger²⁵ reported that as coordination of upper- and lower-extremity movements with trunk control emerges and infants begin upright mobility, they spend up to 50% of their day performing balance- and mobility-based activities, varying the surface, distance, and other parameters each time the task is performed (Fig. 2.6). On the basis of research conducted with infants acquiring independent mobility, Adolph and Berger²⁵ estimate that an infant walks up to 29 football fields each day.

Acquisition of independent mobility is complicated by new manipulative skills, as discussed by Corbetta and Thelen.²¹⁰ They found that while infants are achieving independent mobility, their manipulative skills are highly variable and vacillate between bimanual and unimanual tasks depending on the nature of other tasks with which the infant is involved. Infants may revert to performing bimanual activities, with upper extremities coupled and movements synchronized, during early acquisition of independent mobility, signaling the presence of multiple tasks requiring attention. Unimanual control signals uncoupling of the upper extremities and asynchronous manipulation in young children.

Analyzing the early development of a child is often done at specific times over the first year, such as at birth, 2 months, 6 months, and 9 months. As important as understanding and analyzing a complex phase of development such as 3 months is analyzing the changes in motor control and learning of a specific motor function over a period of time. The development of head control is a good example of how the nervous system adapts and learns given different environmental restraints over a period of time. The complexity and integration of movement patterns involved in a child gaining functional control over the head in all spatial environments can be delineated into many components. Each component can then become a variable in determining how and if a child has or will develop a specific movement pattern such as head control (see Fig. 2.2).

Weight is one factor that plays a role in acquisition of motor skills. Dinkel and colleagues²¹¹ examined sitting development in infants who were normal and overweight. While the authors did not see differences in the temporal aspects of skill acquisition, they noted that overweight in-

fants employed different postural strategies than normal weight infants. Overweight infants demonstrated lower sway amplitude during sitting skills acquisition, and their sway pattern was more confined to mediolateral movement than their normal-weight counterparts. As they became more skilled in performing the behavior, the postural control resembled strategies employed by normal weight infants.

Early Childhood (1 to 5 Years)

Whereas the first year of life is characterized by periods of rapid physical growth and acquisition of motor skills, the second year signals a slower rate of growth, refinement of current skills, and acquisition of new motor skills.²¹² Concurrently the toddler experiences rapid differentiation in other domains including cognition, speech, and social-emotional domains.

At the onset of the second year of life, independent ambulation becomes refined as other forms of mobility wane. Dynamic balance in an upright bipedal posture evolves as the infant develops more mature gait characteristics. Modification of parameters indicative of a more mature gait include narrowing of the base of support, decreased cocontraction in the lower extremities, and improved intralimb coordination, as well as learning to modulate displacement and velocity.²⁵ As gait matures and toddlers have more opportunity to explore their environment, more challenges appear. Attempts to solve these problems and challenges result in the appearance of more complex motor behaviors that include running, climbing, and jumping. Toddlers find particular pleasure in throwing, kicking, and catching balls. In addition, toddlers assert their independence through such activities as propelling themselves with riding toys.

Toddlers continue to explore and assert independence through activities involving bimanual and unimanual tasks. Challenges to fine motor skills of toddlers involve manipulating functional objects (large buttons, eating utensils, crayons, door knobs, and blocks; opening and closing jars to retrieve small objects [cereal, raisins]). Achieving these tasks enables the toddler to perform rudimentary aspects of ADLs such as eating and dressing and adds another degree of independence. Fig. 2.7 illustrates development of ambulatory skill over a lifetime.

Preschool-aged children pedal a tricycle and use a narrow base of support to walk along a balance beam. By age 3 years most children ascend stairs using alternating feet and by 4 years most descend stairs alternately. Fig. 2.8 shows a preschooler descending stairs. The gait pattern matures with reciprocal arm swing and a heel-to-toe gait

Fig. 2.7 Functional Ambulation Over the Life-Span. (A) Early independent walking. (B) Two young adults walking on sand. (C) Three adults of different body sizes, each walking independently. pattern. Early in the preschool period, children mimic a “true” run and have difficulty efficiently controlling all aspects of the behavior. Finally, receipt and propulsion of balls of all shapes and sizes improve qualitatively.

Fine motor skills expand significantly during the preschool period. The environmental demands of preschool and day care preparation for entering primary grades are the driving force behind acquisition of many manipulative behaviors. Most children begin to cut with scissors, copy circles or crosses, use a crayon to trace a circle, match colors, and often demonstrate hand preference. Although maturity certainly plays a role in skill performance, the efficiency with which skills are performed is also influenced by genetics, affordances and constraints of the environment, practice, and intrinsic motivation.

Use of digital screen devices has changed the way children play or spend leisure time. Lin and colleagues²¹³ examined fine motor proficiency in preschool children using screen devices as compared to children using blocks and other fine motor manipulatives. The researchers indicated that fine motor skill development was better in preschool children using manipulatives than those using screen devices. Expanding research in this area is critical to fully examining the impact using digital devices on fine motor skill development.

Equally as important is gross motor performance and physical activity in preschool age children. The incidence of obesity in preschool children increased dramatically in children age 2 to 5, with a greater increase in males than females.¹⁹⁸ Efforts to reduce obesity found to be most effective included family behavioral training (FBT) and parent behavioral training (PBT). These training programs provided parents and children with ways to improve nutrition, time spent on digital devices, and physical activity for parents and their children.

Childhood (5 to 10 Years)

Childhood is characterized as a period when children begin their formalized education, usually in a structured environment separate from their families. Consequently, a new set of dynamics comes into play. Children take on new roles with peers and adults outside of the family. During this period of social-emotional change, other systems also undergo changes.

Motor skills that children display during this period include galloping, hopping on one foot for up to 10 hops (hopscotch), jumping rope, kicking a ball with improved control (soccer), and bouncing a large ball (basketball). Often these skills emerge while playing with peers during directed (physical education or community-based team sports)

Fig. 2.8 Child Descending Stairs Successfully. **(A)** Attention on stepping down. **(B)** Success at the task.

and nondirected (recess) periods. Mobility, balance, and fine motor skills improve dramatically. Girls and boys exhibit similar abilities in speed up to age 7 years, but by age 8 years boys begin to outperform girls.²¹²

During childhood, manipulative skills increase exponentially. **Fig. 2.9A–E** shows the amazing skill developed between birth and age 4 years. Manipulative skills assume a predominant role as part of the academic experience, requiring high levels of practice and opportunities for refinement of the skills. Hand preference is confirmed by this age. As components of independence, many of the manipulative skills achieved are directly related to self-care activities. Skills that improve dramatically include dressing, including fastening and unfastening clothing; tying shoes; using an implement for writing (coloring and handwriting); and successfully manipulating utensils not only to eat, but to socially interact while eating. As children approach preadolescence (9 to 12 years of age), manipulative

skills improve dramatically. Children produce cursive handwriting and complex drawings.

Perceptual development often improves significantly, often in direct relationship to the demands of the tasks along with practice, feedback, and motivation.²¹² Visual-perceptual systems are nearing maturity and allow children to participate in sophisticated activities such as archery, baseball, dance, and swimming. **Fig. 2.10** helps bring to light complex skill development during a lifetime. That skill development may begin with a fun team sport activity and lead to a lifetime of professional accomplishment.

The musculoskeletal system enters a period when muscle growth is rapidly increased, accounting for a large percentage of the weight gained during this period.²¹² Constraints and affordances of the musculoskeletal system along with demands of the tasks and environment are highly interactive and influential in skilled activities. Children are generally flexible because muscle and ligamentous structures are not firmly attached to bones. Although this allows for flexibility, it also poses risks for musculoskeletal injury. Care should be taken when participation in high-level athletic activities is a consideration.

Qualitative changes in coordination, balance, speed, and strength improve while existing motor skills become more refined and controlled, more efficient, and more complex.²¹² Qualitative improvements of motor skills may be attributed to an asynchronous growth in children's limbs in relation to the trunk. Consequently, better leverage is attained. Motor skills strongly influence social domains as boys and girls begin to perform in organized sports teams in school and the community. Competition within sports becomes a powerful force in motivating children to practice motor skills or directing children away from organized sports. Children with poorly developed motor skills, as a result of either genetics or opportunity, may be excluded from team activities and experience social isolation.²¹² Similarly, a child may have the genetic potential to become a master in an area that uses a specific motor task, but if he or she is never introduced to the specific environment, such as playing a piano, and the motor skill is never actualized.

Children identified as obese reportedly have poorer gross and fine motor skills, decreased physical fitness, and often exhibit delayed motor development.²⁰² Children aged 5 to 6 years who are obese were noted to have poorer fine motor skills, balance, postural control, balance, and agility.²¹⁴ Skills identified as less proficient include running, hopping, kicking, sliding, and dribbling. Obesity in childhood often leads to obesity in adulthood/older adulthood, may negatively impact the individual's quality of life, and place the individual at increased risk for chronic diseases in adulthood.

Adolescence (11 to 19 Years)

Early adolescence signifies a period characterized by improved quantitative performance and qualitative changes in skills along with physical growth (size and strength).¹³ By age 12 years, reaction times closely resemble those of the mature adult. Although skills involving balance, coordination, and eye-hand coordination also continue to improve with respect to perceptual development and information processing, the rate is not as dramatic. Elite athletes, in contrast, often continue to show steady improvement in qualitative and quantitative skill performance well into adulthood.

During later adolescence, when periods of physical growth have stabilized, motor skills acquired previously continue to develop in speed, distance, accuracy, and power. Many adolescents are involved in competitive sports. However, few exhibit performance levels identified with elite athletes. Those athletes that do reach this high level of skill

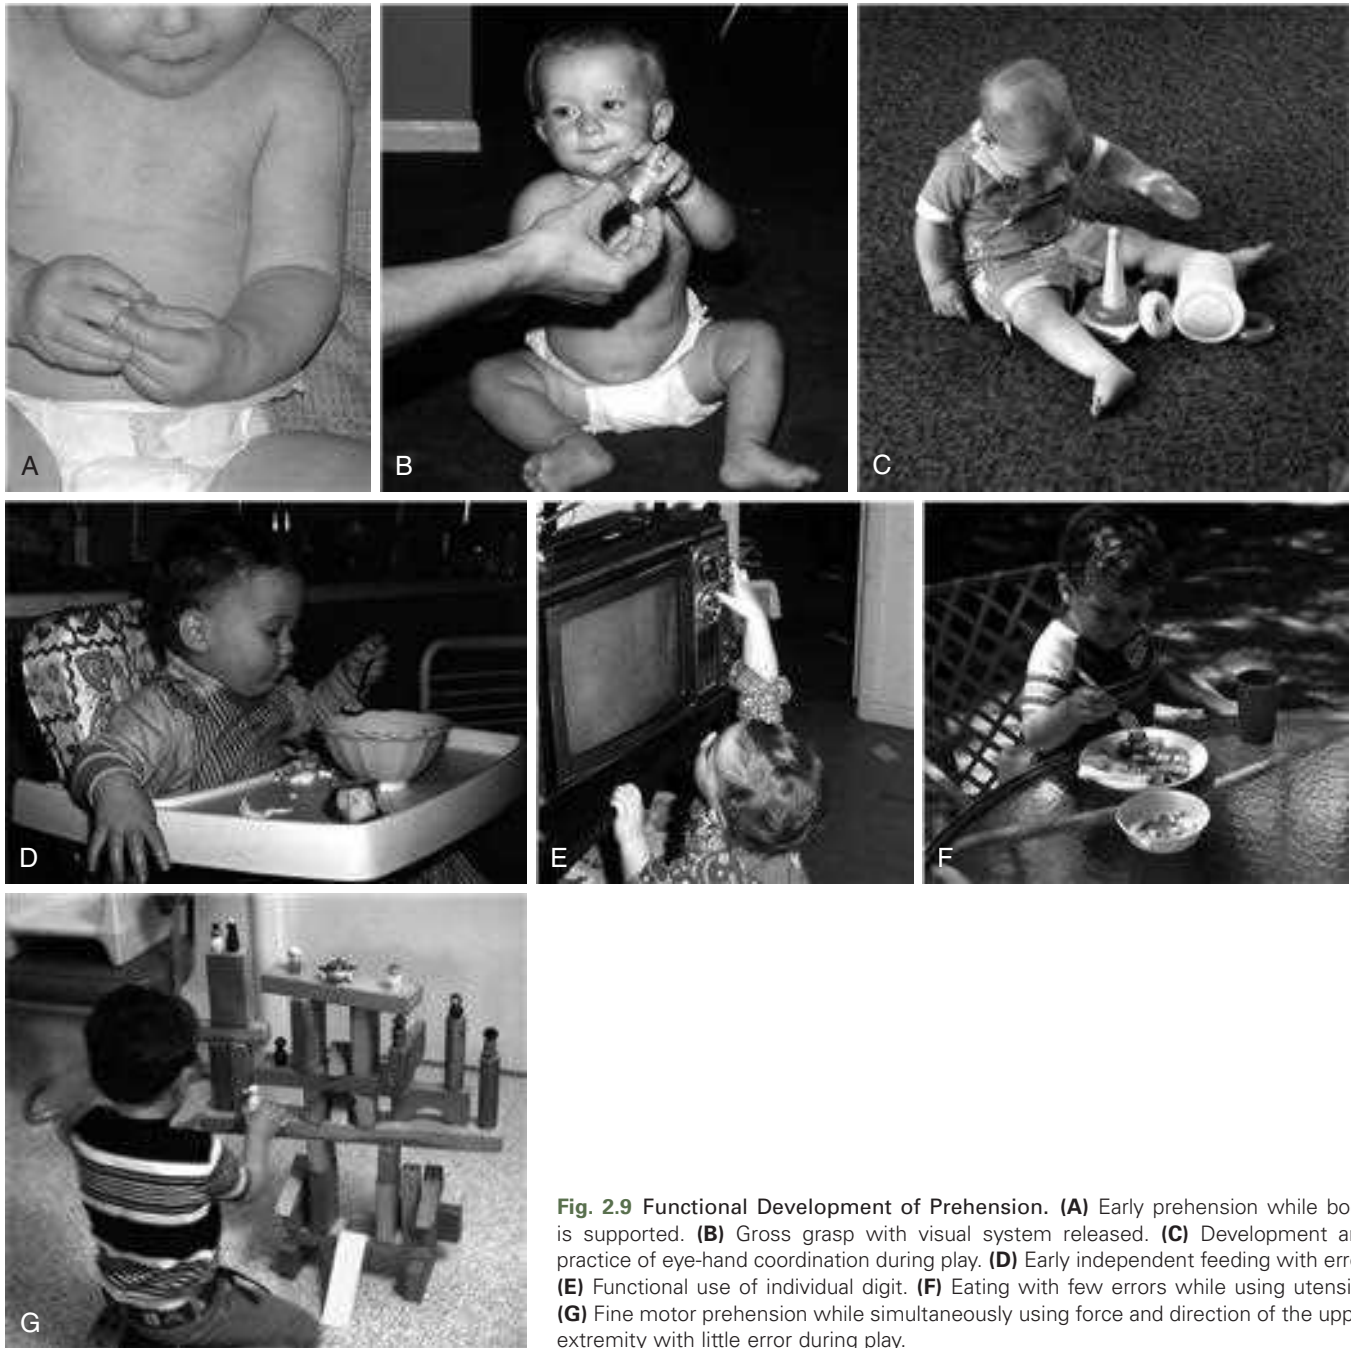

Fig. 2.9 Functional Development of Prehension. **(A)** Early prehension while body is supported. **(B)** Gross grasp with visual system released. **(C)** Development and practice of eye-hand coordination during play. **(D)** Early independent feeding with error. **(E)** Functional use of individual digit. **(F)** Eating with few errors while using utensils. **(G)** Fine motor prehension while simultaneously using force and direction of the upper extremity with little error during play.

often have a genetic predisposition, environmental affordances, adequate opportunities for high-level practice and performance, and strong motivation. More often, adolescents performing in competitive sports will find this is their avocation rather than their vocation (see Fig. 2.10).

Manipulative skills of adolescents resemble those of adults. Greater dexterity of the fingers for more complex tasks including art, sewing, crafts, knitting, wood carving, and musical performance enables adolescents to perform these motor tasks with greater precision and proficiency.

Upwards of 81% of the 11- to 17-year-old children and youth fail to meet their recommended physical activity levels.²¹⁵ TV and digital

screens (smartphones, tablets, videogames, computers) usage places adolescents at higher risk for developing obesity. The risk for becoming obese is thought to stem from decreased physical activity, increased intake of sugary drinks/foods, and disrupted sleep. Recently the subgroup with the greatest increase in obesity is 16- to 19-year-old females.¹⁹⁸ Current estimates are that 21% of white adolescent females are classified as obese.²⁰¹ Efforts by public health officials to reduce the incidence of obesity in children and adolescents led to a parent challenge to control screen time and intake of sugary beverages and food, as well as increase physical activity and limit the use of digital devices prior to bedtime. Family and parent participation was found to be an effective intervention strategy with parents serving as role

Fig. 2.10 Complex Skill Development. **(A)** Child participating in a team sport. **(B)** Adult demonstrating advanced skill development as a professional baseball player.

models for improving physical activity and modifying nutritional intake and reducing the likelihood the individual will develop comorbid conditions such as cardiovascular disease, hypertension, type II diabetes, or hyperlipidemia. Additionally, engaging children and adolescents in physical activity is thought to improve motor competence and self-concept of physical abilities among these groups and improve their overall health across the life course.²¹⁵

Adulthood (20 to 39 Years)

Motor performance is relatively consistent in adulthood. Skillful performance of movements may be characterized not only through consistency, but also through the infinite ways in which the skill is performed. Hence change is generally focused on leisure activities or elite athletic competition. Leisure activities of many adults involve exercise of some form. Maintaining a healthy lifestyle through exercise and fitness is one method for staving off effects of aging and degenerative diseases. Although many adults participate in exercise for health and wellness, others who do not routinely exercise are at risk for obesity and associated health problems. Obesity is thought to negatively impact an individual's emotional and physical well-being as well as functional performance.²¹⁶ Often some of the physical activity expressed through the motor system is an example of parent-child bonds and creates a fun environment for play. Parent-child interaction through physical activity provides a positive environment that is thought to decrease the incidence of obesity in children and adolescents.²¹⁷ When a task-specific activity is selected and challenged by family members, the motivation to perform becomes high. An example of a parent-child activity can be seen in Fig. 2.11A. An observer might think that all three individuals are performing similarly with similar strategies. In reality, single-leg stance increases in difficulty as the base of support decreases and the body size changes. Note that the smallest individual has the smallest foot and the largest base of support in proportion to his body size. The adolescent is not as tall as his father, but his foot size is significantly larger, which (1) increases his base of support, (2) gives him less input proportional to his foot size or representation on the somatosensory cortex, and (3) gives him higher degrees of freedom when shifting his weight, which can either increase or decrease the task difficulty depending on practice. Fig. 2.11B shows the way both taller individuals use strategies to initially assume the upright stance position while the smaller child attained the single leg stance by stepping from a table. Body height, weight, and amount of practice all are variables that will help determine outcome. All three individuals achieve success, although the specific motor patterns and strategies used to succeed may be different. In Fig. 2.11C, a child with severe sensory organization problems would not be able to solve the challenge presented in Fig. 2.11A, because he cannot even begin to stand independently on a large, stable surface. Again, therapists need to be able to match the motor program impairments causing the child with learning disabilities to fail at the task and identify what programs are needed or expressed in the success of all three individuals in Fig. 2.11A.

The peak of muscular strength occurs at 25 to 30 years of age in both men and women. After that period, muscle strength decreases as result of a reduction in the number and size of the muscle fibers.²¹⁸ Loss is related to genetic factors, nutritional intake, exercise regimen, and daily activities.

Middle Adulthood (40 to 59 Years)

Changes associated with aging have been identified in the neuromuscular, musculoskeletal, and cardiovascular and pulmonary systems. These age-associated changes can greatly affect motor performance, although the degree is highly variable. Between 30 and 70 years of age, strength loss is moderate, with about 10% to 20% of total strength lost, for most activities—insignificant and undetectable by the individual.^{77,219} Participating in regularly scheduled exercise regimens that emphasize aerobic and strengthening activities may reduce effects associated with aging. Furthermore, developing muscle mass and competence in motor skills early in life may have long-term positive effects on adult skills and reduce the risk of disability and frailty later in life.²²⁰

Fig. 2.11 A Complex Task Performed by Individuals With Different Foot Size and Body Composition. **(A)** Three individuals of differing age, body composition, and experience successfully performing the same task. **(B)** The strategy used by the adolescent and adult to find verticality. **(C)** A child with learning difficulties failing at independent one-legged stance.

Older Adulthood (60+ Years)

Age-related changes may be attributed to alteration in perception, compensations in the neural mechanisms, and changes between and within the different systems involved in motor skill performance.²²¹ Integrated effects may include slowing in movement production and increased activation of agonist-antagonist muscle groups. An example of agonist-antagonist activation is during dynamic balance activities.²²² After age 70 years, most individuals incur losses in muscle strength of up to 30% over the next 10 years. Overall, the loss of muscle strength through adulthood may be as much as 40% to 50% by the time an individual reaches 80 years of age.⁷³ The percentage decline

is inversely related to the demand by the individual for repetition of the movements. Continuing to regularly play preferred activities including tennis, running, golf, or skiing may significantly decrease the percentage of loss of strength compared with individuals who do not participate in such activities.

Although some effects are age associated and may be reduced with regular exercise and increased motor activity, not all are modifiable. Willardson⁹⁴ reported that older adults who maintain more active lifestyles are more likely to have a more favorable outcome than are peers who were not as active. Fig. 2.12 is an example of an 81-year-old adult who regularly bicycles 8 to 10 miles 3 to 4 times/week. He

Fig. 2.12 Image is an example of an 81-year-old adult who regularly bicycles 8 to 10 miles 3 to 4 times/week.

attributes his overall health to regular exercise he and his spouse continue to participate. Findings by Hamer and colleagues²²³ and Voelcker-Rehage and Willimczik¹²⁰ supported the findings of Willardson⁹⁴ in regard to older adults and lifestyle. Hamer and colleagues²²³ indicated that even when older adults participate in regular exercise later in life, there were still significant health benefits. In addition, Voelcker-Rehage and Willimczik¹²⁰ found that older adults aged 60 to 69 years were able to acquire and refine a novel task (juggling) at a level comparable to children 10 to 14 years old and adults 30 to 59 years old. Only young adults aged 15 to 29 years performed at a higher skill level. Furthermore, adults older than age 70 years were found to have limitations in their ability to learn the novel motor skill. Moreover, as individuals age, they generally have a decreased ability to produce force, and they tend to coactivate agonist-antagonist muscles.²²⁴ The researchers suggested that older adults may coactivate agonist-antagonist muscles as a strategy to (1) modulate movement variability and (2) maintain accuracy in movement. The investigators also reported that older adults' coactivation strategy compromised the subjects' ability to rapidly accelerate their limbs in exchange for improved accuracy of control.

One factor contributing to loss of motor performance and/or quality of movements in older adults is being overweight or obese.²⁰² Maintaining an exercise regime as part of one's life course reduces the incidence of obesity, preserves the white matter, and improves motor control of older adults.

In addition, information processing appears to be slowed in older adults.²²¹ Motor times have also been found to be delayed in older adults, particularly when a higher-level force is required.

Temporal coupling also appears to be altered in older adults.²²¹ Perhaps as individuals age, they are less able to modulate timing of muscles during contraction and relaxation phases and are more likely to coactivate agonist-antagonist muscles. The outcome behaviors are typified by poorly coordinated motor activities and increased time to produce adequate muscle force to elicit the behavior.

In addition to reduced efficiency in movement production, variability in performance of motor skills also increases with age. Although small changes in individual systems may not have a significant effect on functional movements, the compounding effects of changes in several systems may have serious implications for older adults and place them at increased risk for falls and injuries.⁶⁶ Fig. 2.13A and B are

Fig. 2.13 As individuals age, more sedentary lifestyles, preexisting long-term health issues such as chronic obstructive pulmonary disease or chronic back pain, and a decrease in environmental challenges can lead to a higher risk of falls. **(A)** Woman with chronic back problems leading to a fixed trunk. **(B)** Man with chronic obstructive pulmonary disease and a fixed flexed posture resulting from inactivity.

examples of movement dysfunctions seen within an elderly population. These alterations are limiting the individual's ability to respond to a given motor task. As individuals age, there can be a large number of potential alterations in the body systems that limit CNS and musculoskeletal options when the individual tries to accomplish a motor activity. These limitations can place individuals at high risk of failure of any one motor task. The greatest fear within this group is not death; it is falling, and as a result losing independence. Prevention will be more and more important as the world's population of elderly individuals enlarges on a yearly basis.

Thirty percent of all community-dwelling elderly persons fall at least once each year.^{219,225} Factors contributing to falls include intrinsic and extrinsic variables.^{226–228} Intrinsic alterations in the older adult have implications for performance of motor skills and potential for falls. Risks associated with falls increase with age and when functions of the neuromuscular, musculoskeletal, cardiovascular and pulmonary, and sensory systems deteriorate. This deterioration of covariant factors and not age itself is more closely related to health and wellness and end-of-life age.²²⁹ Another critical variable that is closely associated with motor decline in the aging is the individual's social interactions and participation in life.²³⁰ Research has yet to determine whether a decrease in motor performance results from a decrease in participation in life.

Researchers examined manipulative skills in older adults and reported changes in muscle performance and flexibility.^{63,231,232} These changes resulted in decreased hand function associated with impaired performance of ADLs. One thought is that decline in perceptual speed may play a significant role in fine motor abilities of older adults (Fauth et al., 2017).

STRATEGIES FOR FOSTERING ACQUISITION AND RETENTION OF MOTOR BEHAVIORS ACROSS THE LIFE-SPAN

Movements occur out of a need to solve problems in the environment. Solving these problems is not dependent on any one system but rather is a collaborative effort of multiple systems. The clinician is responsible for examining the patient's performance by evaluating the underlying conditions and the strategies that the individual may use to modify a behavior. Fig. 2.14A–F presents an example of individuals standing up from a chair. The first panels (see Fig. 2.14A and B) show a child whose feet are not on the surface because the child's legs are not long enough. No matter the variance of the task, the child was motivated to succeed. The second individual (see Fig. 2.14C and D), an elderly man, has lost the ability to shift his weight forward over his feet and thus is rising posterior on his heels, which will require anterior flexor power to prevent him from falling backward. The third individual (see Fig. 2.14E and F) has residual motor problems after a stroke. She has been taught to come to stand over her less-involved leg versus centering her base of support between her two feet. The specific way an individual learns, maintains, and relearns a specific motor task as a functional activity will vary, but the important principle will be to empower the individual to succeed with fluid, dynamic motor pattern options. Therapists need to visualize movement and place the movement pattern of the individual on top of that image. The specific motor impairments will then become obvious, and treatment options will be generated. Examination is vital to this process, although it often occurs in an environment far removed from the patient's natural surroundings.

Through acquisition of motor skills, individuals of all ages are afforded the opportunity to meet the environmental demands imposed

by work, play, family, or personal activities. Refer to Fig. 2.14 as an example of common motor activities used at work, play, and home. Motor skill acquisition, retention, and decline are influenced by constraints or affordances that affect opportunities for practice in an environment that challenges and drives the individual to perform optimally. The patient's investment in achieving a successful outcome can help foster persistence in reaching the desired outcome. Practitioners recognize the importance of patient's goals in motivating him or her to move beyond his or her current functional abilities. Creating an environment that challenges the patient to attempt and complete movements in preparation for successfully completing preferred activity(ies) enables the therapist and patient to work collaboratively and achieve the goals, designing sessions that enable the patient to complete movements that culminate in the preferred activity and working toward his or her stated goal.

Fine motor abilities are implicit in performance of instrumental activities of daily living (IADLs) and should be examined during functional evaluations. Additionally, therapeutic intervention focused on improving ADL-related performance in older adults should consider the role of perceptual speed and variability in the overall approach to intervention.

Practice, the primary method for acquisition and retention of motor tasks, is exciting for very young children because each attempt is a new opportunity to achieve the outcome and reach a new level of independence. In contrast, practice in adolescent and adult populations may not be seen in the same light but rather as tedious and boring. Instead, physical and occupational therapists have the responsibility to challenge the cognitive, affective, motor, perceptual, sensory, and physiological systems through patient-selected activities. Activities directed toward the age and needs of the individual, such as interactive dance mats for adolescent patients or ballroom dancing for the older adult, may provide the motivation necessary to practice the task a sufficient number of times to achieve the desired outcome. Fig. 2.15A–H show age-appropriate challenges to individuals. The activity used with a child may be inappropriate for use with an adult, although a similar motor behavior may be the desired outcome. If the individual identifies the activity, he or she will be more motivated and more likely to practice a desired skill. Carryover from a clinical setting to a home or environmental setting is critical when looking at movement function over a life-span.

Strategies used to achieve desired motor outcomes may include a variety of feedback mechanisms to correct errors and identify more efficient strategies to attain the motor skill. Embracing the concept of enablement rather than disablement may also serve to motivate the patient because individual abilities are acknowledged and promoted while strategies are used for acquisition or relearning of motor skills. The needs of adolescent and adult patients are unique and differ significantly from those of the young child or infant.

Opportunities for exploration that engage the infant or young child are the primary motivation for movement. Although motor activities serve as the primary focus, engaging the infant or child provides stimulation that promotes development across multiple domains (e.g., cognition, social, communication). Environmentally challenging activities place demands on the child that maintain a level of curiosity or motivation and encourage persistence in attaining a motor skill that is successful and efficient. As the child matures, play-based activities shift the focus, depending on the expected outcomes. Overall, play is the primary mechanism that children use to mimic adult-like behaviors. Finally, children and adults use play or leisure activities as a means of promoting skill acquisition and proficiency across all developmental domains.

Fig. 2.14 Three Individuals Coming to Stand Using Different Motor Patterns. **(A and B)** A child rising to stand from a chair by shifting his weight over his base of support and rising vertically. **(C and D)** An elderly man rising to stand without adequate weight shifting forward over his base of support, requiring additional flexor power to prevent falling backward into the chair. **(E and F)** A woman after a stroke rising over her less involved leg, thus decreasing her symmetrical weight distribution and ability to step in any direction with either foot as a response to center of gravity shifting outside her base of support.

Development of Head Control as an Example of Movement Development Across the Life-Span and Its Impact on Quality of Life

When analyzing the development of head control by viewing movement of a young child over the first few years, it becomes clear that

the motor control of the head in all spatial positions is very complex, requiring the integration of a variety of movement patterns. The infant needs to develop both the flexors that bend the head forward as well as the flexors that tuck the chin. These flexor patterns will be integrated into diagonal movements in order to roll over from supine to prone. A neck-righting program orients the body to the head

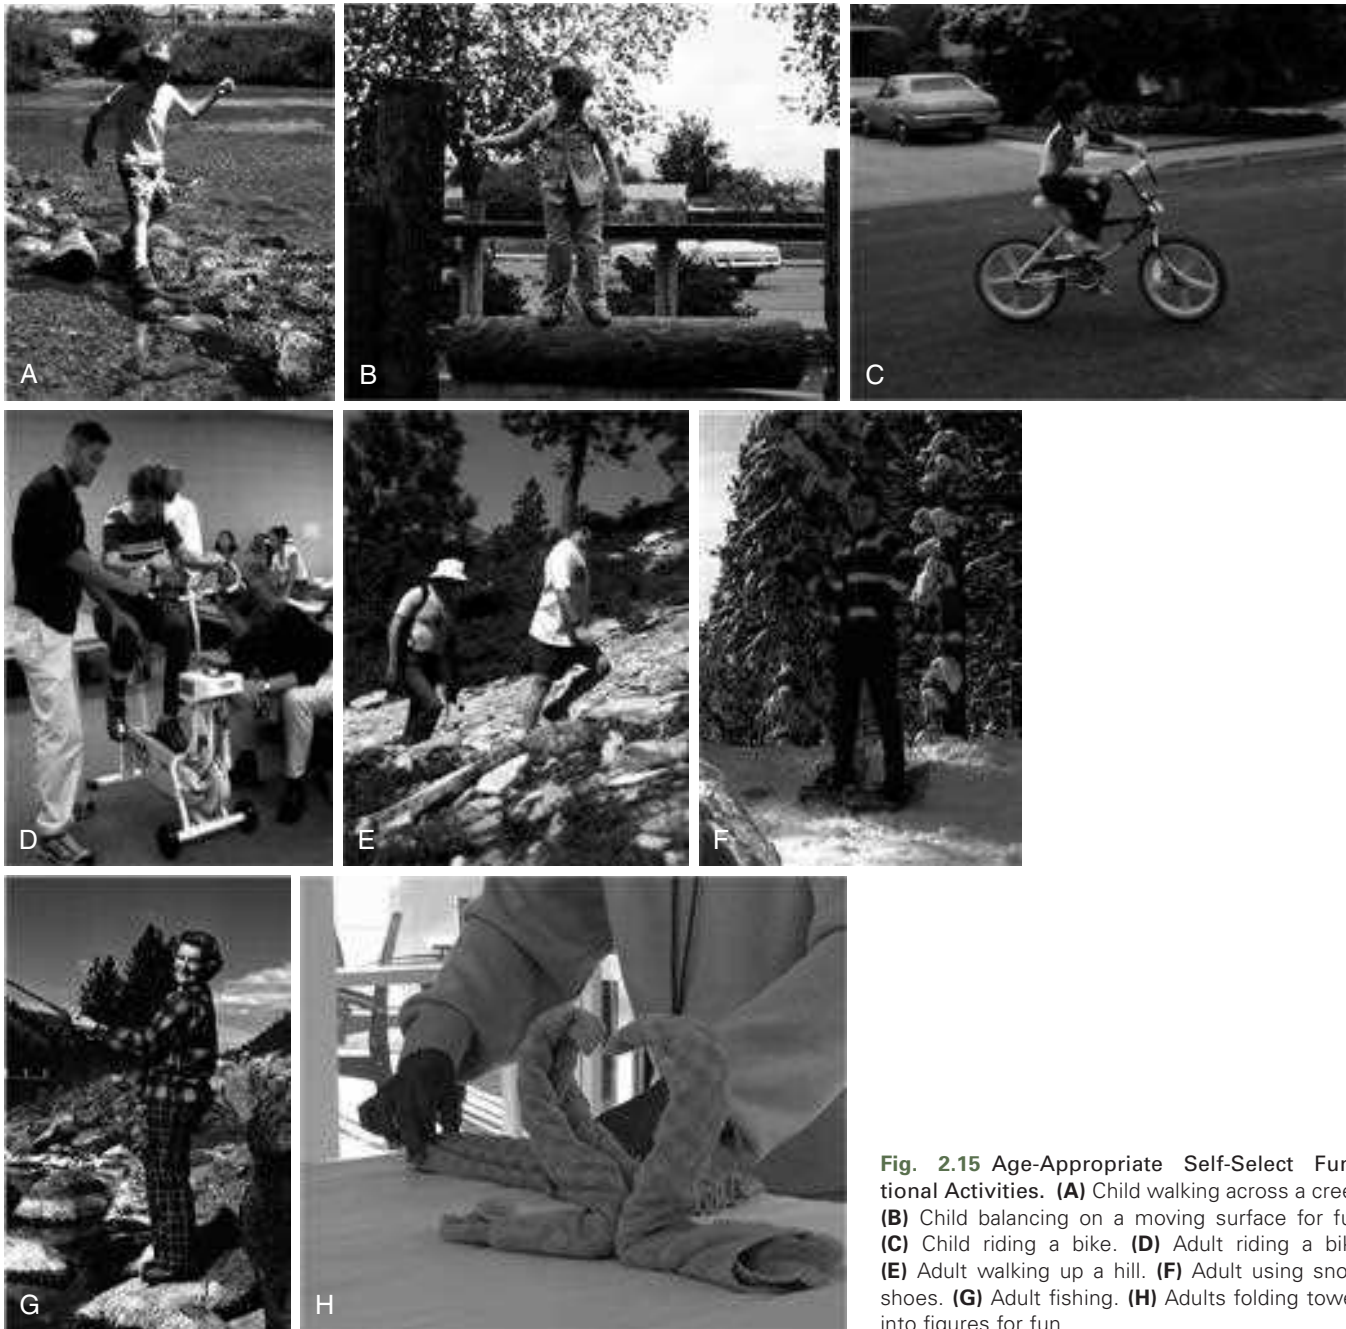

Fig. 2.15 Age-Appropriate Self-Select Functional Activities. (A) Child walking across a creek. (B) Child balancing on a moving surface for fun. (C) Child riding a bike. (D) Adult riding a bike. (E) Adult walking up a hill. (F) Adult using snowshoes. (G) Adult fishing. (H) Adults folding towels into figures for fun.

when the head is initially moving. Although the neck-righting program is present at birth, it will take the child a couple of months to gain the power necessary to independently flex and rotate the head against gravity with the body following the head in order to roll over. As the flexor power improves, it will be integrated into patterns of coactivation with postural extensors. The extensor movements of the head include (1) extension from a flexion position through hyperextension and/or rotation of the head in all spatial planes; and (2) postural extension, holding and/or stabilizing each vertebra within the spinal column. These postural programs help coactivate the flexors and postural extensors simultaneously to stabilize the

head in space. There are a variety of motor programs that assist in gaining this control of the head. Head-righting reactions, using the semicircular canals, are programmed to right the head, or bring it to face vertical, no matter where the head is in space. The righting programs need the underlying power to produce the force necessary to right the head. The heavier the head, whether in weight of the cranium or its positioning against gravity, the harder it is to right the head to vertical. Thus it could be hypothesized that if the head were in a vertical position or vertical in reference to gravity, it would be easier to control the head in space. The force production would be nominal compared with the force production needed when bringing

the head up from horizontal or just holding it against gravity when horizontal. There are motor programs triggering extensor tone due to the position of the otoliths in the inner ear. The degree of tone will depend upon whether the head is horizontal in supine, vertical, or in between. This response has been labeled the *tonic labyrinthine reaction* (TLR). The TLR is strongest in the supine position because of the optimal pull of the otoliths by gravity. When an individual is supine, the tactile input from pressure to the surface of the skin increases extensor tone. Thus in the supine position the tactile input and the information from the hair cells of the otoliths are activating the motor pool of the extensors and simultaneously decrease the motor pool of the flexors. These systems decrease the ability of the motor control system to generate flexor tone in supine. When the child is placed prone, the skin sensitivity decreases extensor tone.

Flexor Control

Fig. 2.16A–F illustrates the patterns of a healthy 4-week-old when being pulled to sit and returned to the floor. Initially the child has difficulty flexing his head when trying to pull the head into flexion from the supine position because of both the extensor tactile system and the labyrinthine mechanism, which inhibit the flexors while facilitating the extensor muscles. This can be seen in Fig. 2.16A–C. This lack of adequate flexor control would be considered normal for the child's age but also defined as a head lag (see Fig. 2.16A–C). As the child approaches vertical, his weight is shifted down through his buttocks and over his base of support. At that point the head control

kicks in (see Fig. 2.16D and E). This motor control of the head in vertical incorporates both postural extensors and flexors while optimizing the use of optic and labyrinthine righting and stretch to both flexors and extensors muscle groups (see Fig. 2.16D). The child is able to maintain better control of head and neck flexors when lowered back down to supine (see Fig. 2.16E and F). This ability to control the head while transitioning from sitting to supine illustrates the fan swing principle: once the flexor program is elicited in the vertical position, it can maintain head control for a longer period of time and through more degrees of motion as the head movement progresses from vertical to horizontal.

Over the next month the child will develop flexor control in space by using head righting, muscle strength, and facilitation of the nervous system to keep the head and eyes oriented toward an object as the head travels through space. Motor control over flexor patterns becomes more flexible, and the power needed to perform tasks increases. Fig. 2.17A–C demonstrates the pull to sit pattern in a healthy 3-month-old infant. She not only has learned to dampen the influence of the TLR in the supine position and the skin's influence on the extensor motor pool, but also has learned that by flexing most of her body parts (flexion facilitates flexion) she will gain additional flexor control of the head when pulled from supine (see Fig. 2.17A). This flexion continues as the child goes through midrange (see Fig. 2.17B) and continues as the child approaches vertical (see Fig. 2.17C). Unfortunately, the child does not have the integrated motor control over flexion and extension or the balance reactions in sitting to extend the legs as she approaches vertical. This movement is a prerequisite for gaining control of long

Fig. 2.16 A 1-Month-Old Child Being Pulled to Sit From Supine and Lowered Back Down. (A) Starting position in supine. (B) Pulled toward vertical, maximal resistance from gravity, inadequate response to stretch by neck flexors. (C) Position of ears and otoliths inhibits flexors; thus inadequate head righting is still seen. (D) Child in vertical, weight through hips, quick stretch to head in all directions facilitates head control. (E) Child lowered back toward horizontal continues to have adequate head control. (F) Maximal stretch from gravity; child still retains adequate neck flexion.

Fig. 2.17 A 3-Month-Old Healthy Child Pulled to Sit. (A) Initial stretch in horizontal pulls in neck flexion along with flexion of the hips and knee. (B) Adequate neck flexion persists as child looks at therapist while being pulled to sit: midrange. (C) Transitioning to vertical; less stress on neck flexors, yet flexion persists in lower extremities.

sitting in vertical. These new motor movements will become the foundation for balance reactions in vertical sitting.

A month later the child's nervous system integrates the flexor patterns into smooth movement through 90 degrees of motion from supine to sitting (Fig. 2.18A–C). The child also demonstrates a more integrated response to being lowered backward from vertical (see Fig. 2.18D). Yet the child's motor system has not developed the rotatory aspects or control of the diagonal flexor patterns as shown in Fig. 2.18E. These rotatory patterns will develop as the child practices

rotation in rolling and then incorporates that rotation when coming to sit in a partial rotation pattern.

The child will not be able to independently initiate motor control over the adult pattern of coming to a sitting position for at least 3 to 5 years but certainly should gain that control by age 6 (Fig. 2.19). As the child's age increases, the movement patterns become more complex, and additional motor programs are learned and integrated. This aspect of head control will be maintained and integrated in movement patterns as the individual explores the environment.

Fig. 2.18 Pull to Sit in 4-Month-Old-Healthy Child. (A) Child looks as therapist places finger to the child's head—recognized tactile stimulus, relaxed supine. (B) Child pulled to sit, neck tucked and hips flexed. (C) In vertical, child relaxes hip flexors in order to have sitting balance. (D) Child lowered toward supine maintains neck and trunk control. (E) Rotation added into lowering to supine pattern; neck response is inadequate.

Fig. 2.19 Normal 6-Year-Old Using Adult Independent Coming-to-Sit Pattern.

Extensor Control

As the child develops flexion, the child also needs to develop the extensor control of the head. There are two extensor component patterns used by the CNS to control extension. The first pattern is controlling extension of the head from a totally flexed position (as if an individual were looking down at his shoes) to a hyperextension position (as if an individual in a standing position were looking up at the stars). This pattern has a large range of motion, and the power needed will change depending on the head's position in space, in relation to gravity, as well as the weight of the head itself. The second pattern is considered "postural" and requires the small muscles of the neck and the shoulder and trunk to hold each vertebra in relation to the vertebra above and the vertebrae below. This is the bony support encompassing the spinal cord. Similarly, in the upper cervical region as the flexor and extensor patterns work together in a coactivation pattern, chin tucking occurs. This pattern allows the head to remain stable in space, keeping the eyes and the ears horizontal to the surroundings, a key component for perceptual learning. This movement pattern is often called *optic and labyrinthine righting of the head* because both the eyes and the ears provide stimuli to trigger this motor response.

Assessment of Head Control

Most individuals analyze the development of postural control by evaluating the extensor aspect of head control in the prone position. But the prone position is not the first position in which a child begins to achieve independent head control. [Fig. 2.20A–C](#) illustrates a newborn (2 days old) extending both the long extensors (see [Fig. 2.20A](#) and [B](#)) as well as

moving into the postural extensor pattern component when tucking the chin (see [Fig. 2.20C](#)). While prone the newborn child has very little independent control over extension and can just clear the airways ([Fig. 2.21](#)). This same limitation is not present when the child is in a supported vertical position. After a week the extensor patterns in the vertical position have already become more functional and demonstrate better motor control and greater power. [Fig. 2.22A–C](#) shows the same child at 1 week of age while supported in a vertical position. [Fig. 2.22C](#) is a beautiful example of the postural pattern one expects to see consistently later in the child's development. Obviously, he is practicing these movements every time he is vertical and given these limited degrees of freedom. Looking at the same child at 1 month of age ([Fig. 2.23](#)), the integration of these postural movements is continuing down his entire spine. This does not mean he can hold this pattern for an extended period of time but does illustrate his ability to move with control into a total postural extension pattern and hold it at least briefly. On the same day and about 15 minutes later, the child ([Fig. 2.24](#)) was placed prone on the floor, clearly demonstrating that he has not developed the necessary power to control his head or upper trunk for postural extension in the prone position. Although he is more relaxed prone at 1 month than at birth (see [Fig. 2.21](#)) and can lift and turn his head in both directions, it will still be 1 or 2 additional months before he can extend his head and trunk enough to prop on his elbows. It will take more time to roll from prone to supine.

While the cervical and upper thoracic muscles are developing postural power, they need to learn to hold the head in space against gravity for longer periods of time. Postural function

Fig. 2.21 When Placed Prone, the Newborn Has Excessive Flexion.

Fig. 2.20 Newborn Neck Extension in Supported Vertical Position. **(A)** Newborn lacks postural extension of trunk and head. **(B)** Newborn initiates neck extension, showing that patterns exist. **(C)** Newborn moves into postural extension of upper cervical region.

Fig. 2.22 Child 7 Days Old in Vertical Extension. **(A)** Child eliciting active neck and trunk extension in vertical at 7 days. **(B)** Child does not have adequate righting of the head in vertical at 7 days but is responding. **(C)** Child pulls into postural extension of the neck and trunk, allowing for binocular vision at 7 days.

Fig. 2.23 A 1-month-old child, when supported in a vertical position, shows postural extension of the neck and trunk while looking at his mother.

Fig. 2.24 Same child when placed prone, 15 minutes after Fig. 2.23 was taken. This child demonstrates that when prone he still has a flexor bias and has little adequate postural extension in this position.

requires coordination and coactivation of the short extensors of the neck and the neck flexors—especially the sternocleidomastoid, hyoid, and scalene muscles—in order to tuck the chin and balance the head in space. These movement patterns play a key role in stabilization of the head in order to move the head in and out of vertical space. The motor control system uses both righting and balance reactions in order to gain full head and neck control of vertical space. The movements become more and more complex, modifying and integrating various additional motor programs in order to have greater flexibility to control and move the head. These patterns give the eyes and ears the visual and auditory orientation needed to process consistent external environmental information. Fig. 2.25 illustrates an individual after head injury who has lost his automatic righting of the head in vertical. He has the ability to bring his head to vertical by hyperextension of the neck but does not do so automatically. This hyperextension pattern dramatically changes the motor patterns of head, neck, and trunk control, which will affect his upright behaviors including balance, gait, feeding, and social interactions.

Fig. 2.25 An individual who sustained a closed head injury with residual lack of postural neck extension has poor head control in vertical.

Application of the Development of Head Control to Rehabilitation

The reason the patterns of head extension in vertical have been presented is to illustrate that motor control progresses from vertical to horizontal and then from horizontal to vertical. Therapists think of the prone position as the first position in which the child develops extensor control because it is the first position in which an observer sees independent selection of extensor movement. However, extensor control begins when an individual passively brings a young baby to sitting or standing. The baby learns to control the head with small movements that displace the center of gravity. Understanding this stage of head control may be a critical component of working with a neurologically impaired youngster or an adult.

Analysis Between Normal and Impaired Motor Function

Differentiating normal age-related reactions of any movement impairment is the responsibility of a movement specialist. For example, differentiating the movement of a normal child who has a lag in head control (see Fig. 2.16B and C) from the movement of a child who does not demonstrate any head control (Fig. 2.26A–E) should guide the therapist in a decision about where to begin treatment. It is an unrealistic expectation for the child in Fig. 2.25 to gain flexor head control by starting at supine. After the child has been pulled to sit, flexor power production is beyond the control of the child's motor system. Once the child is vertical, the influence of gravity on the weight of the head has decreased. The vertical position also inhibits any influence of the otoliths when supine. The upright position helps to facilitate the labyrinthine and optic righting of the head. Fig. 2.26D and E demonstrates how the tone within the neck and shoulder girdle changes once the head attains a vertical position. A therapist should not only see a change to more normal tonal patterns but also observe relaxation of

the facial muscles—closure of the mouth and a more functional position of the eyes in space for visual processing.

Movement demonstrates the ease or difficulty the motor system is experiencing while trying to complete an activity. The activity analyzed may be a basic pattern such as head control or a complex one as seen in Fig. 2.3E. Differentiating between the movements in Figs. 2.15A and 2.25A should guide the clinician in establishing realistic prognoses. The first child, with practice and CNS maturity, should automatically develop head control, whereas the second child has gone beyond his age-appropriate movement delays and has abnormal responses to the stretch stimuli.

Similar analysis can be made when looking at the extensor component of head control. The vertical position that optimizes extension is kneeling or standing because compression down through the joints and spine facilitates extension. Using kneeling or standing may pull in too much extension, especially if it results in hyperextension. In that case sitting may be appropriate even though it may facilitate flexion. When kneeling or standing, if inadequate extension still exists, then adding additional compression down through the head or shoulder girdle may help. Using an apparatus that takes away some of the weight of the head or trunk reduces the demand on the nervous system and may help the individual regain postural neck, shoulder girdle, and upper trunk control. As the individual begins to demonstrate that control, the therapist can slowly take away the assistance with the expectations that the individual will gain independence in that activity.

As the individual ages, changes in the control of the head can lead to new problems. Fig. 2.13B is an example of a man who has a fixed flexed posture. If the flexed posture is permanent, treatment alternatives must take into consideration the impact this posturing will have on all ADLs. As stated earlier, any patient can exhibit a range of problems in head control. How those movement impairments present themselves and which treatment alternatives a therapist might select

Fig. 2.26 Child 2½ years old with cerebral palsy being pulled to sit, and muscle action facilitated once vertical. **(A)** Initial pull toward sit; no response to stretch of neck flexors. **(B)** Continued pull toward vertical, head at end range of neck extension. **(C)** Trunk in vertical but neck remains in horizontal; no flexor response. **(D)** Child pulled beyond vertical as trunk extensors begin to activate from stretch and mouth closure is beginning. **(E)** Therapist facilitates head into vertical as mouth continues to relax and close and eyes are looking at a target.

will depend on the clinician's ability to analyze normal movement and create an optimal environment for patients to engage and practice those patterns.

Clinical Example

Cervical torticollis in a child is an imbalance in rotation of the neck and muscle groups secondary to position of the fetus in utero. Cervical torticollis in adults is a focal dystonia or an imbalance of excitation and inhibition of the neck muscles. These patients have impaired integrative balance responses. Standard medical intervention is botulinum toxin injections followed by physical therapy focusing on range of motion and strengthening exercise. The emphasis needs to be on restoring and progressing head control from vertical to supine—that is, trying to help the neck muscles to retrain a stable condition in the vertical position by using a collar for support. Compression down through the cervical and thoracic spine can facilitate flexors, extensors, and rotator muscles. Then, as in the infant, with arms fixed on a stable support surface, slowly let the patient move

out of vertical toward horizontal, moving only as far as head control is maintained, which may be as limited as 10 to 20 degrees. Repeat this activity many times in order for this activity to become procedural. Patients can hold onto some stable support object at home in order to practice. The challenge for both the therapist and the patient is to retrain head control in order for the individual to be able to participate in life.

Head Control Development Summary

Normal development of head control has been highlighted because so many clinicians become frustrated with patients who do not have adequate head control. The examples of the development of head control serve as a foundation for every movement pattern that people use, whether stationary or in motion. The process used to analyze the development of head control can be used to analyze all movement patterns, whether the movement problem is caused by a bodily system (biomechanical, cardiopulmonary, CNS, or another system problem) or by some environmental factor.

SUMMARY

Clinicians must focus best practice toward successful patient management geared toward promotion of function and prevention of chronic illness or disability for the youngest of the young to the oldest of the old. As practitioners, we must embrace tenets central to the *Healthy People 2020* project.²³³ Physical and occupational therapists serve as role models for individuals of all ages and educate diverse groups of individuals about the multifaceted, interactive systems involved in the acquisition, retention, and deterioration of motor behaviors. Recognizing internal and external constraints or affordances that influence motor behaviors enables the clinician to devise a plan of care and the scientist to design a study targeting the needs of the whole person. Analyzing, understanding, and visually recognizing movement patterns that are efficient, fluid, and goal oriented and that vary across the life-span are the first steps or prerequisites to evaluating abnormal movement patterns that do not fall within a normal parameter. Fig. 2.27A–G shows an example of rolling, a basic movement strategy controlled by the child midway through the first year of life that can become an extremely challenging activity after a CNS insult. Differentiating between components of a normal movement and deviations that prohibit normal movement falls into the clinical expertise of occupational and physical therapists. Without the knowledge of normal movement, analysis of the causation of abnormal movement would be difficult if not impossible. This chapter has been written to help the reader understand normal movement across the life-span. It is the first step, and in sighted individuals the analysis begins as soon as visual images are recorded in the visual cortex.

Scientists acknowledge that development is characterized as nonlinear, emergent, and dynamic, rather than sequential, predictable, and stage like. Dynamic systems theory, although it does have certain limitations, provides a better explanation for development than do neuromaturational theories. The emphasis or responsibility does not lie with any one system but varies across different systems because of age, genetics, or experience.¹²⁷ That said, future studies directed at

examining human movement and optimal variability through nonlinear dynamics may provide new perspectives in motor development and control. Although the research may provide valuable insights into how the brain develops and exactly what controls which aspects of movement, the movements themselves and the sequences children use to move from one functional skill to the next may not vary tremendously.

Human behavior is by nature complex. As such, no one system or skill develops in isolation but rather emerges from a complex interaction among multiple systems. Complex behaviors are evident beginning in utero and continuing throughout life. No one theory explains the development of complex motor behaviors, and none encompass the essence of interindividual and intraindividual variability in aging. Aspects of various theories provide evidence that an integrative perspective is a more accurate reflection of aging. As theorized earlier, lifestyle choices and other modifiable behaviors have potent effects on aging. Activities should be promoted that the individual enjoys and strategies employed that encourage the individual to participate in preferred motor activities across his or her life-span, in a safe and supportive environment. After the individual executes the task(s) in a supported environment, the next step is participating in real-life leisure activities with family and peers and providing additional social interactions. Interventions designed to provide older adults with strategies to positively influence successful aging, rather than being sought after a negative outcome of aging is realized, may improve the quality of life. Optimal quality of life is what all individuals hope to obtain, whether learning to reach a cracker, climbing the highest mountain, or playing a game of bridge.

Maintaining that quality before the end of life, no matter the age, is often based on movement function. The patient, whenever possible, should determine identification of the specific function. Identification of the necessary steps to get from existing skill to desired skill is the role of a movement specialist, whether that therapist is dealing with preventive care or postinsult care.

Fig. 2.27 Rolling—An Activity Achieved Within the First Year. **(A)** Child beginning rolling in supine position. **(B)** Child semiprone with trunk rotation. **(C)** Child brings arm through to become symmetrical while proceeding toward prone position. **(D)** Child prone with postural extension. **(E)** Adult with traumatic brain injury; first try at rolling toward prone position from supine. **(F)** Adult's second try at rolling, changing programming. **(G)** Once prone, he is stuck, unable to extend.

Abstract: A life-span perspective to movement provides a framework for examining the interactive effects of body systems/subsystems and the potential impact on movement. Using a life-span approach, as a method for understanding and conceptualizing the dynamic nature of human development, supports employing a multidimensional approach in selecting measurement tools and designing therapeutic interventions. As practitioners' understanding of life-span processes increase, they are better prepared to exploit intrinsic and extrinsic variables as a means of improving and more effectively impacting movements. Exploiting the structural and functional changes across/within systems, enables one to regulate

development afforded by opportunities and challenges in the environment. This perspective underscores the importance of structuring a therapeutic environment that enables the individual to produce functional behaviors, improve quality of life and achieve the desired outcomes. Using this approach, better prepares the practitioner to explore variables influencing motor behaviors and employ strategies that allow the individual to move and effectively impact his/her environment.

Contemporary Issues and Theories of Motor Control, Motor Learning, and Neuroplasticity*

Margaret L. Roller, Susan V. Duff, Darcy A. Umphred, and Nancy N. Byl

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify the evolution of motor control theories and discuss the utility of current theory in clinical practice.
2. Identify body structures and functions that contribute to the control of human posture and movement.
3. Relate the cognitive, associative, and autonomous stages of motor learning to behavior and skill performance.
4. Describe the variety of practice conditions that may be used to enhance motor learning within a practice session.
5. Apply motor learning variables related to person, task, and environment within the therapeutic setting.
6. Discuss neuroplasticity theories that explain how the nervous system adapts to demands placed on learning and performance.
7. Discuss the relationships between motor control, motor learning, and neuroplasticity in the production of functional movement behaviors.

KEY TERMS

motor control theory

motor learning

neuroplasticity

The production and control of human movement is a process that varies from a simple reflex loop to a complex network of neural patterns that communicate throughout the central nervous system (CNS) and peripheral nervous system (PNS). Neural networks and motor pattern generators develop as the fetus develops in utero and are active before birth. These simple patterns become building blocks for more skilled, complex, goal-directed motor patterns as a person develops throughout life. New motor patterns are learned through movement, interactions with rich sensory environments, and challenging experiences that drive a person to solve problems. The personal desires and goals of the individual shape the process of learning new motor skills at all stages of life. If a condition exists or develops or if an event occurs that damages the nervous system and prevents normal transmission, processing, and perception of information in the PNS and CNS, movement control becomes abnormal, slow, labored, uncoordinated, or weak—or movement may not be produced at all. The damaged nervous system is able to repair itself, change, and adapt to some extent by means of nerve regeneration and neuroplasticity. However, when nerve cells die and neural connections are not viable, there are alternative pathways within the nervous system that can take the place of the normal processes and provide some means of meeting the movement goal—whether it is to walk, use an arm to eat, or make a facial expression. This process of change, healing, or motor learning depends on many factors, including inherent elements of the individual such as age, the extent of tissue damage, and other physiological and cognitive processes as well as external factors such as interactions with sensory and motor system challenges and goal-directed practice of meaningful, functional motor skills.

This chapter introduces the reader to basic concepts of motor control, motor learning, and neuroplasticity. Figures and tables are provided to emphasize and summarize concepts. Patient case examples are used to illustrate concepts in this chapter as they apply to the evaluation and management of people with neurological conditions.

MOTOR CONTROL

Motor control is defined as “the systematic transmission of nerve impulses from the motor cortex to motor units, resulting in coordinated contractions of muscles.”¹

This definition describes motor control in the simplest terms—as a top-down direction of action through the nervous system. In reality, the process of controlling movement begins before the plan is executed and ends after the muscles have contracted. The essential details of a movement plan must be determined by the individual before the actual execution of the plan. The nervous system actively adjusts muscle force, timing, and tone before the muscles begin to contract, continues to make adjustments throughout the motor action, and compares movement performance with the goal and neural code (instructions) of the initial motor plan. This extension of the definition takes into account that the body *accesses sensory information* from the environment, *perceives* the situation, and *chooses a movement plan* appropriate to the task that the person wants to complete; this plan is then *coordinated* within the CNS. Finally the plan is *executed* through motor neurons in the brain stem and spinal cord that communicate with muscles in postural and limb synergies as well as muscles in the head and neck that are timed to fire in a specific manner. The movement that is produced supplies *sensory feedback* to the CNS to allow the person to (1) modify the plan during performance, (2) know whether the goal of the task has been achieved, and (3) store the information

*Videos for this chapter are available at studentconsult.com.

for future performance of the same task-goal combination. Repeated performance of the same movement plan tends to create a preferred pattern that becomes more automatic in nature and less variable in performance. If this movement pattern is designed and executed well, it means that the person has developed a new skill. If this pattern is incorrect and does not efficiently accomplish the movement goal, it means that the outcome is abnormal.

Theories and Models of Motor Control

A summary and historical perspective of motor control theories is given in Table 3.1. The control of human movement has been described in many different ways. The production of reflexive, automatic, adaptive, and voluntary movements and the performance of efficient, coordinated, goal-directed movement patterns involve multiple body systems (input, output, and central processing) and multiple levels within the nervous system. Each model of motor control that is discussed in this chapter has both merits and disadvantages in its ability to supply a comprehensive picture of motor behavior. These theories serve as a basis for predicting motor responses during patient examination and treatment. They help explain motor skill performance, potential, constraints, limitations, and deficits. They allow the clinician to (1) identify problems in motor performance, (2) develop treatment strategies to help patients remediate performance problems, and (3) evaluate the effectiveness of intervention strategies employed in the clinic. Selecting and using an appropriate model of motor control is important for the analysis and treatment of patients with dysfunctions of posture and movement. As long as the environment and task to be performed necessitates change in the CNS, and the individual has the desire to learn, the adaptable nervous system will continue to learn, modify, and adapt motor plans throughout life.

Motor Programs and Central Pattern Generators

A motor program (MP) is a learned behavioral pattern defined as a neural network that can produce rhythmic output patterns with or without sensory input or central control.¹⁴ MPs are sets of movement

commands, or “rules,” that define the details of skilled motor actions. An MP defines the specific muscles that are needed; the order of muscle activation; and the force, timing, sequence, and duration of muscle contractions. MPs help to control the degrees of freedom of interacting body structures and the number of ways in which each individual component acts. A generalized motor program (GMP) defines a pattern of movement with a lesser degree of specificity, rather than defining every individual aspect of a movement. GMPs allow for the adjustment, flexibility, and adaptation of movement features according to environmental demands. The existence of MPs and GMPs is a generally accepted concept; however, hard evidence that an MP or a GMP exists has yet to be found. Advancements in brain imaging techniques may substantiate this theory in the future.^{14,15}

In contrast to MPs, a central pattern generator (CPG) is a genetically predetermined movement pattern.^{16,17} CPGs exist as neural networks within the CNS and have the capability of producing rhythmic, patterned outputs resembling normal movement. These movements have the capability of occurring without sensory feedback inputs or descending motor inputs.¹⁸ Two characteristic signs of CPGs are that they result in the repetition of movements in a rhythmic manner and that the system returns to its starting condition when the process ceases.¹⁹ Both MPs and CPGs contribute to the development, refinement, production, and recovery of motor control throughout life.

The Person, the Task, and the Environment: An Ecological Model for Motor Control

Motor control evolves so that people can cope with their environment. A person must focus on detecting information in the immediate environment (perception) that is determined to be necessary for performance of the task and achievement of the desired outcome goal. The individual is an active observer and explorer of the environment, which enables the development of multiple ways in which to accomplish (choose and execute) any given task. The individual analyzes a particular sensory environment and chooses the most suitable and efficient way to complete the task. The *person* consists of all functional

TABLE 3.1 Theories of Motor Control

Motor Control Theory	Author and Date	Premise
Reflex Theory	Sherrington, 1906 ²	Movement is controlled by stimulus-response. Reflexes are combined into actions that create behavior.
Hierarchical Theory	Jackson, 1932 ³	Higher centers are in control of lower centers.
Motor Program Theory	Adams, 1971 ^{4,5} Schmidt, 1976 ⁶	Cortical centers control movement in a top-down manner throughout the nervous system. Closed-loop mode: sensory feedback is needed and used to control the movement. Adaptive, flexible motor programs (MPs) and generalized motor programs (GMPs) exist to control actions that have common characteristics. Open-loop mode: movements are preprogrammed, and feedback is used to update the program.
Ecological Theories	Gibson and Pick, 2000 ^{7,8}	The person, the task, and the environment interact to influence motor behavior and learning. The interaction of the person with any given environment provides perceptual information used to control movement. The motivation to solve problems to accomplish a desired movement task goal facilitates learning.
Systems Model	Bernstein, 1967 ⁹ Shumway-Cook, 2017 ¹⁰	Movement emerges to control degrees of freedom. Multiple body systems overlap to activate synergies for the production of movements organized around functional goals. Considers interaction of the person with the environment.
Dynamical Systems Theory	Turvey, 1977 ¹¹ Kelso and Tuller, 1984 ¹² Thelen et al., 1987 ¹³	Patterns of movements self-organize within the characteristics of environmental conditions and the existing body systems of the individual. Functional synergies are developed naturally through practice and experience and help solve the problem of coordinating multiple muscles and joint movements at once.

Cano-de-la-Cuerda R, Molero-Sanchez A, Carratala-Tejada M, et al. Theories and control models and motor learning: clinical applications in neurorehabilitation. *Neurologica*. 2015;30(1):32-41.

and dysfunctional body structures and functions that exist and interact with one another. The *task* is the goal-directed behavior, challenge, or problem to be solved. The *environment* consists of everything outside of the body that exists, or is perceived to exist, in the external world. All three of these motor control constructs (person, task, environment) are dynamic and variable, and they interact with one another during learning and the production of a goal-directed, effective motor plan.¹⁰

Body Structures and Functions That Contribute to the Control of Human Posture and Movement

Keen observation of the quality of motor output during the performance of functional movement patterns helps the therapist to determine activity limitations and begin to hypothesize impairments within sensory, motor, musculoskeletal, cardiopulmonary, and other body systems.

Table 3.2 shows the body system processes involved in motor control, their actions, and the body structures included. The following chapter sections explain these processes in more detail.

Role of Sensory Information in Motor Control

Sensory receptors from somatosensory (exteroceptors and proprioceptors), visual, and vestibular systems as well as taste, smell, and hearing fire in response to interactions with the external environment and to movement created by the body. Information about these various modalities is transmitted along afferent peripheral nerves to cells in the spinal cord and brain stem of the CNS. All sensory tracts with the exception of smell then synapse in respective sensory nuclei of the thalamus, which acts as a filter and relays this information to the appropriate lobe of the cerebral cortex (e.g., somatosensory to the parietal lobe, visual to the occipital lobe, vestibular, hearing, and taste to the temporal lobe). Sensory information is first received and perceived and then associated with other sensory modalities as well as memory in the association cortex. Once multiple sensory inputs are associated with one another, the person is able to *perceive* the body, its posture and movement, the environment and its challenges, and the interaction and position of the body with objects within the environment. The person uses this perceptual information to create an internal representation of the body (internal model) and to choose a movement program, driven by motivation and desire, to meet a final outcome goal. Although the sensory input and motor output systems operate differently, they are

inseparable in function within the healthy nervous system. Agility, dexterity, and the ability to produce movement plans that are adaptable to environmental demands reflect the accuracy, flexibility, and plasticity of the sensorimotor system.

The CNS uses sensory information in a variety of ways to regulate posture and movement. Before movement is initiated, information about the position of the body in space, body parts in relation to one another, and environmental conditions is obtained from multiple sensory systems. Special senses of vision, vestibular inputs that respond to gravity and movement, and visual-vestibular interactions supply additional information necessary for static and dynamic balance and postural control as well as visual tracking. Auditory information is integrated with other sensory inputs and plays an important role in the timing of motor responses with environmental signals, reaction time, response latency, and comprehension of spoken word. This information is integrated and used in the selection and execution of a movement strategy. During movement performance, the cerebellum and other neural centers use feedback to compare the actual motor behavior with the intended motor plan. If the actual and intended motor behaviors do not match, an error signal is produced and alterations in the motor behavior are triggered. In some instances, the control system anticipates and makes corrective changes before the error signal is detected. This anticipatory correction is termed *feedforward control*. Changing one's gait path while walking in a busy shopping mall to avoid a collision is an example of how visual information about the location of people and objects can be used in a feedforward manner.

Another role of sensory information is to revise the reference of correctness (central representation) of the MP before it is executed again. For example, a young child standing on a balance beam with the feet close together falls off of the beam. An error signal occurs because of the mismatch between the intended motor behavior and the actual motor result. If the child knows that his feet were too close together when he fell, then he will space his feet farther apart on the next trial. The child will then use this information about what happened, falling or not falling, in planning movement strategies for balancing on any narrow object such as a balance beam, log, or wall in the future.

Sensory information is necessary during the acquisition phase of learning a new motor skill and is useful for controlling movements during the execution of the motor plan.^{10,20,21} However, sensory information is not always necessary when a person is performing

TABLE 3.2 Components of Motor Control: Body System Processes Involved in Motor Control, Their Actions, and the Body Structures Included

Process	Action	Body Structures Involved
Sensation	Acquires sensory information and feedback from exteroceptors and proprioceptors	Peripheral afferent neurons, brain stem, cerebellum, thalamus, sensory receiving areas in the parietal, occipital, and temporal lobes
Perception	Combines, compares, and filters sensory inputs	Brain stem, thalamus, sensory association areas in the parietal, occipital, visual, and temporal lobes
Choice of movement plan	Use of the perceptual map to access the appropriate motor plan	Association areas, frontal lobe, basal ganglia
Coordination	Determines the details of the plan, including force, timing, tone, direction, and extent of the movement of postural and limb synergies and actions	Frontal lobe, basal ganglia, cerebellum, thalamus
Execution	Executes the motor plan	Corticospinal and corticobulbar tract systems, brain stem motor nuclei, and alpha and gamma motor neurons
Adaptation	Compares movement with the motor plan and adjusts the plan during performance	Spinal neural networks, cerebellum

well-learned motor behaviors in a stable and familiar context.^{20,21} Rothwell and colleagues²¹ studied a man with severe sensory neuropathy in the upper extremity. He could write sentences with his eyes closed and drive a car with a manual transmission without watching the gear shift. He did, however, have difficulty with fine motor tasks such as buttoning his shirt and using a knife and fork to eat when denied visual information. The importance of sensory information must be weighed by the individual, who is unconsciously filtering and choosing appropriate and accurate sensory inputs to use to meet the movement goal.

Sensory experiences and learning alter sensory representations, or cortical “maps,” in the primary somatosensory, visual, and auditory areas of the brain. Training, as well as use and disuse of sensory information, has the potential to drive long-term structural changes in the CNS, including the formation, removal, and remodeling of synapses and dendritic connections in the cortex. This process of cortical plasticity is complex and involves multiple cellular and synaptic mechanisms.²² Plasticity in the nervous system is discussed further in the third section of this chapter.

Choice of Motor Pattern and the Control of Voluntary Movement

A choice of body movement is made based on the person’s perception of the environment, his or her relationship to objects within it, and the goal to be met. The person chooses from a collection of plans that have been developed and refined over his or her lifetime. If a movement plan does not exist, a similar plan is chosen and modified to meet the needs of the task. Once the plan has been chosen, it is customized by the CNS with what are determined to be the correct actions to execute, given the perceived situation and goal of the individual.

Coordination

The movement plan is customized by communications between the frontal lobes, basal ganglia, and cerebellum, with functional connections through the brain stem and thalamus. During this process specific details of the plan are determined. Postural tone, coactivation, and timing of trunk muscle firing are set for proximal stability, balance, and postural control. Force, timing, and tone of limb synergies are set to allow for smooth, coordinated movements that are accurate in direction of trajectory, order, and sequence. The balance between agonist and antagonist muscle activity is determined so that fine distal movements are precise and skilled. This process is complicated by the number of possible combinations of musculoskeletal elements. The CNS must solve this “degrees of freedom”²³ problem so that rapid execution of the goal-directed movement can proceed and reliably meet the desired outcome.^{9,24} Once these movement details are complete, the motor plan is executed by the primary motor area in the precentral gyrus of the frontal lobe.

Execution of Movement Plans

Pyramidal cells in the corticospinal and corticobulbar tracts *execute* the voluntary motor plan. Neural impulses travel down these central efferent systems and communicate with motor neurons in the brain stem and spinal cord. The corticobulbar tract communicates with brain stem motor nuclei to control muscles of facial expression; mouth and tongue for speaking and eating; larynx and pharynx for voice and swallow; voluntary eye movements for visual tracking, saccades, and vergence; and muscles of the upper trapezius for shoulder girdle elevation. The corticospinal tract communicates with motor neurons in the spinal cord. The ventral corticospinal tract system communicates primarily with proximal muscle groups to provide the appropriate amount of voluntary activation needed to stabilize the trunk and limb girdles, thus allowing for dexterous distal limb movements. The lateral

corticospinal tract system communicates primarily with muscles of the arms and legs—firing α motor neurons in coordinated synergy patterns with appropriate activity in agonist and antagonist muscles so that movements are smooth and precise. Other motor nuclei in the brain stem are programmed to fire just before corticospinal tract activity in order to supply postural tone and anticipatory muscle activity. These include lateral and medial vestibular spinal tracts, the reticulospinal tract, and the rubrospinal tract systems. Adequate and balanced muscle tone of flexors and extensors in the trunk and limbs is supplied automatically, without the need for conscious control. These brain stem nuclei have tonic firing rates that are modulated up or down to effectively provide more or less muscle tone in body areas depending on stimulation from gravity, limbic system activity, external perturbations, or other neuronal activity.

Adaptation

Adaptation is the process of using sensory inputs from multiple systems to adapt motor plans, decrease performance errors, and predict or estimate consequences of movement choices. The goal of adaptation is the production of consistently effective and efficient skilled motor actions. When all possible body systems and environmental conditions are considered in the motor control process, it is easy to understand why there is often a mismatch between the movement plan that is chosen and how it is actually executed. Errors in movements occur and cause problems that the nervous system must solve in order to deliver effective, efficient, accurate plans that meet the task goal. To solve this problem, the CNS creates an internal representation of the body and the surrounding world. This acts as a model that can be adapted and changed in the presence of varying environmental demands. It allows for the ability to predict and estimate the differences between similar situations. This ability is learned by practicing various task configurations in real-life environments. Without experience, accurate movement patterns that consistently meet desired task goals are difficult to achieve.²⁵

Anticipatory Control

Anticipatory control of posture and postural adjustments stabilizes the body by minimizing displacement of the center of gravity. Anticipatory control involves motor plans that are programmed to act in advance of movement. A comparison between incoming sensory information and knowledge of prior movement successes and failures enables the system to choose the appropriate course of action.^{15,26}

Flexibility

A person should have enough flexibility in performance to vary the details of a simple or complex motor plan to meet the challenge presented by any given environmental context. This is a beneficial characteristic of motor control. When considering postural control, for example, a person will typically display a random sway pattern during standing that may ensure continuous, dynamic sensory inputs to multiple sensory systems.²⁷ The person is constantly adjusting posture and position to meet the demand of standing upright (earth vertical), as well as to seek information from the environment. Rhythmic, oscillating, or stereotypical sway patterns that are unidirectional in nature are not considered flexible and are not as readily adaptable to changes in the environment. Lack of flexibility in postural sway may actually render the person at greater risk for loss of balance and falls.

Role of the Cerebellum

The primary roles of the cerebellum in motor control are to maintain posture and balance during static and dynamic tasks and to coordinate movements before execution and during performance.²⁸ The cerebellum processes multiple neural signals from (1) motor areas of the

cerebral cortex for motor planning, (2) sensory tract systems (dorsal spinal cerebellar tract, ventral spinal cerebellar tract) from muscle and joint receptors for proprioceptive and kinesthetic sense information resulting from movement performance, and (3) the vestibular system for the regulation of upright control and balance at rest and during movements.²⁹ It compares motor plan signals driven by the cortex with what is received from muscles and joints in the periphery and makes necessary adjustments and adaptations to achieve the intended coordinated movement sequence. “Instructions” for movements that are frequently repeated are stored in the cerebellum as procedural memory traces. This increases the efficiency of its role in coordinating movement. The cerebellum also plays a role in the function of the reticular activating system (RAS).³⁰ The RAS network exists in the brain stem tegmentum; it is a network of nerve cells that maintain human consciousness and help people focus attention and block out distractions that may affect motor performance. Damage to the cerebellum, its tract systems, or its structure creates problems of movement coordination—not execution or the choice of which program to run. The cerebellum also plays a role in language, attention, and mental imagery functions that are not considered to take place in motor areas of the cerebral cortex (see Table 3.2).

The cerebellum plays the following four important roles in motor control³¹:

1. *Feedforward processing*: The cerebellum receives neural signals, processes them in a sequential order, and sends information out, providing a rapid response to any incoming information. It is not designed to act like the cerebral cortex and does not have the ability to generate self-sustaining neural patterns.
2. *Divergence and convergence*: The cerebellum receives a great number of inputs from multiple body structures. It processes this information extensively through a structured internal network and sends the results out through a limited number of output cells.
3. *Modularity*: The cerebellum is functionally divided into independent modules—hundreds to thousands—all with different inputs and outputs. Each module appears to function independently, although each shares neurons with the inferior olives, Purkinje cells, mossy and parallel fibers, and deep cerebellar nuclei.
4. *Plasticity*: Synapses within the cerebellar system (between parallel fibers and Purkinje cells and synapses between mossy fibers and deep nuclear cells) are susceptible to modification of their output strength. The influence of input on nuclear cells is adjustable, which provides great flexibility in adjusting and fine-tuning the relationship between cerebellar inputs and outputs.

Role of the Basal Ganglia

The basal ganglia are a collection of nuclei located in the forebrain and midbrain and consisting of the globus pallidus, putamen, caudate nucleus, substantia nigra, and subthalamic nuclei. The basal ganglia have primary functions in motor control and motor learning. They play a role in deciding which motor plan or behavior to execute at any given time and have connections to the limbic system; they are therefore believed to be involved in “reward learning.” The basal ganglia play a key role in eye movements through midbrain connections with the superior colliculus and help to regulate postural tone as a basis for the control of body positions, preparedness, and central set (i.e., the nervous system’s internal model of strategies for reactive balance control).³² Refer to Chapter 18 for additional information on the basal ganglia.

Information Processing

The processing of information through the sensory input, motor output, and central integrative structures occurs by various methods to produce movement behaviors. These methods allow us to deal with the

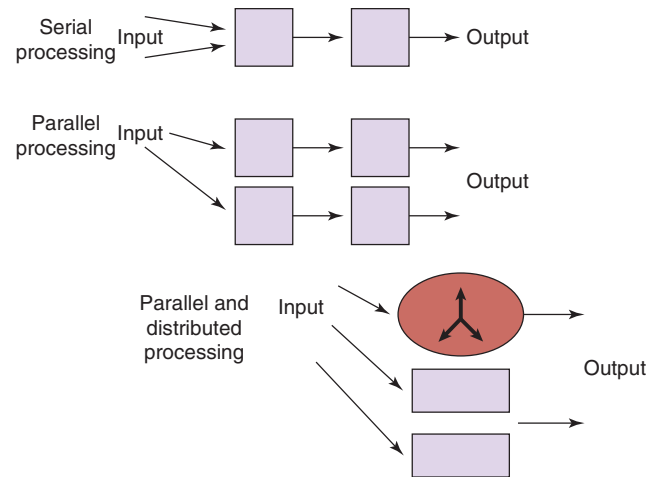

Fig. 3.1 Methods of Information Processing.

temporal and spatial components necessary for coordinated motor output and to anticipate, so that a response pattern may be prepared in advance. *Serial processing* is a specific, sequential order of processing of information (Fig. 3.1) through various centers. Information proceeds in lockstep through each center. *Parallel processing* is processing of information that can be used for more than one activity, and by more than one center simultaneously or nearly simultaneously. A third and more flexible type of processing of information is *parallel-distributed processing*.³³ This type of processing combines the best attributes of serial and parallel processing. When the situation demands serial processing, this type of activity occurs. At other times parallel processing is the mode of choice. For optimal processing of intrinsic and extrinsic sensory information by various regions of the brain, a combination of both serial and parallel processing is the most efficient mode. The type of processing depends on the constraints of the situation. For example, maintaining balance after an unexpected external perturbation requires rapid processing, whereas learning to voluntarily shift the center of gravity to the limits of stability requires a different combination of processing modes.

In summary, information processing reinforces and refines motor patterns. It allows the individual to initiate compensatory strategies if an ineffective motor pattern is selected or if an unexpected perturbation occurs. And, most important, information processing facilitates motor learning.

Movement Patterns Arising From Self-Organizing Subsystems

Coordinated movement patterns are developed and refined via dynamic interaction among body systems and subsystems in response to internal and external constraints. Movement patterns used to accomplish a goal are contextually appropriate and arise as an emergent property of subsystem interaction. Several principles relate to self-organizing systems: reciprocity, distributed function, consensus, and emergent properties.³⁴

Reciprocity implies information flow between two or more neural networks. These networks can represent specific brain centers—for example, the cerebellum and basal ganglia (Fig. 3.2). Alternatively, the neural networks can be interacting neuronal clusters located within a single center—for example, the basal ganglia. One model to demonstrate reciprocity is the basal ganglia regulation of motor behavior through direct and indirect pathways to cortical areas. The more direct pathway from the putamen to the globus pallidus internal segment provides net inhibitory effects. The more indirect pathway from the putamen through the globus pallidus external segment and subthalamic

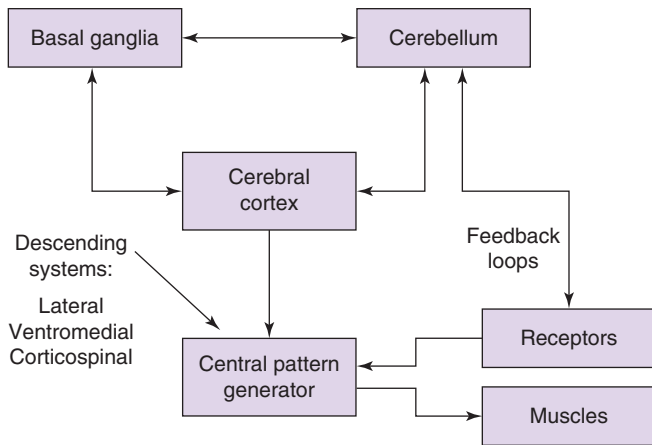

Fig. 3.2 Systems Model of Motor Control.

nucleus provides a net excitatory effect on the globus pallidus internal segment. Alteration of the balance between these pathways is postulated to produce motor dysfunction.^{35,36} An abnormally decreased outflow from the basal ganglia is postulated to produce involuntary motor patterns; these produce excessive motion such as chorea, hemiballism, or nonintentional tremor. Alternatively, an abnormally increased outflow from the basal ganglia is postulated to produce a paucity of motions, as seen in the rigidity observed in individuals with Parkinson disease (see Chapter 18).

Distributed function presupposes that a single center or neural network has more than one function. The concept also implies that several centers share the same function. For example, a center may serve as the coordinating unit of an activity in one task and as a pattern generator or oscillator to maintain the activity in another task. An advantage of distributing function among groups of neurons or centers is to provide centers with overlapping or redundant functions. Neuroscientists believe such redundancy is a safety feature. If a neuronal lesion occurs, other centers can assume critical functional roles, thereby producing recovery from CNS dysfunction.^{37–42}

Consensus implies that motor behavior occurs when a majority of brain centers or regions reach a critical threshold to produce activation. Also, through consensus, extraneous information or information that does not require immediate attention is filtered. If, however, a novel stimulus enters the system, it carries more weight and receives immediate attention. A novel stimulus may be new to the system, may reflect a potentially harmful situation, or may result from the conflict of multiple inputs.

Emergent properties may be understood by the adage “the whole is greater than the sum of its parts.” This concept implies that brain centers, not a single brain center, work together to produce movement. An example of the emergent properties concept is continuous repetitive activity (oscillation). In Fig. 3.3A, a hierarchy is represented by three neurons arranged in tandem. The last neuron ends on a responder. If a single stimulus activates this network, a single response occurs. What is the response if the neurons are arranged so that the third neuron sends a collateral branch to the first neuron in addition to the ending on the responder? In this case (see Fig. 3.3B), a single stimulus activates neuron No. 1, which in turn activates neurons No. 2 and No. 3, causing a response as well as reactivating neuron No. 1. This neuronal arrangement produces a series of responses rather than a single response. This process is also termed *endogenous activity*.

Another example of an emergent property is the production of motor behavior. Rather than having every MP stored in the brain, an abstract representation of the intended goal is stored. At the time of

A. A single response per stimulus

B. Emergent property: more than one response

Key:

R-t = response 1; response 2, etc.

Fig. 3.3 Emergent Property.

motor performance, various brain centers use the present sensory information combined with past memory of the task to develop the appropriate motor strategy. This concept negates a hardwired MP concept. If MPs were hardwired and if an MP existed for every movement ever performed, the brain would need a huge storage capacity and would lack the adaptability necessary for complex function.

Controlling the Degrees of Freedom

Combinations of muscle and joint action permit a large number of degrees of freedom that contribute to movement. A system with a large number of degrees of freedom is called a *high-dimensional system*. For a contextually appropriate movement to occur, the number of degrees of freedom must be constrained. Bernstein⁹ suggested that the number of degrees of freedom could be reduced by muscles working in synergies—that is, coupling muscles and joints of a limb to produce functional patterns of movement. The functional unit of motor behavior is then a *synergy*. Synergies help to reduce the degrees of freedom, transforming a high-dimensional system into a low-dimensional system. For example, a step is considered to be a functional synergy pattern for the lower extremity. Linking together stepping synergies with the functional synergies of other limbs creates locomotion (interlimb coordination).

Functional synergy implies that muscles are activated in an appropriate sequence and with appropriate force, timing, and directional components. These components can be represented as fixed or “relative” ratios, and the control comes from input given to the cerebellum from higher centers in the brain and the peripheral or spinal system and from prior learning (see Chapter 19).^{39,41,43} The relative parameters are also termed *control parameters*. Scaling control parameters leads to a change in motor behavior to accomplish the task. For example, writing your name on the blackboard exemplifies scaling force, timing, and amplitude. Scaling is the proportional increase or decrease of the parameter to produce the intended motor activity.

Coordinated movement is defined as an orderly sequence of muscle activity in a single functional synergy or the orderly sequence of functional synergies with appropriate scaling of activation parameters necessary to produce the intended motor behavior. Uncoordinated movement can occur at the level of the scaling of control parameters in one functional synergy or inappropriate coupling of functional synergies. The control parameter of duration will be used to illustrate scaling. If muscle A is active for 10% of the duration of the motor activity and muscle B is active 50% of the time, the fixed ratio of A/B is

1:5. If the movement is performed slowly, the relative time for the entire movement increases. Fixed ratios also increase proportionally. Writing your name on a blackboard very small or very large yields the same result—your name.

Timing of muscle on/off activation for antagonistic muscles such as biceps and triceps or hamstrings and quadriceps must be accurate for the coordination and control of movement patterns. If one muscle group demonstrates a delayed onset or maintains a longer duration of activity overlapping with triceps “on” time, the movement will appear uncoordinated. Patients with neurological dysfunction often demonstrate alterations in the timing of muscle activity within functional synergies and in coupling functional synergies to produce movement.^{44,45} These functional movement synergies are not hardwired but represent emergent properties. They are flexible and adaptable to meet the challenges of the task and the environmental constraints.

Finite Number of Movement Strategies

The concept of *emergent properties* could conceivably imply an unlimited number of movement strategies available to perform a particular task. However, limiting the degrees of freedom decreases the number of strategies available for selection. In addition, constraints imposed by the internal environment (e.g., musculoskeletal system, cardiovascular system, metabolic activity, cognition) and external environment (e.g., support surface, obstacles, lighting) limit the number of movement strategies. Horak and Nashner³² observed that a finite number of balance strategies were used by individuals in response to externally applied linear perturbations on a force plate system. With use of a life-span approach, VanSant⁴⁶ identified a limited number of movement patterns for the upper limb, head-trunk, and lower limb for the task of rising from supine to standing.

The combination of these strategies produces the necessary variability in motor behavior. Although an individual has a preferred or modal profile, the healthy person with an intact neuromuscular system can combine strategies in various body regions to produce different movement patterns that also accomplish the task.^{47,48} Persons with neurological deficits may be unable to produce a successful, efficient movement pattern because of their inability to combine strategies or adapt a strategy for a given environmental change (e.g., differing chair height for sit-to-stand transitions).

Variability of Movements Implies Normalcy

A key to the assessment and treatment of individuals with neurological dysfunction lies in variability of movement and in the notion that variability is a sign of normalcy, and stereotypical behavior is a sign of dysfunction.

Age, activity level, the environment, constraints of a goal, and neuropathological conditions affect the selection of patterns available for use during movement tasks.⁴⁹ When change occurs in one or more of the neural subsystems, a new movement pattern emerges. The element that causes change is called a *control parameter*. For example, an increase in the speed of walking occurs until a critical speed and degree of hip extension are reached, thereby switching the movement pattern to a run. When the speed of the run is decreased, there is a shift back to the preferred movement pattern of walking. A control parameter shifts the individual into a different pattern of motor behavior.

This concept underlies theories of development and learning. Development and learning can be viewed as moving the system from a stable state to a more unstable state. When the control variable is removed, the system moves back to the early, more stable state. As the control variable continues to push the system, the individual spends more time in the new state and less time in the earlier state until the individual spends most of the time in the new state. When this occurs,

the new state becomes the preferred state. Moving or shifting to the new, preferred state does not obviate the ability of the individual to use the earlier state of motor behavior. Therefore new movement patterns arise when critical changes occur in the system because of a control parameter, but they do not eliminate older, less-preferred patterns of movement.

Motivation to accomplish a task in spite of functional limitations and neuropathological conditions can also shift the individual's CNS to select different patterns of motor behavior. The musculoskeletal system, by nature of the architecture of the joints and muscle attachments, can be a constraint on the movement pattern. An individual with a functional contracture may be limited in the ability to bend a joint only into a desired range, thereby decreasing the movement repertoire available to him or her. Such a constraint produces adaptive motor behavior. Dorsiflexion of the foot needs to meet a critical degree of toe clearance during gait. If there is a range of motion limitation in dorsiflexion, then biomechanical constraints imposed on the nervous system will produce adaptive motor behaviors (e.g., to achieve toe clearance during gait). Changes in motor patterns during the task of rising from supine to standing are observed when healthy individuals wear orthoses to limit ankle dorsiflexion.⁵⁰ The inability to easily open and close the hand with rotation may lead to adaptations that require the shoulder musculature to place the hand in a more functional position. This adaptation uses axial and trunk muscles and will limit the use of that limb in both fine and gross motor performance. Refer to Chapter 19 for more information in this regard.

Preferred, nonobligatory movement patterns that are stable yet flexible enough to meet ever-changing environmental conditions are considered *attractor states*.¹⁰ Individuals can choose from a variety of movement patterns to accomplish a given task. For example, older adults may choose from a variety of fall-prevention movement patterns when faced with the risk of falling. The choice of motor plan may be negatively influenced by age-related declines in the sensory input systems or a fear of falling. For example, when the Multi-Directional Reach Test⁵¹ is being performed, an older adult may choose to reach forward, backward (lean), or laterally without shifting her center of gravity toward the limits of stability. She has the capability of performing a different reaching pattern if asked but prefers a more stable pattern.

Obligatory and stereotypical movement patterns suggest that the individual does not have the capability of adapting to new situations or cannot use different movement patterns to accomplish a given task. This inability may be a result of internal constraints that are functional or pathophysiological. The patient who has had a stroke has CNS constraints that limit the number of different movement patterns that can emerge from the self-organizing system. With recovery, the patient may be able to select and use additional movement strategies. Cognition and the capability to learn may also limit the number of movement patterns available to the individual and the ability of the person to select and use new or different movement patterns.

Obligatory and stereotypical movement patterns also arise from external constraints imposed on the organism. Consider the external constraints placed on a concert violinist. External constraints can include, for example, the length of the bow and the position of the violin. Repetitive movement patterns leading to cumulative trauma disorder in healthy individuals can lead to muscular and neurological changes.^{51–55} Over time, changes in dystonic posturing and changes in the somatosensory cortex have been observed. Although one hypothesis considers that the focal dystonia results from sensory integrative problems, the observable result is a stereotypical motor problem.

To review, the nervous system responds to a variety of internal and external constraints to develop and execute motor behavior that is

efficient to accomplish a specific task. Efficiency can be examined in terms of metabolic cost to the individual, type of movement pattern used, preferred or habitual movement (habit) used by the individual, and time to complete the task. The term *attractor state* is used in dynamical systems theory to describe the preferred pattern or habitual movement.

Individuals with neurological deficits may have limited repertoires of movement strategies available. Patients experiment with various motor patterns in order to learn the most efficient, energy-conscious motor strategy to accomplish the task. Therapists can plan interventions that help to facilitate refinement of the task to match the patient's capability, allowing the task to be completed using a variety of movement strategies rather than limited stereotypical strategies, leading to improved function.

Errors in Motor Control

When the actual motor behavior does not match the intended motor plan, an error in motor control is detected by the CNS. Common examples of errors in motor control are loss of balance; inappropriate scaling of force, timing, or directional control; and inability to ignore unreliable sensory information, resulting in sensory conflict. Any one or combination of these errors may be the cause of a fall or an error in performance accuracy.

Errors also occur when unexpected factors disrupt the execution of the MP. For example, when the surface is unreliable (unstable, moving), this will force the individual to adapt motor responses to meet the demand of the environment. Switching between closed environments (more stable) and open environments (more unpredictable) will challenge the individual to adapt motor responses. When an individual steps off a moving sidewalk, a disruption in walking occurs. The first few steps are not smooth because the person has to switch his movement strategies from one incorporating a moving support surface to one incorporating a stationary support surface.

Errors occur in the perception of sensory information, in the selection of the appropriate MP, in the selection of the appropriate variable parameters, or in the response execution. Patients with neurological deficits may demonstrate a combination of these errors. Therefore an assessment of motor deficits includes analysis of these types of errors. If a therapist observes a motor control problem, there is no guarantee that the problem has arisen from within the motor system. Somatosensory problems can drive motor dysfunction; cognitive and emotional problems express themselves through motor output. Thus it is up to the movement specialist to differentiate the cause of the problem through valid and reliable examination tools (see Chapter 8). Once the cause of the motor problem has been identified, selection of interventions should lead to positive outcomes.

All individuals, both healthy and those with CNS dysfunction, make errors in motor programming. These errors are assessed by the CNS and are stored in past memory of the experience. Errors in motor programming are extremely useful in learning. Learning can be viewed as decreasing the mismatch between the intended and actual motor behavior. This mismatch is a measure of the error; therefore a decrease in the degree of the error is indicative of learning. Errors, then, are an important part of the rehabilitation process. However, this does not mean that the therapist allows the patient to practice errors over and over. The ability of the patient to detect an error and correct it to produce appropriate and efficient motor behavior is one key to recovery and an important consideration when intervention strategies are developed. This is discussed further in the next section of this chapter.

Motor Control Section Summary

Motor control theories have been developed and have evolved over many years as our understanding of nervous system structure and

function has become more advanced. The control of posture and movement is a complex process that involves many structures and levels within the human body. It requires accurate sensory inputs, coordinated motor outputs, and central integrative processes to produce skillful, goal-directed patterns of movement that achieve desired movement goals. We must integrate and filter multiple sensory inputs from both the internal environment of the body and the external world around us to determine position in space and choose the appropriate motor plan to accomplish a given task. We combine individual biomechanical and muscle segments of the body into complex movement synergies to deal with the infinite "degrees of freedom" available during the production of voluntary movement. Well-learned motor plans are stored and retrieved and modified to allow for flexibility and variety of movement patterns and postures. When the PNS or CNS is damaged and the control of movement is impaired, new, modified, or substitute motor plans can be generated to accomplish goal-directed behaviors, remain adaptable to changing environments, and produce variable movement patterns. The process of learning new motor plans and refining existing behaviors by driving neuroplastic changes in the nervous system is discussed in the next sections of this chapter.

MOTOR LEARNING

Therapeutic interventions that are focused on restoring functional skills to individuals with various forms of neurological problems have been part of the scope of practice of physical therapists (PTs) and occupational therapists (OTs) since the beginning of both professions. These two professions have emerged with a complementary background to examine, evaluate, determine a prognosis, and implement interventions that empower patients to regain functional control of activities of daily living (ADLs) (e.g., getting out of bed, bathing, walking, and eating, as well as working, playing, and interacting socially) and resume active participation in life after neurological insult. These two professions specialize in the analysis of movement and possess knowledge of the scientific background to explain why the movement is occurring, what strengths and limitations exist within body systems to produce that movement, and how different therapeutic interventions can facilitate or enhance functional movement strategies that remediate dysfunction and ultimately carry over into an individual's improved performance of ADLs and participation in life. PTs and OTs are also knowledgeable about diseases affecting body systems (neurological, musculoskeletal, integumentary, cardiopulmonary, and integumentary systems) and how the existence or progression of these pathological states affects motor performance and quality of life. Consideration and training of caregivers and family members to help patients maintain functional skills during transitional disease states is also a component of practice and of treating the patient in a holistic manner.

It is therefore important for clinicians to understand how individuals learn or relearn motor tasks and how the learning of motor skills can best be achieved to optimize outcomes.

Motor learning results in a permanent change in the performance of a skill because of experience or practice.⁵⁶ The end result of motor learning is the acquisition of a new movement or the reacquisition and/or modification of movement.⁵⁷ The patient must be able to prepare and carry out a particular learned movement⁵⁸ in a manner that is efficient (optimal movement with the least amount of time, energy, and effort),⁵⁹ consistent (same movement over repeated trials),⁶⁰ and transferable (ability to perform the movement under different environments and conditions) to be considered to have learned a skill.

Learning of a particular motor task allows patients to use select motor skills to optimize function. This type of learning is expressed in

explicit (declarative) and implicit (procedural) memory. Explicit memory is expressed by conscious recall of facts or knowledge.⁶¹ An example of this could be the patient verbally stating the steps needed when going up the stairs with the use of crutches. Conversely, implicit learning involves movement performed without conscious thought (e.g., riding a bike or walking). The interplay of explicit (cognitive and emotional) and implicit memory affects ultimate learning to influence the time needed to learn or relearn a functional movement and use it in everyday activity.

The learning of a motor skill is measured indirectly by testing the ability of a patient to perform a particular task or activity over time or in different environmental contexts or conditions. The testing must be done over a period of time to determine long-term learning and minimize the temporary effects of practice. In *retention tests*, a patient performs the task under the same conditions in which the task was practiced. This type of test evaluates the patient's ability to learn the task. This is in contrast to *transfer tests*, in which a patient performs the activity under different conditions from those in which the skill was practiced. This evaluates the ability of the patient to use a previously learned motor skill to solve a different motor problem.

Motor skills can be categorized as discrete, continuous, or serial. Discrete motor skills pertain to tasks that have a specific start and finish. Repetitive tasks are classified as *continuous* motor skills. Serial skills involve several discrete tasks connected in a particular sequence that rapidly progress from one part to the next.⁵⁹ The category of a particular motor skill is a major factor in making clinical decisions regarding the individual-, task-, and environment-related variables that affect motor learning. This is discussed later in the chapter.

An Illustration of Motor Learning Principles

Motor learning is the product of an intricate balance between the feedforward and feedback sensorimotor systems and the complex central processor—the brain—for the end result of acquiring and refining motor skills. People go through distinct phases when they learn new motor skills.

Observe the sequential activities of the child walking off the park bench in Fig. 3.4A–C. A clear understanding of this relationship of

walking and falling is established. In frame A, the child is running a feedforward program for walking. The cerebellum is procedurally responsible for modulating appropriate motor control over the activity and will correct or modify the program of walking when necessary to attain the directed goal. Unfortunately a simple correction of walking is not adequate for the environment presented in frame B. The cerebellum has no prior knowledge of the feedback presented in this second frame and thus is still running a feedforward program for stance on the left leg and swing on the right leg. The cerebellum and somatosensory cortices are processing a massive amount of mismatched information from the proprioceptive, vestibular, and visual receptors. In addition, the dopamine receptors are activated during the goal-driven behaviors, creating a balance of inhibition and excitation. Once the executive or higher cognitive system recognizes that the body is falling (which has been experienced from falling off a chair or bed), a shift in motor control focus from walking to falling must take place. To prepare for falling, the somatosensory system must generate a sensory plan and then relay that plan to the motor system through the sensorimotor feedback loops. The frontal lobe will tell the basal ganglia and the cerebellum to brace and prepare for impact. The basal ganglia are responsible for initiating the new program, and the cerebellum carries out the procedure, as observed in Fig 3.4C. The child succeeds at the task and receives positive peripheral and central feedback in the process. It is possible that this experience has created a new procedural program that in time will be verbally labeled “jumping.” The entire process of the initial motor learning takes 1 to 2 seconds. Because of the child's motivation and interest (see Chapter 4), the program is practiced for the next 30 to 45 minutes. This is the initial acquisition phase and helps the nervous system store the MP to be used for the rest of the child's life. If this program is to become a procedural skill, practice must continue within similar environments and conditions. Ultimately the errors will be reduced and the skill will be refined. Finally, with practice, the program will enter the retention phase as a high-level skill. The skill can be modified in terms of force, timing, sequencing, and speed and is transferrable to different settings. This ongoing modification and improvement are the hallmarks of true procedural learning. Modifications within the program will be a function of the

Fig. 3.4 (A) Experiencing the unknown. (B) Identifying the problem. (C) Solving the problem.

plasticity that occurs within the CNS throughout life as the child ages and changes body size and distribution. Similar plasticity and the ability to change, modify, and reprogram motor plans will be demanded by individuals who age with chronic sensorimotor limitations. Unfortunately, in many of these individuals, the CNS is not capable of producing and accommodating change, which creates new challenges as they age with long-term movement dysfunctions.

Stages of Motor Learning

Several authors have developed models to describe the stages of motor learning. These models are presented in Table 3.3. Regardless of the model, it is widely accepted that the process of learning a motor task occurs in stages. During the initial stages of learning a motor skill, the intent of the learner is to understand the task. To be able to develop this understanding requires a high level of concentration and cognitive processing. In the middle and later stages, the individual learns to refine the movement, improve efficiency and coordination, and perform the skill within different environmental contexts. The later stages are characterized by automaticity and a decreased level of attention needed for successful completion of the task. It is important to emphasize early that because the activities performed by a learner during each stage of learning will be different, the role of the clinician, the types of learning activities, and the clinical environment must also be different.

The learning model described by Fitts and Posner⁶⁴ consists of a continuous progression through three stages: cognitive, associative, and autonomous.

A learner functions in the *cognitive stage* at the beginning of the learning process. The person is highly focused on the task, is attentive to all that it demands, and develops an understanding of what is expected and involved in performance of the skill. Many errors are made in performance; questions are asked; cues, instructions, and guidance are given by the clinician; and demonstrations are found to be helpful in this phase of learning. Performance outcomes are variable and inconsistent, but the improvements achieved can be profound.

During the *associative stage* the learner refines movement strategies, detects errors and problem solves independent of therapist feedback, and is becoming more efficient and reliable at achieving the task goal. The length of time spent in this phase tends to be dependent on the complexity of the task. The ability to associate existing environmental inputs with motor plans for improved timing, accuracy, and coordination of activities to accomplish a task goal is improved. Although variability in performance decreases, the patient continues to explore solutions to best solve a movement problem.

Focused practice with repetition over time leads to the automatic performance of motor skills in the *autonomous stage* of learning. The individual is in control of the learned movement plan and is able to use it with little cognitive attention while involved in other activities. Skills

are performed with preferred, appropriate, and flexible speed, amplitude, direction, timing, and force. Consistency of performance is a hallmark of this phase, as is the ability to detect and self-correct performance errors. Individuals who do not have the cognitive skill to remember the learning can go through a much longer repetitive practice schedule to learn the motor skill, but there will be very little carryover into other functional movements or activities.^{62,65,66}

In summary, the overall process of the stages of motor learning as introduced by Fitts and Posner⁶⁴ suggests that first a basic understanding of a task be established, along with a motor pattern. Practice of the task then leads to problem solving and a decrease in the degrees of freedom during performance, resulting in improved coordination and accuracy. As the learner continues to practice and solves the motor task problem in different ways and with different physical and environmental constraints, the movement plan becomes more flexible and adaptable to a wide range of task demands.

Bernstein⁹ presented a more biomechanical perspective as he addressed the problem of degrees of freedom during motor learning. He also broke the motor learning process down into three stages: novice, advanced, and expert. He proposed that these three stages are necessary to allow a learner to reduce the large number of degrees of freedom that are inherent in the musculoskeletal system, including structure and function of muscles, tendons, and joints. He proposed that as a person learns a new motor skill, he or she gains coordination and control over the multiple interacting variables that exist in the human body to master the target skill.

The *novice stage* is defined by the coupling of movement parameters—degrees of freedom—into synergies. During this stage some joints and movements may be “frozen” or restrained to allow successful completion of the task. An example of this is posturally holding the head, neck, and trunk rigid while learning to walk on a narrow surface.

The *advanced stage* is achieved by combining body parts to act as a functional unit, further reducing the degrees of freedom while allowing better interaction and consideration for environmental factors. He considers that motor plans must be adapted to the dynamic environmental conditions in which the task must be performed. In this stage the learner explores many movement solutions, reduces some degrees of freedom, develops more variable movement patterns, and learns to select appropriate strategies to accomplish a given task. This stage of motor learning is accomplished through practice and experience in performing a task in various environments. To achieve this stage the learner progressively releases some couplings, allowing more degrees of freedom, greater speed and amplitude of movement, and less constraints on the action. Performance of the task becomes more efficient, is less taxing on the individual, and is executed with decreased cognitive effort. Variability of performance becomes an indicator that a level of independence in the activation of component body parts during a given task has indeed been achieved.

In Bernstein’s *expert stage*, degrees of freedom are now released and reorganized to allow the body to react to all of the internal and external mechanisms that may act on it at any given time. At the same time, enhanced coactivation of proximal structures is learned and used to allow for greater force, speed, and dexterity of limb movements.⁶⁷

Gentile presented a two-stage model of motor learning.^{68,69} She considered motor learning from the goal of the learner and strongly considered how environmental conditions influence performance and learning.

Stage one requires the patient to problem solve strategies to get the idea of a movement and establish a motor pattern that will successfully meet the demands of the task. As with the models presented previously, this process demands conscious attention to the components of the task and environmental variables to formulate a “map” or framework of the

TABLE 3.3 Stages of Motor Learning—Three Models

Motor Learning Model	Stage One	Stage Two	Stage Three
Fitts and Posner (1967) ⁶²	Cognitive	Associative	Autonomous
Bernstein (1967) ⁹	Novice	Advanced	Expert
Gentile (1998) ⁶³	Get in the ballpark, Acquire the plan	Develop consistency and adaptability	

movement pattern. Once this framework is established, the patient has a mechanism for performing the task; however, errors and inconsistency in performance accuracy are often present.⁷⁰

During *stage two*, the patient attains improved consistency of performance and the ability to adapt the movement pattern to demands of specific physical and environmental situations. Greater economy of movement is achieved, and less cognitive and physical effort is expended to reach the task goal. Practice in appropriately challenging conditions leads to consistent, efficient, correct execution while maintaining adaptive flexibility within the motor plan, allowing the patient to react quickly to changing conditions of the task.

The three motor learning theories just presented simplify a complex process into simple stages to give a broad picture of the development of skilled movement performance. Each theory can be used to assist the therapist in the process of teaching and facilitating long-term learning or relearning of motor skills before and after insult to the nervous system. The ultimate goal of motor learning is the permanent acquisition of adaptable movement plans that are efficient, require little cognitive effort, and produce consistent and accurate movement outcomes.

Variables That Affect Motor Learning

The ecological model (constraints theory) of motor control and learning states that motor learning involves the individual, the task, and the environment.⁶³ For a purposeful and functional movement to occur, the *individual* must generate movement to successfully meet the *task* at hand, as well as the demands of the *environment* where the task must be performed. For motor learning to be successful, several variables related to each of these three constructs must be taken into account.

Variables Related to the Individual

The clinician must first differentiate general motor performance factors that are under the control of the individual's cognitive and emotional systems and those that are controlled by the motor system itself. These concepts are presented in Fig. 3.5. There are many cognitive factors—such as arousal, attention, and memory, as well as cortical pathways related to declarative or executive learning—that have specific influences over behaviors observed after neurological insult.^{71,72} Other factors—such as limbic connections to cortical pathways affected by motivation, fear and belief, and emotional stability and instability—also dramatically affect motor performance and declarative learning. Some of these factors may also limit activity and participation. Therapists must learn how to discriminate between problems due to motor output, somatosensory input, cortical processing, and limbic emotional state problems and to identify how the last two systems affect motor

output. With that differentiation, clinicians should also be able to separate specific motor system deficits from motor control problems arising from dysfunction within other areas of the CNS. Last, the patient's fitness level; current limitations in strength, endurance, power, and range of motion; or pain level may also influence learning.^{57,73–78}

Variables Related to the Task

The two major variables related to the task itself that must be considered when facilitating motor learning include practice of the task and feedback related to task performance.

Practice. Practice is defined as “repeated performance in order to acquire a “skill.”⁷⁹ As the definition implies, multiple repetitions of the task are usually required to be able to achieve skillful performance of a task. With other variables being constant, more practice results in more learning.⁵⁷ To be effective, these repetitions must involve a process of problem solving rather than just repetition of the activity.⁸⁰ The therapist can manipulate variables related to practice in order to optimize motor learning in an individual with a pathological movement pattern.

Practice conditions. The term *practice conditions* refers to the manner in which the task or exercise is repeated with respect to rest periods, the amount of exercise, and the sequence in which these tasks or exercises are performed.

According to the apportionment of practice in relation to rest periods, massed tasks or exercises can be classified as *massed practice* or *distributed practice*. Massed practice is when the rest period is much shorter in relation to the amount of time the task or exercise is practiced.⁸¹ This is contrasted against distributed practice, in which the time between practice sets is equal to or greater than the amount of time devoted to practicing a particular task or activity such that the rest period is spread out throughout the practice.⁸² In terms of neurological physical therapy practice, it is important to consider the effect of physical and mental fatigue when a person is training. For example, physical fatigue sets in during massed practice of a particular balance exercise activity in standing and may cause a patient to fall. Moreover, individuals who are cognitively impaired may not respond positively to sustained activity that requires considerable concentration and therefore might fail in the performance of the skill. On the other hand, to be functional and useful in daily life, certain activities have to be performed without significant amounts of rest. For example, taking significant rest breaks when one is ambulating for even a short distance limits the person's ability to use walking in a functional manner. Sometimes a patient needs more rest periods in the initial stages of learning a skill to compensate for impairments in muscular endurance or cardiopulmonary function with the intent of decreasing these rest periods to achieve skill performance that reflect how that activity is used in real-life situations. Therefore therapists should consider the skill demands and desired results when they are choosing one practice type versus another.⁸²

Complete, functional tasks or activities can usually be divided into smaller subcomponents for practice. The way those subcomponents are practiced relative to the entire task or activity can be manipulated to optimize motor learning. This includes practice of the entire task or parts of the task, whole learning, pure-part learning, progressive-part learning, or whole-part learning methods. Fig. 3.6 summarizes these concepts.

Whole learning suggests that the learner practice the entire movement as one activity. Asking a person to stand up incorporates the entire activity of coming to stand from sitting. Simple movements such as rolling, coming to sit, coming to stand, and walking might best be taught as a whole activity as long as the individual has all the component parts to practice the whole.

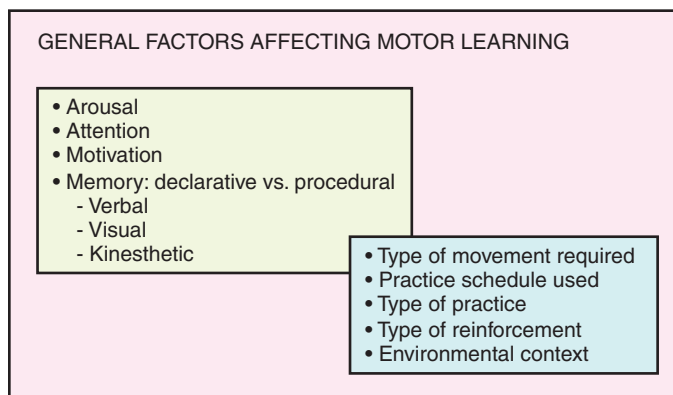

Fig. 3.5 Concepts Affecting Motor Learning.

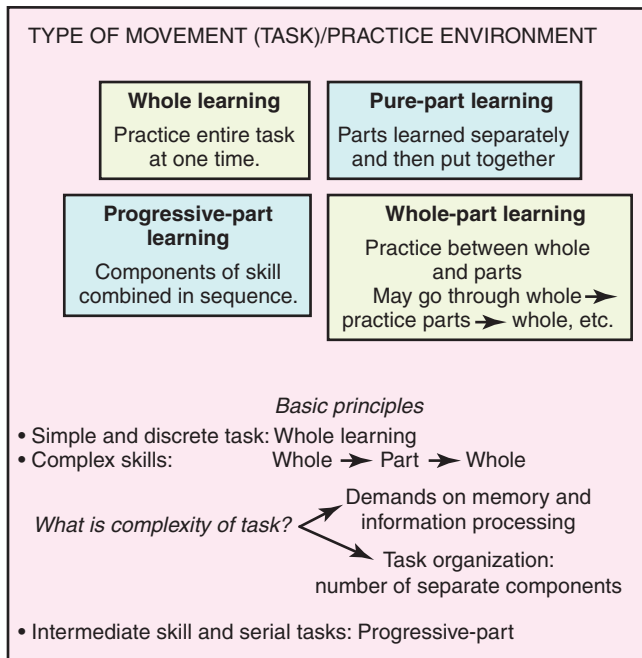

Fig. 3.6 Type of Movement (Task) and Practice Environment.

In *pure-part learning* the therapist introduces one part first; then this part is practiced by the learner before another new part is introduced and practiced. Each part is critical to the whole movement, but which one is learned first does not matter. Learning a tennis serve is an excellent example of an activity that can be taught as a pure part. Learning to toss the ball vertically to a specific spot in space is a very different and separate part from swinging the tennis racket as part of the serve. Learning to squeeze the toothpaste onto the brush is a very different movement strategy from brushing the teeth.

Progressive-part learning is used when the sequence of movements and the component parts to be learned need to be programmed in a specific order. Line dancing is an activity taught using progressive part learning. Individuals with sequencing deficits must often be taught using progressive parts, or they will mix up the ordering of parts during an activity. Therapists see this in the clinical arena when an individual stands up from a wheelchair and then tries to pick up the foot pedals and lock the brakes. Given that problem, such a patient must practice progressive-part learning by first locking the brakes, then picking up the foot pedals, and finally standing. If the activity is not practiced using progressive-part learning, the patient will have little consistency in how the parts are put together, thereby placing that him at high risk of failing at the functional task.

Whole-part learning can be used when the skill or activity can be practiced between the whole and the parts. In the clinical environment, a common application of this concept is *whole to part to whole learning*.⁸³ First the therapist has the patient try the whole activity, such as coming to stand or opening a door. Next, the therapist has the patient practice a component part that is deficient (e.g., gripping the door-knob). Finally the whole activity is practiced as a functional pattern. In this way therapists work on the functional activity and then work on correcting the impairment or limitation, such as power production, range, or balance. Then they go back to the functional activity in order to incorporate the part learning into the whole. An example might be asking a patient to first stand up from a chair. As she tries to stand she generates too much power, holds her breath, and cannot repeat the activity more than once. The therapist decides to practice a component

part by first assisting the patient to a relaxed standing posture, then having her eccentrically begin to sit into a partial squat, and then having her return to standing. As the patient practices, she will increase the range of motion and eventually will sit and return to stand. Once that is accomplished, she will continue to practice sit to stand to sit as a whole activity.

Therapists change the sequence in which component parts of a task are practiced using blocked or random practice. In *blocked practice* the patient first practices a single task over and over before moving to the next task. With *random practice* the component skills are practiced in random order without any particular sequence. The contextual interference effect explains the difference in motor performance found when these two types of practice are compared. Studies have shown that performance may be enhanced by using blocked practice; however, learning is not enhanced by using this type of practice. Random practice has been shown to enhance learning because this type of practice forces the learners to come up with a motor solution each time a task is performed.^{84,85}

Feedback. The use of feedback is another important variable related to motor learning. Feedback is defined as the use of sensory information—visual, auditory, or somatosensory—to improve performance, retention, or transfer of a task. Internal feedback pertains to sensory information that the patient receives that can be used to improve performance of that particular task or activity in the future. The therapist provides extrinsic or augmented feedback with the intent of improving learning of the task. In people with neurological dysfunctions, extrinsic feedback is important because the patient's intrinsic feedback system may be impaired or absent.

Extrinsic feedback can further be classified as knowledge of performance (KP) or knowledge of results (KR). KP is given concurrently while the task is being performed and can therefore also be called *concurrent feedback*. Feedback given concurrently, especially during the critical portions of the task, allows the patient to successfully perform the activity.

KR pertains to feedback given at the conclusion of the task (therefore it is also called *terminal feedback*) and provides the patient with information about the success of his or her actions with respect to the activity. KR can be classified as faded, delayed, or summary. In faded feedback the therapist provides more information in the beginning stages of learning of the skill and slowly withdraws that feedback as the patient demonstrates improvement in the performance of the task. With delayed feedback, information is given to the patient when a period of time has elapsed after the task has been completed. The intent of this pause between the termination of a task and feedback is to give the patient some time to process the activity and generate possible solutions to the difficulties encountered in the previous performance of the task. In contrast, summary feedback is provided after the patient has performed several trials of a particular task without receiving feedback. Studies show that subjects who were given more frequent feedback, compared with those who received summary feedback, performed better during the task acquisition stage of learning but worse on retention tests.^{86,87}

Additional concepts related to long-term learning are presented in Fig. 3.7.

Variables Related to the Environment

Therapists can alter environmental conditions to optimize motor learning. Gentile^{68,69} described the manipulation of the environment in which a task is performed to make an activity more appropriate for what the patient is able to do. Patients with neurological dysfunction may benefit from practicing in a *closed environment* that is stationary and predictable. It allows the skill to be practiced with minimal

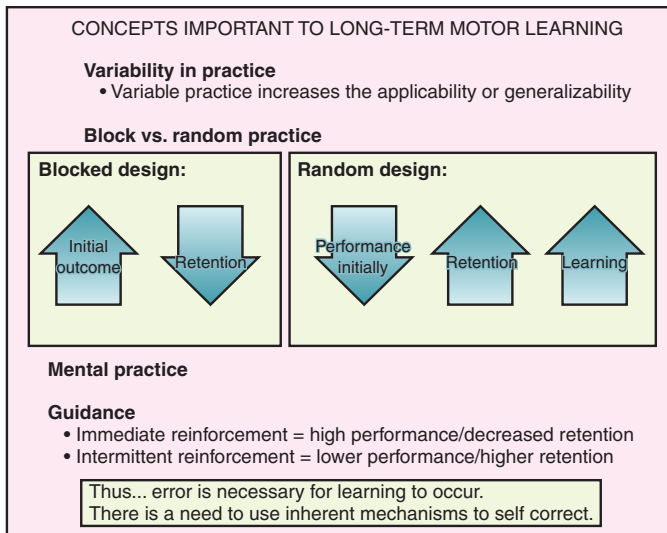

Fig. 3.7 Concepts Important to Long-term Learning.

distractions or challenges from the environment, enabling the patient to plan the movement in advance. An example of this would be performing gait training in a quiet, empty therapy gym. As the patient improves, it is important to practice this activity in an *open environment* that is less predictable, more distracting, or in motion to provide a real-world application of the task. An example of this would be gait training the patient in a busy gym environment, in a crowded cafeteria, on a moving walkway, or in a noisy hallway.

If prior procedural learning has occurred, then creating an environment that allows the program to run in the least restrictive environment should lead to the most efficient outcome in the shortest time.^{74,75} If a patient must learn a new program, such as walking with a stereotypical extension pattern, then goal-directed, attended practice with guided feedback will be necessary. It may be easier to bring back an old ambulatory pattern by creating an environment to elicit that program than to teach a patient to use a new inefficient movement program.^{76–78}

A therapist must identify what MPs are available and under what conditions. This allows the therapist to (1) determine whether deficits are present, (2) anticipate problems in performance, and (3) match existing programs with functional activity challenges during training. Similarly, knowing available MPs and the component body systems necessary to run those programs aids the therapist in the selection of intervention procedures.

If the patient has permanent damage to either the basal ganglia or the cerebellum, then retaining the memory of new MPs may be difficult and substitution approaches may become necessary. Through evaluation, the clinician must determine whether anatomical disease or a pathological condition is actually causing procedural learning problems and whether identifying and teaching a substitution pattern or teaching the patient to compensate with an old pattern will allow him to succeed at the task. However, therapists should never forget that the plasticity of the CNS can promote significant recovery and adaptation through the performance of attended, goal-directed, repetitive behavior.^{88,89}

The provision of an appropriate level of challenge to the learner can optimize motor learning. The clinician must learn to expertly manipulate the environment to best facilitate learning. A task that is too difficult for the patient will result in persistent failure of performance, frustration, and lack of learning; then the only option will be to compensate through available patterns of movement that limit function.

An activity that is too easy and routinely results in 100% success also does not result in learning because the learner becomes bored and no longer attends to the experience. The most beneficial level of challenge for training will create some errors in performance, require the patient to solve problems to meet the demands presented, and allow a level of success that inspires continued motivation to practice and achieve a higher standard of skill.

PRINCIPLES OF NEUROPLASTICITY: IMPLICATIONS FOR NEUROREHABILITATION

Rehabilitation, Research, and Practice

Rehabilitation is the process of maximizing functional learning. The integration of basic neuroscience into clinical practice is critical for guiding the questioning of researchers and maximizing the recovery of patients. Over the past 30 years, researchers have made enormous advances in understanding the adaptability of the CNS. Because of this revolution, clinicians have moved toward a focus on recovery rather than compensation. There is sufficient evidence that the CNS continues to develop and mature from infancy into adolescence. During early and late adulthood, the CNS can recover from serious disease and injury, maintaining sensory, motor, and cognitive competency through spontaneous healing, appropriate medical management, physical exercise and activity, balanced nutrition, and opportunities to learn. Across the life-span, individuals can maximize independence and quality of life by capitalizing on learning from enriched environments, task-specific training, and attentive, progressive, self-generated, goal-oriented, repetitive behaviors. Unfortunately the nervous system can adapt negatively to repetitive and atypical patterns of movement based on neuromuscular deficits, structural anomalies, pain, abnormal biomechanics, or bad habits (see the section on motor learning earlier in this chapter). To promote recovery versus negative adaptation, rehabilitation professionals must be cognizant of a patient's learning potential and be aware of the resources available at the environment, task, and individual level.

The paradigm shift in rehabilitative intervention strategies based on neuroplasticity is ongoing. Researchers in basic and translational science must collaborate with clinicians to determine how research findings can influence recovery.^{92–94} Furthermore, clinicians cannot simply provide the same familiar treatment of yesterday because it is comfortable and requires minimal effort. Rehabilitation professionals must be dynamic, enthusiastic, evidence-based, and committed to lifelong learning, ready to accept the challenge and unique opportunity to work with other members of the health care team to translate neuroscience to practice. Failure to translate research findings into clinical practice will significantly impede the potential for patient recovery.

Over the past 50 years, conferences have begun to address key issues in neuroscience and rehabilitation to move the field forward.^{95–100} In 1966, the Northwestern University Special Therapeutic Exercise Project (NUSTEP) conference in Chicago brought researchers, basic scientists, educators, and master clinicians together for 6 weeks to identify commonalities in approaches to interventions and to integrate basic science into those commonalities. A huge shift from specific philosophies to a bodily systems model occurred in 1990 in Norman, Oklahoma, the site of the Second Special Therapeutic Exercise Project conference (II STEP). During the next 15 years, motor learning and control concepts began to influence the intervention philosophies of both occupational and physical therapy. Simultaneously, newer approaches such as locomotion training with partial weight support,^{101,102} task-specific training,^{103,104} constraint-induced movement therapy,^{105,106} neuroprotective effect of exercise,¹⁰⁷ mental and physical practice,^{108,109}

patient-centered therapy,^{110–112} and sensorimotor training¹¹³ were frequently found in peer-reviewed literature. The third STEP conference, Summer Institute on Translating Evidence into Practice (III STEP), occurred in July 2005 in Salt Lake City, Utah. At this conference, unique clinical models for intervention were embraced that continue to direct professional education. The IV STEP Conference, with a focus on the 4 P's in rehabilitation (prediction, prevention, plasticity, and participation),^{98–100} took place in July 2016 at The Ohio State University in Columbus. The IV STEP conference highlighted the progress made since the III STEP Conference and challenged attendees to push forward as new breakthroughs provide an impetus for ongoing change in personalized rehabilitation. Related conferences included the recent Progress in Clinical Motor Control: Neurorehabilitation at Pennsylvania State University in State College in July 2018. These conferences further challenge the research and rehabilitation community to provide strong evidence for intervention strategies aimed at fostering neural recovery and function. Although the inclusion of new, evidence-based, intervention strategies into clinical practice continues to lag behind research findings, the goal of integration remains.

There are many challenges to implementing effective, neuroscience-based interventions. The first is the patient. Patient-centered therapy is critical for effective therapeutic outcomes. The patient can be both the obstacle to successful recovery^{114,115} and the critical link to success.^{116,117} To achieve optimum neural adaptation, the patient must be attentive during self-generated goal-directed novel progressive activity. There is no measurable neural adaptation with passive movements or passive stimuli. To achieve a change in neural response, a stimulus must be novel and the individual must attend to it. This adaptive process can be implicit or explicit. For example, if the process is explicit, the individual is aware, makes a decision about what to do, and receives some feedback regarding the appropriateness or accuracy of the outcome.¹¹⁸ This progressive decision making has to be done repetitively and advance in difficulty over time. Adaptive behaviors may be difficult to achieve when a person is depressed, feels hopeless, lacks motivation or cognition, is emotionally unstable, or neglects one or more parts of the body.

Another obstacle to bringing scientific evidence into practice is the barrier created by living in a society in which the economics of health care rather than the science or patient benefits drive the delivery of services. When a physician or therapist recommends a new approach to intervention, the third-party payer may deny payment for service because it is “experimental.” Furthermore, third-party payers may deny the opportunity to apply findings from animal studies to human subjects. Another constraint from the third-party payer is the timing of intervention. Despite the evidence that the CNS can be modified under conditions of goal-oriented, repetitive, task-relevant behaviors years after stroke, insurance companies deny coverage of service late in the recovery process. The insurance company may interpret “medically necessary services” as the services provided during the first 30 days after injury, the time when the greatest spontaneous recovery occurs. Furthermore, even though neural adaptation research confirms that enriched environmental conditions and sensory inputs can facilitate both greater and continued recovery, the insurance company may claim that the services^{119–122} are simply for maintenance. Thus as the science of neuroplasticity continues to develop, it is critical to improve the interface between the scientist, the practitioner, the patient, and the third-party payer. It is vital that clinicians and researchers regularly inform third-party payers about current research evidence.

Integration of Sensory Information in Motor Control

One's understanding of neural adaptation must include attention to sensory as well as motor systems. In virtually all higher-order

perceptual processes, the brain must correlate sensory input with motor output to assess the body's interaction with the environment accurately. Thus a problem in the somatic motor system affects the motor output system. Both systems are independently adaptive, but functional neural adaptation involves the interaction of both sensory and motor processing.

The sensory system provides an internal representation of the inner and outer worlds to guide the movements that make up our behavioral repertoire. Movement is controlled by the motor systems of the brain and the spinal cord. Our perceptual skills reflect the capabilities of the sensory systems to detect, analyze, and estimate the significance of physical stimuli. (Augmented therapeutic intervention for each sensory system is discussed in Chapter 8.) Our agility and dexterity reflect the capabilities of the motor systems to plan, coordinate, and execute movements. The task of the motor systems in controlling movement is the reverse of the task of sensory systems in aiding or updating internal representations. Perception is the end product of sensory processing, whereas an internal representation is the beginning of motor processing.

Sensory psychophysics looks at the attributes of a stimulus: its quality, intensity, location, and duration. Motor psychophysics considers the organization of action, intensity of muscle contraction, recruitment of distinct motor neuron populations, coordination and accuracy of movement, and the speed of movement. The complex behaviors in the sensory and motor systems depend on the modalities available. The distinct modalities of pain, temperature, light touch, deep touch, vibration, and stretch are found in the sensory system; whereas the modalities of reflex responses, intra- and interlimb rhythmic patterns, automatic and adaptive responses, and voluntary fine and gross movements are found in the motor system.^{123–143} Although all motor movement requires integration of sensory information for motor learning, once motor control has been attained, the system can often run on very little feedback. The relationship of incoming sensory information is particularly complex in voluntary movement, which constantly adapts to environmental variance. For voluntary movements, the motor system requires muscle contraction and relaxation with appropriate timing and sequencing, recruitment of appropriate muscles and their synergies, the distribution of the body mass, and appropriate postural adjustments.

There must be adjustments to compensate for limb inertia and the mechanical arrangement of muscles, bones, and joints before and during movement to ensure and maintain accuracy. The control systems for voluntary movement involve (1) a continuous flow of sensory information about the environment, body/limb orientation, and degree of muscle contraction; (2) the spinal cord; (3) the descending systems of the brain stem; and (4) the motor pathways of the cerebral cortex, cerebellum, and basal ganglia. Each control system is organized hierarchically and in parallel and uses sensory information relevant for the functions it oversees via feedback and feedforward mechanisms. These systems control activation of sensations and movement as well as inhibition (e.g., globus pallidus). Some brain regions are engaged during new learning (e.g., cerebellum) and others during maintenance of learning (e.g., globus pallidus, hippocampus). The hierarchical but interactive organization permits lower levels to generate reflexes without involving higher centers, whereas the parallel system allows the brain to process the flow of specific types of sensory information to produce discrete types of movements.^{144,145}

Ultimately the control of graded fine movement involves the muscle spindle, which contains the specialized elements that sense muscle length and the velocity or changes in spindle length. In conjunction with the tendon organ, which senses muscle tension, the muscle spindle provides the CNS with continuous information on the mechanical

Fig. 3.8 Classification and Anatomical Locations of Cortical Map.

state of the muscle. Ultimately the firing of the muscle spindles depends on both muscle length and the level of gamma motor activation of the intrafusal fibers. Similarly, joint proprioceptors relay both closed- and open-chain input and mobility (range) information from within the joint structures to the CNS. This illustrates the close, integral relationship between sensory and motor processing.¹⁴⁶

Foundation for the Study of Neuroplasticity

The principal models for studying cortical plasticity have been based on the representations of the movement and skin of the hand in the New World owl monkey (*Aotus*) and the squirrel monkey (*Saimiri*). These primate models have been chosen because their central sulci usually do not extend into the hand representational zone in the anterior parietal (S1) or posterior frontal (M1) cortical fields. In other primates the sulci are deep and interfere with accurate mapping. Even though there are differences in hand use among primates, in all primates the hand has the largest topographical and distinct representation for the actual size of the extremity. Thus the hand has the greatest potential for skilled movement and sensory discrimination. Findings from studies of this cortical region are applicable across the different cortices as well as the other cornerstones of the brain such as the thalamus, basal ganglia, brain stem, and cerebellum.^{147,148} See Fig. 3.8 to identify specific anatomical locations and their respective classifications.

To understand neural adaptation and be able to apply the principles to practice, it is essential to measure change objectively. Positive change in neural structure can be measured with a variety of imaging techniques (e.g., magnetic resonance imaging [MRI], functional MRI [fMRI], magnetoencephalography, magnetic source imaging [MSI], and diffusion tensor imaging [DTI]). The types of outcomes that can be expected are summarized in Table 3.4. Electroencephalography (EEG) can be used to examine recovery patterns and dynamic change during select activities.^{149,150} The specific type of intervention to address the principles of neuroplasticity may vary, but the outcomes must be clearly documented.

Research has now begun to explore the role of neurotrophic factors and genetics and the potential for neural recovery and adaptation. For example, the protein brain-derived neurotrophic factor (BDNF), which serves to improve the function of neurons, has been found to influence neuroplasticity and motor learning.¹⁵¹ The release of BDNF is reportedly activity-dependent, with increased levels noted in response to aerobic exercise and skill learning.^{152,153} However, there is variability in the release of BDNF in the case of genetic polymorphisms or

TABLE 3.4 Neuroprotective Motor Enrichment Factors Affecting Outcomes

	Negative Plasticity	Positive Plasticity
Stimulation	Disuse, unskilled	Intensive, skilled
Quality of sensory input	Noisy, nonspecific	Appropriate, specific
Modulation	Not challenging	High stakes, novel, challenging
Outcome	Negative behaviors	Positive behaviors

variations in DNA. In reference to BDNF, a common single-nucleotide polymorphism has been reported, called val66met, which involves an amino acid substitution from valine to methionine at codon 66. This substitution results in a BDNF val66met polymorphism and a reduction in the activity-dependent release of BDNF.¹⁵⁴ As more information is gained from this line of research, among other contributing factors, we may be better able to predict which individuals will best respond to particular intervention strategies and which will need alternative programming to foster responsiveness.

Principles of Neural Adaptation

To achieve maximal neural adaptation, several basic principles must be kept in mind (Box 3.1). Learning is the key to neural adaptation. Plasticity is the mechanism for encoding, the changing of behaviors, and both implicit and explicit learning. During neural adaptation, the fundamental questions are as follows: As we learn, how does the brain change its representations of inputs and actions? What is the nature of the processes that control the progressive elaboration of performance abilities? In different individuals, what are the sources of variance for the emergence of improved performance? What changes in cortical plasticity facilitate the development of “automatic” motor behaviors? Why are some behaviors hard to change? What limits plasticity processes? What are the critical elements of brain circuitry, genes, synapses, neural chemistry, neuronal networks, and neural connections for the restoration of lost function? What guidelines must be followed to drive the greatest change in brain structure and function? How do spontaneous compensatory behavioral strategies contribute to or interfere with restoring lost neuronal function? How does the less affected side following stroke contribute to or interfere with neuroplastic changes and restoration of function? Does damage to the brain alter the neuronal response to learning (e.g., cascade of cellular activity for healing altered circuitry, new neural connections)?

The most informative studies on neuroplasticity are those specifically directed toward defining the changes induced by learning. One approach has been to document the patterns of distributed neural response representation of specific inputs before and after learning. In particular, neuronal responses have been measured in the primary auditory, somatosensory, and motor cortices in animals. These animal studies have been paired with behavioral studies in humans. Both the animal and human studies provide strong evidence documenting the ability of the brain to functionally self-organize. This capacity for change occurs not only during development but also in adulthood, specifically after learning-based activities. The basic processes for neural adaptation are discussed in the following paragraphs.

1. *Neural circuits must be actively engaged in learning-based activities to prevent degradation and atrophy.*

We know that if infants are deprived of sensory and motor experiences during development, the brain does not develop sufficiently. For example, without exposure to light, there is a reduction in the number of neurons in the visual cortex.¹⁵⁵ Similarly, if infants are

BOX 3.1 Neuroplasticity Principles Translated to Guide Clinical Practice

Basic Principles

The task of translating basic science to clinical practice over time is a challenging one. There is no exact protocol. Learning activities must be adapted and matched to the abilities, goals, and objectives of each individual. Based on research evidence, the following principles can help to guide training:

1. *Use it or lose it*—Stay active and keep challenging learning. Failure to regularly engage specific and general brain functions can lead to functional degradation.
2. *Use it and improve it*—Engaging in training behaviors that drive specific brain functions can lead to enhancement of the function.
3. *Be specific*—The training experience must match the desired outcome; the nature of neural plasticity is dictated by the nature of the training.
4. *Repetition is essential*—Learning requires repetition, progressive in difficulty and spaced over time.
5. *Intensity matters*—Plasticity changes require a sufficient training intensity to ensure the durability of pathways.
6. *Salience is important*—The training must be salient and must match the outcome behavior desired and the goals of the individual.
7. *Age must be addressed*—Training-induced plasticity occurs most readily in a young brain, but neural adaptation continues across the life-span with learning-based training. With aging, greater efforts at variety, integration, and discovery may be needed.
8. *Transference*—Plasticity in response to one training experience can also enhance the acquisition of similar behaviors and adaptations in other experiences and other parts of the body.
9. *Interference*—Plastic changes after one training experience may interfere with the acquisition of changes in similar systems.
10. *Patient expectation*—Patient expectation can facilitate the outcomes of training; patients who expect to get better can enhance their learning.
11. *Reward or feedback*—Feedback enables the modification of training behaviors, correction of errors, and improvement in the accuracy of learning.
12. *Environment*—The environment can be enriched simply by noticing everything in the environment, expanding the environment to include new opportunities, and providing opportunities to interact with others.
13. *Fun*—Learning is greatest when it is associated with discovery and fun.
14. *Helping others*—The fitness of the brain is maintained best when individuals look beyond themselves to help and involve others.

Integrate the Principles of Neural Adaptation Into Neurorehabilitation

In embarking on a rehabilitation program with someone, it is important to match the principles of neuroplasticity to interactions with the patient, the family, the health care team, and the job, emphasizing the importance of the following:

1. Thinking positively about health and recovery; expecting to get better
2. Setting clear goals and objectives for retraining
3. Encouraging the family to be involved in the retraining activities
4. Creating learning activities that are attended-goal directed, repetitive, progressed in difficulty, increased in variety and depth, spaced over time, rewarded, and complemented with feedback on accuracy
5. Linking activities temporally (in time) and spatially but progressively sequenced; making the stimulus strength adequate for detection and appropriate to avoid abnormal behaviors
6. Integrating training behaviors into meaningful functional activities
7. Making training activities age appropriate
8. Integrating training activities across multiple sensory modalities appropriate for desired outputs
9. Performing training activities in different postural orientations and different environments, thus facilitating the best performance
10. Matching training behaviors with progression of healing and recovery as well as development
11. Strengthening positive responses with meaningful rewards

12. Making it difficult to use the unaffected side (e.g., wearing a glove)
13. Avoiding activities that stimulate the repetition of abnormal movements
14. Maintaining high levels of attention and cognitive function within the context of all daily activities; avoiding habitual unattended behaviors
15. Maintaining self-esteem
16. Avoiding an egocentric focus; thinking about how to help and be involved with others
17. Being fit, thinking “tall,” and challenging balance by interacting in new unstable environments

Research-Validated Outcomes Following Central Nervous System Training

With thoughtful, attentive, regular physical exercise; integrated learning-based activities; daily learning; and specific practice to improve skills, there is scientific evidence confirming the following positive outcomes:

1. Strengthened and elaborated neuronal interconnections
2. Improved health and vigor of nerve cell populations (including neurotransmitters, nerve brain growth factors, dopamine)
3. Increased physical size of brain centers and a slowing down of shrinkage and atrophy of the brain with aging and disuse
4. Increased accuracy of neuronal processing
5. Improved strength of associative memory processes and the capacity for the brain to remember what is seen, heard, felt, or learned
6. Faster brain processing and more reliable connections to improve sharpness and completeness of how our brain represents and records information
7. Improved coordination of neuronal activities across brain subsystems
8. Improved abilities to broaden and control one's attention, shift attention, and take in more information with better acuity
9. Improved integration in vision, listening, feeling, and awareness of joint and trunk position in space
10. Improved ability to suppress noise and distractions to stay on track
11. Improved security of mobility and more reliable postural reactions to protect from falling in familiar and stable as well as unfamiliar and unstable environments
12. Reactivation of long underpracticed skills that support independent mental and physical actions (e.g., riding a bike, skipping, throwing and catching balls, playing an instrument)
13. Restoration of fluency, self-confidence, liveliness, and happiness
14. Increased longevity
15. Increased blood flow and oxygen to the heart and nervous system
16. Physical exercise combined with attended learning-based exercise in order to decrease the risk for heart disease, cancer, metabolic failure, and Alzheimer disease

Methods of Measuring Neural Adaptation Neurophysiological and Neuroanatomical Outcomes

Neurophysiological and neuroanatomical changes can be measured in the CNS with learning. Measurements have been made with a variety of techniques (e.g., neurophysiological mapping after craniotomies, electroencephalography [EEG], magnetic source imaging [MSI], functional magnetic resonance imaging [fMRI], electromyography [EMG], cortical response mapping with positron emission tomography, diffusion tensor imaging [DTI], and spectroscopy with the potential for neurochemical analysis of neurotransmitters, growth hormones, inhibitors, corticosteroids). With learning it is possible to measure the following:

1. Achievement of specialized cortical representations of behaviorally important inputs
2. Growth in the number of neuron populations excited with progressively greater specificity in the neuronal representations and stronger temporal coordination
3. Strengthening of neural connections (synapses) following important behavioral inputs

BOX 3.1 Neuroplasticity Principles Translated to Guide Clinical Practice—cont'd

4. Increased oxygenation
5. Decreased atrophy of the brain
6. Shortening of the time between the stimulus and neuronal activation (latency)
7. Modification of the amplitude of neuronal firing
8. Improvement in the ability to turn off neurons once fired
9. Increased ability to inhibit unwanted neuronal firing in response to an input
10. Shortened integration time between the processing of inputs and production of outputs
11. Specialization of representational firing in response to familiar inputs
12. Improved temporal sequencing of firing following familiar inputs
13. Increased myelination
14. Increased complexity of dendrites and change in number and complexity of synapses
15. Increased consistency of response (e.g., density of neuronal responses)
16. Improved selective excitation
17. Increased specificity of neuronal response
18. Increased salience of the response
19. Change in cortical (and noncortical) topography
20. Increased area of representation
21. Smaller receptive fields
22. Increased density of receptive fields
23. Improved precision and order of receptive fields

Clinical Documentation of Outcomes After Learning-Based Training

Basic science and clinical research studies report positive correlations between functional outcomes and neural adaptation. With timely prevention, appropriate management of acute insults to the CNS, spontaneous recovery, and thoughtful attention to activities of daily living (ADLs) and task practice, disabling CNS problems can be minimized. Furthermore, early treatment after CNS injury or onset of disease may prevent more extensive damage to the brain. Learning activities may not only be neuroprotective but also drive more complete recovery of function. Changes in neural adaptation can be measured clinically in terms of improvements in function, including the following:

1. Fine and gross motor coordination
2. Sensory discrimination
3. Balance and postural control
4. Reaction time
5. Accuracy of movements
6. Rhythm and timing of movements
7. Memory storage, organization, and retrieval
8. Alertness and attention
9. Sequencing
10. Logic, complexity, and sophistication of problem solving
11. Language skills (verbal and nonverbal)
12. Interpersonal communication
13. Positive sense of well-being
14. Insight
15. Self-confidence
16. Self-image
17. Signal/noise detection; able to make finer distinctions
18. Ability to “chunk” information for memory and use
19. Learning skills including faster learning
20. Achievement of developmental milestones
21. Appropriate sensitivity of the nervous system (e.g., reduction in hyperactivity and sensory defensiveness)
22. Ability to perform a skill from memory

23. Flexible behaviors; variability in task performance
24. Flexibility for experience-based learning

Practical Suggestions for Maintaining Physical and Brain Health Across the Life-Span^{39,135}

Make living a learning experience by creating goal-directed activities that require attention and can be progressed in difficulty or variety over time. Where possible, provide conditions where feedback about performance is received. Try to maintain variability in activities and vary the environments for performing the same and different tasks. Take some risks by changing activities that are familiar and comfortable. Walk around on unstable surfaces as well as familiar surfaces with the eyes closed to challenge balance and postural reactions. Assume different positions to perform common tasks. More specifically,

1. Integrate low- to moderate-intensity physical exercise into the day, balanced with healthy eating, good hydration, and stress management.
2. Stop all negative learning behaviors; minimize or eliminate bad habits.
3. Be actively engaged at the cutting edge of all activities; minimize habitual behaviors.
4. Improve skills; progressively practice to perform each task better and use mistakes to guide practice.
5. Improve language listening skills and expand the words and the language used.
6. Be a lifelong learner; take classes, go to lectures, listen to audio books, and discuss what was learned with others.
7. Engage in conversational listening (review what is remembered about a conversation right after the conversation ends).
8. Keep hobbies alive; mix life with work and play.
9. Consider learning to play a musical instrument (e.g., take lessons, practice, and carefully listen while playing).
10. Sing along with music; sing out loud in the car (loud, clearly, and slowly), and consider joining a choir to share the joy of singing with others.
11. Take time and opportunities to dance; consider taking some lessons.
12. Volunteer in the community to interact with others.
13. Wear a hearing aid if one has been prescribed; wear glasses if they are needed.
14. Improve everyday activities by learning something new or by challenging observation and recall skills: have a puzzle out and add pieces or have challenging crossword puzzles to work on.
15. Play games that require fine motor skills (e.g., shuffling cards, Ping-Pong, bowling, tennis).
16. After walking to the store, reconstruct all of the things that were seen on the way and at the store and what was accomplished.
17. When waiting for scheduled appointments, review the details of the environment; examine what has changed since the last visit.
18. Before going to social gatherings, try to remember the names of the people who are expected to be there; afterward, review who was there by name.
19. When idle or waiting, instead of sitting, walk around and mentally review items in the environment, organize these items, review tasks that need to be done (including steps required), play a game.
20. Find different ways to get to common places; evaluate which way is fastest, easiest, most interesting, most fun.
21. Constantly read and listen to the news, attend lectures, listen to or watch educational programs.
22. When with others, especially with children or grandchildren, play progressive or problem-solving games (e.g., Boggle, chess, card games, checkers).
23. Look beyond the self; think what you can do to make others happy.
24. Avoid stress; instead enjoy life and share joy with others.
25. Take a walk or ride a bike every day.
26. Find something fun to do every day.

Data from Byl N, Merzenich MM, Cheung S, et al. A primate model for studying focal dystonia and repetitive strain injury: effects on the primary somatosensory cortex. *Phys Ther*. 1997;77:269–284; Kleim J, Jones TA. Principles of experience-dependent neural plasticity: implications for rehabilitation after brain damage. *J Speech Lang Hear Res*. 2008;51(1):S225–S239; and Merzenich M. *Soft-Wired: How the New Science of Brain Plasticity Can Change Your Life*. 2nd ed. San Francisco, CA: Parnassus Publishing; 2013.

not exposed to sound, there is a reduction in the neurons in the auditory cortex.¹⁵⁶ Even in adults, when neural circuits are not used over an extended period of time, they begin to degrade, and the unused area of the brain is allocated to serve another part of the body.¹⁵⁷ Similarly, if task performance is practiced, then the topography expands and becomes more detailed, as might occur in someone who is blind and reads Braille.¹⁵⁸ It is also interesting to note that although a person is blind, the visual cortical areas may become active when the individual is reading Braille.¹⁵⁹ Similarly, a person who is deaf may demonstrate activation of the auditory cortex when visual stimuli are presented.

2. *With skill learning, the distributed cortical representations of inputs and brain actions “specialize” in their representations of behaviorally important inputs and actions.*

A minimal level of repetitive practice is needed to acquire a new skill that will be maintained over time. This may lead to specialization or change in the underlying neurophysiological processing.^{160–162} Such specialization develops in response to selective cortical neuron responses specific to the demands of sensory, perceptual, cognitive, and motor skill learning.^{163–166} This adaptation has been clearly documented in animal studies. For example, if an animal is trained to make progressively finer distinctions about specific sensory stimuli, then cortical neurons come to represent those stimuli in a progressively more specific and “amplified” manner.

3. *Important behavioral conditions are essential to the learning phase of plasticity.*
 - a. If behaviorally important stimuli repeatedly excite cortical neuron populations, the neurons will progressively grow in number.
 - b. Repetitive, behaviorally important stimuli processed in skill learning lead to progressively greater specificity in the spatial and temporal dimensions.
4. *The growing numbers of selectively responding neurons discharge with progressively stronger temporal coordination (distributed synchronicity).*

Through the course of progressive skill learning, a more refined basis for processing stimuli and generating actions critical to skilled tasks is enabled by the multidimensional changes in cortical responses. Consequently, specific aspects of these changes in distributed neuronal responses are highly correlated with learning-based improvements in perception, motor control, and cognition.^{167–170} In these processes the brain is not simply changing to record and store content but is selectively refining its processing capacities to fit each task at hand by adjusting its spatial and temporal filters. Ultimately it establishes its own general processing capabilities. This process of “learning to learn” determines the facility with which specific classes of information can be stored, associated, and manipulated. These powerful self-shaping processes of the forebrain machinery are operating not only on a large scale during development but also during experience-based management of externally and internally generated information in adults. This self-shaping with experience allows the development of organization of perception, cognition, motor, and executive management skills.

5. *The growing numbers of selectively responding neurons discharge with progressively stronger temporal coordination (distributed synchronicity).*

The process of coincidence-based input co-selection leads to changes in cortical representation. Coincident, temporally and spatially related events that fire together are strengthened together. In skill learning, this principle of concurrent input co-selection results from repetitive practice that includes the following:

- a. A progressive amplification of cell numbers engaged by repetitive inputs.^{169–171}

- b. An increase in the temporal coordination of distributed neuronal discharges evoked by successive events to mark features of behaviorally important inputs is a consequence of a progressive increase in positive coupling between nearly simultaneously engaged neurons within cortical networks.^{169,172}
- c. A progressively more specific “selection” of all input features that collectively represent behaviorally important inputs is expressed moment by moment in time.^{171,172} Thus skill learning results in mapping temporal neighbors in representational networks at adjacent spatial locations when they regularly occur successively in time.^{88,173,174} Changes in activation patterns, dendritic growth, synapses, and neuronal activities may also be observed.

The basis of the functional creation of the detailed, representational cortical maps converting temporal to spatial representations is related to the Hebbian change principle.¹⁷⁵ This principle applies to the development of interconnections between excitatory and inhibitory inputs within the cortical pyramidal neurons and their connections to extrinsic inputs and outputs. On the basis of the Hebbian principle, the operation of coincidence-based synaptic plasticity in cortical networks results in the formation, strengthening, and continuous recruitment of neurons within neuronal “assemblies” that “cooperatively” represent behaviorally important stimuli.

6. *Plasticity is constrained by anatomical sources and convergent-divergent spread of input.* Every cortical field includes the following:
 - a. Specific extrinsic and intrinsic input sources
 - b. Dimensions of anatomical divergence and convergence of its inputs, limiting dynamic combination Hebbian input co-selection capacities^{176,177}

Anatomical input sources and limited projection overlap to enable change by establishing input-selection repertoires and to determine the limits for change. There are relatively strict anatomical constraints at the “lower” system levels, where only spatially limited input, coincidence-based combined outcomes are possible. In the “higher” system hierarchies, anatomical projection topographies are more powerful, with neurons and neuronal assemblies developing that respond to complex combinations of features of real-world objects, events, and actions.

7. *Plasticity is constrained by time constants governing coincident input co-selection and by time structures and potentially achievable coherence of extrinsic and intrinsic cortical input sources.*

To effectively drive representational changes with coincident input-dependent Hebbian mechanisms, temporally coordinated inputs are prerequisite, given the short duration (milliseconds to tens of milliseconds) in the time constants that govern synaptic plasticity in the adaptive cortical machinery.¹⁷⁸ Consistently uncorrelated or low discharge-rate inputs induce negative changes in synaptic effectiveness. In addition, stimuli occurring repetitively simultaneously can also degrade the representation. These negative effects also contribute importantly to the learning-driven “election” of behaviorally important inputs.

8. *Cortical field-specific differences in input sources, distributions, and time-structured inputs create different representational structures.*

- a. There are significant differences in the activity from afferent inputs from the retina, skin, or cochlea generated in a relatively strictly topographically wired V1 (area 17), S1 proper (area 3b), or A1 (area 43) compared with the inferotemporal visual, insular somatosensory, dorsotemporal auditory, or prefrontal cortical areas that receive highly diffuse inputs (see Fig. 3.8). In the former cases, heavy schedules of repetitive, temporally coherent inputs are delivered from powerful, redundant projections in

strictly topographically organized thalamic nuclei and lower-level, associated cortical areas. Yet neighboring neurons can share some response properties, neurons, or clusters of neurons that respond selectively to learned inputs. These neurons are distributed widely across cortical areas and share less information with neighboring neurons. In the “lower” levels, afferent input projections from any given source are greatly dispersed. Highly repetitive inputs are uncommon, inputs from multiple diffuse cortical sources are more common with more varied complex input combinations. These differences in input schedules, spreads, and combinations presumably account for the dramatic differences in the patterns of representation of behaviorally important stimuli at “lower” and “higher” levels.¹⁷⁹

- b. Despite these differences in representational organization across the cortex, it progressively differentiates cortical cells to accomplish specific operational tasks. There is a serial progression of differentiation to allow the development of functional organization, which enables an individual to progressively master more elaborate and differentiated perceptual, cognitive, monitoring, and executive skills.
 - c. The sources of inputs and their field-specific spreads and boundary limits, the distributions of modulatory inputs differentiated by cortical layers in different cortical regions, the basic elements and interconnections in the cortical processing machine, and crucial aspects of input combination and processing at subcortical levels are inherited (see reference Quinn¹⁸⁰ for review). Although these inherited aspects of sensory, motor, and cortical processing circuits constrain the potential learning-based modification of processing within each cortical area, changes in representation can occur as a result of environmental interaction and purposeful behavioral practice.
9. *Temporal dimensions of behaviorally important inputs also influence representational “specialization.”* In at least four ways, the cortex refines its representations of the temporal aspects of behaviorally important inputs during learning.
- a. First,
 - (1) The cortex generates more synchronous representations of sequenced and coincident associative input perturbations or events, not only recording their identities but also marking their occurrences. These changes in representation appear to be primarily achieved through increases in positive coupling strengths between interconnected neurons participating in stimulus- or action-specific neuronal cell assemblies.^{165,180a,181–201} The strength of the interconnectedness increases representational salience as a result of downstream neurons being excited in direct relation to the degree of temporal synchronization of their inputs.
 - (2) Increasing the power of the outputs of a cortical area drives downstream plasticity. Hebbian mechanisms operating within downstream cortical (or other) targets also have relatively short time constants. The greater the synchronicity of inputs, the more powerfully those change mechanisms are engaged. The strength of the interconnections also helps protect against noise. For example, by simple information abstraction and coding, the distributed representation of the “signal” (a temporally coordinated, distributed neuronal response pattern representing the input or action) is converted at the entry levels in the cortex into a form that is not as easily degraded or altered by “noise.” The strength of the interconnectedness also confers robustness of complex signal representation for spatially incomplete or degraded inputs.
 - b. Second,
 - (1) The cortex can select specific inputs through learning to exaggerate the representation of specific input time structures. Conditioning a monkey or a rat with stimuli that have a consistent, specific temporal modulation rate or interstimulus time, for example, results in a selective exaggeration of the responses of neurons at that rate or time separation. In effect, the cortex “specializes” for expected relatively higher-speed or relatively lower-speed signal event reception.
 - (2) Both electrophysiological recording studies and theoretical studies suggest that cortical networks richly encode the temporal interval as a simple consequence of cortical network dynamics.^{202,203} It is hypothesized that the cortex accomplishes time-interval and duration selectivity in learning by positively changing synaptic connection strengths for input circuits that can respond with recovery times and circuit delays that match behaviorally important modulation frequency periods, intervals, or durations. However, studies on including excessive, rapid, repetitive fine motor movements can sometimes lead to serious degradation in representation if the adjacent digits are driven nearly simultaneous in time. This may be associated with negative learning and a loss of motor control.²⁰⁴
 - c. Third,
 - (1) The cortex links representations of immediately successive inputs presented in a learning context.
 - (2) As a result of Hebbian mechanisms, it establishes overlapping and neighboring relationships between immediately successive parts of rapidly changing inputs yet retains its individualized, distinct cortical representation.^{88,205}
 - d. Fourth,
 - (1) The cortex generates stimulus sequence-specific (“combination-sensitive”) responses, with neuronal responses selectively modulated by the prior application of stimuli in the learned sequence of temporally separated events.
 - (2) These “associative” or “combination-sensitive” responses have been correlated with evidence of strengthened interconnections between cortical cell assemblies representing successive event elements separated by hundreds of milliseconds to seconds in time.^{206,207} The mechanisms of origin of these effects have not yet been established.
 - e. *Temporal dimensions of behaviorally important inputs also influence representational “specialization.”* Cortical networks engage both excitatory and inhibitory neurons by strong input perturbations. Within a given processing “channel,” cortical pyramidal cells cannot be effectively reexcited by a follow-up perturbation for tens to hundreds of milliseconds. These integration “times” are primarily dictated by the time for recovery from inhibition, which ordinarily dominates poststimulus excitability. This “integration time,” “processing time,” or “recovery time” is commonly measured by deriving a “modulation transfer function,” which defines the ability of cortical neurons to respond to identical successive stimuli within cortical “processing channels.” For example, these “integration” times normally range from about 15 to about 200 ms in the primary auditory receiving areas.^{208–210} Progressively longer processing times are recorded at higher system levels (e.g., in the auditory cortex, they are approximately a syllable in length, 200 to 500 ms in duration) in the “belt cortex” surrounding the primary auditory cortex.²¹¹
 - f. These time constants govern—and limit—the cortex’s ability to “chunk” (i.e., separately represent by distributed, coordinated

discharge) successive events within its processing channels. Both neurophysiological studies in animals and behavioral training studies in human adults and children have shown that the time constants governing event-by-event complex signal representation are highly plastic. With intensive training in the correct form, cortical “processing times,” as reflected by the ability to accurately and separately process events occurring at different input rates, can be dramatically shortened or lengthened.^{212–215}

10. *Plasticity processes are competitive.*

- a. If two spatially different inputs are consistently delivered non-simultaneously to the cortex, cortical networks generate input-selective cell assemblies for each input and actively segregate them from one another.^{172,214,216–218} Boundaries between such inputs grow to be sharp and are substantially intensity independent. Computational models of Hebbian network behaviors indicate that this sharp segregation of nonidentical, temporally separated inputs occurs secondary to a wider distribution of inhibitory versus excitatory responses in the emerging, competing cortical cell assemblies that represent them.
- b. This Hebbian cell assembly formation and competition appear to account for how the cortex creates sharply sorted representations of the fingers in the primary somatosensory cortex.^{173,219} The Hebbian network probably accounts for how the cortex creates sharply sorted representations of native aural language-specific phonemes in lower-level auditory cortical areas in the auditory and speech processing system of humans. If inputs are delivered in a constant and stereotyped way from a limited region of the skin or cochlea in a learning context, the associated skin surface or cochlear sector is an evident competitive “winner.”^{169,220} By Hebbian mechanisms, the cortical networks will co-select that specific combination of inputs and represent it within a competitively growing Hebbian cell assembly. The competitive strength of that cooperative cell assembly will grow progressively because more and more neurons are excited by relevant behavioral stimuli with increasingly coordinated discharges. That means that neurons outside of this cooperative group have greater numbers of more coordinated outputs contributing to their later competitive recruitment. Through progressive functional remodeling, the cortex clusters and competitively sorts information across sharp boundaries dictated by the spatiotemporal statistics of its inputs. If it receives information on a heavy schedule that sets up competition for a limited input set, it will sort competitive inputs into a correspondingly small number of largely discontinuous response regions.^{221,222}
- c. Competitive outcomes are, again, cortical level dependent. The cortex links events that occur in different competitive groups if they are consistently excited synchronously in time. At the same time, competitively formed groups of neurons come to be synchronously linked in their representations of different parts of the complex stimulus and collectively represent successive complex features through the coordinated activities of many groups.
- d. Neurons within the two levels of the cortex surrounding A1 (see Fig. 3.8) have greater spatial input convergence and longer integration times that enable their facile combination of information representing different spatiotemporal details. Their information extraction is greatly facilitated by the learning-based

linkages of cooperative groups that deliver behaviorally important inputs in a highly salient, temporally coordinated form to these fields. With their progressively greater space and time constants, still higher-level areas organize competitive cell assemblies that represent even more complex spatial and serial-event combinations. Note that these organizational changes apply over a large cortical scale. In skill learning over a limited period of training, participating neuronal members of such assemblies can easily be increased by many hundredfold, even within a primary sensory area such as S1, area 3b, or A1.^{169,172,204,214,223}

- e. In extensive training in complex signal recognition, more than 10% of neurons within temporal cortical areas can come to respond highly selectively to a specific, normally rare, complex training stimulus. The distributed cell assemblies representing those specific complex inputs involve tens or hundreds of millions of neurons and are formed by enduring effectiveness changes in many billions of synapses.
11. *Learning is modulated as a function of behavioral state.*
- a. At “lower” levels of the cortex, changes are generated only in attended behaviors.^{170,171,179,223–225} Trial-by-trial change magnitudes are a function of the importance of the input to the animal as signaled by the level of attention, the cognitive values of behavioral reinforcement, and internal judgments of trial precision, or error based on the relative success or failure of achieving a target goal or expectation. Little or no enduring change is induced when a well-learned “automatic” behavior is performed from memory without attention. Interestingly, at some levels within the cortex, activity changes can be induced even in nonattending subjects under conditions in which “priming” effects of nonattended reception of information can be demonstrated.
 - b. The modulation of progressive learning is achieved by the activation of powerful reward systems releasing the neurotransmitters norepinephrine and dopamine (among others) through widespread projections to the cerebral cortex. Norepinephrine plays a particularly important role in modulating learning-induced changes in the cortex.^{214,225,226}
 - c. The cortex is a “learning machine.” During the learning of a new skill, neurotransmitters are released trial by trial with application of a behaviorally important stimulus or behavioral rewards. If the skill can be mastered and thereafter replayed from memory, its performance can be generated without attention (habituation). Habituation results in a profound attenuation of the modulation signals from these neurotransmitter sources; plasticity is no longer positively enabled in cortical networks.
12. *Top-down influences constrain cortical representational plasticity.*
- Attentional control flexibly defines an enabling “window” for change in learning.²¹² Progressive learning generates progressively more strongly represented goals, expectations, and feedback^{227,228} across all representational systems that are undergoing change and to modulatory control systems weighing performance success and error. Strong intermodal behavioral and representational effects have also been recorded in experiments that might be interpreted as shaping expectations.^{229,230} These shaping expectations would be similar to those observed in a human subject using multisensory inputs such as auditory, visual, and somesthetic information to create integrated phonological representations, to create fine motor trajectory patterns that underlie precise hand control, or to make a vocal production.

13. *The scale of plasticity in progressive skill learning is massive.*

- a. Cortical representational plasticity must be viewed as arising from multiple-level systems broadly engaged in learning, perceiving, remembering, thinking, and acting. Any behaviorally important input (or consistent internally generated activity) engages many cortical areas. Repetitive training drives all cortical areas to change.^{164,177,231} Different aspects of any acquired skill are contributed from field-specific changes in the multiple cortical areas that are remodeled in its learning.
- b. In this kind of continuously evolving representational machine, perceptual constancy cannot be accounted for by brain representations in constant locations; relational representational principles must be invoked to account for it.^{164,232} Moreover, representational changes must obviously be coordinated level to level. It should also be understood that plastic changes are also induced extracortically. Although it is believed that learning at the cortical level is usually predominant, plasticity induced by learning within many extracortical structures significantly contributes to learning-induced changes that are expressed within the cortex.

14. *Enduring cortical plasticity changes appear to be accounted for by local changes in neural anatomy.*

Changes in synapse turnover, synapse number, synaptic active zones, dendritic spines, and the elaboration of terminal dendrites occur in a behaviorally engaged cortical zone.^{177,233–238} Through many changes in local structural detail, the learning brain is continuously physically remodeling its processing machinery, not only across the course of child development but also after behavioral training in an adult with a neural insult.

15. *Cortical plasticity processes in child development represent progressive, multiple-staged skill learning.*

- a. There are two remarkable achievements of brain plasticity in child development. The first is the progressive shaping of the processing to handle the accurate, high-speed reception of the rapidly changing streams of information that flow into the brain. In the cerebral cortex, shaping appears to begin most powerfully within the primary receiving areas of the cortex. With early myelination, the main gateways for information into the cortex are receiving strongly coherent inputs from subcortical nuclei, and they can quickly organize their local networks on the basis of coincident input co-selection (Hebbian) mechanisms. The self-organization of the cortical processing machinery spreads outward from these primary receiving areas over time to ultimately refine the basic processing machinery of all the cortex. The second great achievement, which is strongly dependent on the first, is the efficient storage of massive content collections in richly associated forms.
- b. During development, the brain accomplishes its functional self-organization through a long parallel series of small steps. At each step, the brain masters a series of elementary processing skills and establishes reliable information repertoires that enable the accomplishment of subsequent skills. Second- and higher-order skills can be viewed as elaborations of more basic mastered skills and the creation of new skills dependent on combined second- and higher-order processing. That hierarchical processing is enabled by greater cortical anatomical spreads, by more complexly convergent anatomical sources of inputs, and by longer integration (processing, recovery) times at progressively higher cortical system levels. This integrating process allows for progressively more complex combinations of

information integrated over longer time epochs as one ascends across cortical processing hierarchies.

- c. As the cortical machinery functionally evolves and consequently physically “matures” through childhood developmental stages, information repertoires are represented in progressively more salient forms (i.e., with more powerful distributed response coordination). Growing agreement directly controls the power of emerging information repertoires to drive the next level of elaborative and combinatorial changes. It is hypothesized that saliency enables the maturation of the myelination of projection tracts delivering outputs from functionally refined cortical areas. More mature myelination of output projections also contributes to the power of this newly organized activity to drive strong, downstream plastic change through the operation of Hebbian processes.
- d. As each elaboration of skill is practiced, neuromodulatory transmitters enable change in the cortical machinery. The cortex functionally and physically adapts to generate the neurological representations of the skill in progressively more selective, predictable, and statistically reliable forms. Ultimately the performance of the skill concurs with the brain’s own accumulated, learning-derived “expectations.” The skill can then be performed from memory, without attention. With this consolidation of the remembered skill and information repertoire, the modulatory nuclei enable no further change in the cortical machinery. The learning machine, the cerebral cortex, move on to the next elaboration. Thus the cortex constructs highly specialized processing machinery that can progressively produce great towers of automatically performable behaviors and progressively mature hierarchies of information-processing machinery capable of achieving more powerful complex signal representations, retrievals, and associations. With this machinery in a mature and efficient operating form, there is a remarkable capacity for reception, storage, and analysis of diverse and complexly associated information.
- e. The flexible, self-adjusting capacity for refinement of the processing capabilities of the nervous system confers the ability of our species to represent complex language structures. This self-adjusting capacity also allows humans to develop high-speed reading abilities; remarkably varied complex modern-era motor abilities; and abstract logic structures characteristic of a mathematician, software engineer, or philosopher. This refinement of the nervous system also creates elaborate, idiosyncratic, experience-based behavioral abilities in all of us.

Neuroplasticity and Learning

How are learning sequences controlled? What constrains learning progressions? Perhaps the most important basis of control in learning progressions is representational consolidation. Through specialization, the trained cortex creates progressively more specific and more salient distributed representations of behaviorally important inputs. Growing representational salience increases the power of a cortical area to effectively drive change wherever outputs from this evolving cortical processing machinery are distributed (e.g., in “higher system levels distributed and coordinated [synchronized] responses” more powerfully drive downstream Hebbian-based plasticity changes).

A second powerful basis for sequenced learning is progressive myelination. At the time of birth, only the core “primary” extrinsic information entry zones (A1, S1, V1) in the cortex are heavily myelinated.^{239,240} Across childhood, connections to and interconnections between cortical areas are progressively myelinated, proceeding from

these core areas out to “higher” system levels. Myelination in the posterior parietal, anterior, and inferior temporal and prefrontal cortical areas is not “mature” in the human forebrain until 8 to 20 years of age. Even in the mature state, it is far less developed at the “highest” processing levels.

Myelination controls the conduction times and therefore the temporal dispersions of input sources to and within cortical areas. Poor myelination at “higher” levels in the young brain is associated with temporally diffuse inputs. They cannot generate reliable representational constructs of an adult quality because they do not effectively engage input-coincidence-based Hebbian plasticity mechanisms. That ensures, in effect, that plasticity is not enabled for complex combinatorial processing until “lower” level input repertoires are consolidated (i.e., become stable, statistically reliable forms).

Although myelination is thought to be genetically programmed, some scientists hypothesize that myelination in the CNS is also controlled by emerging temporal response coherence and is achieved through temporally coordinated signaling from the multiple branches of oligodendrocytes that terminate on different projection axons in central tracts and networks. It has been argued that central myelination is positively and negatively activity dependent and that distributed synchronization may contribute to positive change.²⁴¹ If the hypothesis that coherent activity controls myelination proves to be true, then the emerging temporal correlation of distributed representations of behaviorally important stimuli is generated level by level. This is done by changes in coupling in local cortical networks in the developing cortex. It would also directly drive changes in myelination for the outputs of that cortical area. These two events in turn would enable the generation of reliable and salient representational constructs at that higher level. By this kind of progression, skill learning is hypothesized to directly control progressive functional and physical brain development through the course of child development. This is accomplished both by refining (“maturing”) local interconnections through response dynamics of information processing machinery at successive cortical levels and by coordinated refinement (“maturing”) of the critical transmission pathways that interconnect different processing levels.

Another constraint in the development of neural adaptation may be the development of mature sleeping patterns, especially within the first year of life.²⁴² Sleep enables the strengthening of learning-based plastic changes and resets the learning machinery by “erasing” temporary unreinforced and unrewarded input produced over the preceding awake period.^{243–245} The dramatic shift in the percentage of time spent in rapid-eye-movement sleep is consistent with a strong early bias toward noise removal in an immature, unorganized, and poorly functionally brain. Sleep patterns change dramatically in the older child, in parallel with a strong increase in a daily schedule of closely attended, rewarded, and goal-oriented behavior. This research should be further explored in patients with CNS damage. This population often has poor breathing habits and capabilities that lead to decreased oxygenation and often broken sleep cycles. It has yet to be determined how much impairment, breakdown, and associated interaction diminishes neuroplasticity.

Top-down modulation controlling attentional windows and learned predictions (expectations and behavioral goals) must all be constructed by learning. Delays in goal development could create an important constraint for the progression of early learning. In the very young brain, prediction and error-estimation processes could be weak if stored higher-level information repertoires are ill formed and unreliable. As the brain matures, stored information enables attentional and predictive controls to operate more reliably. This provides a

stronger basis for success and error signaling with modulatory control nuclei, enabling syntactic feedback to increase representational reliability.

Attention, reward and punishment, accuracy of goal achievement, and error feedback gate learning through a modulatory control system critical for learning. The modulatory control systems that enables learning is plastic, with their process of maturation providing constraint or facilitation of progressive learning. These subcortical nuclei are signaled by complex information feedback from the cortex itself. The salience and specificity of that feedback information grows over time. The ability to provide accurate judgment of error or goal-achievement signaling must progressively grow. The nucleus basalis, nucleus accumbens, ventral tegmentum, and locus coeruleus must undergo their own functional self-organization based Hebbian plasticity principles to achieve “mature” modulatory selectivity and power. The progressive maturation of the modulatory control system occurs naturally with development or training. This system can provide other important constraints on the progression of skill development involving regulation of postural/balance control and fine motor coordination.

What facilitates the development of permanent “automatic” motor behaviors? The creation and maintenance of cortical representations are functions of the animal’s or human’s level of attention at a task. Cortical representational plasticity in skill acquisition is self-limiting. Because the behavior becomes more “automatic,” it is less closely attended, and representational changes induced in the cortex fade and ultimately disappear or reverse (unlearning effects).^{246–248} The element of behavioral performance that enables maintenance of the behavior with minimal involvement of the cortical learning machinery is probably stereotypical movement sequence repetition. As a movement behavior is practiced, an effective, highly statistically predictable movement sequence is adopted that enables the storage of the learned behavior in a permanent form that requires minimal to no attention. If behavioral performance declines or brain conditions change to render a task more difficult, attention to the behavior will need to increase, producing an invigorated cortical response to the new learning challenge.

By this view, the cerebral cortex is clearly a learning machine. William James²⁴⁹ was the first to point out that the great practical advantage for a self-organizing cortex was the development of what he called “habits.” When a skill is overlearned, it will engage pathways that are so reliable that they can be followed without attention.

Why are some habits retained and others lost? Can sensorimotor learning be sustained when the adaptive representations of the learned behavior “fade” in the cerebral cortex? These areas have not been well researched. However, there are several possibilities. Habits could come to be represented in an enduring form extracortically. The cortex could modify processing in the spinal cord, the basal ganglia, the red nucleus, or the cerebellum. For example, the learning of manual skills requires a motor cortex, but overlearned motor skills may not be significantly reduced by the induction of a wide area four lesion.

Another possibility is that behaviorally induced cortical changes endure in a highly efficient representational form that can sustain the representation of its key features on the cortex itself, engaging only limited distributed populations of cortical neurons to represent the behavior with high fidelity. Thus recall of past learning may take less time to restructure than reformatting new learning, whether it be a cognitive or motor task. The fact that a monkey improves its discriminative abilities or movement performance after modifying the cortical neuron response with heavily practiced behaviors supports this alternative. However, many behaviors, such as musical performance,

require constant, attended practice at a highly cognitive level to maintain both the representational changes and the performance. It also appears that continued learning with heavily practiced behaviors may be neuroprotective with aging, maintaining function despite loss of cortical neurons as a natural part of aging.

INTEGRATION AND IMPLEMENTATION INTO CLINICAL PRACTICE

Over the years, learning has been linked with critical periods of development, with the assumption that if a particular skill or behavior was not learned during the critical period, the opportunity to acquire that skill was lost. After this critical period of development, aging was associated with inevitable deterioration of brain and neurophysiological function. Yet today there is substantial evidence that the brain is an incredibly specialized representational machine that can adapt to meet the specific inputs that engage it. The beauty of the brain is that it not only self-organizes but also stores the contents of its learning to create a foundation that increases in depth and breadth and makes predictions on even novel inputs to facilitate acute and efficient operations. The earlier the exposure to multisensory stimuli, the easier it is for competitive neuronal processes to adapt and to make extensive connections. With growing neuronal specificity and salience, more powerful predictions continue until there is greater learning and mastery.

Among the important findings of the 20th century was the validation that the brain is a learning machine that operates throughout life. The aging process can restrict the ability to store information and may reduce both the complexity of the information processed and the individual's ability to retrieve it. But if an individual is able to maintain good hydration, balanced nutrition, physical exercise, and regularly goal-directed progressive learning, CNS pathways of representation and prediction can not only be preserved but can continue to adapt. These activities can also slow the aging process. Thus it is possible to drive improvement in function in individuals with abnormalities related to development, disease, injury, or aging. Learning is not necessarily specifically staged but rather represents complex abilities developed mostly from system interaction and integration. Therapists must develop the ability to determine what inputs are reliable and salient to effectively create functional and physical brain maturation, adaptation, and learning. In the face of different types of challenges (structural, emotional, pathological), clinicians must develop more effective strategies that can help facilitate neural adaptation, learning, substitution, and representational changes allowing meaningful maintenance and improvement in function despite anatomical or physiological variances in structure. Although strong behavioral events can be associated with measurable neural adaptability, new, more permanent neural connections and synapses must be strengthened with repetition and increased complexity. Patients with CNS disorders may have sustained damage to certain areas of the brain, which may not recover; however, with learning-based activities it is possible to reorganize the brain, stimulate neurons from adjacent areas, establish new synapses and dendritic pathways,²⁵⁰ and activate neurons in the contralateral, uninjured parts of the brain.^{251–257} Creating the best environment to learn a skill may initially need to be contrived, with limitations controlled externally by the therapist's hands or clinical arena. In time, those limitations must be eliminated and variability within the natural environment reintroduced to achieve true learning and ultimate neuroplasticity.

The elements of neuroscience research on neural adaptation have been summarized into 14 principles to guide rehabilitation programs

designed to facilitate experience-dependent plasticity.^{123,258,259} These principles, outlined in [Box 3.1](#), are similar to those suggested by Nudo¹⁶² as well as Kleim and Jones¹⁶¹ and Byl and colleagues.²⁶⁰ Although these principles are particularly relevant to patients with a head injury or stroke, they are also relevant for aging adults^{261–265} and those with neurodegenerative disease. These principles are not meant to be exhaustive or mutually exclusive but to highlight the principles of experience-dependent plasticity. They can also serve as a reference for therapists who are designing creative intervention programs based on the translation of basic science to clinical practice and to help organize the extensive research on neuroplasticity.

These principles can be applied across a broad range of activities and conditions to improve cognition and intellect as well as physical capability. Priming the system before learning can take many forms, including aerobic exercise, cortical stimulation, and skill learning. As reviewed earlier, BDNF, which is necessary for activity-dependent learning, can be increased with aerobic exercise and skill learning.¹⁵¹ Yet the influence of BDNF polymorphisms in different individuals needs further research. It is clear that the timing of enrichment (e.g., sensory and motor training) is important not only during development but across the life-span. An exercise program initiated too early (e.g., in less than 24 hours after acute neural injury) may be associated with an exaggeration of cellular injury.²⁶⁶ Yet waiting too long to intervene can limit the efficacy of the learning-based training experience.²⁶⁷ Learning-based training may also be enhanced with cortical stimulation,²⁶⁸ repetitive transcranial magnetic stimulation (rTMS),²⁶⁹ transcranial direct current stimulation (tDCS),²⁷⁰ bilateral mechanical priming,²⁷¹ and mental imagery.²⁷¹ It is critical to create a positive foundation to maximize learning (e.g., good hydration to maximize blood flow and oxygenation of tissues, adequate nutrition to energize the body, and aerobic activity to increase endorphins and BDNF, as well as positive expectations of getting better [limbic system]). Rehabilitation specialists must not only translate basic neuroscience into practice but participate in clinical research, serve as advocates for patients, ensure access to appropriate rehabilitative services, and be politically active in health care reform.

To ensure maximum neural adaptation, rehabilitation programs must include strong, carefully outlined home programs. Therapists must educate patients and their families about the principles of neuroplasticity to empower them to create progressive learning activities at home and in the community. Patients should revisit health care team members to facilitate ongoing learning. Patients must become their own best therapists, consistently motivating themselves to learn something new, perform attended behavioral activities, observe and integrate new information from their environment, have fun, stay engaged with family/friends/community, and avoid habitual stereotypical behaviors. Learning should be an excuse to travel to new places and learn new skills. Every day should include a new learning experience. Learning and aerobic exercise may not only be neuroprotective but could be critical for slowing down the natural neurodegenerative aspects of aging. Computer gaming, new technology, and robotics can be integrated to expand daily learning-based activities at home.

The maximum attainment of skilled performance cannot necessarily be determined. The original injury can be used only as an estimate of the damage with some indicators for prognosis and recovery. The rest of the success of rehabilitation and restoration of function will reside with the motivation and commitment of the individual. How that motivation and commitment are initially established and continually reinforced is based on the patient, the therapist's interactive skills and emotional bond, and the family and other support systems surrounding the patient.

CASE STUDY 3.1 The Person With Parkinson Disease

People with Parkinson disease develop an array of deficits in motor control that interfere with multiple ADLs and can eventually degrade quality of life. When motor control deficits are evaluated in this population, the severity of the disease, the activity level of the person, and the medication schedule are important considerations. Following are several motor control deficits that are evident in this disease.

Motor control impairments of rigid tone and bradykinesia create alterations in stride length, speed, and step frequency in the gait pattern of persons with Parkinson disease. The person may demonstrate a gait pattern characterized by decreased amplitude of leg movement, duration of the gait cycle, trunk rotation, and arm swing. Difficulty initiating gait, or “freezing,” is an observable motor control problem, and small shuffling steps and a festinating gait pattern are also common. Impaired righting and balance reactions can contribute to gait instability. When the demands on gait velocity and frequency are altered, metabolic cost increases and the ability of the individual to safely complete the functional movement with appropriate coordination of postural and motor control is challenged.

A practical outcome measure that can be used to capture the effect of these motor deficits on functional mobility is the Timed Up-and-Go (TUG) test. This quick test can be used to capture the time it takes for a person to initiate sit-to-stand, transition from sit-to-stand, walk 3 m, turn around, walk back, turn, and sit down. During the performance of these sequential movement patterns the clinician can observe gait deviations, postural abnormalities, movement amplitude, and safety awareness. Episodes and duration of “freezing,” or failed initiation, can be accounted for, and the number of steps to turn 180 degrees can be documented.²⁷² The overall time to complete the test can supply the clinician with objective data related to fall risk.

Overshooting or undershooting the 3-m line before turning may be demonstrated. Although patients with Parkinson disease are able to prepare the motor strategy and use advance information, the primary problem is slow onset of execution of movement; therefore changing motor patterns (e.g., switching from walking to turning) can be quite difficult.

To illustrate the multiple motor control deficits, imagine a patient performing the TUG.²⁷³ The person may have difficulty accelerating to walk and decelerating to turn around and decelerating on approaching the chair and sitting down. Postural instability may be observed during transfers and turning, and a loss of balance in the backward direction without the activation of an automatic stepping response may occur. The motor control deficits exhibited in the patient with Parkinson disease are numerous and intertwined, and their severity is influenced by the progression of the disease. As mentioned earlier, the patient cannot appropriately control

the increase and decrease in the rate of force production, which is evident in the acceleration and deceleration phases of the movement. If the rate of force production is altered, the amplitude of force production may also be affected.

The person may have a decreased ability to predict and prepare the motor pattern for turning before the actual turn. There appears to be a slow initiation of the turning task. This phenomenon could be caused by an inability to sequence the motor behavior as a whole. Several researchers have observed that the person completes one movement before starting the next movement in the sequence rather than executing a smooth, continuing movement pattern.⁴⁵ Another reason for the decrease in the ability to perform this task smoothly is the patient's dependence on visual feedback. Relying more heavily on visual feedback to accomplish a task slows the movement.

The movement deficits observed may also be a result of the inability to effectively coordinate movements such as those observed between postural and motile components of the task. Postural strategies may be classified on a continuum that includes postural preparations, postural adaptations, and postural reactions.²⁷⁴ The person with Parkinson disease may not predict and make appropriate postural adjustments before the movement and may have deficits in adaptive and reactive postural responses (e.g., righting and equilibrium reactions, and adapting to environmental demands). In the case of the TUG, movement and balance strategies are assessed when the patient stands up and sits down. If the patient does not use a controlled descent into the chair but rather falls backward, what are the possible causes for the sudden descent? The patient's goal may be to land in the chair, but the preferred pattern may be to fall into the chair. The individual may not be able to predict the time and force needed to activate the muscles for a smooth descent, the individual may be deconditioned and not have the strength or endurance to perform a smooth descent, or the individual may not have the balance strategies required to perform this maneuver.

The patient with Parkinson disease is one example of a patient with a neurological condition that affects motor output and control. Regardless of the diagnosis, all aspects of motor control need to be examined, and activity-based tests must be conducted to determine how the impairments interact to affect the execution of functional tasks. A few key deficits in gross and fine motor control and postural control are examined in this example. It is not within the scope of this chapter to present all the motor and postural control deficits but to highlight the complexity of patients with neurological pathology. Accurate identification of motor control problems in patients assists the therapist and the patient in the development of realistic functional goals and effective intervention programs.

Abstract: This chapter introduces the reader to basic concepts of motor control, motor learning, and neuroplasticity.

Key words: motor control theory, motor learning, neuroplasticity

The Limbic Network: Influence Over Motor Control, Memory, and Learning*

Marcia Hall Thompson and Darcy A. Umphred

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe the structures of the limbic network.
2. Understand the complexity of the limbic network and the influence of the limbic network on both behavior and function.
3. Describe the behavioral responses directly and indirectly influenced by the limbic network.
4. Identify signs of both positive and negative limbic network influence on observable behavior, motor learning, neuroplasticity, and functional responses.
5. Identify patient populations with the potential for negative limbic network influence over observable behavior, motor learning, and ultimately functional outcome.
6. Differentiate between limbic-driven motor control responses and frontal, cerebellar, and basal ganglia motor regulation of motor responses.
7. Describe the role of the limbic network on both declarative and procedural learning.
8. Describe physical therapy examination procedures or tests and measures that could identify the presence of limbic network involvement requiring intervention and establish a responsive intervention baseline.
9. Describe interventions or program modifications with potential to improve motor learning through integration of limbic network treatment techniques into current intervention models.
10. Understand the influence of the therapist over the limbic network and behavioral and functional responses.

INTRODUCTION

Our understanding and respect for the limbic network has expanded since the publication of the sixth edition, particularly when analyzing emotions, behavior, learning, and their influence on activities and participation in normal personal and societal roles. At no time has this understanding been more critical, with the prevalence of known mental health challenges faced within our country. In the United States, 18.3%, or 44.7 million adults, experience mental illness (AMI) or a mental, behavioral, or emotional disorder each year.¹ This represents approximately one in five adults, which theoretically could reflect one to two patients of a given therapist's treatment load per day. Beyond those mental health disorders that can be considered functional disorders of the limbic system, the prevalence of key central

nervous system (CNS) disorders, in which the structures of the limbic network are involved, is also high, including patients with acquired brain injury (ABI, such as concussion or traumatic brain injury [TBI]), cerebrovascular accident (CVA), tumors, inflammatory disorders, Alzheimer disease, Parkinson disease, and vestibular disorders. Clearly, the prevalence of coincident limbic system impairment in our patients may therefore be substantial within the practice of any physical therapist.

This chapter has been prominently positioned within this textbook on basic neurological rehabilitation. Traditionally, the limbic system may have only been discussed within a basic science course of neuroanatomy and neurophysiology. In other curricula, the role of the limbic system in declarative memory and emotional responses may be presented as part of a discussion on behavior or cognitive function within a psychology course. Yet today, motivation and attention are stressed and accepted as key factors in neuroplasticity and motor learning.²⁻⁴

*Videos for this chapter are available at studentconsult.com.

Therapists are familiar with the need to prioritize primary body system impairments as they relate to a movement disorder. Moreover, they are familiar with the need to individualize treatment to the primary impairment(s) identified through the evaluation process. However, they are less comfortable with those “other systems” encountered as Doctors of Physical Therapy or Occupational Therapy in their role as functional diagnosticians. The profession’s acceptance of the foundational, integrated role of the cardiopulmonary system to the function of all other systems has advanced, and the acceptance of the role of the limbic system(s) needs to be similarly advanced, given the current evidence illuminating the role of the limbic network in motor output, control, and learning. Coincident is the opportunity to identify, develop, and validate requisite screening and examination tools that help physical therapists to determine the state of the limbic network and its implications for diagnosis, prognosis, and treatment planning. This chapter is intended to continue to advance our understanding of and respect for this complex, integrated system, such that its contribution is considered within the evaluation of every patient regardless of setting or diagnosis.

This chapter is designed to address this opportunity regardless of experience, from the student learner to the more seasoned clinician. For the student learner, the first section of the chapter is an overview of the limbic network and a discussion of limbic behavior and how to begin to differentiate true motor responses from those entangled in limbic interactions. For the therapist learner desiring ongoing clinical mastery, the second section delves into the anatomy and physiology of the limbic network and the the biology of learning and memory, neurochemistry, and neuroplasticity. The third section discusses the immediate relevance of this material to both the student and the practicing clinician—how can we apply our understanding of the limbic network to our patient assessments, treatment, environment, and interactions? In other words, how might it change what we do as rehabilitation professionals “come Monday morning”? And finally, in the last section, current advances and future research possibilities in the role of the limbic network and its impact on the professional roles of physical and occupational therapists are explored.

THE LIMBIC NETWORK

Our discussion must begin with a working definition of the limbic network and an overview of its function. It is not easy to find a generally accepted definition of the “limbic network or complex,” its boundaries, and the components that should be included. Mesulam⁵ likens this to a 5th century BC philosopher’s quotation: “the nature of God is like a circle of which the center is everywhere and the circumference is nowhere.” Brodal⁶ suggests that functional separation of brain regions becomes less clear as we discover their interrelatedness through continuing research. He sees the limbic network reaching out and encompassing the entire brain and all its functional components and sees no purpose in defining subdivisions. Although the anatomical descriptions of the limbic network may vary from author to author, the functional significance of this system is widely acknowledged in defining human behavior and behavioral neurology.⁷

Morgane and colleagues describe the limbic network as both an “anatomical entity as well as a physiological concept.” Historically termed a limbic *system*, more current evidence suggests it to Limbic *network* comprises several emotional, behavioral, learning, and memory neuroanatomical subsystems. The term “limbic *cortex*” refers to only an anatomical part of the network and the two C-shaped gyri surrounding the corpus callosum, specifically comprising the cingulate gyrus, the parahippocampal gyrus, and the olfactory lobe.

Brooks⁸ divided the brain anatomically and functionally into a limbic brain and a nonlimbic somatomotor brain, Fig. 4.1 with the somatomotor portion involved in both the perception of afferent sensory input and the generation of efferent motor output. Historically, the limbic brain was seen as primitive and essential for survival, sensing the “need” to act.⁸ Today, the limbic network is considered in evolutionary terms as an older brain system that provides fundamental support (alertness, motivation, memory, and learning) to enable the phylogenetically newer brain systems to regulate more complex behaviors, movement, and function. Thus the overall purpose of the limbic network is to initiate need-directed motor activity for survival based on experience, through its neuronal connections up to the frontal lobe (intentional responses) or down to the brain stem (automatic responses), thus regulating motor output.

We will discuss the neuroanatomy and neurobiology as they relate to both function and dysfunction of the limbic network later in this chapter, but briefly outline the major interacting systems, structures, and neurotransmitters here. The limbic network can generally be thought to include two system divisions: the prefrontal-limbic “forebrain” system (emotional and behavioral) and the limbic mid-brain (motor control and movement). The major structures comprising the network include the limbic cortex (anterior cingulate cortex/gyrus [ACC]), parahippocampal gyrus, and olfactory lobe), the prefrontal cortex, amygdalar complex, limbic thalamus, stria medullaris (epithalamus), hippocampus, nucleus accumbens (NAc), the ventral tegmental area (VTA), and midbrain raphé nuclei of the basal ganglia. These structures are primary components of the network as well as essential neuromodulators upon the network. As one example, the ACC, amygdala, and hippocampus serve to connect the limbic network and the prefrontal cortex, while the network is modulated by the hypothalamus, basal ganglia, and midbrain. Given the broad structural components, the neurotransmitters of the system are also extensive and include serotonin, norepinephrine (NE), dopamine, and acetylcholine. As one major example, dopamine plays a critical role in the motivation to move as well as motor function (Fig. 4.2).^{9,10}

This summary does not account for the direct and indirect influences of the limbic network upon other body systems. In the past, review of the literature on the limbic network was limited to

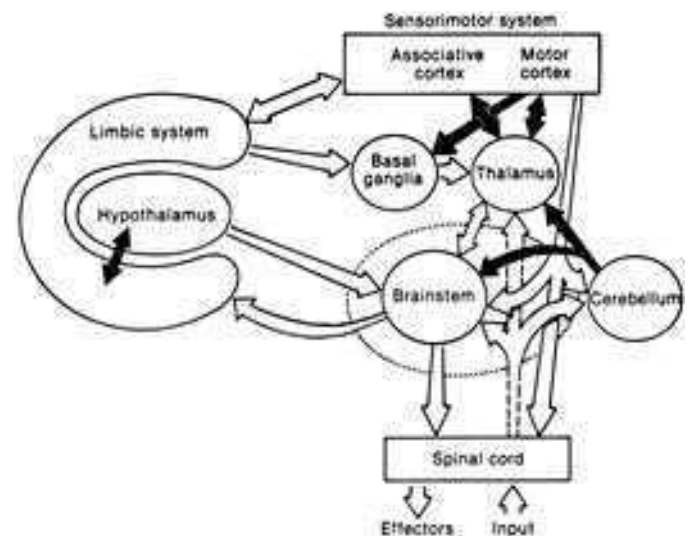

Fig. 4.1 Divisions and interconnections between the limbic and nonlimbic cortices (sensory and motor areas).

Fig. 4.2 Interlinking Neuron Network Within the Limbic Network. (Adapted from Kandel ER, Schwartz JH, Jessell TM. *Principles of Neural Science*. 4th ed. New York: McGraw-Hill; 2000.)

investigating potential interactions of other systems with nuclei within the limbic network. This is no longer the case, as neuroscience research has helped to identify the critical nature of behaviors modulated or influenced by the limbic network. Based on research at a cellular level,^{11–13} a consciousness level,^{14–17} a bodily systems level,^{18–20} and a quantum level^{21–23} it is now clear that many systems are affected by the complex limbic network, and most notably, the motor systems.^{24–31} A patient example of the complex and critical interactions between the limbic network, body systems, and its influence upon human behavior can be considered in Clinical Case 4.1.

The Limbic Network “MOVES” Us

Moore³² eloquently describes the limbic network as the area of the brain that moves us. The word *MOVE* can be used as a mnemonic for the functions of the limbic network that drive movement. As seen in Fig. 4.3 the *M* (motivation, memory) depicts the drive component of the limbic network; the *O* (olfaction) refers to the sense of smell and of other sensory inputs that drive motor, emotional, or visceral responses; the *V* (visceral) outlines the visceral and autonomic responses that serve as an indicator of the limbic network state; and *E* (emotional), the value or significance of individual feelings, attitudes, and beliefs that possess emotional significance for attention and learning.

Motivation

“The most powerful force in rehabilitation is motivation.”²⁶ Without motivation the individual will not attend to the task and the neurobiology of learning will not occur. Motivation drives our motor system to develop motor programs that will enable us to perform and execute movements with the most efficient patterns available. In addition, motivation drives our ability to integrate the somatosensory map of functional skills² (cortical) and attention (limbic) necessary to process both sequential and simultaneous components (parts) of the movement task to be learned (whole).

Moore³² considers motivation and memory as part of the MOVE system. Esch and Stefano³³ link motivation with reward, illustrating how the limbic network “learns” through repetition and reward. They state that the concept of motivation includes drive and satiation,

CLINICAL CASE 4.1

A patient example of limbic interactions can be found in a case description of a middle-aged woman admitted to the intensive care unit (ICU) with multiple pelvic fractures and diagnosed with severe internal bleeding, kidney failure, pneumonia, pulmonary emboli, and severe clotting in the lower extremities. The physician took her husband aside to let him know that she was going to die, to which her husband replied, “I understand. Juggling one system problem is easy, juggling two systems takes a little practice, and three-system involvement may challenge the best medical skill. She is presenting four or five body system failures, and you are sure no one can juggle that many problems.” The doctor said yes, and the patient’s husband then said, “Please keep juggling and don’t worry about me, because if you do, I would then be one more ball to juggle.” And it did seem that every time the doctors got a handle on a body system problem, another system would fail. She required services from an endocrinologist, infection control specialists, interventional radiologists, a pulmonologist, a hematologist, a vascular surgeon, an internal medicine specialist, a urologist, and a nephrologist. Each specialist shared his or her limited experience with a complex clinical problem like this and that there was nothing in the literature to help his or her respective understanding. After 2{1/2} months in the ICU, the woman survived. The physician who had foretold her death met again with the patient and her family. He stated, “How are you still alive? I know what we did medically, but that was not enough to keep you alive.” And he was right. No model within each respective field could account for her recovery. However, the piece not considered within her medical management was the beliefs and spiritual strength of the patient and her family, a positive limbic network influence on the function of each failing body system.

goal-directed behavior, and incentive. They recognize that these behaviors maintain homeostasis and ensure the survival of the individual and the species. Motivation mediated by limbic (forebrain) and subcortical structures forms an interlocking neural network with the cognitive representation within the frontal regions and thus plays an important role in movement execution.^{26,34}

Memory

The brain stores sensory and motor experiences as memory. Current theory supports a “dual memory system,” each utilizing different pathways in the nervous system. Terms such as *verbal* and *nonverbal* and *intrinsic* and *extrinsic* have been given to these two memory systems. For this discussion, two specific categories of learning—*procedural* and *declarative*—will be used, although in today’s neuroscience environment, the terms *implicit* and *explicit* memory are used as frequently. The limbic network plays a key role in both declarative and procedural aspects of memory and learning.^{35–38} Before the limbic network’s impact on learning and memory can be delved into, a clear understanding of what is meant by these functions is needed. Declarative (explicit) memory entails the capability to recall and verbally report experiences. This recall requires deliberate conscious effect, whereas the procedural counterpart is the recall of “rules, skills, and procedures (implicit),”³⁹ which can be recalled unconsciously. Both categories of learning have been correlated to limbic function.^{40–42} These systems do not operate autonomously, and many therapeutic activities seem to combine these memory systems to achieve functional behavior.³⁹ The limbic amygdala and hippocampal structures and their intricate circuitries play a key role in the declarative aspect of memory.^{35–38} The hippocampus may be more concerned with sensory and motor signals relating to the external environment, whereas the amygdala is related

Limbic Network Function – MOVE

Memory and motivation: drive

- Memory: attention and retrieval, declarative learning
- Motivation: desire to learn, try, or benefit from the external environment

Olfaction

- Only sensory system that does not have to go through the thalamus as a second-order synapse in the sensory pathway before it gets to the cerebral cortex

Visceral (drive: thirst, hunger, and temperature regulation; endocrine functions)

- Sympathetic and parasympathetic reactions
- Hypothalamic regulation over autoimmune system
- Peripheral autonomic nervous system (ANS) responses that reflect limbic function

Emotion: feelings and attitude

- Self-concept and worth
- Emotional body image
- Tonal responses of motor system affected by limbic descending pathways
- Attitude, social skills, opinions

Fig. 4.3 Limbic Network Function—MOVE.

more to those of the internal environment. They both contribute in relation to the significance of external or internal environmental influences.^{43,44–49} Procedural learning is vital to the development of sequence-specific learning and motor control. Acquisition and learning (memory) of new motor tasks involves dopaminergic projections from the VTA to the primary motor cortex for motor execution and initiating neuroplastic change, and from the NAc for the reward and reinforcement of that motor learning. The dorsal prefrontal cortex and the ACC are more active in the skill acquisition phase of motor learning than in the execution of pre-learned motor skills, consistent with the need for motivation as a requisite. Consolidation and retention occur as information passes through the limbic network nuclei; it is stored in cortical areas and retention and retrieval occurs without limbic involvement.^{10,50–54}

Olfaction

The *O* refers to olfaction, or the incoming sense of smell, which exerts a strong influence on alertness and drive. This is clearly illustrated by the billions of dollars spent annually on perfumes, deodorants, mouthwashes, and soap as well as scents used in stores to increase customers' motivations to purchase. Olfactory input first synapses within the olfactory bulb. Subsequently, afferents travel to and synapse within the cerebral cortex without second-order synapse in the thalamus, as well as with structures within the limbic network. Although collaterals do project to the thalamus, unlike all other sensory afferent information, olfaction does not need to use the thalamus as a relay center to access the cortical structures.^{39,55} Olfactory input that enters the limbic network may be used to calm or to arouse the patient, based upon the specific odor selected; for example, the use of aromatherapy to promote muscle relaxation prior to therapeutic massage.^{56,57} Thus olfaction indirectly influences motor output via the limbic network's influence on muscle tone through brain stem modulation of the indirect or "emotional" motor pathways. Through brain stem connections to the reticular activating system, olfaction can have a powerful effect upon alertness. The evaluation of this system seems even more critical when a patient's motor control system is locked, with no volitional movement present. Research has shown that retrieval processing and retrieval of memory have a distinctive emotionality when they are linked to odor-evoked memories.^{58,59}

Beyond olfaction, input from the other senses may not be reaching the cortical levels, such as in patients with lesions in the internal capsule or thalamus, and the patient may have a sensory-deprived environment. If the sensory input to the patient is deprived, the limbic

network may place the patient in a "limbic low" state and the patient may withdraw physically or mentally, lose focus or attention, decrease motivation, and demonstrate a decrease in motor tone and output. Conversely, if the sensory input to the patient is excessive, whether through internal (patient/systems generated) or external (therapist, environment generated) feedback, the limbic network may go into an alert, protective mode, or "limbic high" state. The patient may withdraw physically or mentally, lose focus or attention, decrease motivation, and become frustrated or even angry. The resultant overload on the reticular system may be the reason for the shutdown of the limbic network versus dysfunction of the limbic network itself. Both are part of the same neuroloop circuitry and as such, in either situation, the CNS will not function optimally and learning will diminish. All these behaviors may be expressed within the hypothalamic-autonomic system as motor output, no matter where in the loop the dysfunction occurs. Having a functional understanding of the neuroanatomical sectors and their relationships with each other helps therapists unravel some of the challenging patient presentations after CNS insult.^{60,61}

Therapists often try to increase motor activity through sensory input; however, they must cautiously avoid indiscriminately bombarding the sensory systems. The limbic network may demonstrate overload from stimulation at the same time the spinal motor generators reflect inadequate activation. One way that a therapist might assess for potential limbic overload would be to closely monitor the autonomic nervous system (ANS) responses, such as blood pressure, heart rate, internal temperature, and sweating, versus observing or measuring muscle tone.

Visceral or Autonomic

The *V* represents visceral or autonomic drives to movement. At the heart of the limbic network is the hypothalamus, the primary regulator of autonomic and endocrine functions. The hypothalamus controls and balances homeostasis of the internal and peripheral (skin) organ systems through regulation of sympathetic and parasympathetic reactions. Protective drives such as thirst, hunger, temperature regulation, and sexuality are controlled by this system.³⁹ However, the hypothalamus is also an important modulator of the limbic network, given its direct connections with the limbic midbrain,³⁹ the amygdala, and hippocampus, as well as close reciprocal interaction with most centers of the cerebral cortex, brain stem, and spinal cord. As such, the fact that autonomic and somatomotor responses controlled by the hypothalamus are closely aligned with the expression of emotions^{62–65} and strong emotions and emotionally linked memories can change or support movement has clearly been established.⁶⁶

Of clinical importance is that autonomic responses may reflect the presence of a limbic network imbalance that may go unnoticed by therapists. For example, patients with unstable body temperature regulation may exhibit signs of hypothalamic-pituitary involvement and overactivity.³⁹ Similarly, severe sweating of the palms or increased oral motor activity may be the first sign that the stress of an activity is becoming overwhelming to a patient. A therapist must continually monitor the patient's response behaviors to ascertain that they reflect true or desired motor output and not limbic influences over the motor system.

Emotional

E relates to emotions: the feelings, attitudes, and beliefs that are unique to that individual. These beliefs include psychosocial attitudes and prejudices, ethnic upbringing, cultural experiences, religious convictions, and concepts of spirituality.⁶⁷ When stimuli or tasks are endowed with emotional value or significance, a patient's attention is drawn to those with emotional significance, selecting these for attention and learning. Emotionally charged events will leave a more significant impression and enhance subsequent recall. All these aspects of emotions are strongly linked to the amygdaloid complex of the limbic network, and activity within the frontal lobe.^{34,68,69} As a primary emotional center, it regulates not only our self-concept but our attitudes and opinions toward our external environment and the people within it. One aspect of self-concept is the emotional component of body image. A second self-concept deals with the patient's perceived worth or value to society, the world, and their role within it.⁷⁰ Both of these attitudes may be changed through enhanced mood or positive experience, enabling emotions to influence what is perceived and learned via the amygdala's reciprocal connections with the cortex.

Preconceived attitudes, social behaviors, and opinions have been learned by filtering the input through the limbic network. If new attitudes and behaviors need to be learned after a neurological insult, the status of the amygdalar pathways seems crucial. Damage to these limbic structures may prevent learning⁷¹; thus socially maladaptive behavior may persist, making the individual less likely to adapt to the social environment. It is often harder to change learned social behaviors than any other type of learning.^{72–75} Because our feelings, attitudes, values, and beliefs drive our behaviors through both attention and motor responses, the emotional aspect of the limbic network has great impact on our learning and motor control. If a patient is not motivated to participate and places little value on a motor output, then low complacency results, and little learning will occur.^{76–78} On the other hand, if a therapist places an extremely high value on a motor output as the expression of motor control success without interlocking that with the patient's sense of control, the behavioral response (limbic influence) may lead to inconsistency, lack of compliance/participation, and thus lack of motor learning and carryover.⁷⁶ In addition, it can cause the patient significant stress, which can prevent recovery and in some cases, cause disease.⁷⁹

Repeated experience of reinforcement and reward leads to learning, changed expectancy, changed behavior, and maintained performance.⁸⁰ Emotional learning through the limbic network is very hard to unlearn once the behavior has been reinforced over and over.^{81,82} For that reason, motor behavior that is strongly linked to a negative emotional response might be a very difficult behavior to unlearn. Repetition of motor performance with either the feeling of emotional neutrality or the feeling of success (positive reinforcement) is a critical element in the therapeutic setting. Consistently making the motor task more difficult just when the patient feels a need to succeed may decrease positive reinforcement or reward, lessen the patient's motivation to try or participate, and decrease the probability of true independence once the

patient leaves the clinical setting. When pressure is placed on therapists to produce changes quickly, strategic and meaningful repetition and thus long-term learning are often jeopardized. Rapid progression based solely upon therapist/clinic requirements may impede progress and yield a dramatic effect on the quality of the patient's life and the long-term treatment effects once he or she leaves the medical facility. Motor control theory (see Chapter 3) coincides with limbic research regarding reinforcement. Inherent feedback within a variety of environmental contexts allowing for error with correction leads to greater retention.⁸³ Repetition or the opportunity to practice a task (motor or cognitive) in which the individual desires to succeed will lead to long-term learning.⁸⁴ Without practice or motivation, the chance of successful motor learning is minimized. This continues to highlight the importance of both therapeutic environment and therapeutic alliance, which we will discuss in greater detail.

Multiple nuclei and interlinking circuits of the limbic network play crucial roles in behavioral and emotional changes^{85–87} and declarative memory.^{9,86–102} The loss of any link can affect the outcome activity of the whole circuit. Thus damage to any area of the brain can potentially cause malfunctions in any or all other areas, and the entire circuit may need reorganization to restore function.

THE NEUROSCIENCE OF THE LIMBIC NETWORK

The limbic network comprises a group of nuclei, tracts, and cortical areas that lie beneath the cortex and surround the thalamic structures. All of the areas of the limbic system are interconnected with each other through both simple and complex reverberating neural pathways. There are extensive connections between the limbic system and the hypothalamus and brain stem structures, these together play a substantial role in the regulation of homeostasis and autonomic control. Similarly, there are extensive connections to the structures of the basal ganglia, thus influencing motivation to move, as well as initiation and modulation of motor output.¹⁰³ A limited overview of the anatomy and physiology of the limbic network is presented in the following sections, designed to guide our understanding of the limbic network. The complexities of the network and its complex circuitry can be found upon deeper review of primary and secondary evidence.^{7,39,104–108}

Neuroanatomy

Basic Structure and Function

Broca¹⁰⁹ first conceptualized the anatomical regions of the limbic lobe as forming a ring around the brain stem. Today, neuroanatomists do not differentiate an anatomical lobe as limbic, but rather refer to a complex network that encompasses cortical, diencephalon, and brain stem structures.³⁹ This description is less precise and includes (but is not limited to) the orbitofrontal and prefrontal cortex, hippocampus, parahippocampal gyrus, cingulate gyrus, dentate gyrus, amygdaloid body, septal area, hypothalamus, and some nuclei of the thalamus.^{39,110–114} Anatomists stress the importance of looking at the inter-related structures, pathways, and functional loops within the complex limbic region.^{85,115}

The limbic network can be best visualized as consisting of both cortical and subcortical structures, with the hypothalamus located at the central position (Figs. 4.4 and 4.5). The hypothalamus is surrounded by a circular alignment of the subcortical limbic structures linked with one another and the hypothalamus. These subcortical structures include the amygdalar complex and the hippocampal formation as the major input structures, and the anterior nuclei of the thalamus (limbic thalamus), as well as the NAc, the fornix, and the septal nuclei areas. The septal area projects to emotion-generating

Fig. 4.4 Anatomy of the Limbic Network: Schematic Illustration.

areas and plays an important role in feelings of social connectedness and bonding. The fornix contains major efferent fibers from the hippocampus, as well as carrying some afferent fibers to the hippocampus from structures in the thalamus and basal forebrain.¹¹⁶ The cingulate fasciculus carries amygdalic and hippocampal projections to and from the prefrontal cortex, linking many basic perceptual strategies, such as body schema, hearing, vision, and smell, to the emotional and learning centers of the limbic network.¹¹⁷

The subcortical structures are again similarly surrounded by a ring of cortical structures collectively called the *limbic cortex*, which includes the frontal cortex, the ACC/gyrus, the parahippocampal gyrus, and the uncus. The limbic network circuitry contains parallel and reverberating connections between the subcortical and limbic cortex structures, the anterior nuclei of the thalamus (*limbic thalamus*), as well as to the limbic forebrain NAc and limbic midbrain structures: VTA and midbrain raphé nuclei of the basal ganglia. There

are neuroanatomists who include the olfactory system and the basal forebrain area (cognition and memory) within the network as well (see Fig. 4.5). Olfaction is included as part of a “mesolimbic” system, linking olfaction to the midbrain structures of the NAc and the VTA.

Vitally linked to the limbic network is the excitatory reticular activating system and other brain stem nuclei of the midbrain. Some consider components of the midbrain a very important region for emotional expression.⁹² Derryberry and Tucker⁹² found that attack behavior aroused by hypothalamic stimulation is blocked when the midbrain is damaged and that midbrain stimulation can be made to elicit “attack behavior” even when the hypothalamus has been surgically disconnected from other brain regions. Recent research has clearly identified the neurochemical precursors to this aggressive behavior.^{39,62,118–120} This “septo-hypothalamic-mesencephalic (mid-brain)” continuum, connected by the medial forebrain bundle (see Fig. 4.5), is suggested as vital to the integration and expression of emotional behavior.¹²¹ The linking of other brain structures to emotions came initially from the work of Papez,¹²² who first identified the hippocampal-fornix circuit. He saw this as a way of combining the “subjective” cortical experiences with the emotional subcortical (hypothalamic) contribution. Earlier, Broca¹⁰⁹ labeled the cingulate gyrus and hippocampus “circle” as “the great limbic lobe.” Today, the concept of the limbic network and its interaction with sensory inputs and motor expression has become extremely complex.¹²³ Mood can change motor output, and motor activity can change mood.^{124,125}

Klüver and Bucy¹²⁶ linked the anterior half of the temporal lobes and the amygdaloid complex to the limbic network. They showed changes in behavior, with specific loss of the amygdaloid complex and anterior hippocampus input, resulting in (1) restless overresponsiveness, (2) hyperorality, or examining objects by placing them in the mouth, (3) psychic blindness of seeing and not recognizing objects and the possible harm they may entail, (4) sexual hyperactivity, and (5) emotional changes characterized by loss of aggressiveness. These changes have been named the *Klüver-Bucy syndrome*.¹²⁷ Myriad connections link the amygdala to the olfactory pathways, the frontal lobe and cingulate gyrus, the thalamus, the hypothalamus, the septum, and

Fig. 4.5 Limbic network circuitry with parallel and reverberating connections and with medial forebrain bundle.

the midbrain structures of the substantia nigra, locus coeruleus, periaqueductal gray matter, and the reticular formation. The amygdala receives feedback from many of these structures it projects to by reciprocal pathways.

At the heart of the limbic network is the hypothalamus. The hypothalamus, in close reciprocal interaction with most centers of the cerebral cortex and the amygdala, hippocampus, pituitary gland, brain stem, and spinal cord, is a primary regulator of autonomic and endocrine functions and controls and balances homeostatic mechanisms. Autonomical and somatomotor responses controlled by the hypothalamus are closely aligned with the expression of emotions.^{62–65}

In the temporal lobe, anteromedially is the amygdaloid complex of nuclei, with the hippocampal formation situated posterior to it. Located medial to the amygdala is the basal forebrain nuclei, which receive afferent neurons from the reticular formation, the hypothalamus, and the limbic cortex. From this basal forebrain, efferents project to all areas of the cerebral cortex, the hippocampus, and the amygdaloid body, providing an important connection between the neocortex and the limbic network. These nuclei represent the center of the cholinergic system, which supplies acetylcholine to limbic and cortical structures involved in memory formation.

Interlinking the Components of the System

The limbic network has many reciprocating interlinking circuits among its component structures, which provide for much functional interaction as well as allow for continuing adjustments with continuous feedback (see Fig. 4.2).^{39,62} Neuroimaging has helped reduce uncertainty concerning the anatomical pathways, and neurochemistry has widened the possibilities of variations across synaptic connections.^{128–130} The largest of the interlinking pathways is the fornix, providing efferent and afferent connections to the hypothalamus and connecting the limbic network structures.¹³¹ The stria terminalis, another of the linking circuitry components, originates in the amygdaloid complex and follows a course close to the fornix to end in the hypothalamus and septal regions. The amygdala is also directly connected to the septal region by a short pathway, the *diagonal band of Broca*. These pathways serve as foundation for emotion memory and bonding. A third pathway, the uncinate fasciculus, connects the amygdala and the orbitofrontal cortex serving as a foundation for decision making.^{39,132,133}

The medial forebrain bundle and other parallel circuits (see Fig. 4.5) are vital connections of the limbic network.¹³⁴ These pathways course through the lateral hypothalamus to terminate in the cingulate gyrus in its ascending limb and in the reticular formation of the midbrain in its descending part; these pathways have strong interconnections and control over the periaqueductal gray area, and thus influence upon descending modulation of pain signals.¹³⁵

Commissural fibers from the vestibular nuclei run through the lateral medullary reticular formation (parvicellular reticular formation [PCRF]) and connect the vestibular nucleus to the reticular formation. The PCRF and the solitary nucleus receive both vestibular and nonvestibular input from the cortex, cerebellum, and the limbic network and are considered functionally as the “vomiting center.” It also receives heavy input from the chemoreceptor region in the floor of the fourth ventricle (area postrema), resulting in vomiting in response to noxious chemicals. The PCRF also projects fibers to the parabrachial nuclei that contain the respiratory centers and to the hypoglossal nucleus to activate and coordinate the protective gag reflex.¹³⁶ Visceral autonomic input from multiple sources, including the vestibular nuclei, converges on the parabrachial nucleus. The locus coeruleus and autonomic brain stem nuclei also receive vestibular nuclear input.^{137–141} Thus cardiovascular activity and respiration

(brain stem–mediated autonomic activity), as well as vomiting, are highly influenced by the status of the vestibular system and the limbic system. This helps us to understand how cold to the neck or forehead, pressure to the wrist, or taste or olfactory input of ginger depresses autonomic reactions and nausea in response to chronic vestibular or interneuronal connection problems. There are three different types of drugs that neuroanatomically suppress or modulate vestibular input and thus have a dramatic effect on dizziness and nausea.¹⁴² Additionally, functional magnetic resonance imaging (fMRI) confirms that there is increased activity within the inferior frontal cortex when nausea is induced by either vestibular stimulation or ingestion of an emetic.¹⁴³ This research supports that there is a strong interconnection among vestibular input, limbic nuclei, and autonomic responses.¹⁴⁴

There are also connections between the parabrachial nucleus and higher brain centers, including the amygdala, which is known to be critical in the development of conditioned avoidance, such as found in agoraphobia, as an example. Thus vestibular input results in a sensory stimulus that may induce a state of general autonomic discomfort as a trigger of avoidance that precedes the onset of a panic attack.^{14,136,138,144} Vestibular firing rates are further modulated and regulated by the dorsal raphe nucleus of the midbrain and rostral pons. The dorsal raphe nucleus is the largest producer of serotonin in the brain, which further explains the significant linkage between vestibular dysfunction and anxiety, and sleep deprivation and anxiety.¹⁴⁵

Additionally, animal research has shown that bilateral vestibular lesions result in changes in the morphology and function of the hippocampus, specifically associated with hippocampal atrophy. The hippocampus contributes to spatial and gravitational orientation, cognition, learning, and memory (spatial and nonspatial), which are symptoms and functional limitations often identified by individuals with vestibular dysfunction.^{146–154}

Central pattern generators found in the caudal brain stem and the spinal cord are understood to generate fixed rhythmic motor output patterns such as biting and swallowing. These motor tracts receive direct and indirect afferent information from the periphery and are part of the interneuronal projection system to motor neurons, contributing to the activity within the motor neuron pool.^{155–157} Their output is linked to the proximal (axial) and distal motor control system through the ventromedial and lateral descending motor pathways, modulated by a variety of structures, and regulated by the prefrontal area.^{135,158–162} Their output is also strongly linked to the limbic network, resulting in an emotional context linked to the motor output.^{158,163} The functional motor implication of these tracts is determined by whether the fibers project as part of the medial or lateral descending system. The medial components of this system originate within the medial portion of the hypothalamus, and the lateral portion originates in the limbic network (lateral hypothalamus, amygdala, and bed nucleus of the stria terminalis). The medial system, through the locus coeruleus, periaqueductal gray matter, and raphe spinal pathways, contributes to the general level of activity of both somatosensory and motor neurons. As such, the limbic network can have an effect on both somatosensory input and motor output. A change in activity in this system can alter the level of excitation at the first order synapse, thus altering the processing or sensitivity to that afferent information as it enters the nervous system. Similarly, it can alter the level of motor activity and thus motor output or expression, which may account for the increase in extensor muscle tone and extension seen with anger and the flexion and decrease muscle tone seen with depression. The lateral system seems to be involved in more specific motor output related to emotional behavior and may explain some of the loss of fine motor skill when one is placed in an emotional situation such as competition. The clinical relevance of this information highlights the

need during patient examination to differentiate whether observed postural/muscle tone abnormalities are deficits within the motor system itself, or are a result of limbic system influence on that motor output. The clinician would need to observe and assess the emotional state, as well as how it changes with patient mood or activity, or with modification of the therapeutic environment. If the abnormal state consistently alters with mood shifts of control of emotional variables, then limbic involvement causing motor control disturbances could be identified. Human social behavior requires motor expression, yet that behavior is driven through the limbic circuitry.^{164–167}

These links enable the limbic network itself and the non-limbic-associated structures to act as one neural task system. No portion of the brain, whether limbic or nonlimbic, has only one function.³⁹ Each area acts as an input-output station. At no time is it totally the center of a particular effect, and each site depends on the cooperation and interaction with other regions. The concept of neuroplasticity within the motor system and motor learning is well understood by physical therapists, but less understood is the integration of this emotional system interaction with sensory and motor components of motor performance and learning. Research is identifying that these neurocircuitries are present and interactive, and therefore should be considered.¹⁶⁴

Neurochemistry

Discussion of the limbic network's intricate regulation of many neurochemical substances is not within the scope of this chapter. Yet therapists need to appreciate how potent this system can be with respect to the influence of neurochemical imbalance or loss on motor control, memory, or motor learning. The amount of research reflecting new understanding of the role of neurochemistry in brain function highlights the importance of frequent review of the literatures.^{168–176}

More than 200 neurotransmitters have been identified within the nervous system.³⁹ The hypothalamus, the physiological center of the limbic network (see Figs. 4.1 and 4.5), is involved in neurochemical production and is essential for the passage of information along specific neurochemical pathways within the network. Squire and colleagues¹⁷⁷ consider it the major motor output pathway of the limbic network, which also communicates with every part of this system.

Neuropeptides

The importance of neuropeptides is being recognized relative to the limbic network's role in the regulation of affective and motivated behaviors.^{34,39,135,178–180} Certain nuclei of the hypothalamus produce and release these neuroactive peptides, which have long-acting effectiveness as neuromodulators, controlling the levels of neuronal excitation and effective functioning at the synapses. Through their long-lasting effects, they regulate motivational levels, mood states, and learning. These peptide-producing neurons extend from the hypothalamic nuclei to the ANS and to the nuclei of the limbic network, where they modulate neuroendocrine and autonomic activities. Lesions in the medial hypothalamus affect hormone production and thus alter regulation of many hormonal control systems.³⁹ For example, head injury may lead to medial hypothalamic lesions general hyperactivity, signs of hostility after minimal provocation, as well as huge weight gain resulting from the increase of insulin in the blood (increasing feeding and converting nutrients into fat) and loss of satiety.

The nuclei of the amygdaloid complex represent the center of the cholinergic system, which supplies *acetylcholine* to limbic and cortical structures involved in memory formation. Depletion of acetylcholine in patients with Alzheimer disease relates to memory loss.^{135,181–183,184}

Monoamines

The monoamines play a critical role in many aspects of function and dysfunction within the limbic network. As a quick overview, the noradrenergic system (noradrenaline and adrenaline) plays a significant general role in the body's response to stressors. In the brain, the noradrenergic system is located primarily in the locus coeruleus and plays a significant role in modulating behavioral and cognitive function within the cortex.¹⁸⁵ The adrenal corticosteroids also contribute to modulation of long-term potentiation within the hippocampus.¹⁸⁶ Novelty or reward-seeking and motivational behaviors of the limbic network seem to be dopamine dependent,¹⁸⁷ whereas coordination of circadian body rhythm and sleep (critical for motor performance and learning) is influenced by levels of all of the monoamine neurotransmitters.^{188–190}

A functional deficiency in monoamines, especially *serotonin*, is hypothesized to be a primary cause of depression.^{191,192} The serotonin systems originate in the rostral and caudal raphe nuclei in the midbrain. Ascending serotonergic tracts start in the midbrain and ascend to the limbic forebrain and hypothalamus; they are concerned with mood and behavior regulation. Damage to the ascending pathways contributes to depression as a mood disorder. In addition, newer evidence has highlighted the important role serotonin plays in motor control.¹⁹³

Descending pathways from the raphe nuclei to the substantia gelatinosa are involved in pain mechanisms. Through a complex sequence of biochemical steps, a reduction in serotonin in the raphe nuclei contributes to the increased sensitization of the presynaptic terminals of the cutaneous sensory neurons. Increased central sensitization of these terminals can lead to a hyperactive withdrawal reflex or hypersensitivity to cutaneous sensory input.³⁹ This would account for the behavior patterns seen in patients with head trauma, when the therapist sees a flexed posture with a withdrawn or depressed affect associated with an extreme sensitivity to touch or even cutaneous input from clothing, air, etc.

Lesions in the lateral hypothalamus lead to damage of *dopamine*-carrying fibers that begin in the substantia nigra and filter through the hypothalamus to the striatum of the basal ganglia. Lesions, either along this tract or within the lateral hypothalamus, lead to aphagia and hypoparousal, as well as marked passivity with decreased functioning. Decreased sensory awareness contributing to sensory neglect is also present in lateral hypothalamic lesions. Disruptions of the indirect (hypothalamic) and direct (independent of hypothalamus) pathways from the mammillary bodies to the anterior thalamus contribute highly to loss of spatial orientation and memory.¹⁹⁴ Bilateral infarcts within the mammillothalamic tract result in acute Korsakoff syndrome.¹⁹⁵

Dopamine is critical for motor cortex plasticity and motor skill acquisition and learning.¹⁹⁶ Dopamine released from the VTA in the midbrain projects to the primary motor cortex (M1) and enables motor skill acquisition.⁵² Moreover, the dopaminergic VTA neurons projecting to M1 are activated when rewards are obtained during motor skill acquisition, but not during task execution in later associative or autonomous stages of motor learning, or when rewards are not associated with performing a skilled movement. Dopamine released from the VTA to the NAc and the frontal cortex plays an important role in reward processing for motor learning.⁵¹ Furthermore, in animal study, destruction of the VTA dopaminergic neurons prevented improvements in forelimb reaching, but learning recovered on administration of levodopa directly into the M1 of these VTA-lesioned animals. Of note is that lesioning the VTA did not affect performance of an already learned skill, meaning movement execution remained intact.⁵²

It is hypothesized that the underlying pathophysiological mechanism of one form of schizophrenia involves an excessive transmission

of *dopamine* within the mesolimbic tract system.³⁹ The dopaminergic cell bodies are located in the VTA and the substantia nigra. Some of these neurons project to the limbic network, specifically to the NAc, the stria terminalis nuclei, parts of the amygdala, and the frontal entorhinal and ACC, serving to modulate the flow of neural activity through the limbic network.³⁹ The NAc may serve a critical role, acting as a filtering system with respect to affect and certain types of memory through its influence over the hippocampus, frontal lobe, and hypothalamus.³⁹

The specific roles of the *noradrenergic* pathway are numerous and affect almost all parts of the CNS. The center for the noradrenergic pathways is located within the caudal midbrain and upper pons. Its nucleus is referred to as the *locus coeruleus*. This nucleus sends at least five tracts rostrally to the diencephalon and telencephalon.³⁹ Of specific interest for this discussion are the projections to the hippocampus and amygdala, which have an excitatory effect on the regions where they terminate.³⁹ Thus the activation of this system will heighten the excitation of the two nuclei within the limbic network that are involved in declarative learning and memory. This excitation or hyperactivation may cause “overload” or impair focus of attention and learning.¹⁹⁷ Decreased activity may prevent learning and memory. Attention to task may depend on continuing noradrenergic stimulation. These tracts, travelling rostrally from the midbrain, play a key role in alertness. The correlation of alertness and attention to performance and learning of motor tasks can be demonstrated.³⁹

In conclusion, the neurochemistry of the limbic network is intricately linked to the neurochemistry of the brain and the body organs regulated by the hypothalamus. All systems within the limbic circuitry seem to be interdependent, with the summation of all the neurochemistry being the determinants of the specific processing of information. Similarly, the interdependence of the limbic network with almost all other areas of the brain and the activities of those areas at any time reflect the complexity of this system.

Neurobiology of Learning and Behavior

Strub and Black¹⁹⁸ view behavior as occurring on distinct interrelated levels that represent behavioral hierarchies. Starting at level 1, a state of alertness to the internal and external environment must be maintained for motor or mental activity to occur. The brain stem reticular activating system brings about this state of general arousal by relaying in an ascending pathway to the thalamus, the limbic network, and the cerebral cortex. To proceed from a state of general arousal to one of “selective attention” requires the communication of information to and from the cortex, the thalamus, and the limbic network and its modulation over the brain stem and spinal pattern generators.^{39,199}

Level 2 of this hierarchy lies in the domain of the hypothalamus and its closely associated limbic structures. This level deals with subconscious drives and innate instincts. The survival-oriented drives of hunger, thirst, temperature regulation, and survival of the species (reproduction) and the steps necessary for drive reduction are processed here, as well as learning and memory. Most of these activities relate to limbic functioning. If an individual or patient is in a perceived survival mode, little long-term learning regarding either cognition or motor programming will occur. Thus making the patient feel safe is initially a critical role for the therapist. This approach may require placing the therapist’s hands on the patient initially to take away any possibility of falling. The therapist would first deal with the emotional aspect of the patient’s environment and then shift to the motor learning and control component, in which the patient is empowered to practice and self-correct within the program she or he can control.

On level 3 only cerebral cortical areas are activated. This level deals with abstract conceptualization of verbal or quantitative entities. It is

at this level that the somatosensory and frontal motor cortices work together to perceptually and procedurally develop motor programs. The prefrontal areas of the frontal lobe can influence the development of these motor programs, thus again illustrating the limbic influence over the motor system.^{200–203}

Level 4 behavior is concerned with the expression of social aspects of behavior, personality, and lifestyle. Again, the limbic network and its relationship to the frontal lobe are vital. The shift to the World Health Organization International Classification of Functioning, Disability and Health (WHO-ICF) model, which reflects patient-centered therapy, has actualized the critical importance of this level of human behavior.^{204–208}

The interaction of all four levels leads to the integrative and adaptable behavior seen in the human. Our ability to become alert and protectively react is balanced by our previous learning, whether it is cognitive-perceptive, social, or affective. Adaptability to rapid changes in the physical environment, in lifestyles, and in personal relationships results from the interrelationships or complex neurocircuitry of the human brain. When insult occurs at any one level within these behavioral hierarchies, all levels may be affected.

A fifth level of limbic function may one day be recognized as the link between the hard science of today and unexplained medical mysteries of healing. Meanwhile, how might the function of the limbic system explain certain mysteries, such as why some people heal from terminal illnesses spontaneously, others heal in ways not accepted by traditional medicine,^{213,214} and others just die without any known disease or pathological condition?^{67,105,215,216} It is proposed that a characteristic of the fifth level of limbic function is the patient’s strong, emotional belief⁶⁷ that he or she will heal or will not heal. How conscious intent drives hypothalamic autoimmune function is being unraveled scientifically, and clinicians often observe these changes in their patients. Through observation it becomes apparent that patients who believe they will get better, often do, and those who believe they will not, generally do not. Whether belief comes from a religious, spiritual, or hard science paradigm, that belief drives behavior, and that drive has a large limbic component. Intellectual curiosity and human compassion motivates practitioners to explore these mysteries that otherwise might remain unexplained, overlooked, disbelieved, or forgotten.

As Western medicine continues to explore the intricate neurochemistry of the limbic network,^{209–212} alternative medicine is establishing effectiveness and efficacy for various interventions, approaches, and philosophies (see Chapter 39). The intersection of evidence and treatment efficacy is this: there is an interlocking dependence among somatosensory mapping of the functional skills² (cognitive), attention (limbic) necessary for any type of learning, and the sequential, multiple, and simultaneous programming of functional movement (motor). The limbic amygdala and hippocampal structures and their intricate circuitries play a key role in the declarative aspect of memory and learning.^{35–38} The dorsal prefrontal cortex and the ACC were activated more when the subjects learned^{53,54} a new sequence than they were when subjects simply paid attention to a pre-learned sequence.^{51,52} Once this syntactical, intellectual memory is learned and taken out of short-term memory by passing through limbic nuclei, the information is stored in cortical areas and can be retrieved at a later time without limbic involvement.⁵⁰

Limbic Influence on Memory and Motor Learning

Recovery of function after injury may involve mechanisms that allow reorganizing of the structure and function of cortical, subcortical, and spinal circuits. In very young infants, areas within opposite hemispheres may “take over” function, whereas in more mature brains reorganization of existing parallel and silent pathways within and between hemispheres, as well as synaptogenesis are accepted recovery

mechanisms within the expanding knowledge of neuroplasticity.^{217–220} For complex behavior, such as in motor functioning requiring many steps, the limbic network, cortex, hypothalamus, basal ganglia, and brain stem work as an integrated unit. As such, damage to one area may cause the whole system to initially malfunction. In addition, a lesion in one area may cause secondary dysfunction of a different area that was not damaged by the primary lesion. Without appropriate task (activity), internal and external environmental challenge designed to promote neuroplasticity, the initial malfunction can become permanent.²²¹ The optimal rehabilitation timing for neuroplastic change has not yet been firmly established; however, it is accepted that there are key plastic “time windows.”²²² The use of drug therapies to alter cellular activity and plasticity within these key windows after CNS damage has become a huge area of pharmaceutical research.^{223–229} This line of research is focused on the effect of the sensorimotor representation of movement within the cortex, which is a net effect of the stimulation of multiple pathways. The activation of specific direct, indirect, or modulating pathways engaged during the process of function-induced neuroplasticity, such as those of the limbic network, is less understood.

“Ultimately, to be sure, memory is a series of molecular events. What we chart is the territory within which those events take place.”³² The brain stores sensory and motor experiences as memory. In processing incoming information, most sensory pathways from receptors to cortical areas send vital information to the components of the limbic network. For example, extensions can be found from the visual pathways into the inferior temporal lobe (limbic network).^{39,230,231} Visual information is “processed sequentially” at each synapse along its entire pathway, in response to size, shape, color, and texture of objects. In the inferior temporal cortex, the total image of the item viewed is projected. In this way the sensory inputs are converted to become “perceptual experiences.” This also applies to other sensory stimuli, such as tactile, proprioceptive, and vestibular. The process of translating the integrated perceptions into memory occurs bilaterally in the limbic network structures of the amygdala and the hippocampus.^{39,43,168,232–241}

Before the limbic network’s impact on learning and memory can be investigated, a clear understanding of what is meant by these functions is needed. Current theories support a “dual memory system” consisting of different pathways in the nervous system. Terms such as *verbal* and *nonverbal*, *habit* versus *recognition*, *intrinsic* and *extrinsic*, and *procedural* and *declarative* have been given to these two memory systems. These systems do not operate autonomously, and many therapeutic activities seem to combine these memory systems to achieve functional behavior.³⁹ As such, in reality, the complexity of memory is not a two-category system. Verbal and nonverbal memory both interact with declarative function.²⁴² Even within spatial memory, additional areas of integration and parallel circuitry have been identified.^{243,244}

For this discussion, two specific categories of learning—procedural and declarative—will be used, although in today’s neuroscience environment, the terms *implicit* and *explicit memory* are used as frequently. Both categories of learning have been correlated to limbic function.^{40–42} Declarative (explicit) memory entails the capability to recall and verbally report experiences. This recall requires deliberate conscious effect, whereas the procedural counterpart is the recall of rules, skills, and procedures (implicit),³⁹ which can be recalled unconsciously.

Procedural learning is vital to the development of motor control. A child first receives sensory input from the various modalities through the thalamus, terminating at the appropriate sensory cortex. That information is processed, a functional somatosensory map is formulated,^{2,245} and the information is programmed and relayed to the

motor cortex. From there, it is sent to both the basal ganglia and the cerebellum to establish plans for postural adaptations, refinement of motor programs, and coordination of direction, extent, timing, force, and tone necessary throughout the entire sequence of the motor act. Procedural learning and memory do not *require* limbic network involvement as long as an emotional value is not placed on the task. This memory deals with skills, habits, and stereotyped behaviors. Summarizing, the frontal lobe, basal ganglia, and cerebellum are critical nuclei for changing and modulating existing programs.³⁹ Storage and subsequent retrieval of memory of these semiautomatic motor plans are thought to occur throughout the motor control system.³⁹ This motor system is involved in developing procedural plans used in moving us from place to place or holding us in a position when we need to stop.³⁹ The complexity of this process has had an impact on the study of motor control and variables that might affect that control.²⁴⁶

Unlike procedural learning and memory, declarative (explicit) learning and memory require the wiring of the limbic network and are closely associated with limbic function. Declarative thought deals with factual, material, semantic, and categorical aspects of higher cognitive and affective processing.²⁴⁷ A strong emotional and judgmental component is linked with declarative thought. Thus as soon as a motor behavior has value placed on the act, it becomes declarative as well as procedural, and the limbic network may become a key element in the success or failure of that movement.^{248,249} Most functional tasks or activities practiced in a clinical setting have value attached to them. That value can be clearly seen by observing the emotional intent placed on the activity by the patient.²⁵⁰

Two reciprocal pathways, or circuits, within the limbic network are intimately involved in the process of declarative learning and memory (1) the amygdaloid, dorsomedial thalamic nucleus, and cortical pathways and (2) the hippocampal, fornix, anterior thalamic nucleus, and cortical pathways. Both pathways contribute in relation to the significance of external or internal environmental to learning of a concept or task.^{43–49} The amygdala may be more concerned with sensory and motor signals relating to the internal environment, whereas the hippocampus is concerned more with those of the external environment. The hippocampus is rich in stem cells and may be a primary nuclear mass that directs the bodily systems to heal after injury. This is especially true when the external environment is enriched and nurtures the emotional environment for that healing.^{251,252}

For initial declarative learning and memory, function of the hippocampus and the amygdala of the limbic network is required.³⁹ These two structures play an important role within the “cortico-limbo-thalamo-cortical” circuit, which plays a significant role in memory storage.³⁹ For memory formation to occur in early motor learning (acquisition), there must be a storing of the “neural representation” of the stimuli in the association and the processing areas of the cortex. This “cortico-limbo-thalamo-cortical” circuit serves as the “imprinting mechanism” by which pathway activation by stimulus is reinforced. Limbic involvement in the declarative memory and learning processes creates a chemical bond that allows cortical storage of “stimulus representation” necessary for subsequent recognition and recall of the information.^{39,44,233,235,236} Therefore on subsequent stimulation, a stimulus recognition or recall would be elicited. In the associative phases of recall and transfer of learning, stored representations of any interconnected imprints might be evoked simultaneously.³⁹

The amygdaloid circuits seem to deal with strongly emotional and judgmental thoughts, whereas the hippocampal circuits are less emotional and more factual. The amygdala may be more involved in emotional arousal and attention, as well as motor regulation, whereas the hippocampus may deal with less emotionally charged learning. It

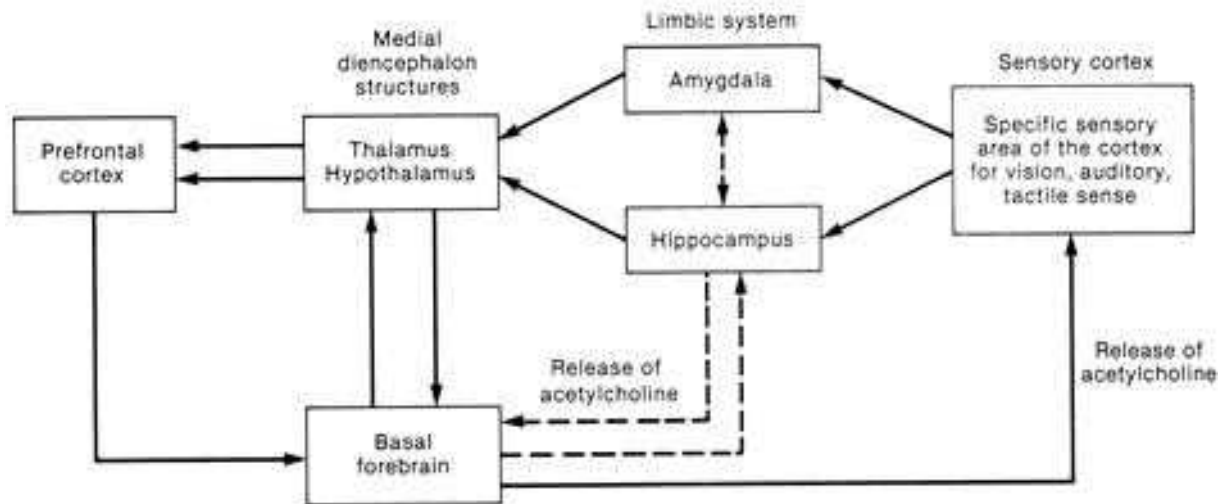

Fig. 4.6 The basal forebrain closes the circuit and causes changes in sensory area neurons, which could lead to correct perception and stored memory. This is neurochemical-dependent.

is postulated that the amygdala is the area of the brain that adds a “positive association,” associating a stimulus and reward and placing an emotional value memories or learning. In this way, stimulus and reward are associated by the amygdala, and an emotional value is placed on them.^{253,254} These limbic circuits seem crucial in the initial processing of material that leads to learning and memory. Once the thought has been laid down within the cortical structures, retrieval of that specific intermediate and long-term memory does not seem to require the limbic network, although new associations will need to be run through the system.^{39,233,235,43}

The hippocampus and amygdala are also linked both structurally and functionally to each other and to specific thalamic nuclei in the medial diencephalon. The medial diencephalon is an important relay station along the pathway that leads from the specific sensory cortical region to the limbic structures in the temporal lobe to the medial diencephalic structures and ends in the ventromedial part of the prefrontal cortex (Fig. 4.6).^{39,255,256} A vital processing area for all sensory modalities is located in the region of the anterior temporal lobe. Patients with temporal epileptic seizures and whose temporal lobes have been surgically removed develop global anterograde amnesia—that is, amnesia develops for all senses, and no new memories can be formed. Experimental removal of only the hippocampus does not bring about these changes, although processing is slowed down. When both the hippocampus and the amygdala are removed bilaterally, the amnesia is both retrograde and anterograde. A third component in the memory pathway involves pathways between the amygdala, hippocampus, and the thalamic nuclei in the medial diencephalon. When the medial diencephalic region is damaged by neurological trauma such as strokes, neoplasms, infections, or chronic alcoholism, global amnesias result. Given that the limbic network and the diencephalon cooperate in the memory circuits, the destruction of these pathways causes the same amnesic effect.

As shown in Fig. 4.6, memories may be stored in the sensory cortex area, where the original sensory input was interpreted into “sensory impressions.” Today, concepts regarding memory storage suggest that declarative memory is stored in categories similar to a filing system. Those categories or files seem to be stored in several cortical areas bilaterally depending on the context.^{257,258} This system allows for easy retrieval from multiple areas. Memory has stages and is continually changing. It was once thought that the hippocampus only dealt with

long-term memory, but it is now accepted that it also supports multi-item working memory.²⁵⁹ To go from short-term to long-term memory, the brain must physically change its chemical structure (a plastic phenomenon). Memory first begins with a representation of information that has been transformed through processing of perceptual systems. The transferring of this new memory into a long-lasting chemical bond requires the neuronal network of the limbic complex. Owing to the multiple tracts or parallel circuits in and out of the limbic network and throughout neocortical systems, patients, even with extensive lesions, can often learn and store new information.^{39,260} This may also explain why damage to the limbic network structures does not destroy existing memory nor make it unavailable because it is actually stored in many places throughout the neocortex. The circular memory circuit illustrated in Fig. 4.6 shows only one system. The reader must remember that many parallel circuits function simultaneously. The circular memory circuit shown reverts to the original sensory area after activation of the limbic structures to cause the necessary neuronal changes that would inscribe the event into retrievable stored memory.²⁶¹ This information can be recognized and retrieved by activation of storage sites anywhere along the pathway.^{39,262} Patients with brain lesions localized in the limbic network components of the amygdala and hippocampus have the ability to acquire and function with “rule-based” games and skills but have lost the capacity to recall how, when, or where they gained this knowledge or to give a description of the games and skills learned. Relating this to clinical performance, patients may develop the skill in a functional activity but not the problem-solving strategies necessary to associate danger or other potentially harmful aspects of a situation that may develop once out of the purely clinical setting.^{119,263–266} Similarly, if a patient needs to learn a procedural task such as walking, transfers, eating, and so on, it may be extremely important to direct the attention off the task while the task is being practiced procedurally.

The last station or system to be added to the circuit is the “basal forebrain cholinergic system,” which delivers the neurochemical acetylcholine to the cortical centers and to the limbic network, with which it is linked. Visual recognition memory can be augmented or impaired by administration of drugs that enhance or block the action of acetylcholine.^{267–269} The loss of this neurotransmitter is linked to memory malfunctioning in Alzheimer disease and plays a key role in dementia problems in Parkinsonism.²⁷⁰ Currently, many chemicals are being

studied for their influence on brain structures and specially limbic structures.^{271,272}

The hippocampus and the amygdala are involved in recognition memory.²⁷³ Hippocampal (indirect) and nonhippocampal (direct and independent) pathways influence the anterior thalamus and thus play an important role in memory, particularly spatial memory and location of objects in space.¹⁹⁴ The amygdala is necessary for the association of memories derived through the various senses with a specific recognition recall. For example, a whiff of ether might bring to mind a painful surgical experience or the sight of some food may cause a recall of its pleasant smell. Removal of the amygdala brings out the behavior shown in Klüver-Bucy syndrome. For patients with this neurological problem, familiar objects do not bring forth the correct associations of memories experienced by sight, smell, taste, and touch and relate them to objects presented.²⁷⁴ Association of previously presented stimuli and their responses appear to be lost. Animals without amygdaloid input had different response patterns that ignored previous fears and aversions. Thus the amygdala adds the “emotional weight” to sensory experience. Loss of the amygdala takes away many positive associations and potential rewards, thereby altering the shaping of perceptions that lead to memory storage.

When stimuli are endowed with emotional value or significance, attention is drawn to those possessing emotional significance, selecting these for attention and learning. This would give the amygdala a “gatekeeping” function of selective filtering. The amygdala may enable emotions to influence what is perceived and learned by reciprocal connection with the cortex. Emotionally charged events will leave a more significant impression and subsequent recall. The amygdala alters perception of afferent sensory input and, hence, affects subsequent actions.^{36,275,276}

In the human, memory functioning has been associated with the phenomenon of long-term potentiation observed in hippocampal pathways.³⁹ This potentiation of synaptic transmission, lasting for hours, days, and weeks, occurs after brief trains of high-frequency stimulation of hippocampal excitatory pathways. Whether this long-term potentiation occurs presynaptically, postsynaptically, or both has not yet been established.^{39,135,277} The adrenal corticosteroids contribute to modulation of long-term potentiation within the hippocampus.¹⁸⁶ Recent literature has linked a neurotropic factor usually considered for long-term potentiation within the hippocampus as a factor in amygdala-dependent learning, thus reiterating the interaction between these two nuclei and their role in memory and learning.³⁶

Learning and memory evoke alterations in behavior that reflect neuroanatomical and neurophysiological changes.^{39,210} These alterations include the phenomenon of long-term potentiation as an example of such changes. The hippocampus demonstrates the importance of input of long-term potentiation in associative learning. In this type of learning, two or more stimuli are combined through the “associative” interaction of afferent inputs. As such, tetanizing of more than one pathway needs to occur simultaneously. If only one pathway is tetanized, the effect is decreased synaptic transmission. Thus long-term potentiation serves as one model for understanding the neural mechanism for associative learning. Hormones interact with this neural mechanism, which, if combined with stress, can change the specific circuitry active during the experience.²⁷⁸ As an example, the amygdala is not only involved in learning related to emotional experiences but is also responsible for changing motor expression or conditioned response generated as part of an autonomic expression, such as with fear.^{164,279} Limbic responses to input stimuli need to be differentiated from limbic memory and initiation of a response without the stimuli. Although this is an area of practice not yet fully understood,

clinical implications to patient examination and evaluation will be generally discussed later in this chapter.

Limbic Influence on Emotions and Behaviors: The F²ARV and General Adaptation Syndrome Continua

Noback and co-workers²⁸⁰ state that the limbic network is involved with many of the expressions that make us human, namely, emotions, behaviors, and feeling states. That humanness is highly individual even in patients with normal functioning limbic networks, and even greater variance with involvement of the primary or modulating limbic network structures or pathways.

As a brief clinical example, a patient with severe brain injury with decreased responsiveness (Rancho Los Amigos Level of Consciousness II–III) may show increased alertness and an increase in base muscle tone or motor function through effective use of sensory stimuli. Alternatively, although the desired response may be improved alertness or a motor response, a patient may become highly oversensitive to a strong odor or noxious tactile stimuli,²⁸¹ and the response may become autonomic or behavioral instead, reflected in an increased heart rate or blood pressure, or even as fear or anger.⁵⁷ Overstimulation may move the patient into a “protective state of survival,” whereas a pleasant/personally desirable smell, touch, or sound (e.g., melody) will more likely lead to “safety.” The former can lead to strong emotions or responses such as anger; the latter often leads to bonding, engagement (attention), and motivation to learn.¹⁶

Both motivation (“feeling the need to act”) and concentration (“ability to focus on the task”) are interlinked with the limbic network and are both critical to participation in the motor activities. The amygdaloid complex with its multitude of afferent and efferent interlinkages is specially adapted for recognizing the significance of a stimulus, and it assigns the emotional aspect of feeling the need to act. These neuroanatomical loops have tremendous connections with the reticular system. Hence, some authors call it the reticulolimbic network.^{39,74} The interaction of the limbic network and the motor generators of the brain stem and ultimate direct and indirect modulation over the spinal system lead to need-directed and therefore goal-directed motor activity. It also filters out insignificant from significant information through selective processing, storing the significant for memory, learning, and recall. These interconnected neuroloop circuitries reinforce the concept that areas have both specialization and generalization and thus work closely together with other areas of the brain.^{81,282}

Some of the earliest understanding of the limbic network was limited to that of a primary protective role in “fight or flight.” With normally functioning limbic networks, patients can appropriately recognize the significance of a stimulus, effectively filter out insignificant from significant stimuli or information, and appropriately assign a need to act. However, in the impaired patient, inaccurate stimulus interpretation and therefore action/reaction occur. The therapist needs to be aware that a patient may overrespond to stress, frustration, or fear of failure in both cognitive and motor activities. A small or unfiltered stimulus may generate one of two powerful and predictable limbic motor response programs: the fear and frustration, anger, rage, and violence continuum (F²ARV) and the general adaptation syndrome (GAS). The F²ARV and GAS continua are often interrelated in individuals who have direct or indirect limbic network involvement.

Fear and frustration, anger, rage, and violence or withdrawal continuum. One sequence of behaviors used to describe the emotional circuitry of the limbic network through the amygdala is the F²ARV continuum (Fig. 4.7).^{74,283,284} This continuum begins with fear or frustration. This fear can lead to avoidance behavior.²⁸⁵ If the event inducing the fear or frustration continues to heighten, avoidance behaviors can continue to develop.²⁸⁵ In a simple example, we recall or

Fig. 4.7 Fear and Frustration, Anger, Rage, and Violence or Withdrawal: F²ARV Continuum.

have seen these behaviors in our teens and as young adults, when the challenges faced in high school can lead to *avoidance* of activities. Alternately, extreme fear and frustration can also lead to *anger*. Anger is a neurochemical response that is perceived and defined cognitively (at the cortical level) as anger. If the neurochemical response continues to build or is prolonged, the anger displayed by the person may advance to *rage* (internal chaos) and finally into *violence* (strong motor response). A common societal example is in the case of domestic discord and violence. Women who attain the level of rage may become withdrawn and thus become victimized by a partner who is also in rage or inflicting physical or emotional violence.²⁸⁶ Another current example is posttraumatic stress disorder (PTSD), in which the prolonged stress of deployment and unique challenges of warfare lead to limited adaptive reserves in warriors and returning veterans.

How quickly and completely any individual will progress from fear to violence is dependent on several factors. First, the genetic neurochemical predisposition (initial wiring) will influence behavioral responses.²⁸⁴ Second, “soft-wired” or conditioned responses resulting from experiences and reinforced patterns will influence output. For example, it is commonly known that abusive parents were usually abused children^{283,287}; they learned that anger quickly leads to violence and that the behavior of violence was somehow acceptable. Last, the quality and intensity of the stimulus initiating the continuum will influence the level of response.

The neurochemistry within an individual’s CNS, whether inherently active or altered through drugs or injury, will have great influence on the plasticity of the existing wiring.^{263,288} Repetitive or prolonged exposure to negative environmental stimuli may also lead to a chronically imbalanced neurochemical state that results in a lowered threshold or tolerance to a given stimulus. Chemistry or wiring can become imbalanced from damage, environmental stress, learning, or other potentially altering situations, changing an individual’s control over this continuum.^{39,227–229,289,290} When neurochemical imbalance exists, these behaviors will persist, and balance may be restored only through natural neurochemical activity (e.g., sleep, exercise, diet, spirituality) or medication support (chemical replacement).

Therapists need to be acutely aware of this continuum in patients who have diffuse axonal shearing within the limbic complex. Diffuse axonal shearing is most commonly seen and reported in research on individuals with head trauma (see Chapter 23).^{291,292} Resulting lesions within the limbic structures may cause an individual to progress down this continuum at a rapid speed. This point cannot be overemphasized. Patients with an accelerated F²ARV continuum, whether through prior learning or due to the injury, may physically strike out at a clinician or caregiver out of simple frustration during care. Knowing the social history of the patient and the causation of the injury often can help the therapist gain insight into how an individual patient might progress

down this continuum. Not all head-injured patients had prior difficulty with the F²ARV continuum; however, it is important to note that many individuals received their head injuries in violent confrontational situations or in wartime conflict. Some individuals, primarily females, when confronted with stress, anger, and potential violence from another, will withdraw and become depressed. This behavior, similar to violence, will change the structure of the limbic network.²⁹³ A brief patient example of accelerated limbic-driven responses along the F²ARV continuum is described in [Clinical Case 4.2](#).

General adaptation syndrome. The autonomic responses to stress also follow a specific sequence of behavioral changes and are referred to as the *general adaptation syndrome*.^{294–300} The sequential stages of GAS are a direct result of limbic imbalance and can play a dramatic role in determining patient progress.

Stress can be caused by many internal or external factors, often unique to the individual. Examples include pain, acute or chronic illness or the ramification of illness, confusion, sensory overload, and a large variety of other potential sources. The initial reaction to a stressor is a neurochemical change or “alarm” that triggers a strong sympathetic nervous system reaction. Heart rate, blood pressure, respiration, metabolism, and muscle tonus will increase. It is at this stage that the grandmother lifts the car off the child as in our previous example. If the overstimulation or stress does not diminish, the body will protect itself from self-destruction and trigger a subsequent parasympathetic

CLINICAL CASE 4.2

A 40-year-old man presented with moderate physical and severe cognitive functioning deficits resulting from a brain aneurysm, associated with violent episodes of rage. He would escalate very rapidly along the F²ARV continuum when presented with unpredictable environmental stimuli, such as passing another patient with his wheelchair in the hallway. Although his physical rehabilitation had progressed well and he had made functional gains in mobility, because his assaultive outbursts posed risks to other patients as well as to caregivers, this patient appeared to be heading for placement in a locked facility, a more restrictive environment than he would need considering his level of physical limitation. Although this unfortunate man had no short-term memory function or insight into his behaviors, assessment revealed that he was highly responsive to calming music and was able to access some intact long-term memories that could be used to elicit a relaxation response. A highly positive or neutral limbic state of deep relaxation was therefore facilitated using meaningful, calming music, and simple verbal cues were presented/timed to develop a conditioned response that any staff member could then call forth with the verbal cue alone. The entire rehabilitation team was briefed on the use of this intervention and reported success using this approach during nursing care and rehabilitation interventions when the patient would become resistant or angry in response to clinician instructions. The patient was able to be trained to self-regulate by giving himself the same verbal cue when confronted with challenging situations. This treatment supported the patient’s ability to regain emotional controls and allowed him the opportunity to be placed in a less-restrictive community environment. The patient never recalled a previous music therapy treatment session and asked each time to have the purpose of the treatment explained to him. But his body remembered the set of behavioral experiences, and he quickly complied with the relaxation procedure. The success of this approach demonstrates that even in the absence of short-term memory and other cognitive functions usually considered essential for new learning, the skillful engagement of positive limbic states and intact areas of patient functioning (strengths) can support development of new adaptive skills, which can be generalized to new environments.

response. At this time, all clinical symptoms reverse and the patient exhibits a decrease in heart rate, blood pressure, and muscle tonus. The bronchi become constricted, and the patient may hyperventilate and become dizzy, confused, and less alert. As the blood flow returns to the periphery, the face may flush and the skin may become hot. The patient will have no energy to move, will withdraw, and again will exhibit decreased postural tone and increased flexion.

This stress or overstimulation syndrome is characterized by common symptoms as described earlier.^{34,301–308} If the acute symptoms are not eliminated, they will become chronic and the behavior patterns much more resistant to change.

GAS is often seen in the elderly, with various precipitating health crises²⁹⁸ (and also in neonatal high-risk infants), victims of head trauma, and other patients with neurological conditions. The initial alarm can be precipitated by moderate to maximal internal instability with less intensive external stress, or by minimal internal instability with severe external sensory bombardment. For instance, in the elderly, stresses such as change of environment, loss of loved ones, failing health, and fears of financial problems can each cause the patient's system to react as if overloaded.³⁰⁰ As another example, individuals with head trauma, vestibular dysfunction, inflammatory CNS problems, and brain tumors often possess hypersensitivity to external input such as visual environments, noise, touch, or light. In these individuals, typical clinical environments and therapeutic activities may create a sensory overload and trigger a GAS response.

Stress, no matter what the specific precipitating incident (confusion, fear, anxiety, grief, or pain), has the potential to trigger the first

steps in the sequence of this syndrome.^{301–306,309} The clinician's sensitivity to the patient's emotional system will be the therapeutic technique that best controls and reverses the acute condition.

Similarly, patients with dizziness and instability, particularly within visually stimulating environments, can develop feelings of panic, which can evolve into full attacks and agoraphobic responses.³¹⁰ These individuals avoid participating in activities that put them within visually overstimulating environments in an effort to control the dizziness and prevent the associated autonomic reactions. Similar types of reactions have been documented, such as space-motion discomfort (SMD),¹³⁷ postural phobic vertigo,³¹⁰ visual vertigo,³¹¹ and dizziness of "psychogenic" origin. Often these individuals are referred first to psychology or psychiatry. However, there is an underlying physiological explanation for these symptoms. In a majority of individuals with SMD, there is a documented increase in vestibular sensitivity (increased vestibulo-ocular reflex [VOR] gain) and an impairment in velocity storage (shorter VOR time constant).³¹² In addition, the dorsal raphe nucleus (dorsal reticular nucleus of the midbrain and rostral pons) is the largest serotonin-containing nucleus in the brain and directly modulates the firing activity of the superior and medial vestibular nuclei. It is this interaction between serotonin and vestibular function that helps to explain the link between vestibular and anxiety disorders. It can also help explain how patients with sleep disorders or other serotonin-depleting disorders develop vestibular-like symptoms and anxiety.^{145,313} A comprehensive clinical example of the influence of the limbic system in patients with vestibular dysfunction can be found in [Clinical Case 4.3](#).

CLINICAL CASE 4.3

A 25-year-old first-grade teacher with a history of whiplash has been referred by the neurology department 5 months after a motor vehicle accident with complaints of severe dizziness and imbalance. She is unable to recall the accident; however, there was evidence to suggest that she struck her head on the steering wheel and briefly lost consciousness. Results of diagnostic testing (MRI and electroencephalography) are inconclusive. Medical management to date has been limited to central depressant medications (alprazolam [Xanax] and diazepam [Valium]; see Chapter 36). She has received physical therapy since the accident for neck and back pain, which exacerbated her symptoms. She denies specific assessment or treatment of her dizziness or imbalance until this time. Her medical history includes a hospitalization 3 months after the motor vehicle accident with "intractable migraine, postconcussive syndrome." Of note is a previous head injury 2 years before with moderate to severe postconcussive syndrome, including vertigo and migraines. She has been referred for psychological assessment and management and was recently diagnosed with obsessive-compulsive disorder. She is now referred to physical therapy for a full postural control and vestibular assessment. The differential medical diagnosis is postconcussive syndrome, rule out aphysiological performance (psychogenic and secondary gain). The physician believes that a large part of her problem is based within the medical psychiatric domain, but he is willing to widen his paradigm to include other possibilities and obtain additional data to assist in his patient's management. The patient's goal is to eliminate the dizziness and imbalance and return to normal activity and work.

Phase I: Evaluation

Unaware of being observed, a well-groomed young woman walks into physical therapy extremely slowly, holding the wall, watching the ground, and stopping periodically to close her eyes. Her color is pale, her build small and thin, and her clothing loose. Her steps are shortened in length and widened in width, with limited time spent in the swing phase. She walks en bloc (rigidly) without arm swing, with no segmental movement of the head or trunk. She periodically stops

and closes her eyes as people move around her. There is visible extraneous eye movement, although no spontaneous nystagmus noted. She is pleasant and cooperative with no overt signs of anxiety in quiet sitting.

System Impairments (Patient Report and Observation)

- Dizziness with severe nausea and vomiting (at least once weekly)
- Dizziness Visual Analog Scale 7.5/10 and Dysequilibrium Visual Analog Scale 7.0/10 (with 10 representing the most severe symptoms imaginable)
- Decreased concentration and memory; forgetfulness
- Diplopia and visual blurring, with headaches
- Photophobia and hyperacusis
- Emotional instability: fight or flight; in both active F²ARV and active GAS (autonomic) states:
 - Rapid change from a state of calm to fits of rage with her family and other support systems.
 - Anger and rage alternated with reports of depression and avoidance.
- Decreasing body mass as observed by loose clothing and supported by reports of severe nausea
- Central depression of vestibular function (treated with medication)

Activity (Patient Report)

- Impaired balance for function, with near falls in dark and eyes-closed environments. Patient reports one true fall in the shower with her eyes closed.
- Impaired balance within visually challenging environments.
- Sleep deprivation and extreme fatigue.
- Long-term stress and sensory intolerance and overstimulation

It is important for a clinician to remember that the long-term stress associated with a chronic disability of this nature can result in a decrease in serotonin, which influences the hypothalamus and alters modulation of the vestibular nuclei through the dorsal reticular nucleus. Loss of sleep can alter levels of serotonin and other neurotransmitters. A decrease in serotonin results in further

CLINICAL CASE 4.3—cont'd

depression and *loss of sleep*, resulting in a physiological *fatigue*. It also can result in an increase in sensitization of presynaptic terminals of the cutaneous sensory nerves, contributing to the *sensory bombardment* and overstimulation.³¹⁴

Participation in Life (Patient Report)

- She attempted to return to work as a first-grade teacher but had a severe exacerbation of all symptoms in the classroom.
- She is unable to drive and requires assistance for shopping.
- She lives alone in an apartment and is independent in function, modified by her symptoms.
- Disability Rating is 4/5 (recent severe disability and medical leave).³¹⁵
- Dizziness Handicap Inventory (DHI) score is significant for physical and emotional impact of her dizziness, including depression. (Total disability score is 79/100, functional subscore 29/32, emotional subscore 30/40, and physical subscore 20/28.³¹⁶)

Based on the signs and symptoms obtained in the intake phase and subjective reporting, the preliminary physical therapy hypothesis would be the presence of a probable vestibular dysfunction of a mixed central and peripheral etiology, sensory integration dysfunction, and anxiety overlay. The patient clearly has limbic network overload. It will be the therapist's responsibility to differentiate that from physical motor system problems with the assessment and treatment. The examination phase is designed to confirm or refute and redirect this hypothesis. (See Chapter 21 for clarification of specific vestibular tests and measures.)

Oculomotor

Oculomotor examination was performed, with results supportive of the hypothesis of vestibular involvement, although inconclusive for peripheral versus central versus combination origin.

Gaze instability—Clinical dynamic visual acuity test revealed a significant five- to six-line deterioration in dynamic visual acuity when head was moving, with loss of postural control in posterior-left direction and symptom exacerbation during testing.

Balance Stability

- SOT of sensory balance function³¹⁷ showed an across-the-board dysfunction pattern,²⁴ although results were incomplete because the patient was not able to complete all 18 trials of the test protocol as a result of extreme symptoms (nausea, respiratory, and anxiety symptoms, particularly on conditions 2, 3, 5, and 6).
- Total dependence (overreliance) on visual information for postural stability.
- Poor position and control of the center of gravity, shifted significantly leftward and anterior of midline.
- Excessive use of a hip strategy for basic equilibrium (versus ankle), even on stable surfaces or the smallest perturbation.
- Inability to effectively:
 - Use somatosensory or vestibular sensory cues on functional demand (reweight)
 - Organize the sensory inputs to the CNS to facilitate appropriate motor output
 - Dampen ANS/vegetative response, particularly in visual-vestibular mismatch conditions (SOT 3 and 6)
- Aphysiological criteria—Aphysiological responses were evident within the SOT raw data traces (exaggerated sway frequency and lateral sway responses). Motor Control Test (of automatic motor responses) results would have strengthened conclusions made regarding an aphysiological component, but were unavailable to this clinician at the time of the examination.³¹⁷

Function and Gait

Self-selected velocity of 1.82 ft/s (normal preferred gait speeds in a 20- to 30-year-old woman should be closer to 3.47 ft/s).²⁴ The patient watched the floor for the entire distance with no head or trunk or arm movement. Thus vision was clearly directing each step, and her preferred head position was compensatory

to decrease extraneous visual flow or input. When she was encouraged to focus on a distant object, velocity declined to 1.34 ft/s and the patient veered consistently leftward 100% of the distance. She could be encouraged to walk at 2.86 ft/s (normal encouraged gait speeds should approach 6.43 ft/s), but with an increase in instability and a leftward loss of balance; however, at this low velocity, she could regain her balance without therapist assistance.

The interactions of the patient and therapist (limbic bonding, as referred to previously within this chapter) became a critical element in the examination. The patient had to trust the therapist that if she followed the therapist's direction in examination, she would not fall or incur additional symptoms outside her control. The therapist, during the evaluation, empowered the patient to take responsibility for her functional movement while making sure the patient was successful if willing to take the risk. This aspect of the therapeutic alliance (interaction) is a limbic-neutral technique, and its success or failure will be reflected in the motor responses of the patient.

Confirmatory Tests and Measures

- Intact sensation but extreme hypersensitivity to vibratory input (with strong ANS response)
- Normal strength and range of motion

Multiple rests were required throughout the examination to decrease symptomatology (nausea, increased respiration, sweating) to patient tolerance. Testing reproduced all subjective dizziness, and there was a resultant gross instability with loss of balance in the posterior direction, necessitating assistance. Imbalance, nausea, and anxiety were residual for 10 min after testing.

In the evaluative phase, the working hypothesis after the examination phase was as follows:

- **Diagnoses** as identified by therapist:
- **Medical**—probable mixed central and peripheral vestibular presentation, without confirmatory medical diagnostics or diagnosis. Further medical workup was requested.
- **PT Rehabilitation**³¹⁸—Primary Problem: Practice Pattern 5D: Acquired impairment of the central nervous system; Secondary Problem: Practice Pattern 5A: Primary prevention of falls
- **Characterized** by (1) space-motion discomfort (SMD) with gaze instability resulting from VOR impairment (probable high gain); (2) central processing impairment; (3) postural control impairment with over-reliance on vision; and (4) limbic high state with autonomic response.
- **Prognosis:** Fair for modified community level independence, physiologically complicated by history (repeated concussions) and chronicity. Improvement intra-trial is a positive physiological sign. However, anxiety overlay and history may have psychogenic versus physiological impact on recovery.
- **Red Flags:** Watch for (1) additional central signs, (2) signs of secondary gain, (3) F²ARV and GAS limbic cascade, or (3) social service issues.

Phase II: Intervention

1. There are three objectives of the treatment phase driven by findings in the clinical assessment:
 - a. Monitor and manage limbic symptoms through environment change of input systems (vision, auditory, kinesthetic) with the goal of the limbic network going neutral if possible.
 - b. Maximize sensory integration, central processing, compensatory impairments of the vestibulospinal reflex (balance control) and VOR (gaze control).
 - c. Integrate gains in balance and gaze control into functional activity with and without emotional overlays.
2. Treatment approach:
 - a. Patient-oriented approach.

Goal: Maximize internal locus of control and trust; quiet the limbic influence (facilitate limbic neutral) to set an environment appropriate for motor learning and functional change.

CLINICAL CASE 4.3—cont'd

Techniques:

- Awareness and validation of the problem. Provide the patient with objective findings of organic and functional involvement (sensory organization, dynamic visual acuity, and other testing). Many of these patients have been told for years that it is “in their head.” The statement is accurate, but the intent is condescending and implies some psychological dysfunction.
 - Awareness of and participation in the plan and approach. The treatment plan should have strong emotional meaning to the patient to turn the “limbic key” to maximize involvement and motivation. It should be goal directed intra- and inter-session. Achieving proper motivation and reward maximizes neuroplastic change.³¹⁹
 - Therapeutic Alliance: The correct patient-therapist pairing for effective execution of the plan. Safe clinician contact may actually be part of the rehabilitation plan, with gradual reduction based on limbic and functional improvements.
 - Therapeutic Environment: The correct environment to effect change. Use appropriate voice (timbre, pitch, and volume), appropriate pacing (onset of sound or other stimuli), sound, light, consistency, and predictability.
- b. Balance retraining using sensory reorganization (reweighting).
Gaze stability (VOR) retraining
Goal: Appropriate timing and predictability of sensory treatment: “dose” to achieve desired limbic and functional outcomes.
- Expose the patient to the problematic sensory conditions identified during the examination, presenting first the easier conditions and progressing in terms of difficulty and complexity on the basis of patient response. Force the development of sensory integration, compensation, or substitution, as well as the development of new and appropriate movement strategies.
 - Provide for selective attention through predictable, short segments of sensory integrative challenge.
 - Avoid sensory overload through proper exercise prescription (intensity, duration, repetitions, and frequency) during sensory integrative treatment.
 - Provide for maximal motor learning environment by keeping the limbic network quiet while achieving the correct balance between error detection and correction versus demotivation through making mistakes.
 - Provide knowledge of performance and knowledge of results frequently. As one example, computerized visual biofeedback provides direct one-on-one feedback of body position in space and motor performance.
- c. Functional activity requires complex integration of balance and gaze control.
- Gait training at controlled pacing in stable environments, progressing to changing pace within predictable visual environments, to unstable visual environments and variable surface environment.
 - Hippotherapy (term derived from Greek “hippo” meaning “horse,”) is a therapeutic riding activity that is meaningful to the patient. Performed in a controlled environment, the rhythmic cadence provided by the animal provides predictable sensory input (somatosensory, vestibular, auditory, and olfactory), controlled rhythmic visual flow, and neutral warmth in a

meaningful, goal-directed activity (as identified by the patient). This can be a very limbic-neutralizing activity when fear is controlled as a factor.

- d. If the patient does not progress in a physiologically normal manner or limbic signs remain unchanged (or increase), then psychological management may take precedent over (or be required before) recovery in rehabilitation (motor learning and neuroplasticity within the CNS) can be achieved.
- Successful life outcome is affected by early management. The extent to which a mild dizziness problem becomes chronic is dependent mainly on the psychological reaction to the symptoms.³¹⁰
 - There are specific management strategies associated with anxiety-type disorders within psychology, including use of medications. One theory of recovery from psychology problems is referred to as exposure. Although exposure is meant to cause habituation of the patient to the triggering events, in our case exposure actually will lead to forced use of the appropriate sensory system(s) as required in activities of daily living.

Conclusion

What makes this a clinical problem within the domain of the limbic network is that this woman's limbic network was overriding all other systems. At first glance this person was referred to therapy with typical vestibular and balance dysfunction. She was anything but typical and could not be approached with a “standard protocol,” or failure for both the therapist and the patient was inevitable. The role of the patient within this setting was to gain an appreciation and integration of how her vestibular, motor, and limbic networks were interacting and when she went into system overload and why. The therapist's role was to (1) help the patient gain this body awareness, (2) empower the patient with regard to her potential for recovery, (3) design interventions that would nurture patient success, (4) collaborate with the patient on needed interventions regarding practice and novelty within the environment along with consistency of practice, and (5) allow the patient to improve at a pace her CNS could manage.

The long-term permanent changes that may or may not have occurred with this patient's vestibular, motor, or limbic networks are not known. The essential role of complete history taking and dedication to reality by the therapist is obvious. The therapist's success within this case was dependent on her ability to listen and watch (visually, auditorily, and emotionally [limbic]) as the patient unfolded the mystery of her CNS problems. The patient was the key to successfully unlocking her complex subsystem problems. In the health care world of stress, limited visits, and expected outcomes after intervention, it is far too easy to blame the patient for our failure as clinicians. It is also easy to quickly identify that the patient has problems in other system areas outside our scope of practice and thus infer that it is those areas that are limiting improvement. The difficulty is that all professions are doing the same thing, and the patient is drowning in the repercussions of the waves. Partnering interventions both with other professionals and with the patient should optimize an environment that nurtures long-term learning and plastic changes within the CNS. The limbic network drives our attention, our motivation, and our willingness to take risks into unknown environments. How you as a clinician accompany those patients throughout the learning experience will depend on your limbic network as much as theirs.

Although there are physiological reasons underlying the vestibular system disorder in a majority of these cases, the symptoms triggered are part of a spectrum of limbic responses to aberrant vestibular, cerebellar, and brain stem interactions. Normal clinic activity or typically appropriate therapeutic activity may trigger an autonomic cascade versus the desired somatomotor response. The rehabilitation of the resultant visual and postural movement dysfunction is typically more complicated in the absence of limbic network management. The clinician's strategic prescription (or “dosing”) of therapeutic activities with

careful monitoring of the patient's emotional system and physiological response will be one of the therapeutic techniques that best controls the aberrant responses and allows vestibular adaptation and compensation to occur. This must be done to manage limbic network activity for successful motor learning to occur.

Developing limbic network assessment tools (or repurposing existing tools) for their ability to screen or identify the presence of direct or indirect limbic involvement is of critical value. In addition, the ability to discriminate the type of limbic involvement (decreased

responsiveness and withdrawal from increased responsiveness or overresponsiveness) is important to treatment planning. Treatment techniques will be discussed later in the chapter. However, the specific techniques appropriate for treating these syndromes are tools all therapists possess. These tools range from simple variations in approach (e.g., lighting, sound, and smell) to more formal therapeutic techniques, such as the Feldenkrais approach, or the Bonny Method of Guided Imagery and Music.³²⁰ How each clinician uses those tools is a critical link to success or failure in clinical interaction.

Limbic Influence on Motor Performance and Function

Kandel and colleagues³⁹ state that functional behavior requires three major systems: the sensory, the motor, and the motivational or limbic systems. When a seemingly simple action, such as swinging a golf club, is analyzed, the sensory system is recruited for visual, tactile, and proprioceptive input to guide the motor systems for precise, coordinated muscle recruitment and postural control. The motivational (limbic) system does the following: (1) provides intentional drive for the movement initiation, (2) integrates the total motor input, and (3) modifies motor expression accordingly, influencing both the autonomic and the somatic somatomotor systems. It thereby plays a role in controlling the skeletal muscles through input to the frontal lobe and brain stem and the smooth muscles and glands through the hypothalamus, which lies at the “heart” of the limbic network (Fig. 4.8).

The motivational or limbic component is further understood to be linked to the NAc, which has been described as the “limbic-motor interface.” The NAc has been found in animal studies to link motor responses with the value of expected rewards associated with a given motor plan. The expected reward is encoded with a behavioral response within a given neural signal. The spatial and motor components of a given behavioral response are similarly encoded together, including the timing and accuracy components of a movement. It is important to note that within this encoding process, the predictability of the behavior and reward are critical for activation of the

NAc neurons. This supports the concept that predictability within the therapeutic tasks, environment, and alliance are critical to motivation and, as such, to motor output and learning.³²¹

Though *MOVE* has been used to delineate specific functions of the limbic network that drive movement, it is important to remember that these functions are highly interactive and individual. Our unique memory storage, our variable responses to different environmental contexts, and our control or lack thereof over our emotional sensitivity to environmental stimuli all play roles in the expression of our motor output, motor performance, and function. As such, an understanding of the influence of the limbic network on an individual's function helps further define our need to assess the state of this system—and for those findings to factor into our treatment plans.

To appreciate the sensory system's influential interaction with the limbic network directly, the reader might also look at the literature on music and how it interacts with emotions.^{322,323} Most people can give examples of instances where music has elicited immediate and compelling emotional responses of various types. Pleasant and unpleasant musical stimuli have been found to increase or decrease limbic network activity and influence both cognitive and motor responses, although the neurological mechanisms are not completely understood.^{324–327} Consider the clinical implications. Reflect on the typical treatment environment: frequent and variable noise, loud-speaker announcements, piped-in music, and a cacophony of therapists' voices can quickly overload the CNS of a patient and result in a limbic response versus a desired motor or functional response. These responses can be highly emotional or *limbic high*, resulting in visceral behavior and affecting motor expression. Alternately, the response may be calming or relaxing to a *limbic neutral* state, allowing for full engagement (motivation, attention) in the movement or task at hand. Musical consonance or dissonance (stable versus unstable) of an auditory stimulus is subjectively experienced by the listener as pleasant or unpleasant. Listening to music uniquely affects limbic emotional states, and the influence may direct the hypothalamus in regulation of blood

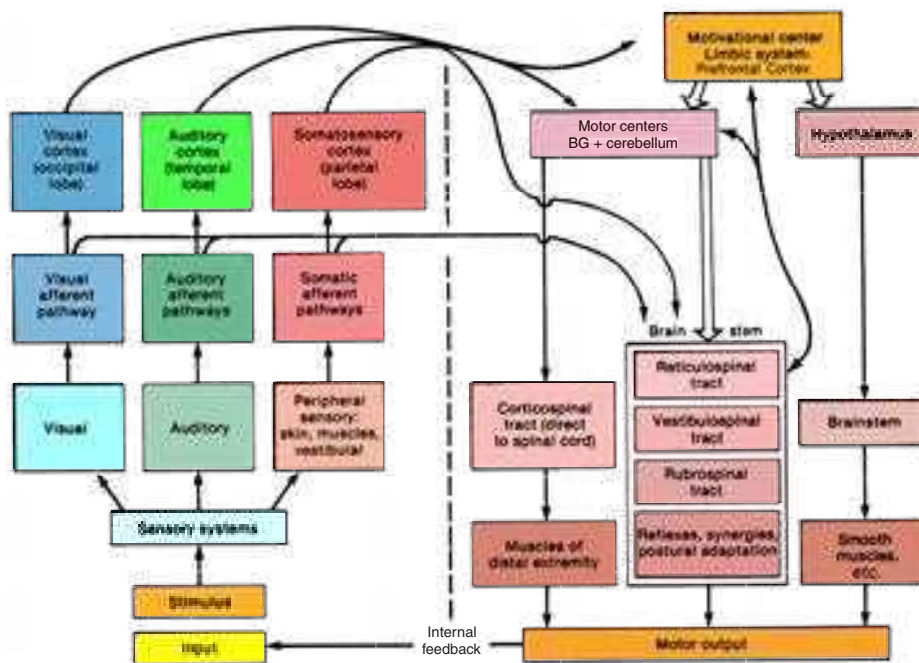

Fig. 4.8 Motivational System's Influence Over the Somatomotor and Autonomic Nervous Systems. (Adapted from Kandel ER, Schwartz JH, Jessell TM. *Principles of Neural Science*. 4th ed. New York: McGraw-Hill; 2000.)

flow within the CNS.³²⁷ With music or sound being just one input system, the therapist must consider that sensory influence from smell, taste, touch, proprioception, and vestibular and organ system dysfunction can lead to potential limbic involvement in all aspects of CNS function and directly affect the emotional stability of the patient.

CLINICAL IMPLICATIONS OF THE LIMBIC STATE

Today the medical profession is rediscovering the importance of how the systems interact with and influence one another.^{328,329} Similarly, it is very important for movement specialists to look at movement not only from a biomechanical, muscular, neurological, cardiopulmonary, or integumentary system perspective, but also to accept that interactions between systems highly influences movement. What is less understood, or perhaps considered, by physical therapists are the interactions between the environment and behaviors, learning and movement, including the therapeutic alliance between therapist and patient. Cognitive impairment and limbic network involvement can lead to tremendous errors in motor responses even when the motor system is intact.

Although far from yielding a complete understanding, this research and knowledge are increasing daily and force today's therapist not only to recognize limbic behavior but also to develop an understanding of how involvement of the limbic network will positively and negatively affect the movement of each patient. Therapists can no longer think of motor control and motor learning as controlled exclusively by an anatomically unique motor system, nor can we understand movement using motor control or motor learning principles alone. Therapists must consider how the limbic network strongly influences motor sequencing and control, behaviors that influence function and participation (attention, motivation, and cooperation), as well as beliefs and attitudes. Any of these factors may affect outcomes through influence on engagement or empowerment over treatment planning and/or responsibility for, and compliance with, home programs. Without an understanding of limbic interactions and modulations over motor expression, patient performance and outcomes may show greater variability, even with consistent and accepted interventions. And, given the limitations in today's health care delivery models, stresses, and the growing dependence on home programs, without a keen awareness of the limbic responses of both the patient and the provider, a therapist will have reduced influence over the best functional outcome for their patients.

The complexity of the limbic network and its associated influence over both the motor control system and cortical structures are enormous. A therapist dealing with a patient with motor control or learning problems needs to understand how the limbic network affects behavioral responses and functional performance. This understanding should lead to a greater awareness of the individual factors associated with limbic network involvement, as well as the clinical activities (interventions) and environmental factors that will result in positive neuroplastic change and motor learning. Without this knowledge of how to differentiate limbic from other system dysfunction within the physical therapist evaluation, objective measurements of motor performance or cognitive abilities may be inaccurate, inconsistent, or variable between therapists or sessions without apparent explanation. Similarly, with aberrant limbic activity (high or low), a patient's ability to store and retrieve either declarative or procedural learning may be negatively affected, thus limiting the patient's ability to benefit from traditional interventions or to achieve optimal quality of life.

Examination and Evaluation

Throughout this chapter we have discussed negative limbic influences or states and positive limbic states. Negative limbic states include the overloaded or overactive state, termed *limbic high*, whereas underactive limbic network states can be termed *limbic low* (underactive). The optimal state of any human limbic network is one that is devoid of negative limbic influences, or a *limbic neutral* state. A limbic neutral state provides a strong foundation for procedural learning to occur. We discuss how various disorders are typically associated with negative limbic states in Table 4.1.

Therapists are familiar with the need to prioritize primary body system impairments as they relate to a movement disorder. Moreover, they are familiar with the need to individualize treatment to the primary impairment(s) identified through the evaluation process. Logically, the next consideration for medical and rehabilitative professionals is how we determine or assess the limbic network state of our patients, using qualitative versus quantitative assessment. The master clinician can surmise this intuitively, based upon both observation and experience. But how do we develop this as a requisite skill in our students and colleagues, and can we agree that there is an opportunity to do so? Considering the evidence presented within this chapter, one might challenge that there is a *need* to do so. And if this is true, what existing assessment tools are there to assist us in doing so?

TABLE 4.1 Interactions Among Limbic State, Medical Conditions, and Behaviors

Limbic State	Often Associated With	Observed Behaviors
Neutral	Health and wellness	Relaxed state
Low	Depression and stroke	Decreased eye contact and crying Lack of motivation
High	Anxiety and panic disorders Vestibular disorders Mild or traumatic head injury Blast injury, PTSD	Anxiety, anger, fear, increased respiratory rate, higher blood pressure, high muscle tension or tone, and hyperactivity
Overload (F ² ARV, GAS)	Traumatic head injury Blast injury, PTSD, frail individual (either young or old), and physiologically unstable individual	Violence, extreme withdrawal, loss of inhibition, and reversal of expected behavior

Many individuals with neurological dysfunction fall into these categories.

GAS, General adaptation syndrome; F²ARV, fear and frustration, anger, rage, violence; PTSD, posttraumatic stress disorder.

Traditionally, observation was our main assessment tool in the identification of these impairments. Observation of patient presentation and behaviors would provide an astute clinician with insight into the system. It was not included as a standard part of the assessment, but rather a notation of extremes. There are no assessment tools validated to provide insight into the limbic network state. This certainly makes sense given the broad-reaching structural and functional influences of the system as outlined within this chapter. Similarly, beyond strategic management of the environmental stimuli for patients with head injury or clear agitation, there was no clear path from observation to screening to assessment to intervention.

As such, it is recommended that we agree to the importance of elevating the limbic network to a primary body system that has significant, well-established influence over movement. As the movement specialists, it is therefore recommended that we commit to the validation and/or development of screening and assessments of the limbic state. Screening of the system is designed to be binary, ruling individuals either in or out of the limbic impaired group. Just as in the identification of fall risk, high specificity and potential errors in ruling in might be considered. However, despite the absence of such tools, we can propose that observation of limbic-associated presentation and behaviors could trigger a therapist to be alert and to set the therapeutic environment in general. In [Table 4.2](#) we outline the ways in which a

therapist might use existing skills and knowledge to quickly screen patients for negative limbic network involvement, with examination of the system if negative influence (*limbic high* or *limbic low* state) is suspected. It might be recommended that all at-risk patients by history, as well as those individuals who have primary or secondary involvement of the limbic structures or have neurochemical risk, undergo examination. The potential population of individuals is described in examples throughout the foundations of this chapter, common disorders summarized at the end of this chapter, and outlined again for the reader here, in the context of the evaluation, in [Table 4.2](#).

Interventions

No single input causes any one or multiple limbic responses, nor does one treatment counteract their progression. Being aware of clinical signs is critical. In a time when therapists are often rushed by the realities of a full schedule or stressed by a third-party or short discharge demands, a clinician may inadvertently miss key signs and opportunities to treat. In addition, he or she may actually create a less optimal environment by physically moving faster than the pace best tolerated by the patient, who may need more time to process stimuli or to practice a target skill. The challenge for both the therapist and the patient is to find harmony within the given environment to allow for optimal outcomes. If a therapist misses these limbic signs that reflect

TABLE 4.2 Patient Evaluation—From Screening Through Examination

	Limbic Low	Limbic High
Observation (behaviors)	<p><i>Vision</i>—decreased eye contact; downward cast eyes</p> <p><i>Voice</i>—low volume and rate and poor articulation</p> <p><i>Muscle</i>—low muscle tone; decreased extensor muscle tone and often increased flexor tone.</p> <p><i>Posture</i>—flexed posture; forward head; and may have flexed extremities, often have poor postural trunk coactivation.</p> <p><i>Activity level</i>—slowed movements/decreased responsiveness or engagement and decreased attention, motivation, and fatigues quickly.</p>	<p><i>Vision</i>—decreased eye contact; darting or scanning eye movement</p> <p><i>Voice</i>—increased rate, variable volume, and poor articulation</p> <p><i>Muscle</i>—high muscle tone; increased extensor muscle tone.</p> <p><i>Posture</i>—extended posture; may have extended extremities.</p> <p><i>Sensory</i>—lower thresholds to stimuli</p> <p><i>Activity level</i>—hyperactive or hypervigilant; “nervous” behaviors (twitching, leg or finger tapping, fidgeting, etc), agitated or irritated engagement; attention deficit.</p>
Systems review	<p><i>Skin</i>—pallor</p> <p><i>Respiratory rate/quality</i>—slowed, shallow or deep; heavy sighs and yawns</p>	<p><i>Skin</i>—can be red, blotchy in color</p> <p><i>Sensory</i>—tactile sensitivity or hypersensitivity; dysesthesias; and Allodynia</p> <p><i>Respiratory rate/quality</i>—rapid and shallow</p>
History	<p><i>Psychological</i>—depression, bipolar depression; grief; substance abuse</p> <p><i>Neurological</i>—left CVA; normal pressure hydrocephalus; acquired cerebral disorders (stroke, tumor, and ventricular disorders); progressive cerebral disorders (PD, MS, ALS, etc)</p> <p><i>Cardiopulmonary</i>—primary cardiac disorders</p> <p><i>Chronic disorders/illness</i>—chronic pain; prolonged hospitalization; multifactorial disequilibrium; and dysequilibrium of aging</p>	<p><i>Psychological</i>—Anxiety? PTSD? Bipolar depression; fear/fear of falling. (Can come from a prior abusive environment)</p> <p><i>Neurological</i>—right CVA; late phase dementia, Parkinson disease; head injury (traumatic of any severity; concussion; blast injury); and vestibular dysfunction</p> <p><i>Cardiopulmonary</i>—primary cardiac disorders; COPD and primary respiratory disorders</p> <p><i>Musculoskeletal</i>—MVA</p> <p><i>Social/vocational</i>—contact sports and military service (with or without blast exposure); domestic violence</p> <p><i>Chronic disorders/illness</i>—chronic pain</p>
Examination (examples, but not limited to)	<p><i>Vital signs</i>—decreased HR, RR, and gait velocity</p> <p><i>Tests and measures:</i></p> <p>Positive and Negative Affective Scale (PANAS)</p> <p>Depression Anxiety Stress Scales (DASS21)</p> <p>Geriatric Depression Scale (GDS)</p>	<p><i>Vital signs</i>—increased HR, RR, gait velocity</p> <p><i>Tests and measures:</i></p> <p>Positive and Negative Affective Scale (PANAS)</p> <p>Depression Anxiety Stress Scales (DASS21)</p> <p>Agitated Behavior Scale</p> <p>Rancho Level of Cognitive Function (RLOCF)</p> <p>Moss Attention Rating Scale</p>

ALS, Amyotrophic lateral sclerosis; COPD, chronic obstructive pulmonary disease; CVA, cerebrovascular accident; HR, heart rate; MS, multiple sclerosis; MVA, motor vehicle accident; PD, Parkinson disease; PTSD, post-traumatic stress disorder; RR, respiratory rate.

the emotional state of the patient, the patient may perceive that the therapist doesn't truly care about him or her as a person and thus the therapeutic alliance (patient/therapist bond) may be negatively affected.

The positive and negative effects of sensory input or the therapeutic environment on the limbic system, on motor output, and on behaviors are as much a part of the treatment plan as are the therapeutic activities. The *limbic network state* may support or limit consistent responses of the motor systems and thus dampen procedural learning and limit the success of the therapeutic setting. The optimal therapeutic environment for an individual is a positive limbic state where the system is open to learning and not trying to protect or withdraw from the learning environment. This state would be described as *limbic neutral*, or devoid of negative limbic influence, to ensure a strong foundation for both declarative and procedural learning to occur. Carryover of procedural learning into adaptive motor responses needs to be practiced with consistency.³⁹ If a patient is frustrated or angry and simultaneously has hypertonicity, then a therapist might spend the entire session trying to decrease the abnormal motor response when the causation may be limbic. If the patient could be helped to neutralize the emotional system during the therapy session and achieve a *limbic neutral* state, then the specific problems could be treated effectively and with confidence that whatever motor problems exist are truly motor-driven. Differentiating the limbic network component from the motor control system when establishing treatment protocols has not typically been within the spectrum of a therapist's skills, but is a skill that must be developed and practiced if rehabilitation professionals are to be considered movement specialists.

The critical responsibility of physical therapists is to strategically manage the interaction between sensory inputs of the **therapeutic alliance** and the **therapeutic environment** and thus the activation of the limbic network or *limbic network state*. Successful management of these components, paired with the correct **tasks or therapeutic activities**, serves to set a strong, neutral foundation for effective motor learning to occur. Initially practicing motor skills with a limbic neutral environment will lead to motor learning. The therapist should then slowly introduce limbic stimuli and continue to practice the motor learning. In that way, the motor system learns the control no matter the emotional environment society might introduce.

Therapeutic Alliance: Clinician and Patient

The concept of patient/client-centered therapy has evolved to become an important aspect of health care delivery.^{204–206,330–337} The desire to improve or regain function can be self-motivated, but very often it is instilled through the clinician to the patient that his or her best interests and unique goals are the focus of the health care team. This belief is based on trust, hope, and attainable steps toward desired and realistic goals, all of which are limbic driven. Patients know when their desires, interests, and needs as unique and valued members of society are considered as part of therapy. They first believe and then recognize that they are persons with specific problems and desired outcomes when the therapist empowers them to link those beliefs to their own therapeutic environment. Although they may have specific medical diagnoses, be placed on clinical pathways, administered drugs, and sent off to the next facility in a couple of days, patients need to feel that they, as individuals, have not lost all individuality and that someone cares. That need is a feeling of security and safety that bonds a patient to a therapist along the journey of learning.^{338–340}

Before understanding and becoming compassionate regarding the needs of other people, such as patients with signs and symptoms of neurological problems, therapists need to understand their own limbic network and how it affects others who might interact with

them.^{288,341–345} The emotions felt by the therapist learner in pursuit of mastery and the ability to have the intellectual memory of the learning are also limbic functions. These behavioral or limbic responses will play an important role in our own lives, but also may either positively or negatively influence the lives and recovery of our patients/clients, and we will investigate this concept further in this chapter.

Many types of emotions create motivation, such as pleasure, reward processes, emotions associated with addiction, appreciation of financial benefits, amusement, sadness, humor, happiness, and depression.^{33,346–350} Some emotions tend to drive learning, whereas others may discourage learning, whether that learning be cognitive or motor. If a person is fearful or apprehensive, motor performance and the ability to learn either a motor skill or intellectual information will be very different^{118,293,351–356} from that of an individual who feels safe, is given respect, and becomes part of the decision making process and thus functions inherently with control.^{39,209,213,355,357–359}

An individual will naturally have feelings of loss and reservations or fears about the unknown future after injury to any part of the body, but especially the CNS. Yet that individual needs to be willing to experience the unknown to learn and adapt. The willingness, drive, and adaptability of that individual will affect the optimal plasticity of the CNS.³⁶⁰ The limbic network is a key player that drives and motivates that individual. The lack of awareness of that variable or its effect on patient performance will ultimately lead to questions and doubts about the effectiveness and efficacy of both assessment and intervention results. Similarly, if this system is overwhelmed either internally or externally, it will dramatically affect neuroplasticity and motor learning as well as cognitive, syntactical learning.

At the conclusion of this chapter it is hoped that therapists will comprehend why there is a need to learn to modulate or neutralize the limbic network so that patients can functionally control movement and experience cognitive learning. Then therapists need to strategically reintroduce emotions into the activity and allow the patient to once again experience movement and cognitive success during various levels of emotional demands and environments. This change in the emotional environment will create novelty of the task. This novelty is a critical motivator for learning and will drive neuroplasticity.^{361–363}

Yet a therapist deals with the limbic network of patients on a moment-to-moment functional level throughout the day. Fig. 4.9

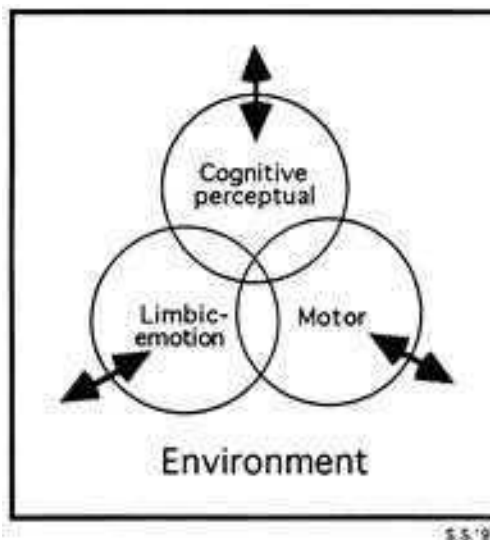

Fig. 4.9 Interlocking Co-Dependence of All Major Central Nervous System Components.

Fig. 4.10 (A) Grief, depression, and compassion responses are seen in the center figures, and rigid, stoic, distancing behaviors are observed in the two left statues. (B) Compassion is easily recognized in the clinic between a therapist and the patient. (A, From Vigeland Sculpture Grounds in the Frogner Park, Oslo, Norway. Adapted from photo by Normann.)

illustrates the interlocking co-dependency of all major CNS components with the environment. At no time does any system stand in isolation. Thus, from a clinical perspective the therapist should always maintain focus on the whole environment and all major interactive components within it, while directing attention to any specific component. How the feedback (internal and external) to the patient's CNS changes the neurochemistry and membrane potential, triggers memory, creates new pathways, or elicits other potential responses is not the responsibility of the clinician or therapist. The responsibility of the clinician is accurate documentation of changes and consistency of those changes toward desired patient outcomes. The professions that focus on movement science are interacting more closely with the neurosciences and other biological sciences and many related professions to unravel many of these mysteries and create better assessment and intervention procedures for future patients.

Because of the potency of the limbic network's connections into the motor system, a therapist's sensitivity to the patient's emotional state would obviously be a key factor in understanding the motor responses observed during therapy. In Fig. 4.10 an entire spectrum of motor responses can be observed in four statues. A patient who feels safe can relax and participate in learning without strong emotional reactions. The woman being held in Fig. 4.10A is safe and relaxed. The man and woman are interacting through touch with deep pressure, warmth, and compassion that are often observed in the patient-therapist interaction of an experienced or master clinician. In Fig. 4.10B, the patient and clinician seem to flow together during the treatment as if they shared one motor system. When looking at the therapist and patient or looking at the man and woman in the statue, it becomes obvious that the two figures seem to flow together. In the statue, those two figures make one piece of art.

With clinical emphasis on patients generating and self-correcting motor programming, it would perhaps seem reasonable for a therapist to conclude that he or she need not, or should not, touch the patient. This conclusion may be accurate when considering the motor system in isolation and assuming that patients can self-correct errors in motor programs. When correction by the therapist is through words rather than touch, external feedback through the auditory system has replaced internal feedback from the somatosensory system. The voice, as well as touch, can be soothing and instill confidence.³⁶⁴ Yet language in and of itself will not replace the trust and safety felt both physically and emotionally through the deep pressure of touch as illustrated in

Fig. 4.10. Bonding and trust occur much more often through touch than through conversation.³⁶⁵ Recall, also, that verbal instructions require intact auditory processing and translation from declarative to procedural information, a cognitive ability that the patient may not possess.

Referring again to Fig. 4.10A, the two men in the statue on the left demonstrate a lack of bonding. In fact, if the artist could have brought them closer together, they might just have rejected or repelled each other with greater intensity. If one of the men were the therapist and one the patient, little interaction would be occurring, and thus an assumption that learning is occurring is probably false. The therapist could do nothing to the other person (and vice versa) without that person perceiving the act as invasive, negative, or even disrespectful, with little consideration of the person's individual values. The therapist's responsibility is to open the patient's receptiveness to learning, not to close it.^{366,367}

These pictures clearly illustrate two types of therapist-patient interactions, or *therapeutic alliance*. If an artist can clearly depict the tonal characteristics of emotion, certainly the therapist should be able to recognize those behaviors in the patient.^{39,368} Achieving a limbic neutral state in the patient through an effective therapeutic alliance is an essential foundation for successful intervention and functional outcome. There are many core tenets and techniques necessary to effectively achieve this neutral state, internal and external therapeutic environment, and optimal performance and learning in the patient. The first component of a successful intervention is self-awareness on the part of the helping professional. "Behavioral activity can often tell us about the inner state of another or ourselves" (p. 19).³⁶⁹ The willingness to be aware of one's own internal state increases the therapist's ability to perceive subtleties in the patient's responses. Differentiating how a patient learns and emotionally responds to therapy from how the clinician learns and emotionally responds to the patient/therapist bond and to therapeutic environments allows the therapist to create a situation where patient can more easily learn. Subsequently, the therapist must establish predictability for their patient's interventions through *Trust, Responsibility, Flexibility and Openness, and Vulnerability*.

Trust. Trust is a critical component of a successful therapy session.³⁷⁰ The therapist gains the patient's trust by his or her actions. The therapist may also build trust through sincere acknowledgment that the patient has life-limiting functional problems and that those problems are limiting normal participation. Trust is further developed when the therapist's words can be supported by data. When the

therapist can illustrate the presence of functional limitations and generate a treatment plan with the patient using objective data, a bond of trust between the patient and the therapist are created.³⁷¹ In today's environment the use of reliable, valid, objective tests and measures allows for this form of communication, which has not existed to the same extent in the past. Honesty and truth lead to trust.^{105,372–376}

A trusting relationship is strengthened when an agreement or “contract” can be established that sets the boundaries for discomfort (fatigue, dizziness, nausea, and imbalance) or pain that the patient will experience within a therapeutic session. As one example, telling a person that you will not hurt them is a therapist-patient contract. If the therapist continually ranges a joint beyond a pain-free range, that behavior is dishonest and untruthful and will not lead to trust. Trust can be earned by stopping as soon as the patient verbalizes symptoms or shows pain with a body response such as a grimace. Being sensitive to a patient's pain, no matter the cause, and working with the patient to eliminate that pain often lead to very strong bonding and trust that will lead to compliance and learning. Ignoring the pain may be perceived as insensitivity and lack of caring, which can lead to distrust and often resistance to learning or performance.

As another example, a patient with vestibular dysfunction associated with significant dizziness and nausea will experience symptoms within the course of recovery (adaptation and compensation), but those symptoms must be carefully controlled in intensity and duration. Symptoms poorly controlled can trigger an ANS or GAS cascade and elevate the limbic state, preventing learning and recovery and destroying trust.

Because these symptoms can be overt or covert, the therapist needs to be aware of both the physical and emotional responses of the patient. The use of analog or perceived exertion scales can be a valuable way to make the covert more overt to the therapist. Symptoms are valuable to the therapist as well as the patient to cooperatively create environments for change. The intensity of those stimuli need close monitoring because they can dramatically affect motor responses and ultimately overwhelm the CNS and prevent learning. Compliance to participation is limbic, and the limbic system has tremendous control over intentional movement, no matter the context of the environment.¹⁰⁵

Once a patient gives his or her trust, a clinician can freely move with the patient and little resistance caused by fear, reservations, or need to protect the self will be felt or observed. When the patient is *limbic neutral* (the limbic network is emotionally neutralized), the tightness or limitations in movement that are present on examination can be considered true impairments within those systems or subsystems. Examination and interventions at this time will more consistently reflect true motor performance. Once limbic neutral has been achieved and examination is complete, it is recommended, for example, that if the pain is a result of peripheral tightness or joint immobility, the therapist does not elicit pain during that session. Deal with those issues in the next session after gaining the trust of the patient. Trust by the therapist or the patient does not mean lack of awareness of potential danger. Trust means acceptance that although the danger is present, the potential for harm, pain, or disaster is very slight and the expected gain is worth the risk (in this case, delay in intervention). In Fig. 4.11, the student's trust that the instructor will not hurt her can be seen by her lack of protective responses and by her calm, relaxed body posture. The student is aware of the potential of the kick but trusts her life to the skills, control, and personal integrity of the teacher. Those same qualities are easily observed in patient-therapist interactions when watching a gifted clinician treat patients. The motor activities in a therapeutic setting may be less complex than in Fig. 4.11, but in no way are they less stressful, less potentially harmful, or less frightening from the patient's point of view.

In addition, therapists must first trust themselves enough to know that they can effect changes in their patients.^{17,377} Understanding one's own motor system, how it responds, and how to use one's hands, arms, or entire body to move someone else is based partly on procedural skills, partly on declarative learning, and partly on self-confidence or self-trust. Trusting that one, as a therapist, has the skill to influence the motor response within the patient has a limbic component. If a therapist has self-doubts about therapeutic skills, that doubt will change performance, which will alter input to the patient. This altered input can potentially alter the patient's output and vary the desired responses if the patient's motor system cannot run independently.

Responsibility. Very close to the concept of trust is the idea of responsibility. Accepting responsibility for our own behavior seems obvious and is accepted as part of a professional role.³⁷⁸ Accepting and

Fig. 4.11 Trust Relaxes the Limbic Network's Need to Protect. **(A)** The skill of the teacher is obvious. **(B)** The student trusts that she is in no danger.

Fig. 4.12 The teacher relinquishes the task to the student, and the student trusts the teacher is right even if self-doubt exists.

allowing the patient the right to accept responsibility for her or his own motor environment are also key elements in creating a successful clinical environment and an independent person.^{204–206,318,379,380}

Fig. 4.12 illustrates the concept through the following example: The instructor asked the student to perform a motor act, in this case, to perform a kick to the teacher's head. The kick was to be very strong or forceful and completed. The student was instructed not to hold back or stop the kick in any way, even though the kick was to come within a few inches of the teacher's head. This placed tremendous responsibility on the student. One inch too far might dangerously hurt the instructor, yet one inch too short was not acceptable. The teacher knew the student had the skill, power, and control to perform the task and then passed the responsibility to the student. The student was hesitant to assume the responsibility, for the consequence of failure could have been very traumatic. However, the student trusted that the teacher would not ask for the behavior unless success was fairly guaranteed. That trust reduced anxiety and thus neutralized the neurochemical limbic effect on the motor system of the student, giving her optimal motor control over the act.³⁸¹ Once the task was completed successfully, the student gained confidence and could repeat the task with less fear or emotional influence while gaining refinement over the motor skill.

Although the motor activities described in this example are complex and different from functional activities practiced within the clinic by therapists and patients, the dynamics of the environment relate consistently with patient-therapist roles and expectations. A gifted clinician knows that the patient has the potential to succeed. When asked to perform, the patient trusts the therapist and assumes responsibility for the act. The therapist can facilitate the movement or postural pattern through the use of his and her hands and own body movements, thereby ensuring that the patient succeeds. This feeling of success by the patient stimulates motivation for task repetition, which ultimately leads to learning. The incentive to repeat and learn becomes self-motivating and then becomes the responsibility of the patient. As the therapist relinquishes control and empowers the patient to more and more of the function, novelty to the learning is occurring.

Current literature has shown that people are more motivated by novelty and change than by success at mastery or accomplishment of a goal.^{96,381,382} The limbic complex and its interwoven network

throughout the nervous system play a key role in this behavioral drive.³⁸³ The task itself can be simple, such as a weight shift, or as complex as getting dressed or climbing onto and off of a bus. No matter what the activity, the patient needs to accept responsibility for her or his own behavior before independence in motor functioning can be achieved. Although the motor function itself is not limbic, many variables that lead to success, self-motivation, and feelings of independence are directly related to limbic and prefrontal lobe circuitry. The variance and self-correction within the movement expression also create novelty and motivation to continue to practice.^{96,381–384}

As another clinical example of responsibility, in a patient with vestibular dysfunction and dizziness compounded by anxiety, symptoms of dizziness are necessary during treatment to drive CNS change. The therapist has a responsibility to prescribe the appropriate activities, dosage (intensity, timing, and so on), and environment to retrain sensory organization and balance (motor output). The patient can be given the responsibility of monitoring and managing her or his own symptoms within these activities. For instance, empowering the patient to determine the maximal level of dizziness within the therapeutic activity is an example of how the patient and therapist can develop an optimal level of interaction and potential positive therapeutic outcomes. A tool as simple as a verbal or visual analog scale can empower the patient to manage symptoms, dampen the limbic network response, and improve motor output for balance control.

Flexibility and openness. Another component of a successful clinical environment deals with learning and flexibility on the part of the therapist. A master clinician sees and feels what is happening within the motor control output system of the patient. Letting go of preestablished beliefs concerning what will happen is difficult.^{385,386} It is important for a clinician to be open to what is present as the motor expression. This openness is critical to actually identifying what is being expressed by the nervous system of the patient. Master clinicians do not get stuck on what they have been taught but use that as a foundation or springboard for additional learning. Learning is constantly correlated to memories and new experiences.

To the therapist, each patient is like a new map, sparsely drawn or sketchy at the beginning, but one that is constantly revised as the terrain (patient's condition) changes. The initial medical diagnosis may link to many paths provided within the map, but the comorbidities can result in great variance among patients.³⁸⁷ That initial map might be a critical care pathway for the patient, given her or his neurological insult. That pathway is a map, but only a sketchy one, and may not even be a map that a particular patient falls within, in spite of his or her medical diagnosis. It is the therapist's responsibility to evaluate the patient and determine whether that pathway or map will work or is working and when features of that map need to be changed, or altered, further. That is, the therapist must let go of an outdated map or treatment technique and create a new one as the environment and motor control system of the patient change. This transference or letting go of old maps or ideas is true for both the patient and the therapist. If a position, pattern, or technique is not working, then the clinician needs to change the map or directions of treatment and let the patient teach the therapist what will work. The ability to change and select new or alternative treatment techniques is based on the attitude of the therapist toward selecting alternative approaches. Willingness to be flexible and open to learning is based on confidence in oneself, a truly emotional strategy or limbic behavior. Master clinicians have learned that the answers to the patient's puzzle are within the patient, not the textbooks.

Fig. 4.13 depicts two maps, each with a beginning point and a terminal outcome or goal. The parameters of the first map illustrate the boundaries of that therapist's experience and education. The clinician, through training, can identify what would seem to be the most direct

Outside Clinical Expertise of Two Disciplines
MAPPING

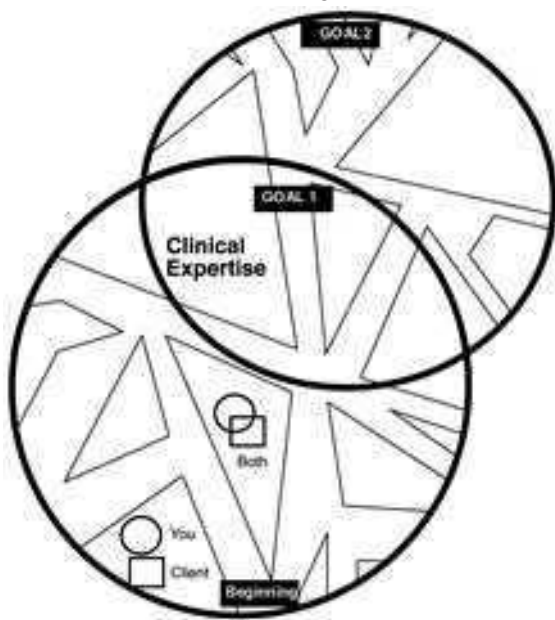

Fig. 4.13 Concept of clinical mapping including patient and therapist and the interactions and importance of overlapping professional goals and staying within the professional expertise.

and efficient route toward the mutually identified goal of the therapist and patient. When the patient becomes a participant within the environment or map, what would seem like a direct path toward a goal might not be the easiest or most direct path for the patient. If empowerment of the patient leads to independence, then allowing, even encouraging, the patient to direct therapy may provide greater variability, force the patient to problem-solve, and lead to greater learning. The therapist needs to recognize when the patient is not going in the direction of the goal. For example, the patient is trying to perform a stand-pivot transfer and instead is falling. If it is important to practice transfers, then practicing falling is inappropriate and the environment (either internal or external) needs modification. Falling can be learned and practiced at another time. Once both strategies are learned, the therapist must empower the patient to take ownership of the map. In the examples of transferring, if the therapist asks the patient to practice transfers and if the patient starts to fall, a change in required motor behavior must be made and the opportunity given to the patient to self-correct. In that way the patient is gaining independent control over a variety of environmental contexts and outcomes. Within the same figure (see Fig. 4.13) is a second map. That second map might represent another professional's interaction and goal with the same patient. It is during these overlapping interactions that both professionals can empower the patient to practice, and that practice will help lead to those functional goals established by both practitioners. In some situations, a clinician from one profession may guide a patient toward obtaining the functional skill necessary for a member of the second profession to begin guiding the patient toward the expected outcomes of the second profession. These interlocking dependencies of the patient and the professions are illustrated in Fig. 4.13. If the patient begins therapy striving for the first goal and ends at the functional outcome of the second goal, then additional functional outcomes have been achieved and both professions interacted for the ultimate prognosis for the patient. That interaction requires respect

and openness of both professionals toward each other as well as toward the patient. Those attitudes and ultimate behaviors are limbic-driven.

Matching maps should be a collaborative effort instead of coincidence. These collaborative efforts include interactions with all professions within the rehabilitation setting. Occupational and physical therapists are very familiar with collaboration, and both often approach interventions as a team effort. There are many additional therapists and individuals within that same setting who could also collaborate. Recreational therapists, psychologists, nurses, family members, and music therapists are but a few. Within a profession such as music therapy, the existence of two maps may overlap within a multidimensional environment. When a physical or occupational therapist needs to challenge a patient, the music therapist may be able to calm the system at the same time (overlapping maps). Research on affective responses to consonance and dissonance in music supports the creation of a map within a rehabilitation environment that could overlap with either physical, occupational, or speech therapy. Words such as *relaxed* or *calm* correlated positively with higher levels of consonance in the music, whereas adjectives associated with negative emotions (*unpleasant, tense, irritable, annoying, dissonant, and angry*) were found to correlate positively with higher levels of dissonance.²⁸¹ Creating a whole environment where potential frustrations within motor learning could be balanced with higher levels of consonance in the music would potentially balance the limbic network emotional response within the overlapping maps and bring balance or stability to the limbic network's influence on motor learning and control. A later study by Peretz and colleagues³²⁷ related the same variables to a happy-sad rating task. Given the research evidence for activity within the limbic network as it relates to music,^{323,388} motor learning,³⁸⁹ and cognitive enhancement,³⁹⁰ a natural multiple map system would be easy to incorporate within a therapeutic setting. The clinician needs to appreciate the uniqueness of each map while holding onto the concept of the interaction of the two maps.

Vulnerability. To receive input from a patient that is multivariable and simultaneous, a therapist has to be open to that information. If a clinician believes that he or she knows what each patient needs and how to get those behaviors before meeting the patient, then the case falls into a category of a recipe for treating the problem. Using the recipe does not mean the patient cannot learn or gain better perceptual and cognitive, affective, or motor control, but it does mean that the individuality of the person may be lost. A more individualized approach would allow the clinician to identify through behavioral responses the best way for the patient to learn how to sequence the learning, when to make demands of the patient, when to nurture, when to stop, when to continue, when to assist, when to have fun, when to laugh, or when to cry. An analogy might be going to a fast food restaurant versus a restaurant where each aspect of the meal is tailored to one's taste. It does not mean that both restaurants are not selling digestible foods. It does mean that at one eating place the food is mass-produced with some choices, but individuality, with respect to the consumer, is not an aspect of the service. Unfortunately, managed care, limited visits, reduced time for treatment, and therapists' level of frustration all are pushing therapeutic interventions toward a "one size fits all" philosophy that may increase the time needed for learning, not reduce it.

To be open totally to processing the individual differences of the patient, the clinician must be relaxed and nonthreatened, and feel no need to protect himself or herself from the external environment. This environment needs to project beyond the therapist-patient relations and envelop all disciplines interacting with the patient.³⁹¹ For these interactions to occur, the clinician's emotional state requires some vulnerability, allowing him or her to be open to new and as-yet-unanalyzed or unprocessed input. This vulnerability implies the role not of an expert

who knows the answers beforehand but of an expert investigator. Being open must incorporate being sensitive not only to the variability of motor responses but also to the variability of emotional responses on the part of the patient.^{392,393} This vulnerability leads to compassion, understanding, and acceptance of the patient as a unique human being. It can also be exhausting. Therapists need to learn ways to allow openness without taking on the emotional responsibility of each patient.

A clinical example can be used to help identify unique characteristics of the patient that will set the stage for effective learning. A 72-year-old woman has sustained a left CVA. She comes from a low socioeconomic background and was a housekeeper for 40 years for a wealthy family of high social standing. She addresses you (the therapist) with “yes, ma’am” or “no, ma’am” and does just what is asked, no more and no less. It may be very hard to empower this patient to assume responsibility for self-direction within the therapeutic setting. She may not feel she has the right or the power to assume such responsibilities within a setting (a medical facility) that may, from her perception, have high social status. The concept of empowerment may play a crucial role in regaining independent functional skill and control over her environment.^{204–206,380,394–396} However, to get optimal outcomes from this patient/clinician interaction, the therapist must find an environment, wherein this person feels worthwhile and empowered to regain functional movement to participate in life activities. This can be very challenging to a therapist but comes automatically to a master clinician. It means that both the patient and the therapist need to be vulnerable and open to the unknown for learning.

Not only does the therapist need to recognize when a patient has not accepted responsibility for motor control or has withdrawn from the therapy environment, but must also notice when the observable motor control is exaggerated by limbic reactions. Newspapers sometimes carry a story that generally reads as follows: “Seventy-nine-year-old, 109-pound arthritic grandmother picks up car by bumper to free trapped 3-year-old grandson.” We read these articles and doubt their validity, questioning the sensationalism used by the reporter. But we know that these events are real. That elderly lady picked up the car out of fear of severe injury to her grandchild. Emotions can create tremendously high tonal responses, either in a postural pattern, such as in a temper tantrum, or during a movement strategy, such as picking up a car. Conversely, fear can immobilize a person and make it impossible to create enough tone to run a motor program or actually move. Evaluating muscle power or tone production in relation to emotional state (versus a pure reflection of motor control) is an aspect of evaluation often overlooked.

Therapeutic Environment

The *therapeutic environment* refers to both the internal and external environmental influences upon the individual that may positively or negatively influence a desired therapeutic outcome, and certainly the therapeutic alliance can contribute to that environment. The therapist must establish consistency and predictability within the treatment environment through (1) facilitating or ensuring neutral or stable function of the patient’s body systems or milieu; (2) facilitating a limbic-neutral learning environment; and (3) linking reward and other motivational factors to desired motor/task outcomes.

Facilitating the internal environment. First, consider that the structure and function of an individual’s body systems influence function of the limbic network and prepare the brain for motor learning. More specifically, the neurobiology must include adequate neurochemicals to enable effective transmission between the key motor learning structures, including the emotional/behavioral prefrontal-limbic “forebrain” system, the cerebellum, and the motor control limbic midbrain and its cortical M1 projections. Similarly, the

environment should avoid oxidative or other stressors that negatively impact effective neurochemical production or transmission.

Nutrition and hydration. The functions of noradrenergic receptors of the locus coeruleus decline in the presence of hyperoxia-induced oxidative stress. The negative effect of hyperoxia and high levels of oxidative stress are blocked by antioxidants, as determined through animal study.^{397,398} Foods high in anthocyanin and other antioxidants, or “super foods” such as key legumes, blueberries, cranberries, raspberries, strawberries,³⁹⁹ etc. have been shown to be neuroprotective during high periods of stress, which can lead to impaired motor learning through “accelerated aging” and cognitive decline. Motor learning and coordination as well as memory are also highly dependent upon calcium. Calcium-dependent plasticity is present in many synapses within the motor output and control loops, and reductions in calcium may result in deficits in long-term potentiation at these various synapses.⁴⁰⁰

Adequate hydration plays a role in behavior (mood, motivation), cognitive (attention), and motor performance. Even small amounts of dehydration (even less than 5%) have been found to impair performance in tasks that require attention, psychomotor, or immediate memory skills.⁴⁰¹

Sleep and biorhythms. Coordination of circadian body rhythm and sleep are critical for motor performance and learning, and as such, lack of or altered patterns of sleep have a negative effect upon performance and retention.^{189,402,403} Sleep influences and is influenced by levels of all of the monoamine neurotransmitters, thus affecting mood, cognition, and learning.^{188,189}

Motor learning occurs “off-line” during sleep and is important for memory consolidation that is unrelated to practice. It is likely that procedural memory is consolidated during stage 2 non-rapid eye movement (REM) sleep as well as in REM sleep. Interestingly, sleep of 60 to 90 minutes duration that occurs between practice and retention testing has shown to improve motor task performance when compared with those who stay awake.¹⁸⁹

Medication compliance and effectiveness. Effectiveness of prescribed medication is a complex issue, extending beyond compliance, with recommended dosing to include evaluation of effectiveness of prescribed dosing. The physical and occupational therapist play an important, supportive evaluative and educational role in both of these areas. Serotonin and dopamine are two key neurotransmitters required for effective motor control, yet endogenous effectiveness can be impaired, and exogenous over- and under-medication can also reduce their effectiveness. In the case of serotonin, in addition to difficulties in determining optimal dosing for effective neuromodulation, up to 50% of individuals with depression are prone to discontinue their prescribed selective serotonin reuptake inhibiting (SSRI) medication.⁴⁰⁴ In the case of dopamine, there are two problems; first, the challenges associated with delivery of an effective dose of its precursor, L-dopa; and second, the changing effectiveness of dopamine replacement as the disease progresses in years and severity. Initially, upon starting therapy, the neurons of the substantia nigra are responsive to dopamine replacement, but they lose their sensitivity; the drug’s prolonged effectiveness drops after about 10 years of the disease.⁴⁰⁵ Within a given day, individuals may experience a sudden improvement of symptoms followed by a rapid decline in symptomatic relief, termed the “On-Off” phenomenon.^{406–408} The “On” phase is of longer duration earlier in the disease; efficacy is decreased, and this phase is of very short duration after years of therapeutic dosing. Overmedication can occur.⁴⁰⁹ In both cases, evaluation of movement control and/or changes can give the prescribing provider valuable information to assist with achieving optimal dosing.

Achieving an optimal external environment. It is critical that a therapist facilitate a limbic-neutral environment to optimize motor

learning. Obtaining a limbic-neutral impact or learning environment is critical before evaluating functional movement to accurately determine true motor system involvement. Highlighting this again as an example, it can be difficult to differentiate hypertonicity resulting from or worsened by stress from true spasticity or clinical hypertonicity. Patient motivation, alertness, and concentration are critical to motor learning because they determine how well we pay attention to the learning and execution of any motor task. These processes of learning and doing are inevitably intertwined: “We learn as we do, and we do only as well as we have learned.”⁴¹⁰

A neutral limbic environment is one that has mitigated all obvious external stressors (extraneous activities or interruptions, visual interference, auditory interference, olfactory interference, etc.) and internal, patient-specific stressors. These patient-specific stressors require observation and intuition on the part of the therapist, and may be triggered by past memories or experiences associated with less obvious individuals or sensory inputs within the environment. The treating professional can also become aware, during assessments or treatments, of environmental sensory input that may trigger stress responses in patients who have limbic network involvement or who may have experienced traumatic physical or emotional injuries. These triggers can be something as simple as the therapist’s tone of voice in a sentence to the patient or as complex as the multiple-noise environment of a busy rehabilitation setting. Some patients may need to be scheduled for early morning, during lunchtime, or in the late afternoon to provide a decrease in the auditory environment.

The same awareness can lead a therapist to identify something within the environment that could result in a positive emotional state for learning. Positive emotional states may create a limbic environment in which the therapist can link reward and pleasure associations to new motor sequences. As one example, music or pleasurable sounds can be used to help neutralize or balance the limbic influence on motor expression, as discussed earlier in this chapter and also in Chapter 39. Within the therapeutic environment, it may be advantageous to purposefully facilitate positive or pleasant physical and affective experiences using music before engaging individuals in more challenging therapeutic interventions. Although it may be impractical to provide appropriate music selections on the basis of individual assessment in the therapeutic environment (e.g., physical, occupational, music), other modalities such as heat, massage, or ultrasound treatment may also elicit relaxed, receptive physical states.

Predictability of the environment is also an important consideration. Gentile presents a taxonomy for the acquisition of motor skills. In this taxonomy, Gentile describes a continuum of predictability, from “closed skills” that are highly predictable and self-paced to “open skills” that are less predictable and externally paced.⁴¹¹ A classic example of closed versus open would be a private room (closed) versus the middle of the gym (open), highlighted above. Closed, predictable activities provide the patient with the greatest control over themselves and their environment.

Decreasing stimulation versus increasing facilitation may lead to attention, calmness, and receptiveness to therapy. When the patient feels that control over her or his life has been returned, or at least the individual is consulted regarding decisions (informed consent as opposed to forced choices), resistance to therapy or movement is often released and stress is reduced. Even patients in a semi-comatose state can participate to some extent. As a clinician begins to move a minimally responsive patient, resistance may be encountered. If slight changes are made in rotation or trajectory of the movement pattern, the resistance is often lessened. If the clinician initially feels the resistance and overpowers it, total control has been taken from the patient. Instead, if the clinician moves the patient in ways her or his body is

willing to be moved, respect has been shown and overstimulation potentially avoided. This highlights the importance of a physical or occupational therapist managing and strategically planning the treatment environment for all patients, not just for those with known head injury or trauma.

Linking motivation and reward. These words are strong and reflect the importance of the limbic network in rehabilitation. Motivated behavior is geared toward reinforcement and reward, which are based on both internal and external feedback systems. Repeated experience of reinforcement and reward leads to learning, changed expectancy, changed behavior, and maintained performance.⁸⁰ Emotional learning, which certainly involves the limbic network, is very hard to unlearn once the behavior has been reinforced over and over.^{81,82} For that reason, motor behavior that is strongly linked to a negative emotional response might be a very difficult behavior to unlearn. For example, a patient who is willing to stand up and practice transfers just to get the therapist off his back is eliciting a movement sequence that is based on frustration or anger. When that same patient gets home and his spouse asks him to perform the same motor behavior, he may not be able to be successful. The spouse may say, “The therapist said you could.” The patient may respond, “I never did like him!” Thus repetition of motor performance with either the feeling of emotional neutrality or the feeling of success (positive reinforcement) is a critical element in the therapeutic setting. Consistently making the motor task more difficult just when the patient feels ready to succeed will tend to decrease positive reinforcement or reward, lessen the patient’s motivation to try, and decrease the probability of true independence once the patient leaves the clinical setting. When pressure is placed on therapists to produce changes quickly, repetition and thus long-term learning are often jeopardized, which may have a dramatic effect on the quality of the patient’s life and the long-term treatment effects once he or she leaves the medical facility. Motor control theory (see Chapter 3) coincides with limbic research regarding reinforcement. Inherent feedback within a variety of environmental contexts allowing for error with correction leads to greater retention.⁸³ Repetition or the opportunity to practice a task (motor or cognitive) in which the individual desires to succeed will lead to long-term learning.⁸⁴ Without practice or motivation the chance of successful motor learning is minimal to nonexistent.

Goal-directed or need-directed motor actions are the result of the nervous system structures acting as an interactive system. Within this system (see Fig. 4.14), all components share responsibilities. The limbic network and its cortical and subcortical components represent the most important level. In response to stimuli from the internal or external environment, the limbic network initiates motor activity out of the emotional aspect of feeling the need to act. This message is relayed to the sensory areas of the cerebral cortex, which could entail any one or all association areas for visual, auditory, olfactory, gustatory, tactile, or proprioceptive input. These areas are located in the prefrontal, occipital, parietal, and temporal lobes, where they analyze and integrate sensory input into an overall strategy of action or a general plan that meets the requirements of the task. Therefore these cortices recognize, select, and prepare to act as a response to relevant sensory cues when a state of arousal is provided by reticular input. The limbic cortex (uncus, parahippocampal gyrus/isthmus, cingulate gyrus, and septal nucleus) has even greater influence over the somatomotor cortices through the cingulate gyrus, both directly and indirectly through association areas.^{412–414} The thalamus, cerebellum, and basal ganglia contribute to the production of the specific motor plans. These messages of the general plan are relayed to the projection system. The limbic structures through the cingulate gyrus also have direct connections with the primary motor cortex. These circuits certainly have the potential to assist in driving fine motor activities through

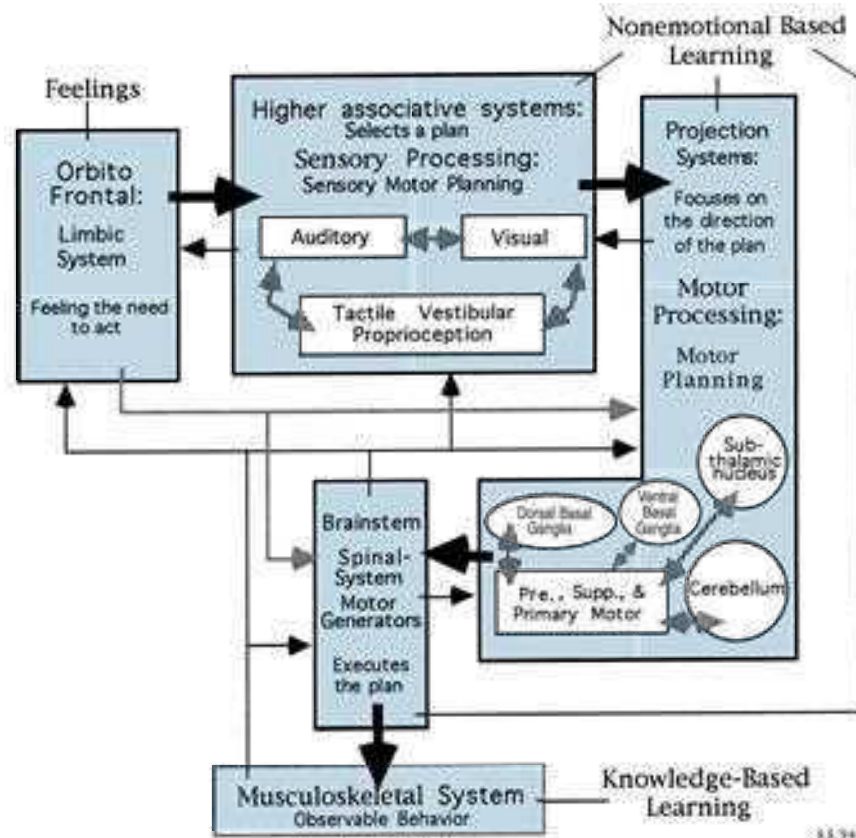

Fig. 4.14 Functional and dynamic hierarchy of systems based on both limbic and motor control interactions. (Adapted from Brooks VB. *The neural basis of motor control*, New York, 1986, Oxford University Press.)

corticobulbar and corticospinal tract interactions. The thalamus, cerebellum, basal ganglia, and motor cortices (premotor, supplementary motor, and primary motor) contribute to the production of the specific motor plans.³⁹ Messages regarding the sensory component of the general plan are relayed to the projection system, where they are transformed into refined motor programs. These plans are then projected throughout the motor system to modulate motor generators throughout the brain stem and spinal system.³⁹ Limbic connections with (1) the cerebellum, basal ganglia, and frontal lobe^{39,415-419} and (2) the motor generator within the brain stem enable further control of limbic instructions over motor control or expression. If the limbic and the cognitive systems decide not to act, goal-driven motor behavior will cease. An individual's belief (emotional and spiritual) can inhibit even the most basic survival skills, as has been clearly shown in history when individuals with particular religious beliefs were pitted against vicious predators and those people chose not to defend themselves.

Within the projection system and motor planning complexes, the specifics are programmed and the tactics are given a strategy. In general, "what" is turned into "how" and "when." The necessary parameters for coordinated movement are programmed within the motor complex as to intensity, sequencing, and timing to carry out the motor task. These programs, which incorporate upper motor neurons and interneurons, are then sent to the brain stem and spinal motor generators, which in turn, through lower motor neurons, send orders regarding the specific motor tasks to the musculoskeletal system. The actions performed by each subsystem within the entire limbic-motor control complex constantly loop back and communicate to all subsystems to allow for adjustments of intensity and duration and to determine whether the plan remains the best choice of responses to an ever-changing three-dimensional world.^{60,416,417}

The limbic network has one more opportunity to modify and control the central pattern generators and control the body and limbs through direct connections to the spinal neuronetwork.^{135,199,420-422} That is, the limbic network can alter existing motor plans by modulating those generators up and down or altering specific nuclear clusters and varying the patterns themselves. Therapists as well as the general public see this in sports activities when emotions are high, no matter the emotion itself. Individuals who have excellent motor control over a specific sport may find high-level performance difficult as the stress of competition increases. Having control over emotional variance as well as motor variance with a functional activity is an accurate example of empowerment. Thus for a therapist to get a true picture of a patient's motor system function, the limbic network should be flowing in a neutral or balanced state without strong emotions of any kind. Generally, that balance seems to reflect itself in a state of safety, trust, and compliance. Once the motor control has been achieved, then the therapist must reintroduce various emotional environments during the motor activity to be able to state that the patient is independent.

In summary, the limbic complex generates need-directed motor activity and communicates that intent throughout the motor system.^{199,421,423,424} This step is vital to normal motor function and thus patient care. Patients need the opportunity to analyze correctly both their internal environment (their present and feedforward motor plans and their emotional state) and the external world around them requiring action on a task. The integration of all this information should produce the most appropriate strategy available to the patient for the current activity. These instructions must be correct, and the system capable of carrying out the motor activity, for effortless, coordinated movement expression to be observed. If the motor system is deficient, lack of adaptability will be observed in the patient. If the limbic

complex is faulty, the same motor deficits might present themselves. The therapist must differentiate what is truly a motor system problem versus a limbic influence over the motor system problem.

Schmidt⁴²⁵ stresses the significance of “knowledge of results feedback” as being the information from the environment that provides the individual with insights into task requirements. This insight helps the motor system correctly select strategies that will successfully initiate and support the appropriate movement for accomplishing the task. This knowledge of results feedback is required for effective motor learning and for forming the correct motor programs for storage.^{426,427}

The reader may better understand the role of the limbic network in motor programming through a nonmedical example. Imagine that you are sitting in your new car. The dealer has filled the tank with necessary fuel. The engine, with all its wires and interlocking components, is totally functional. However, the engine will not perform without a mechanism to initiate its strategies or turn on the system. The basal ganglia or frontal lobe motor mechanism plays this role in the brain. The car has a starter motor. Yet the starter motor will not activate the motor system without the driver’s intent and motivation to turn the key and turn on the engine. The limbic complex serves this function in the brain. Once the key has been turned, the car is running and ready for guidance. Whether the driver chooses reverse or drive usually depends on prior learning unless this is a totally new experience. Once the gear has been selected, the motor system will program the car to run according to the driver’s desires. It can run fast or slow, but for the plan to change, both a purpose and a recognition that change is necessary are required. The car has the ability to adapt and self-regulate to many environmental variables, such as ruts or slick pavement, to continue running the feedforward program, just as many motor systems within the CNS, especially the cerebellum, perform that function. The limbic network may emotionally choose to drive fast, whereas one’s cognitive judgment may choose otherwise. The interactive result will drive the pedal and brake pressure and ultimately regulate the car. The components discussed play a critical role in the total function of the car, just as all the systems within the CNS play a vital role in regulating behavioral responses to the environment.

Brooks⁸ distinguishes insightful learning, which is programmed and leads to skills when the performer has gained insight into the requirements, from discontinuous movements, which need to be replaced by continuous ones. This process is hastened when patients understand and can demonstrate their understanding of what “they were expected to do.” Improvement of motor skills is possible by using programmed movement in goal-directed behavior. The reader must be cautioned to make sure that the patient’s attention is on the goal of the task and not on the components of the movement itself. The motor plan needs programming and practice without constant cognitive overriding. The limbic/frontal system helps drive the motor toward the identified task or abstract representation of a match between the motor planning sequence and the desired outcome. The importance of the goal being self-driven by the patient cannot be overemphasized.^{200,204–206,428,429}

Without knowledge of results, feedback, and insight into the requirements for goal-directed activity, the learning is performing by “rote,” which merely uses repetition without analysis, and meaningful learning or building of effective motor memory in the form of motor holograms will be minimal. Children with cognitive and limbic deficits can learn basic motor skills through repetition of practice, but the insights and ability to transfer that motor learning into other contexts will not be high.

Schmidt⁴²⁵ suggests that to elicit the highest level of function within the motor system and to enable insightful learning, therapy programs should be developed around goal-directed activities, which means a

strong emotional context. These activities direct the patient to analyze the environmental requirements (both internal and external) by placing the patient in a situation that forces development of “appropriate strategies.” Goal-directed activities should be functional and thus involve motivation, meaningfulness, and selective attention. Functional and somatosensory retraining uses these concepts as part of the intervention. Specific techniques such as proprioceptive neuromuscular facilitation, neurodevelopmental therapy, the Rood method, and the Feldenkrais method can be incorporated into goal-directed activities in the therapy programs, as can any treatment approach, as long as it identifies those aspects of motor control and learning that lead to retention and future performance and allows the patient to self-correct.⁴²⁵ With insights into the learned skills, patients will be better able to adjust these to meet the specific requirements of different environments and needs, using knowledge of response feedback to guide them. The message then is to design exercise activities or programs that are meaningful and need-directed, to motivate patients into insightful goal-directed learning. Thus understanding the specific goals of the patient, patient-centered learning, is critical and will be obtained only by interaction with that patient as a person with needs, desires, and anticipated outcomes.^{430,431} A therapist cannot assume that “someone wants to do something.” The goal of running a bank may seem very different from that of birdwatching in the mountains, yet both may require ambulatory skills. If a patient does not wish to return to work, then a friendly smile and the statement, “Hi, I’m your therapist, and I’m going to get you up and walking so you can get back to work,” may lead to resistance and decreased motivation. In contrast, a therapist who knows the goal of the patient may help him or her become highly motivated to ambulate; that patient may be present in the clinic every day to meet the goal of birdwatching in the mountains, although never wishing to walk back into the office again.

Therapeutic Activities

Strategic exercise prescription has a significant effect upon limbic activity and motor learning. First, exercise has a positive effect on high and low limbic network states, such as seen in chronic stress, anxiety (high), or in depression (low), for example. A recent Cochrane Collaboration Review investigated the effect of exercise upon depression through meta-analysis.⁴³² Though there were methodological errors, the authors were able to conclude that exercise is moderately more effective than a control intervention for reducing symptoms of depression, but not more effective than psychological or pharmacological interventions alone. Individuals with depression can be considered to exhibit a low limbic state, which has been discussed as impairing motor learning. No similar systematic review has been published through the Cochrane Collaboration for anxiety. No Clinical Practice Guidelines could be identified to guide exercise prescription for the depression or anxiety populations, which would be reflective of limbic network involvement.

Exercise similarly establishes an internal environment favorable for neuroplasticity and for neuroprotection. Specifically, high-intensity aerobic exercise facilitates an exercise-induced response of peripheral brain-derived neurotrophic factor (BDNF), which improves the ability to achieve neuroplastic change and motor learning.⁴³³ For a discussion of neuroplasticity and the positive effects of exercise on neuroplastic change and motor learning in the cortex, the reader is referred to Chapter 3. What is less discussed is the effect of exercise on interaction between motor and limbic networks for effective motor learning.⁴³⁴ High intensity exercise also improves neurotransmission of dopamine and glutamate in the basal ganglia, both of which play important roles in the initiation and control of movement.^{435,436} As such, a positive neuroprotective effect can decrease the rate of degeneration of the

dopaminergic cells within the basal ganglia; this can reduce the amount of medication required by an individual to control their symptoms and improve learning and carry-over to function.

Patient education concerning all aspects of limbic network influence on motor performance and learning can provide insight, enabling patients to achieve acceptance and engagement. In particular, education in those aspects of their internal and external environment within their control (sensory inputs, sleep, pharmacological management, etc.) may help maximize patients' participation in interventions, activities, and in societal roles.

Emerging Interventions

Advances in surgical neuromodulation of the limbic circuitry underlying these disorders offer hope for individuals suffering from addiction, PTSD, or memory disorders. Emerging evidence shows that deep brain stimulation (DBS) to specific nuclei within the limbic system may be at least as successful as traditional pharmacological therapies to improve dynamic memory and learning processes.⁴³⁷ In a single patient case investigation, Freund and colleagues reported that treatment with DBS of the nucleus basalis in the basal forebrain enhanced the synthesis of nerve growth factor, resulting in markedly improved cognitive function, specifically attention, concentration, alertness, and drive.⁴³⁸ The critical importance of these cognitive functions to motor learning has been stated frequently throughout the evidence presented within this chapter.

Advancements in genetic profiling and genetic modification bear close attention, with meaningful influence upon all aspects of brain function. As one example, it is understood that adequate dopamine must be present for brain plasticity, motor skill acquisition, and motor learning, given projections from the midbrain VTA to the M1 primary motor cortex.⁵² Electrical stimulation of the VTA resulted in improved function of the dopaminergic pathway and improved expression of the gene *c-fos* in M1 by more than 142%, which has been shown to improve the function of the primary motor cortex. Five genetic polymorphisms have been identified as having effect upon dopaminergic neurotransmission. Specifically the DRD2/ANKK1 genotype has been significantly associated with motor learning and its modulation through medication management of dopamine precursors (L-dopa).⁴³⁹ These genetic variations help to explain the individual differences in patient response to medications designed to improve motor performance (in Parkinson disease [PD]); insight into pharmacological management can be based upon these biological subgroups. The knowledge of genetic variation and specific polymorphisms that negatively impact motor learning can direct future efforts in genetic modification. The knowledge of genetic advancements may assist physical and occupational therapists to help their patients understand their unique positive, neutral, or negative responses to interventions or pharmacological management.

COMMON DISORDERS WITH LIMBIC NETWORK PROBLEMS

Throughout the existence of humankind, emotions have been identified in all cultures. A child knows when a parent is angry without a word being spoken. A stranger can recognize a person who is sad or depressed. People walk to the other side of the road to avoid being close to someone who seems enraged. Emotions are easily recognizable as they are expressed through motor output of the face and body. Emotions similarly have an impact on functional motor control. The effect and intensity of emotions and limbic influence on motor control are an important part of the therapy evaluation. Many lesions or neurochemical imbalances within the limbic network drastically

affect the success or failure of physical, occupational, and other therapy programs. This chapter does not discuss in detail specific problems and their treatment, but instead it is hoped that identification of limbic involvement may help the reader develop a better understanding of its role in specific medical disorders or neurological conditions. Table 4.1 helps differentiate the level of limbic activity with observed behavioral states cross-referenced with various medical conditions.

Grief, Depression, and Anxiety

Notably, 6.7% or 162 million people had at least one major depressive episode in the past year.⁴⁴⁰ Depressive disorders are the sixth-most-costly health condition and the most costly among mental health and substance abuse disorders, with \$71 billion spent in 2013.⁴⁴¹

Dysregulation within the structures of the cortico-limbic network play a role in clinical depression and the major depressive disorders (MDD).^{442–444}

Individuals with MDD demonstrate changes in volume within key limbic structures, specifically lower cingulate (cognitive division) volume and higher amygdala volumes. Individuals with clinical depression also demonstrate changes in neurochemistry, primarily associated with a reduction of *serotonin* production.¹⁹² Ascending serotonergic tracts start in the raphe nuclei of the midbrain and ascend to the limbic forebrain and hypothalamus; they are concerned with mood and behavior regulation.

Emotions such as depression or grief can be expressed by the motor system, typically classified within a limbic low state.^{39,445} Thus the observed or behavioral responses are usually withdrawal, decreased postural extension with increased flexion, and reported feelings of fatigue and/or exhaustion (see Fig. 4.15A and B). Sensory overload, especially in the elderly, can create low muscle tone and excessive flexion. Again, because of the strong emotional factor, these motor responses are considered to be the result of the limbic network's influence over motor control.¹⁹⁹ These individuals can develop an associated sense of learned helplessness, which therapists should identify in an effort to mitigate it.²⁷⁷ When patients are encouraged or allowed to become dependent, their chances of benefiting from services and regaining motor function are drastically reduced.^{446,447}

Fear

Fear is an emotional response and thus is initiated and controlled by the limbic network, specifically the reticulolimbic network.^{39,74} The amygdala recognizes the significance of stimuli, adds the "emotional weight" to sensory experiences or memory, and assigns it with a feeling associated with the need to act. That ascribed "need" to act can be either appropriate, exaggerated, or accelerated. The resultant response or action can either be commensurate with the need (realistic), or can generate an inappropriate response, such as a GAS or F²ARV response. Fear typically is associated with a limbic high state, but can, over prolonged periods of the stress associated with fear, result in a general adaptation avoidance or limbic low state.

Fig. 4.16A illustrates two people riding a rollercoaster, which may or may not generate emotions of fear. The boy looks scared and obviously exhibits fear. However, the woman's expression could be one of either joy or fear, based upon her motor responses. Her facial expression with fixed eyes could represent a limbic motor reaction, which could be a semiautomatic fear response. The amygdala nuclei also play a critical role in regulation of facial responses to fear, pain, or other incoming stimuli.⁴⁴⁸ In Fig. 4.16B, the rollercoaster has stopped, and she still has the same expression. In fact, it took over a minute before she was able to relax her face and regain the feeling that she had some control over her emotional reaction. This was followed by crying and observable frustration at her inability to control her initial response.

Fig. 4.15 (A) Behavior responses elicited by concern, pain, and grief. **(B)** Pain or grief elicits flexion and can modify postural extension. **(A)**, From Viegeland Sculpture Grounds in the Frogner Park, Oslo, Norway. Adapted from photo by Normann.)

Fig. 4.16 (A) Two individuals riding a roller coaster. Individual on right looks scared; this facial expression represents fear. The facial expression of the individual on the left could represent enjoyment, with eyes open and a smile, or extreme fear, with hyperextension of her head causing her mouth to open. **(B)** Individual's facial expression after the roller coaster stopped. She was unable to relax her facial muscles for more than 2 minutes because she had been so scared or demonstrated extreme fear.

These responses are often observed in healthy normal individuals such as those seen in Fig. 4.6, but similarly can be seen in patients who are extremely fearful, no matter the cause.

Fear of falling is a common problem in the elderly, especially in those individuals who have functional limitations resulting from a neurological disorder.^{449,450} Therapists working with individuals who have a fear of falling need to first acknowledge that the fear is normal and then must establish a strong therapeutic alliance. That therapeutic alliance must establish trust of the clinician and predictability for the patient and provide the patient with maximal opportunity

for control over their mobility and safety during interventions. The specifics of the therapeutic alliance were previously discussed in this chapter.

Fear of pain is another emotional response housed within the limbic network that drives many individuals' motor responses. Whether individuals have fear of movement after a musculoskeletal injury,⁴⁴⁸ fear of going to the dentist after a dental procedure,⁴⁵¹ fear of pain intensity after a chronic pain problem,⁴⁵² or fear of falling,⁴⁵³ fear will drive motor responses, and that fear will often lead to a lower quality of life.⁴⁴⁹ For that reason alone, therapists need to differentiate the

limbic system's and the motor system's summated responses when observing the movement patterns of the individual in therapy.

Anxiety and Posttraumatic Stress Disorder

Individuals with anxiety disorders display excessive anxiety and behavioral disturbances that can interfere with daily activities. An estimated 19.1% of US adults had any anxiety disorder in the past year; 31.1% experience anxiety at some point in their lifetime.⁴⁵⁴ These individuals can be classified between a limbic neutral and a limbic high state at baseline.

PTSD is considered an anxiety disorder that specifically develops following a traumatic event, typically one that is life-threatening. It includes perceptual, cognitive, affective, physiological, and psychological components, and is characterized by emotional dysregulation, a hyperarousal state, vivid and intrusive memories of the event(s), and exaggerated fear-avoidance behaviors.⁴⁵⁵ An estimated 3.6% adults were diagnosed with PTSD in the past year, with a lifetime prevalence of 6.8%. Of those, 30.2% of cases are categorized as “mild” and as such, represent highly functional individuals.⁴⁵⁶ However, even the most “mildly” affected of these individuals can most typically be classified within a limbic high state at baseline.

PTSD as a disorder can be a sequelae of many types of trauma associated with emotion, including mild head injury or concussion from accident or domestic abuse, or a frightful experience such as a near-drowning. This problem is especially apparent when treating soldiers injured on the battlefield who have returned home; it is considered a signature injury of war-related activities.⁴⁵⁷ The presence of lower density in the limbic and para-limbic cortices was found to be associated with a diagnosis of PTSD, the degree of trauma, and psychotherapy treatment outcome from eye movement desensitization and reprocessing (EMDR).⁴⁵⁸

A therapist always needs to understand the environment within which the injury occurred, as well as being aware of preexisting complications. In an injury sustained in a violent confrontation or in a frightful experience, the emotional system was at a high level of metabolic activity at the time of the insult. With knowledge of that information, a therapist should assess the state of the limbic network for high (anxiety, fear) or low (depression, avoidance) influence.

Both environmental noise and “background” music, such as present in many clinics, may present in auditory triggers that elicit limbic network and ANS activity, with the potential for eliciting the F²ARV continuum. In treating more than 200 patients following trauma, Körlin⁴⁵⁹ found that certain kinds of musical elements often triggered intrusive and traumatic re-experiences of the event. (For a theoretical discussion of this phenomenon, see Goldberg.⁴⁶⁰) The phenomenon of auditory triggering has implications for the rehabilitation setting, where patients may be recovering from traumas related to accident, injury, or difficult medical procedures.

Suicide and domestic violence have become a more common occurrence between deployments, necessitating a dramatic shift in mental health policy in the last 5 years.^{461–464}

Anger

Anger itself creates muscle tone through the amygdala's influence over the basal ganglia and the sensory and motor cortices and their influence over the motor control system. This is clearly exhibited in a child throwing a temper tantrum (see Fig. 4.17) or an adult putting his fist through a wall. How far a patient or a friend will progress through the F²ARV continuum (discussed earlier within this chapter) depends on a large number of variables. When a patient loses control, the therapist must first determine whether the intervention forced the patient beyond her or his ability to control. If so, changes within the therapeutic environment need to be made to allow the patient opportunities to develop control and modulation over that continuum.

Fig. 4.17 Extensor behavior responses caused by anger. (*Angry Boy*, Vigeland Sculpture Grounds in the Frogner Park, Oslo, Norway.)

Creating opportunities to confront frustration and fear or even anger in real situations while the patient practices modulation will lead to independence or self-empowerment. The patient simultaneously needs to practice self-directed motor programming without these emotional overlays. Thus true motor learning can result. In time, practicing the same motor control over functional programs when confronted with a large variety of emotional situations should lead to independence in life activities and thus meet a therapeutic goal.

Similarly, being unaware of a patient's anger may lead the therapist to the false assumption that that individual has adequate inherent postural tone to perform activities such as independent transfers. If the patient is angry with the therapist and performs the transfer only to get the therapist “off my case,” when the patient is sent home she or he may be unable to create enough postural extension to perform the transfer. Thus this transfer skill was never functionally independent because the test measurements were based on limbic or frontal influence over the extensor component of the motor system. The patient needs to learn how to do the activity without the emotional overlay. When a therapist is unwilling, unaware, or unable to attend to these variables, the reliability or accuracy of functional test results becomes questionable.

Substance Abuse and Dependence

The National Institutes of Health National Institute on Drug Abuse (NIDA) has estimated the annual cost related to substance use disorders, crime, lost work productivity, and health care to the United States at more than \$740 billion annually.⁴⁶⁵

The NIDA Division of Neuroscience and Behavior (DNB) advances the science of substance abuse and addiction through basic and clinical research. Whether medical, illicit, or recreational (such as in alcohol consumption), drugs and alcohol can have dramatic effects on the CNS and often are associated with limbic behavior.⁴⁶⁶ A large body of animal and human evidence over the last several decades has shown that the mesocorticolimbic reward pathway

plays a critical role in the process of addiction. The NAc is a critical structure within that neural circuitry that contributes to reward processing, goal-directed behavior and motivation.⁴³⁷ Recent research has investigated the effect of bilateral stereotactic ablation of the NAc in humans to block the mesocorticolimbic dopamine circuit, resulting in the reduction of drug-seeking behaviors in individuals addicted to opioids. Although full remission has not yet been achieved, decreased symptoms of withdrawal were experienced making it a viable future treatment option.⁴⁶⁷

Korsakoff's syndrome is perhaps the most well-known of the disorders resulting from chronic alcoholism and its related nutritional deficiencies. This syndrome is identified by the structural involvement of the diencephalon, specifically the mammillary bodies and the dorsal medial and anterior nucleus (AN) of the thalamus³⁹ (see the anatomy section and Fig. 4.4). The most dramatic sign observed in a patient with Korsakoff syndrome is severe memory deficits.^{447,468–470} These deficits involve declarative memory and learning losses, but the most predominant problem is short-term memory loss.⁴⁷¹ As the disease progresses, patients generally become totally unaware of their memory loss and are unconcerned. Initially, confabulation may be observed,⁴⁷² but in time most patients with a chronic condition become apathetic and somewhat withdrawn and are in a profound amnesic state. They are trapped in time, unable to learn from new experiences because they cannot retain memories for more than a few minutes and are unable to maintain their independence^{447,468–470,473}; many may become social isolates and homeless. Beyond the notable implications to motor learning through rehabilitation processes, the severe memory limitations paired with the lack of insight into those losses should be considered within the management plan from a safety and a behavioral point of view.

The use of alcohol affects not only adults but also children and adolescents. Still another population of children affected by alcohol abuse has surfaced as a specific clinical problem. These children are infants who have the effects of fetal alcohol syndrome. A variety of researchers have investigated the effects of alcohol and other toxic drugs on neuromotor and cognitive development.^{474–479}

The use of systemic drugs such as cocaine and alcohol can lower the threshold for seizures. Cocaine reduces seizure threshold in patients with underlying epilepsy (direct toxic effect) or indirectly by contributes to poor compliance with antiepileptic medications, poor diet, or poor sleep habits.⁴⁸⁰ The anterior temporal lobe and its connections with the hippocampus and amygdala have a lower threshold for epileptic seizures than do other cortical structures.³⁹ These seizures are often accompanied by sensory auras and alterations in behavior, with specific focus on mood shifts and cognitive dysfunction.⁴⁸¹ Similarly, the AN of the thalamus is an integral part of the limbic system that plays a role in modulating alertness and is involved in learning/memory, but is also associated with intractable seizures. DBS of the AN has been shown not only to reduce seizure activity, but also to improve learning.⁴⁸²

Obviously, the precise association between behavior and emotions or temporolimbic and frontolimbic activity is not understood, yet the associations and thus their impact on a therapeutic setting cannot be ignored.^{294,483}

Disorders of Cognition and Memory

The most challenging of the disorders of cognition and memory is Alzheimer disease. The reader is referred to Chapter 27 for a detailed description and discussion. But relative to the limbic network, the hippocampus and nucleus basalis are the most severely involved structures, with associated neurofibrillar degeneration of the anterotemporal, parietal, and frontal lobes.^{181–183,447,484} The initial symptoms fall into emotional, social, and cognitive categories. Depression and

anxiety often are seen during the early phases because of the neuronal degeneration within the prefrontal lobes and limbic network.^{183,485–487} During the second stage, the emotional, social, and intellectual changes become more marked. Patients have difficulty with demands, business affairs, and personal management. Their memory and cognitive processing continue to deteriorate, whereas their awareness of the problem is often still insightful, causing additional anxiety and depression. During this phase patients may be unable to recognize familiar objects and become fearful because they are losing control of the environment both internally and externally. Thus the patient may become combative out of a defensive autonomic “fight-or-flight” response. For that reason, therapists need to make sure the patient feels safe during therapy to optimize learning and compliance.

The third phase of advancing Alzheimer disease manifests itself with moderate to severe aphasia, apraxia, and object agnosia, or the failure to recognize objects. Distractibility and inattentiveness are also common during this third stage. In the final stage, the individual becomes uncommunicative, with little meaningful social interaction, and often takes on the features of the Klüver-Bucy syndrome. Thus they exhibit emotional outbursts, inappropriate sexual behaviors, severe memory loss, constant mouth movements, and often a flexor-type postural pattern. In this latter phase, the patient is virtually decorticate and clinically indistinguishable from persons with other dementias. The prognosis of Alzheimer disease was only a few years ago totally bleak, but today there are hopes that in the future, pharmacological interventions may slow and even reverse the damage inflicted by this disease.^{488–491}

The continual degeneration of the limbic network through each phase is a key distinguishing factor in Alzheimer disease and constantly affects the behavioral patterns of the individual.^{492–498} The neurochemical state within the limbic network can be influenced by the drugs often used to prevent or slow the progression of Alzheimer disease (see Chapter 36).^{499–503} Similarly, gene therapy may prove to have great therapeutic value given the genetic predisposition identified in some patients with Alzheimer disease.^{39,504–507} Because music is able to activate many different brain areas, music therapy can be particularly valuable in the treatment of persons at all stages of Alzheimer disease.⁵⁰⁸ Long after declarative memory is lost, individuals can sing entire songs (procedural memory), dance with a loved one they no longer recognize (procedural memory), or be soothed and calmed by hearing someone who cares about them singing familiar favorite songs or lullabies (limbic response). In earlier phases of the disease, individuals who have lost words can recall words such as song lyrics through the linking with melody. When melody is lost, individuals still retain rhythmic responses. In the final, palliative stage of Alzheimer disease care, agitated patients are observed to calm to simple music such as familiar lullabies. Thus Alzheimer disease patients are able to continue to respond to music through the progression of the disease, and the response to rhythm may represent overlearned motor responses that are tied to positive limbic states. For example, nonambulatory individuals, when presented with familiar and preferred music, may stand and move with the rhythm of the sound. Their bodies may remember how to dance with the spouse whose name they no longer know.⁵⁰⁹ A physical or occupational therapist can instruct a caregiver to use music as part of everyday activities. The therapeutic effects of music to engage and maintain attention, activate long-term memory, and modulate emotion states are well suited to the needs of both the person with Alzheimer disease and his or her caregivers.⁵⁰⁹

Hippocampal and anterior cingulate volumes have been correlated with both gait and executive function. Hippocampal, anterior cingulate, and NAc volumes have been correlated with stride length. Older adults with mild cognitive impairment demonstrated

significantly slower gait speed and shorter stride length when asked to walk quickly.⁵¹⁰

Head Injury

A detailed understanding of nontraumatic and traumatic head injury can be found in Chapters 22 and 23. The behavioral sequelae after any head injury reflect many signs of limbic involvement. In studies of both the pediatric and adult populations,^{117,511–516} behaviors of impulsiveness, restlessness, overactivity, destructiveness, aggression, increased tantrums, and socially uninhibited behaviors (lack of social skills) are frequently reported. These behaviors all reflect a strong emotional or limbic component. Given Moore's concept of a limbic network that MOVes us and the F²ARV continuum regarding emotional control over noxious or negative input, it is no wonder so many patients have difficulty with personal and emotional control over their reactions to the therapeutic world. If the imbalance were within the patient, then the external environment would be one possible way to help center the patient emotionally.^{517,518} This centering requires that the therapist be sensitive to the emotional level of the patient. As the patient begins to regain control, an increase in external environmental demands would challenge the limbic network. If the demand is excessive, the patient's emotional reaction as expressed by motor behavior should alert the therapist to downgrade the activity level.

Head injuries affect many areas of the CNS, however, no matter the commonalities of the site or extent of the lesions. Each patient is different because of prior learning, conditioning of the limbic network, and their respective perception of quality of life.⁵¹⁹ The overall limbic state (low, neutral, or high) and response of two patients to the same clinical learning environment may have great variance and should be carefully observed, evaluated, and documented by the clinician. The therapist should provide undivided attention to the patient at all times and be willing to make moment-to-moment adjustments within the external environment to achieve a neutral limbic state and help the patient maintain focus on the desired learning. A patient with spasticity, rigidity, or ataxia may exhibit an increase in motor responses when in a limbic high state, when the limbic network becomes stressed. The therapist must differentiate a true motor output and control problem from limbic over- or under-activity that negatively influences the motor control systems. Therapists should be able to identify the true underlying cause of the motor control problem and plan their respective treatments accordingly.⁵²⁰

Traumatic Injury

Diffuse axonal injury sustained within a traumatic closed head injury can result in severe limbic network instability.^{291,292,511–513,521} The long associative bundles or fibers that transverse the cortex on a curved route can be sheared by an impact or a blow to the head, or sustain micro-trauma through stretch, particularly one with torsion in the mechanism of injury. One of these long associative bundles is the cingulate fasciculus, which carries the amygdala and hippocampal projections to and from the prefrontal cortex. Many basic perceptual strategies, such as body schema, hearing, vision, and smell, are linked into the emotional and learning centers of the limbic network through the cingulate fasciculus.¹¹⁷ Thus declarative learning through sensory and cognitive processing can become impossible. If the pathways to and from the hippocampus and amygdala are sheared bilaterally, total and permanent global anterograde amnesia will be present.^{522,523} If destruction of both tracts on one side occurs, but the contralateral side is left intact, the individual can compensate, but learning will be slower or the rate of processing delayed.⁷⁴ If only one tract on one side is damaged, such as the tract to and from the hippocampus, the amygdaloid system on the same side will compensate but be slower than without the lesion.⁷⁴ Thus the

specific degree of involvement will vary and depend on the extent of shearing. Those with total shearing on both sides will usually be in a deep coma and will not survive the injury.⁵²⁴ Those with less severe insult will show signs ranging from total amnesia to minor delays in declarative learning.⁵²⁵ The emotional problems of traumatic head injury can often be associated with other limbic problems such as post-traumatic stress syndrome. This problem is especially apparent when treating soldiers injured on the battlefield who have returned home.⁴⁵⁷

Cerebral contusions (bruises) have long been a primary sign of traumatic head injury.⁵²⁶ Regardless of area of impact, the contusions are generally found in the frontal and temporal regions. There are long-term neuropsychological ramifications after mild traumatic brain injury even when there is no loss of consciousness.⁵¹⁴ The regions most frequently involved are orbitofrontal, frontopolar, anterotemporal, and lateral temporal surfaces. The limbic network's connection to these areas would suggest the potential for direct and indirect limbic involvement. The greater the contusion, the greater the likelihood that the limbic structures might simultaneously be involved. Impulsiveness, lack of inhibition, and hyperactivity are a few of the clinical signs associated with orbitofrontal or limbic involvement.⁵²⁷ The dorsomedial frontal region, involved in the hippocampal-fornix circuit (once referred to as the *Papez circuit*),¹²² when damaged seems to induce a pseudo-depressed state, including slowness, lack of initiation, and perseveration.

Nontraumatic Head Injuries

Nontraumatic head injuries include anoxic or hypoxic brain injury. Lack of oxygen to the brain, regardless of the cause, seems not only to have a dramatic effect throughout the cortex but also results in selective damage to the hippocampal regions.⁵²⁸ The loss of hippocampal declarative memory systems bilaterally would certainly provide one reason for the slowness in processing so commonly observed in head injury.⁵²⁹ A hypothesis could also be made regarding the limbic network's interrelation with other cortical and brain stem structures. In cases of hypoxia, many structures interconnecting in the limbic network are potentially affected, so information sent to the limbic network may be distorted. These distortions could cause tremendous imbalances within the limbic processing system, with not only attention and learning problems but also the hypothalamic irregularity often seen in head trauma. Individuals who demonstrate obstructive sleep apnea, another cause of hypoxia, have been shown to have an imbalance in the hippocampal area.⁵³⁰ This imbalance may lead to severe cognitive dysfunction.⁵³¹ This preexisting hypoxic environment certainly can have a long-term effect on any patient who has CNS damage at any age.

A therapist always needs to understand the environment within which the injury occurred as well as being aware of preexisting complications. If the event was anoxic, then those areas with the highest oxygen need or at the highest metabolic state might be the most affected or damaged after the event. Knowing that information, a therapist's analytical problem-solving strategies should guide her or him toward limbic assessment.

Vestibular Disorders

The vestibular system has extensive neuronal connections and commissural influences on the limbic network and structures; conversely, the limbic network has significant influence on the vestibular nuclei. Details of the neuroanatomical connections have been described previously in this chapter, and a detailed discussion of vestibular disorders can be found in Chapter 21.

It is generally accepted that vestibular dysfunction results in erroneous input to the CNS. This erroneous sensory information creates a

mismatch between the external (afferent) cues and the internal conceptual model for movement contained by the cerebellum. This mismatch creates an imbalance in vestibular and cerebellar signals to the CNS, flooding the central limbic structures and resulting in symptoms such as vertigo, motion sickness, nausea, or decreased postural control. Detection of this mismatch results in an attempt by the cerebellum to compensate for the imbalance, which becomes a core tenet of recovery.¹³⁶ Alternately, this neural stimulation may create an internal stressor and trigger an adverse limbic response, such as a GAS response.

Newer evidence from animal research has demonstrated that vestibular lesions result in dramatic changes in the morphology and function of the hippocampus. Of note is that bilateral vestibular lesions have been associated with hippocampal atrophy. The hippocampus makes unique contributions to memory, both spatial and nonspatial. Thus vestibular lesions impair learning and memory, particularly those tasks that require spatial processing. In addition to the more well-known deficits in spatial and gravitational orientation for balance control, vestibular lesions can also result in impaired cognition, learning, and memory through damage to this connection. Decreased concentration, thought processes, and memory are among the most common complaints in patients with vestibular disorders. In the past these complaints were often attributed to competitive resources, suggesting that cognitive resources were being devoted to the basic tasks of staying balanced during function. It is now clear that there is a true physiological explanation for these secondary symptoms, which are quite limiting to activity and participation in normal daily activities, particularly working. It has also been suggested that treatment activities that stimulate the function of the vestibular system also stimulate activity within the hippocampus and can improve memory, which has important implications for treatment.^{146–154}

Thus vestibular dysfunction can influence the therapeutic environment both in the assessment and the treatment of this system. However, the vestibular system is not a primary consideration of most physicians and therapists during evaluation. On the basis of benchmarking data from within specialized balance centers, the average patient with a vestibular disorder (dizziness or imbalance) travels within the medical system an average of 52 months before finding a solution. During this time, he or she has seen on average four physicians. There is also at least one visit to the emergency department in crisis and one visit to a psychiatrist. Typically, there has been no rehabilitation referral or intervention during this time.⁵³²

The patient with a chronic vestibular disorder can have myriad symptoms, including vegetative, autonomic, motoric, cognitive, psychological, and behavioral symptoms that are often misdiagnosed during this search for an outcome as other, more serious medical diagnoses. As an example, of those patients diagnosed with dizziness or imbalance of a psychological origin, evidence has determined that more than 70% of these patients have underlying vestibular dysfunction on key vestibular function tests (electronystagmography and calorics, rotary chair, computerized dynamic posturography, auditory brain stem response, and acoustic reflexes).^{310,311,316,533,534} Conversely, of those patients with chronic dizziness and imbalance, only 16% were found to have dizziness of a true psychogenic origin.⁵³⁵ Acknowledgment of a patient's symptoms, use of data, and explanation (in understandable detail) that there is a physiological explanation for his or her complaints builds the patient-therapist relationship and begins to neutralize the patient's abnormal limbic state (anxiety versus depression). It can lower the GAS or autonomic cascade, maximizing the treatment time before the onset of limiting symptoms (i.e., raising the symptom threshold).

Even patients with motion sickness have documentable physiological and functional changes. Some of the best current evidence is in

our military personnel with symptoms of motion sickness. On examination, these soldiers have physiological changes identifiable by results of rotary chair (60% with abnormally long-time constants) and computerized dynamic posturography (70% with abnormal Sensory Organization Test [SOT] condition 5 and 6).⁵³⁶

Patients who have sustained a mild head injury, postconcussive syndrome, blast exposure or injury (positive or negative pressure event), or whiplash often have concomitant involvement of the vestibular apparatus or nuclei. This often goes undetected within the initial medical workup and management plan excepting in specialty vestibular practices.^{536–540} When the disorder is undetected and left unchecked, the patients do not respond to standard treatment interventions. They also complain of atypical symptoms or responses to these typical treatments. When the patient does not respond in predictable ways to standard treatment, the label “aphysiological” is applied, particularly in situations where disability or secondary gain is a factor. Fortunately there are well-established performance criteria that can effectively differentiate true balance or vestibular impairment from embellishment for secondary gain.⁵⁴¹ (Refer to Chapters 20 and 21.)

In treatment, recovery is based on long-term compensation mediated by the cerebellum, and symptoms must be reproduced for recovery to occur. However, stimulation of the vestibular system must be controlled, with every effort made to maintain a limbic (emotional) neutral state. Some patients have true vestibular dysfunction that affects only motor responses, whereas other patients have true limbic psychiatric problems that do not manifest themselves with vestibular symptoms. These two behaviors are located at the polar ends of the curve between limbic motor and vestibular motor dysfunction. Before prescribing appropriate intervention strategies, the clinician must be clear regarding the degree of limbic overlay on the vestibular dysfunction, and the question “What are the best vestibular and limbic interactive environments that will challenge and drive neuroplastic change?” must be answered. Although researchers^{310,316} have identified tools that differentiate the two extremes, today researchers are trying to clarify the midrange of patients who clearly have symptoms on the basis of the interaction of both systems.^{541,542} Development of tools that can further discriminate whether the behaviors are first driven by vestibular and followed by limbic responses, or vice versa, is a key to treatment planning. The reader is again referred to Clinical Case 4.3, outlining the complex interactions between the vestibular system and limbic network.

Parkinson Disease

The motor impairments seen in individuals with PD are widely accepted, understood, and treated by physical and occupational therapists and are discussed in detail within Chapter 18 and throughout this chapter. An important consideration not commonly factored in by physical and occupational therapists is that individuals diagnosed with PD often have limbic involvement in addition to their motor involvement. In addition to primary and secondary depression discussed below, dopamine plays a direct role in both the motivation to move and motor function.¹⁰ From a motor perspective, recall that dopamine is released from the VTA in the midbrain and projects to the primary motor cortex (M1), effecting motor output and enabling motor skill acquisition.⁵² Dopaminergic VTA projection neurons are activated when rewards are obtained during motor skill acquisition, but not during task execution in later stages of motor learning. In addition, reward-seeking and motivational behaviors of the limbic network's connection to the NAc and frontal cortex are dopamine-dependent.^{51,187}

As one unique example of linked limbic and motor output, a masked expression is widely accepted as a cardinal motor sign of this

disease and is linked directly to the rigidity expressed within the motor system. Yet, a masked expression is also associated with fear as an emotion (see Fig. 4.6). Similarly, the ability to extinguish this fear response or masked expression is also based on the infralimbic prefrontal lobe and the number of dopamine receptors.⁵⁴³ These areas may not be directly damaged by PD, but the amount of available dopamine is dramatically reduced. Given this interaction, patients with PD may have difficulty facially expressing what they are feeling. Thus when a therapist sees a patient with a fixed facial expression, that therapist cannot draw a conclusion from that facial expression.

Similarly, depression is commonly seen in individual with degenerative disease.^{544,545} Although thought first to be reactive to the disease state, depression also results from a neuroanatomical perspective through involvement of the limbic system and its associated motor responses. Depression from a motor response perspective causes lower postural tone with increased flexion in the neck (see Fig. 4.17B). This flexed pattern within the trunk is also considered the postural pattern of individuals with PD. The question thus arises, “Is the tone generated from the motor system alone, from the limbic influence on the motor system alone, or from a combination of the two?”

Procedural learning impairments are not early symptoms of PD, but emerge with progression of the disease, independently of cognitive dysfunction or dopaminergic medication.⁵⁴⁶ As the disease progresses, motor learning studies have shown that persons with PD have difficulty in initiating and maintaining movement without external cues. It is thought that these external cues reroute movement initiation from the automatic basal ganglia pathway through nonautomatic pathways.⁵⁴⁷ Effective external cues typically include musical rhythms or marches, rhythmic tones, tactile directional cues, or visual cues.⁵⁴⁸ However, extrinsic or declarative verbal cues that help to provide motor sequencing may provide cognitive interference to learning in individuals with PD. Extrinsic verbal cues designed to focus attention to missing components, for example, step length or arm swing, have been shown to improve performance.⁵⁴⁷

Cerebrovascular Accidents

The reader is referred to Chapter 22, which offers a detailed discussion of stroke. The most common insult in CVA results in occlusions in the distributions of the middle cerebral artery.³⁹ When this occlusion is in the right cerebral hemisphere, studies have shown that patients are often confused and exhibit metabolic imbalance.⁵⁴⁹ A primary problem associated with this confused state is inattention and impulsivity. After brain scans, it has been shown that focal lesions existed within both the reticulocortical and limbic cortical tracts, suggesting direct limbic involvement in many middle cerebral artery problems.⁵ Conversely, individuals with left MCA distribution involvement present with an increase in attention to deficits, frustration with functional limitations, and cautious engagement in rehabilitation interventions. In each of these presentations, the patient may show emotional components out of sync with their actual neurophysiological deficit; the patient with right CVA may present as limbic low to neutral, whereas the patient with left CVA may present with higher frustration or fear, in a limbic high state.

With the use of MRI, specific lesion deficits after CVA can help physicians and therapists identify specific motor and limbic behavioral problems that would limit quality of life of the patients.^{457,550,551} Many patients who have had a CVA do not have direct limbic involvement, yet the stresses placed on the patient,^{552,553} whether external or internal, are often reflected in the limbic network's influence over cognition and the motor control systems.⁵⁵⁴ Personal (emotional), performance, or physical stresses experienced within the rehabilitation process increase activity within the limbic network and overflow into the motor system via the reticulospinal pathways. Increased activation of the

reticulospinal pathways results in increased hypertonicity within the muscles of the involved extremities due to the lack of cortical inhibition. The patient is usually unaware of this buildup of hypertonicity but can release it once attention is drawn to it. Neuromuscular rehabilitation interventions serve to introduce therapeutic handling or sensorimotor techniques that serve to reduce extraneous stress and limbic input upon the reticular system and its outputs, thus decreasing overall tonus. This reduction in the overall limbic network activity enables the therapist to facilitate more normal task-specific engagement of motor output.

Similar to individuals with other neurological disorders, there are two types of depression to consider. The first is the reaction to the CVA and losses itself, and the next is the depression resulting from involvement of the limbic network structures and their connections to the primary motor cortex. Differentiating the contribution of the two can be quite challenging. The first step would be to insure appropriate medication focused on a possible reactive depression component, followed by interventions focused on increasing the activity of a depressed limbic network through therapeutic alliance and maximized engagement.

Often mistaken for depression is a post-stroke phenomenon called pseudobulbar affect (PBA). Also known as “emotional lability” or “emotional incontinence,” PBA is a disinhibition syndrome characterized by uncontrollable outbursts of crying or emotion that can happen at any time, even in inappropriate social situations; it is typically disproportionate to the emotions actually being experienced. Prevalence estimates range from 9.4% to 37.5%, resulting in an estimated 1.8 to 7.1 million affected individuals in the United States across several neurological disorders, including amyotrophic lateral sclerosis (ALS), multiple sclerosis (MS), Alzheimer disease, stroke, PD, and traumatic brain injury.

In PBA, the corticolimbic pathways modulated by serotonin and the widespread pathways modulated by glutamate are disrupted. Although the neuroanatomical processes are still being investigated, one component of the disorder appears linked to a reduction of the inhibitory input from the frontal lobe that results in disinhibition of the limbic responses.^{555,556} About 30% to 35% of individuals with PBA suffer from associated depression and anxiety and have poor social functioning. Current treatment has typically been focused on tricyclic antidepressants and SSRIs designed to increase availability of serotonin at the synapses in corticolimbic and cerebellar modulation pathways.⁵⁵⁵ Physical and occupational therapy interventions have been heavily focused on patient and family education surrounding the behavioral versus the neurological basis of the disorder. With the introduction of newer pharmacological agents, such as dextromethorphan the therapist's role expands to assist in the evaluation of medication efficacy and maximized, positive behavioral outcomes.

Tumor

Brain tumors are discussed in detail in Chapter 25. Any brain tumor, regardless of whether it directly affects the limbic structures, will certainly arouse the limbic network because of the stress, anxiety, and emotional overlay associated with the diagnosis. The degree of emotional involvement will obviously affect the declarative learning of the patient as well as the limbic network's influence over motor response.

Tumors specifically arising within limbic structures^{557,558} can cause dramatic changes in the patient's emotional behavior and level of alertness, especially with hypothalamic tumors.⁵⁵⁹ The behaviors reported include aggressiveness, hyperphagia, paranoia, sloppiness, manic symptoms, and eventual confusion.³⁹ Tumors within the hypothalamus cause not only behavioral abnormalities but also autonomic endocrine imbalances, including body temperature changes, menstrual abnormalities, and diabetes insipidus.¹⁹⁸

When the tumor is located within the frontal and temporal lobes, associated with limbic structures, psychiatric problems may manifest, ranging from depression to anorexia to psychosis.^{198,560} Obsessive-compulsive disorder resulting from limbic tumor has been used as a tumor marker for relapse.⁵⁶¹ Amnesia has been reported in patients with dorsomedial thalamus, fornix, midbrain, and reticulolimbic pathway lesions. This again reinforces the importance of the limbic network's role in storage.^{124,198,562}

The neurochemistry within the limbic network is very complex and will be discussed within the next large section, but even without a keen understanding of the specific chemistry, therapists need to recognize behavior and mood changes within the patient. These changes often signal neurochemical problems affecting the individual's motor system. If medical intervention includes medicine, pharmacists should be able to explain how those behaviors are being regulated by pharmacological intervention. Literature is now reporting that what were once thought to be idiopathic seizures are now believed to be neurochemical imbalances within the limbic structure and may someday be controlled with medications that directly affect the immune system.⁵⁶³

Ventricular Swelling

Ventricular swelling resulting from trauma to or inflammation in the CNS or following spinal defects in utero are discussed throughout a variety of chapters in greater detail. Although the effects of ventricular swelling after trauma, inflammation, and in utero cerebrosplinal malformations are not discussed in great detail in the literature with respect to limbic involvement, the proximity of the lateral and third ventricle to limbic structures cannot be ignored. It is common knowledge that most people exposed to hot, humid weather begin to swell; become more irritable, less tolerant, and moody; and may complain of headaches. Some people become aggressive, others lethargic. All these behaviors are linked to some extent with limbic function. Thus ventricular swelling causing hydrocephalus, whether caused by trauma, inflammation, or obstruction, would potentially affect the limbic structures. Reported behavioral changes such as seizures, memory and learning problems, personality alterations, alertness, dementia, and amnesia can be tied to direct or indirect limbic activity.³⁹

Chronic Pain

Although not considered a mental health disorder, chronic pain sequelae manifest in behavioral and emotional change. According to the U.S. Department of Public Health, in 2016 approximately 20 percent of adults living in the U.S. were living with chronic pain.⁵⁶⁴

Pain is a complex phenomenon, and the more it is understood, the more complex it becomes (see Chapter 30).^{565–570} Hippocampal volume has been identified as a variable in pain ratings in the elderly.⁵⁷¹ Similarly, the amygdala plays an important role in regulation of and the emotional reaction to both chronic and acute pain.^{572,573} Whether the pain is peripherally induced or centrally induced because of trauma or emotional overload, often the same motor responses will exist. A withdrawn flexor pattern from pain makes postural activities exhausting because of the work it takes to override the existing central pattern generators. Thus daily living activities, which constantly require postural extension against gravity, may be perceived as overwhelming and just not worth the effort. The therapist needs to learn to differentiate between peripheral physical pain and central or emotional pain and between mixed peripheral and central induced pain. To the patient, “pain is pain!”^{569,574–580} With the current opioid epidemic, primary care physicians as well as physical therapists have recognized that pain, especially chronic pain, is a common, complex, and challenging condition, having a biological component as well as being associated with the limbic system.^{581,582} Thus when dealing with both

chronic and acute pain patients, the importance of the patient's emotional acceptance of the plan of care co-established by the therapist and the individual receiving care cannot be overemphasized.⁵⁸³

Summary of Clinical Problems Affected by Limbic Involvement

It is easy to identify limbic problems when behaviors deviate drastically from normal responses. It is much more difficult to determine subtle behavior shifts in patients. The therapist should be sensitive to these minor mood shifts because they may represent early signs of future problems. Similarly, noting that a particular patient is always irritable and has difficulty learning on hot days should help direct the therapist toward establishing a treatment session that regulates humidity and temperature to optimize the learning environment. The limbic network is not just a neurochemical bundle of nuclei and axons found within the brain. It is a pulsating center that links perception of the world and the way an individual responds to that perception. Quality of life is a value, and that value has a strong limbic component. If functional outcomes leading to maintaining or improving the quality of life of our patients is the goal of both physical and occupational therapy,^{318,584,585} then the limbic network is no less important during examination, evaluation, prognosis, and intervention than the motor system itself.

THE “MIND, BODY, SPIRIT” PARADIGM: INSIGHTS ON THE LIMBIC SYSTEM FROM A MASTER CLINICIAN

By DARCY UMPHRED

As neuroscientists, safe and deep within a Western allopathic model of linear research, establishing efficacy and evidence-based practice for what is taught to new learners is critically important.^{318,379,586} Yet there are too many unexplainable behavioral unknowns occurring daily in the clinical environment that cannot be researched using standard Western research tools common to physical or occupational therapists. Identifying with treatment approaches that base their philosophy on energy fields, flow patterns of those fields through the body, rhythms that do not seem to be proven as existing, or planes of consciousness and belief seems to contradict that comfortable groundedness of basic science. (Refer to Chapter 39 on Complementary and Integrative Therapies.) Thus for many health care practitioners, denial of all those potential parameters that might affect evaluation and intervention outcomes is an easy way to feel safe and linked to what is believed to be efficacy- or evidence-based practice within respective professions. Most allopathic medical physicians within the clinical environment are the first to reject what seem like irrational claims or ideas regarding philosophical approaches. Therapists are not far behind those physicians with their attitudes and verbal expressions toward both patients and colleagues who bring in ideas regarding potential approaches that seem to be outside of our reductionist, linear research models used to establish efficacy. In the clinical arena, clinicians are realizing that effectiveness of practice with objective outcome measures is another way to establish evidence. Similarly, effectiveness can be subdivided into variables that pose questions. Researchers might be able to select variables that can be researched to establish efficacy of treatment approaches used within a clinical environment. Western medicine has taught both medical practitioners and therapists to strongly question anything that reflects concepts of energy, healing, or spiritual beliefs with regard to outcomes of therapy. Yet electromagnetic tools have been embraced by physicians and neuroscience researchers in the form of computed tomography, MRI, PET, and fMRI to diagnose and study neurological damage and neuroplasticity. These

evaluation and research tools create their own electromagnetic field while the human body is placed within that field.^{587,588} Practitioners can still deny that there is a natural energy field and that this field has anything to do with health, but it is getting harder and harder to deny the presence of such a force. All of us have received an electric shock between our body and a metal surface. That shock is called an *electromagnetic charge*, and the voltage depends on the inherent voltage of that individual. Where did this voltage come from? What is meant by *inherent voltage of an individual*? We all have learned that there is a static electromagnetic field around us, but it is very hard to identify how that charge might affect our body systems. As long as practitioners do not inquire about the physics of these energy fields and the bioelectric or biochemical reactions of our human cells to these fields, the idea that the electromagnetic and electrochemical fields have nothing to do with neuroplasticity and changes with patients after neurological insults unfortunately can remain a myth. Over a decade ago, some allopathic physicians stepped out of their established model and developed a subspecialty in psychoneuroimmunology. Checking PubMed for articles from 2018, a reader can find over 2400 published articles under the term *psychoneuroimmunology*. This subspecialty incorporates the relationships among emotion, the endocrine and immune systems, and the CNS and peripheral nervous system.^{328,207,208,589} As the limbic neuronetwork intricately links various nuclei that deal with emotion, endocrine production, and autoimmunity, there is little doubt that this system is involved with belief in healing, emotions, and spirituality.^{590,591} “Despite such conceptual progress, the biological, psychological, social and spiritual components of illness are seldom managed as an integrated whole in conventional medical practice.”³²⁹

Fortunately or unfortunately, there are scientists and therapists who are “myth busters” and who challenge the rigid paradigm of linear research, stating that there are many more variables and systems involved in neurorecovery or neuroplasticity than have yet been identified. Physicians and neuroscientists studying the effects of disease and neuroplasticity after trauma⁵⁸⁷ or application of drugs^{592–594} are trying to unravel a complex maze of chemical and electrical reactions at the level of the cell membrane.¹⁰⁴ Quantum physicists are studying the universe and the electromagnetic pull of suns on planets and solar systems on one another.^{595–597}

Science is a long way from unraveling the mysteries explored by cellular biologists and quantum physicists and how they might relate to each other. But many scientists trust that there is a relationship. As humans, we are made up of billions of these cells; each cell has a membrane potential and the ability to adapt and change; and they play an important role in the existence of our species. Similarly, the universe is made up of billions of masses; each has some relationship to energy pull, whether that be one solar system in relation to another, one planet in relationship to a sun, one moon in relationship to a planet’s oceans, one person in relationship to the gravity on a planet, or one person in relationship to another person. If those cells are what make a person human, and if what holds the person together is electromagnetic energy, then it is hard to ignore the possibility that one person might affect another person just by being present.⁵⁹³

Therapists want to study the interaction of brain responses between a practitioner and the patient during a therapeutic treatment session.⁵⁹⁸ It is obvious that this interaction cannot be explained by one variable within linear space, nor that it is one variable alone that is causing all change over a linear set in time. Establishing efficacy on what seems to be a multidimensional construct using a basic science research model is not realistic. Thus efficacy research on the totality of the mind, the physical body, and the human spirit eludes basic scientist researchers in a manner similar to the way that researching the effectiveness of intuition eludes psychiatric researchers.

As research practitioners we use various tools to manipulate both the internal and external environments within which our patients function to measure effectiveness of specific or generalized outcomes. Each person is so complex and unique that finding the best combination of tools and environments has a very person-specific answer.^{594,599} Thus what we as researchers are trying to do is find evidence that shows that one treatment paradigm has a better chance of creating change than another, without placing rigid restrictions that say all persons will optimally benefit from any one particular approach.^{600–607} MRI, PET, and fMRI tools are certainly capable of identifying changes in the CNS after interventions. Even when researchers or clinicians try to control as many variables as possible, many additional external and internal input possibilities exist.

This brings us full circle to the question regarding additional variables that might affect health, well-being, and recovery outcomes from therapeutic interventions.^{608–618}

After 40 years of clinical practice and hearing Western physicians say, “Physical therapy and occupational therapy just make the patients *feel* better,” it is obvious, first, that many physicians do not understand the depth and breadth of our professions or what is provided to the patients. Second, those physicians do not understand the limbic interconnections to “*feel* better” and how that might drive the neuroplasticity of the CNS and the autoimmune system’s response to disease or pathology.^{14,615,619–624} Similarly, after many patients have been observed over the last 40 years regaining consciousness, whether the vegetative state lasted 6 months, 9 months, a year, or 4 years, the fact remains that each individual shifted from what might be considered a level 2, 3, or 4 on the Rancho Levels of Cognitive Functioning to a 6, 7, or 8 on the same scale after 5 to 20 minutes. This reality made me ask the question from the beginning of my professional career, “What are the variables that cause changes in these patients?” The answers are not yet fully understood, although the behavioral outcomes keep presenting themselves. Every time a patient comes out of this vegetative state, I (DAU) feel wondrous, emotional, and humbled. Something happens that is far beyond our scientific understanding, something simple but extremely complex, cellular, and universal, all at the same time. Similarly, the bond between that therapist and that patient is very strong and deeply spiritual. The memory of those patients stays forever embedded in the mind of the therapist even if the clinical environment existed for only 30 minutes. All the words used to explain such clinical experiences link closely to the limbic network and its role in creating change, both within the therapist and the patient; certainly at this time, these experiences fall outside the paradigm of Western medical science. According to a report on the BBC, the use of appropriate fMRIs shows that many individuals in a vegetative state are awake but still have little to no awareness because of the severe brain injury.⁶²⁵ This explains the fact that a therapist “*feels*” that a patient is aware but does not explain how the therapist-patient interaction brings that patient to a conscious state of attention.

Medical schools and health science programs are becoming increasingly aware of the need to train the practitioners of the future to enter into a healing relationship with the whole patient,^{626,627} a relationship that empowers the patient to engage endogenous healing capacities, even while we work to better understand these mechanisms through both basic and applied research. Master clinicians have long appreciated this dynamic healing relationship, which affects both the therapist and patient. Thus even when our patients can verbally communicate with the therapist, it is still important to listen directly to the body and, on a deeper level, to more subtle input that we do not yet have the ability to describe and quantify with scientific method. It has been demonstrated that even for persons in very low awareness and response states, appropriately selected music can provide time-organized and emotionally

meaningful stimuli to gently activate intact neural networks, and to communicate with the person still alive inside the disabled body.⁶²⁸ The sounds we make and the way we touch communicate to the deeper levels of being and do not require words to convey caring, instill hope, and motivate the will to keep trying to get better.

The success or failure of many forms of alternative medical practice, and for that matter Western allopathic medicine and therapeutic practices, may depend on the limbic network.^{597,613,629} At times research can prove unequivocally that certain variables do not show a healing effect, after double blind studies.⁶³⁰ If a patient “believes” an intervention will work, even if it is a placebo, the chances of success far exceed those when the patient does not think it will work.^{631–634} If it is a placebo and the body heals, then logic dictates that the body and the mind did the healing. Similarly, when the drug itself aided in neuroplasticity and change, is it the drug itself or the individual’s belief that the drug will work that creates the change or both? How these changes occur is yet to be totally understood, but research substantiates that both neurochemical and neuroelectrical changes occur within an individual’s physical body when the individual believes that change is possible.^{67,105,610,619,630,633}

When I was a novice therapist, a nurse once said, “I am very glad you are not a nurse because you are so idealistic. You believe these patients in comas are going to wake up and walk out of here. And what is even worse is that most of them do!” That moment should have told me that I would be clashing with allopathic doctrine throughout my professional career, but instead I was confused about the nurse’s use of the term *idealistic*. If the patients awoke and walked back into life with function and quality, then should that not be considered a *realistic* expectation? In that same job situation, my boss asked me to treat all the patients who were considered vegetative; once they were awake, my colleagues would treat them from there. My response was, “Emotionally for both the patient and myself, I could not do that. Once I bonded with a person, gained his or her trust, and found the patient was willing and capable of regaining consciousness, I could not just abandon the patient and go on to another person.” The significance of that statement took many years to understand, and it was not until I began my study of the limbic network that I truly comprehended the accuracy of that perception, once considered naive.^{610,621,629,635,636} It was not until the writing of the 6th edition of this chapter that I could shrug off comments such as “This has nothing to do with physical therapy.”^{13,213,328,329,637}

After 45 years of practice and often treating individuals in front of colleagues in workshop situations, I cannot deny that something more than just “feeling good” occurs during physical or occupational therapy interventions although that feeling good is certainly a limbic response. When working with patients, I find myself feeling very open and bonding in some way that is neither “physical” nor “mental”—and thus the only option left is a definition of “spiritual.” If, when treating a patient in a vegetative state, that bond tells me that the patient is lost within another plane of consciousness and wants to regain consciousness as defined by healthy people, and the physical body of the patient seems capable, then the treatment is goal directed, the direction of the intervention is identified, and thus the outcome is selected by the patient. The map has been established, and together the patient and the therapist proceed. As with all therapists, the intervention will be guided by the motor responses and control of the patient and the window within which the patient can run those programs independently. At times, when treating patients in a vegetative state, I feel unable to locate the “spirit”; at other times it feels as if that person has not decided whether to venture to an awake state, but more often I sense a frightened, confused individual who just wants to find her or his way back to what we call “life or reality.” Those patients often gain

consciousness during therapy. It is not a miracle, nor can I ever say, “I healed something.”²⁵² The term *healing* refers to a concept of “whole.” The only person who can regain the structure of the whole is the patient.⁶³⁸

As a therapist, I am a teacher or a guide, helping others relearn and regain control over their respective lives. If after a 30-minute treatment session a person regains feeling and control of an extremity 18 years after a CVA or regains functional use of a hand 6 years after incomplete spinal cord injury, there is more to the intervention than merely following a clinical pathway or a treatment regimen geared to all individuals at a specific stage of a disease process or a specific motor impairment.

One variable that always seems to be present when patients achieve dramatic recovery is strong motivation by the patient to retain the control and an appreciation for the instruction on how to do that. A strong bond or compassionate appreciation for each other always seems to be present as another interlocking variable. Thus the clinical question “What is spirituality?” presented itself to me more than 40 years ago. It is a variable that is very difficult to define. That variable, when researched, has been shown to affect health and healing in individuals with health problems. *Spirituality* and *healing* are both words that each individual defines according to her or his own beliefs, cultural experiences, and use of verbal language.^{106,107,639–646} The literature is available for those who wish to pursue this topic.^{524,274,647–654}

Over the last 7 years since the sixth edition of this text was published, thousands of articles dealing with health, healing, spirituality, energy fields, quality of life, energy medicine, and emotional balance have been published in a large variety of types of journals.^{655,656} The reader is encouraged to survey internet resources not only for evidence published in mainstream medical journals but also to understand that patients will glean information about complementary therapy from many other sources, such as blogs, advertisements, and online chat rooms. Refer to Chapter 39 for discussion of these topics as well as related literature. Within this chapter a system that affects all areas of the CNS and peripheral function has been discussed. How this system is affected by or affects one’s spirituality is open for many lifetimes of future study.^{657,658} Yet if spirituality affects healing and an individual believes that this potential is available, then this variable may play a critical role in patient compliance, neuroplasticity, and the limbic interface with other treatment procedures. Ignoring this variable is no different from ignoring cognitive perceptual deficits when dealing with abnormal motor behavior. Owing to the strong emotional foundation for an individual’s spirituality, one could easily assume that the limbic network plays a strong role in establishing and storing memories that reflect these beliefs.

Until we can measure simultaneous synaptic activity of all interactions within the therapist’s and the patient’s CNS, we will not, from a grounded neuroscience efficacy base, be able to demonstrate exactly what occupational, speech, music, cognitive, or physical therapists do, even though we know they play a role.⁶⁵⁹ Until then, outcomes need to be measured objectively. Even if interactions seem unmeasurable and subjective, clinicians still need to record the event change in the patient record and not bury that outcome deep somewhere in the subconscious level of the therapist’s mind. The mind, the body, and the spirit are connected as a whole. If therapists treat only one part, it may help the whole, but if the whole is treated simultaneously, the outcome is more likely to change the whole.^{660,661} The concept is no different from focusing on strengthening an isolated muscle and hoping it will lead to functional use versus strengthening that muscle in functional patterns and in relation to other muscles that also work together within that movement sequence.

After years of clinical experience and thousands of patients responding positively to various interventions, the question arises

regarding clinical decision making and choice of interventions. There is not a “variable” that has been identified that guides that decision. It has been shown that humans bring to consciousness about 10% of all incoming information. Yet the human brain is making decisions using 100% of the input information. Given that relationship, quite a bit of human decision making may be based on nonconscious information regarding the external and internal world.^{105,662,663} Thus the word all neuroscientists shudder over—*intuition*—may to a large extent be the unraveling of that nonconsciously received data.^{664,665} I have effectively taught colleagues how to feel blood pressure and heartbeats of clinical partners by just barely touching the top of the hand, which might be explained by the high level of sensitivity of Meissner corpuscles within our skin.⁶⁶¹ If a clinician can sense an autonomic response such as heart rate when touching a patient’s skin, then knowing how the limbic network is interacting within a motor response can also be deduced. This would allow the clinician to modulate the rate used to move the patient during an activity such as bed mobility, while maintaining a consistent state of the motor generators. That steady state should decrease any need for limbic fear by the patient. Fear has been shown to be very detrimental to motor performance.^{666–668} Therapists may interpret these tactile responses as intuitive, but they are not. When one clinician seems to know how fast to move the patient and another clinician has no idea how to determine that decision or control that variable, we say it is the *art* of therapy and not the *science*. Yet it is the science of therapy. Similarly, helping someone shift consciousness levels seems similar to hypnosis. The exact identification of these variables is very hard, let alone finding reliable and valid research tools. This may just be a case of one clinician being open to receiving information and processing it. The other therapist, for some reason, is either not receiving or not processing the available information. This is not an example of “intuition.”

Intuition has been a source of fascination over centuries. Recently, with consumer dissatisfaction with health care and the upsurge in alternative medical practices, intuition has again sparked the interest of scholars and the public. To many it reflects mystery, magic, and even voodoo. Individuals with a strong ethnic, cultural, and even religious bias may find it hard to scientifically analyze this human strategy. For more than 43 years my husband has answered questions I have posed in my mind. It took at least the first decade of our marriage for my left brain to actually accept that I was not subvocalizing the thought or that he could not have extrapolated the thought from an environmental stimulus. Yet he consistently has told me that I did vocalize the thought because he hears me ask the question or state a fact in my voice patterns. Obviously, my thoughts have traveled to the primary and associative receiving areas of his left temporal lobe and he “hears” the thought in my voice. The dilemma that confronted me as a scientist is, if the information did not come in through his eighth cranial nerve, then how did it enter into his system and get to his temporal lobe? The answer would seem to be intuition. A definition might be knowing something without entering the data through traditional input systems. The next question is, “What is intuition?”

Unfortunately, after 40 years of study, I cannot answer that question. I do acknowledge that it is something, it can be learned, and master clinicians use it as a part of their clinical decision making, even if they choose not to verbalize it to their colleagues or even acknowledge it within their conscious mind. Much research and literature are available regarding intuition.^{105,669–692} Yet the answer to that simple question “What is intuition?” is unavailable and does not seem so simple. No answer exists that has shown to be definitively efficacious and reliable, although research over the last 15 years has begun to identify components of intuition.^{665,669–688,693}

It may be that intuition is more than one variable and can be accessed in more than one way. In fact, after studying various alternative medical practices, all using very different interventions based on different philosophies and belief systems, it seems as if all approaches may be tapping into the same human system, just opening to that system through different paradigms.

In the late 1960s, I (DAU) was beginning to present an integrated approach to neurological disabilities. I was integrating various treatment philosophies using the behavioral responses of patients and known science to guide intervention. I was told at that time that integrating approaches could not be done and that I would potentially injure patients by using approaches from different philosophical techniques. Today, of course, with our understanding of motor control, motor learning, and neuroplasticity, an integrated approach from the 1960s based on a systems model is a tool available to all therapists. However, researchers think that those tools were based on the science of the time, and thus they reject many of those techniques because they think they were based on inaccurate understanding of science. The master clinicians of the time based their techniques on movement responses of the patient and how those patients regained normal control over those movements. Today, I now present a similar model based on today’s science of the brain, movement analysis across the life-span, and the external and internal environments of both the therapist and patient. This incorporates complementary approaches to intervention and the concept of intuition.

There are a number of variables that seem to open one’s intuition: bonding, being dedicated to the patient, having openness in listening to the patient, letting preconceived knowledge be a springboard from which to expand that knowledge, having not only a willingness to learn but an insatiable appetite to continue learning, and possessing the ability to let go of one’s importance and just be another person within the environment. These variables may be the best place for a learner to begin learning how to develop this skill. It would seem as if intuition is like an aptitude. Some individuals come into this life already with a high level of potential, others are nurtured to develop that potential, and still others never have an opportunity or an environment in which to develop those strategies. Some individuals have had strong intuitive senses from childhood but share those experiences with few, if any, other people.

Experiencing intuition is an all-knowing experience. One knows something first, then one can become emotional regarding that knowledge. It is a knowledge that has a “wholeness” component and that can develop a strong emotional base on the limbic system. For example, I *knew* I was going to lose a parent. Which parent, I did not know, but I moved home for a year to make sure there wasn’t anything I should have said to either parent before I went on with my life. A year later I was married and home for a holiday. When my husband and I left my parents’ home, I cried all the way back to our dwelling across the country because I knew I would never see my father again. I was right; he passed two weeks before I was to return home six months later. My father had been a very healthy man with no health issues that would indicate any life-threatening health problems. I had known what was going to happen as a whole (intuition) and then had had a very strong emotional response to that intuition. Also, when my brother called to say that our father was critically ill, I had already adjusted to the probability of his loss and was the one individual within the family who could make cognitive decisions or answer press questions by phone. If I were to hazard a guess, the intuitive center is probably in the right anterior temporal lobe, owing to the “whole” understanding and its strong emotional connection. If that proves true, it will solidify the limbic network’s connection to intuition. Experiences often create the first questions that lead to hypotheses and later to research that establishes efficacy.

During the first 10 years of my professional life, I (DAU) hid from most people that aspect of my person because I was becoming a neuroscientist and wanted to be grounded in scientific efficacy like all my colleagues. Unfortunately, my clinical experiences did not allow me to hide that intuitive aspect of my clinical decision making from my family or close colleagues or those colleagues who recognized that something had happened during a treatment that made no sense whatsoever. Those individuals recognized changes within the patient that, although very positive, should not have happened or were very far from our basic scientific understanding.

In 1980 I treated a woman who had a severe head injury and who after 6 months was at a Rancho level III. After 30 minutes of intervention the woman volitionally moved all of her limbs and trunk without cognitive confusion. That motor function and cognition might be partially explained by recent research using fMRI.⁶²⁵ But something that goes far beyond today's fMRI followed the intervention. I innocently stepped out of the safety of scientific understanding. I shared with my colleagues this woman's medical and social history. That information was critical to their understanding the course of progression of this woman through the rehabilitation process and the future plan of care. I discussed the patient's social background, her education, her family, her children, and her husband, who had shot her in the head. This all made perfect sense, until the head of the department asked me how I knew that information. I said, "I read it in the chart." The director informed me that I had not seen the chart. I said, "You told me?" The director responded with, "We did not discuss the case!" I asked if I had been wrong, and the director said "no." In fact, she was amazed at how accurate I had been and just wondered how I had known that about the patient.

At that moment, my life was changed. I could no longer hide whatever this "intuition" was, nor could I truthfully tell colleagues what I had done during interventions without bringing up this topic. Also, I could only tell them ways to develop intuition but had no understanding of the basic neuroscience behind its function. I could not tell anyone exactly what it was because I did not have any verbal knowledge of how and where the information is processed, so I could not translate that knowledge into verbal language to explain it to colleagues. That unknown is still present, although some of the variables may have been identified. The future will unravel those answers. What I have found since that day is that "masters," whether they are physicians, therapists, or teachers, often use this additional source of information gathering to help them in their clinical reasoning. I do not make this statement lightly nor without tremendous professional risk. I will leave you with an interaction that solidified my belief that this direction of scientific study needs to be pursued. Two decades ago, I was a keynote speaker at an international neurosurgical conference on brain tumors. I was the token "other," and the only speaker who was not a neurosurgeon. I presented the topic "The Limbic System's Influence on Motor Output." With this audience of 500 neurosurgeons and 50 token others, I, of course, used charts and pictures and based every sentence on efficacy-based scientific research. At dinner that night when all the speakers were together, the master neurosurgeon whom everyone acknowledged asked if he could sit next to me. I was aghast—a little nervous but honored nonetheless. He opened by saying, "I think many physical and occupational therapists are intuitive." With that, I knew him, his life, his experiences, and so on. Of course, I needed to let my left brain validate my intuition, and I said, "Yes, it is like walking into a room, looking at a patient, knowing where and what type of tumor the patient has, and using instruments such as positron emission tomography (PET) scan to validate what you already know." He responded with a smile and said, "Yes, it is exactly like that!" I do not need to continue to discuss the fascinating interactions of that night but leave the reader

with the thought that even the master of the masters in neurosurgery uses intuition as a variable in clinical decision making. It gave this man one additional bit of information that his colleagues could not use in clinical reasoning. No physician or therapist uses intuition as the only variable; intuition just gives additional information that helps in the process of clinical reasoning. It would seem as though intuition is highly integrated into the limbic network and often gives direction to a therapist as to the selection of specific examination tools to validate that assumption, and then gives insight as to which intervention tools would best match the person's needs.

As said previously, intuition is knowing something. As a result one can experience great emotion: "I know, thus I fear." If the sequence of events begins with an emotion or fear and leads to what is perceived as knowledge or truth, one might question whether intuition was the driving force behind the belief. When emotions become elevated an individual may progress with "I fear, thus I think I know." Research that looks at intuition assumes that when the limbic network is involved, the experience is highly emotional, and one might argue that an individual can be highly emotionally charged and still be neutral as far as a balance in emotions. Fear is not what drives intuition; instead it is emotional balance. Emotional balance or centering is not a state of being without emotion but rather a heightened state of emotional awareness without emotion, all at the same time. To become truly intuitive, one needs to become emotionally centered. In our everyday world where each of us is overstimulated as a day-to-day experience, this emotional balance is extremely difficult to achieve. It is even harder to find that balance in a clinical arena where patients are arriving with more acute diseases along with chronic secondary problems, often patients' schedules overlap with other patients' time, and therapists not only are limited in time for intervention but also find that the number of allowed visits falls well short for optimal opportunity for learning by the patient. That reality does not mean that the therapist's responsibility has changed. It is always up to the therapist to find those avenues by which better care may be provided within the existing environment. This reality just says that the challenges and questions are enormous. Finding emotional balance within that environment is very hard. Yet intuition seems to be a variable that gives some colleagues additional information that is then used as part of the clinical reasoning process.

Intuition, as a variable, needs to be identified, studied, researched, and taught once it is clearly understood. It is up to all of us to find the answers to these questions and the solutions to today's clinical problems and develop evidence-based practice to progress into the 21st century.^{694,695}

The concept of integration of mind, body, and spirit as a critical element in maintaining or regaining quality of life between birth and death is not new.^{696–699} Western society has tried to separate this concept into three distinct categories. The mind is made up of perception, cognition, and emotion. The body is made up of all systems external to the nervous system such as peripheral organs, muscles, bones, and skin. Both the peripheral and central motor systems, which control the body, are also included in the concept of body. The last component, the spirit, is a transcendental concept and is thought to depend on individuals' beliefs. Some individuals believe that spirit means belonging to a religious order. Others define spirit or spirituality as beyond religion—the essence that links the person to a greater energy force. For decades this last category has been considered outside the domain of responsibilities of Western allopathic health care delivery and was comfortably relegated to religious leaders or spiritual guides.

Today, everything is changing. Some scientists refer to energy fields around cells; others talk about energy fields around solar systems. Complementary practitioners talk about energy fields around the

living organisms. Physicians are being taught cultural sensitivity training while in medical school to be more empathetic to the populations of people they will service. Physical therapy curricula are responsible for creating culturally sensitive professionals.^{700–703}

Occupational therapy programs are responsible for including spirituality as one of the competencies a graduate is to have met.^{704,705}

None of these professions have identified how these competencies relate to evaluation and intervention outcomes after treatment, but even the accrediting bodies believe they are important. Thus even at the entry level, for student therapists, emphasis is placed on making sure not only that the therapists' limbic systems have become sensitive to spirituality, but also that they be able to identify its significance in their patients' lives. Where does the interaction of the mind, body, and spirit play a critical role in quality-of-life issues and empowerment of the patient? The answers to that question cannot be found within this text or any other text in print today. Individuals with strong beliefs in a specific paradigm that includes spirituality can project the answer to this question, but establishing efficacy is an entirely different issue. Our professions are tethered to research, science, behavioral observations, and current knowledge. We as clinicians can stretch that tether. Much of our early treatments developed from behavioral observations that included individuals' beliefs, which clearly required the limbic network for processing, storage, and direct effect on bodily system reactions. If a patient lacks motivation, a therapist knows part of the job is to motivate the person. If the person believes his "God" will heal him, the therapist should never undermine that belief because everyone knows it cannot hurt and often creates a positive change.⁷⁰⁶ How that interaction occurs is unknown today, but clinical observation would reinforce that it does help. Because spirituality uses belief and hope, memory of those feelings must be processed and later stored with the help of the limbic network.

These dilemmas exist with every professional dealing with health and wellness and quality-of-life issues. I (DAU) will leave you with one additional example. I spent over 2 months in the ICU a few years ago after a severe fall that caused two fractures to the pelvis, followed by severe internal hemorrhages. To summarize the medical problems, I had 18 initial arterial ruptures treated with radiological interventional surgery, followed by four more ruptures 1 week later leading to more surgery. I also had bilateral kidney failure, a large pulmonary

embolism on the right side, pulmonary collapse in the left inferior lobe, massive internal infections, infusion of 12 units of blood, thrombophlebitis, fevers of over 105°F, very low blood pressure, and low oxygen absorption, along with external bleeds through most external orifices. In addition, the two bleeds destroyed my adrenal glands bilaterally, throwing me into another life-threatening imbalance of chemistry within my body. The doctor kept telling my husband with confidence that I would die. As my husband had been told this many times before, he kept telling the doctor he would wait for 3 days after I had been declared dead before he would accept that conclusion. Two weeks after the initial hospitalization, the doctor came into the room. He shut the door, sat down in a chair, addressed both of us and asked, "I know what medical problems you have had, I know that we did everything medically that we could, but it was not enough, so *how come you are still alive?*" I responded with, "There is a lot more to healing than what we understand, and that is what is fun about being a health professional." Life has taught me the lesson, whether as an intuitive, as a neuroscientist, or as a therapist, that there will be unknowns or mysteries along one's life journey. Sometimes one can solve the problems or answer the questions, but more often than not, one just has to file them in memory with the hope that one will sometime find an answer. The unknowns are always present even as answers are discovered. Having those unknowns creates an exciting challenge and adventure for every clinician who has or will have the opportunity to interact with individuals who have been brought into the health care delivery system because of a CNS problem. Those individuals want to be considered as a whole human being even if part of their physical body is dysfunctional. A circle has been drawn, and this chapter needs to end with a question. What is that whole? Refer to Case Study 4.1 as a clinical example.

Abstract: This chapter is intended to continue to advance our understanding and respect for this limbic system, which is a complex system integrated in ways that its contribution is considered within the evaluation of every patient, regardless of setting or diagnosis. The first section of the chapter includes an overview of the limbic network and a discussion of limbic behavior and how to begin to differentiate true motor responses from those entangled in limbic interactions. The second section delves into the anatomy and physiology of the limbic network, the biology of learning and memory, neurochemistry, and neuroplasticity. The third section applies our understanding of the limbic network to our patient assessments, treatment, environment, and interactions. In the last section, current advances and future research possibilities in the role of the limbic network and its impact on the professional roles of physical and occupational therapists are explored.

Keywords: amygdala, declarative memory and learning, emotional behavior, F2ARV (fear and frustration, anger, rage, violence/withdrawal) continuum, General Adaptation Syndrome (GAS), hippocampus, hypothalamus, limbic network, limbic neutral state, motor learning, MOVE (motivation or memory, olfaction, visceral, autonomic nervous system, emotional), procedural memory and learning, therapeutic alliance, therapeutic environment

Psychosocial Aspects of Adaptation and Adjustment During Various Phases of Neurological Disability*

Rochelle McLaughlin and Janet A. Hiley

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe adaptation and adjustment as parts of a flexible, flowing, and dynamic human process of meaning-making, not as static disembodied, stages.
2. Describe elements of the grief process that foster greater clarity and literacy around dominant cultural narratives around grief and the importance of mourning throughout the life-span and especially during times of significant life changes.
3. Integrate elements of mindfulness, resilience, coping, emotion-focused problem solving, and learning styles into the treatment process.
4. Integrate the family, community, and our human need for belonging with the patient's styles of coping and capacity for resilience into therapeutic treatment strategies.
5. Expanding our network of inner and outer resources of support available to us as a way to be strengthened as essential elements for coping and healing ourselves.
6. Accept the role of patient advocate, knowing state law as part of state licensure requirements, and the responsibility to report any abuse.

KEY TERMS

acceptance
adaptation
adjustment and coping
bonding
emotion-focused problem solving
family network, belonging, and community

inner and outer support systems
loss, grief, and suffering
meaning-making
mindfulness
resilience and stress hardiness

It is a part of the human condition to have intense life experiences that can range from relatively benign to absolutely catastrophic, and there are incredibly complex ways in which we might respond and adjust to these kinds of life experiences. Adjusting to a disability is an ongoing process, just as adjusting to all other aspects of life is for everyone. This process of moving forward is a lifelong one. To move forward with a disability, it is important to turn toward and acknowledge and be present to and acknowledge the situation at hand, thereby opening oneself up to the potential hidden within the situation. If we turn away from and deny the situation, we are at risk of never fully coming to terms with and adjusting to the experience.

Adjusting to a disability is not unilateral. It is layered and deep. The family and support system must be involved in this process. Therapists may be tempted to treat the impairment in isolation and not be involved in the adjustment process for the individual or their support system. This would be a major mistake. Technicians address the mechanical (technical) aspects of treatment, but clinical professionals must treat the whole person and must be involved in the process of adjustment at all times. It

is a fatal flaw to reduce the individual to just the impairment and not see or try to understand the bigger picture with regard to what is really being called for during treatment intervention. A technician may obtain good physical results, but if the individual has not begun the process of adapting to the life-altering event, the physical results may never be maximized. If an individual's support system has not been adjusting to the impairment, he or she may hold the patient back from optimal functioning or put unnecessary pressure simply out of a lack of knowing how to respond to the situation. Proper training and practice can foster the empowerment of the patient and the support system. In this chapter, we will pursue topics that cover important aspects of the adjustment process for the individual with a disability and his or her support system.

PSYCHOLOGICAL ADJUSTMENT

In clinical practice, theoretical foundations for adjustment to disability appear to be elusive because they represent a fluid process: all people are constantly changing. This is especially true for people who have recently become physically disabled. They do not reach a certain state of adjustment and stay there but progress through a series of adaptations. Therapists see patients in a crisis state¹⁻⁶ and therefore identify

*Videos for this chapter are available at studentconsult.com.

their adjustment patterns from this frame of reference. How well the individual adjusts to the crisis, however, does not necessarily indicate how well he or she will adjust to all aspects of the disability or the rate of progress from one point of adaptation to another.^{6–15} Disabilities are an unimaginable insult to an individual's self-perception and identity.^{16–19} A month or even a year after the injury may not be long enough to put the disability into perspective.^{10,16,17,19–22}

For most people, progressing from the shock of injury to the acceptance of and later adaptation to disability is a process filled with psychological ups and downs and may not be linear. The process may even be considered like a spiral rather than a linear progression, and the word “progress” is used loosely here.

Several authors have discussed the possible stages of adjustment and grieving.^{10,14} The research of Kübler-Ross²³ into death and dying has application to this topic of adjustment to disability. She discussed the concept of loss and grief in relation to life; loss of function may result in just as profound a reaction. The practice of mindfulness may be important in disengaging individuals from automatic thoughts, habits, and unhealthy behavior patterns, and thus could play a key role in fostering informed and self-endorsed behavioral regulation and adjustment to catastrophic life events.²⁴ Peretz²⁵ and others^{26–28} discuss the grieving process in relation to the loss of role function as well as loss of body function. These losses must be grieved for before the patient can fully benefit from therapy or adjust to a changed body and lifestyle. Therapists must be aware that the patient can and must deal with the death of certain functional abilities. At the same time our dominant North American culture does not foster the skills of grieving over the course of one's life-span. Death is largely swept under the rug, and grief and sadness are not given much space in our fast-paced lifestyles. So we all are developmentally challenged to know what appropriate grief looks or feels like, and most of us might even be inclined to say, “Enough already, it's time to move on now, get on with it, move on . . . etc.,” even if we may not say this out loud. You are encouraged to notice when this might arise in yourself without condemning yourself but acknowledging this as powerful cultural messages we swallow being raised in this dominant North American narrative. So how do we proceed if we as practitioners lack the skills to wrestle with our own suffering? If you are like most of us, you learn to numb yourself from your suffering or the suffering of others. And today's society offers us a smorgasbord of options to numb out now more than ever before. What can we do then? We can learn to grieve, to engage with and acknowledge our own suffering, and to “adapt” right alongside our patients. At the same time, the development of mindfulness in our own lives is essential to ground us within our own embodied experiences of the present moment so that we are not so easily swept up by other people's suffering. We must begin to build a strong sense of rootedness within oneself to enhance our therapeutic use of self.

Some authors have questioned the concept of stages of adjustment^{1,29} and call for more empirical research into adaptation and adjustment; this has been started.³⁰ One alternative concept that has been developed is cognitive adaptation theory.³¹ This concept examines self-esteem, optimism, and control. In this theory, if the individual feels good about himself or herself and has an optimistic view of life and a sense of control over life, the individual will adapt to the functional limitations and will participate in life. Cognitive adaptation theory does not consider the organic changes that may take place when brain damage has occurred, but the basic goals are very much worth taking into consideration. These should be examined in relation to the limbic system (see Chapter 4) because limbic involvement is crucial to reaching all goals and plays a key role in establishment of motivation.

The components of successful psychological adjustment to a physical disability (activity limitations) are varied and complex. To bring a

patient to a level of function that is of the highest quality possible for that individual, therapists must look holistically at the psychosocial aspects and at the adjustment processes involved, evaluate each component, and integrate the processes into the therapeutic milieu to promote growth in all areas. There is much more to evaluation and treatment than just the physical component; the mind and body have intricately interrelated influences, and both must be considered, evaluated, and treated individually and as a whole.

WE UNDERSTAND MORE ABOUT SUFFERING THAN WE THINK

Clinical professionals have a wellspring of knowledge to draw from beyond their extensive traditional education. We are all human beings, and being human comes with a great deal of innate suffering. If we bring awareness to the fact that we have all suffered in our lives, we may not feel so separate from our patients. We may realize that we have more to offer our patients than just the knowledge we have gained about their disability and how we might help them gain function. The more we allow ourselves to slow down and be present with suffering—our own or that of another—the more we will be able to be open to the mystery and joy of our lives just as they are without requiring them to be any different.³² It may be our lifetime's journey to be servants of the healing arts; this is our job, and it also takes enormous skill and bravery to bear witness to the full catastrophe of the human condition.³² One of the benefits of our profession is the stimulus to examine our lives through the experiences of others. This can improve our function and help us grow as professionals and individuals, but if we are not open to the patients' experiences, we may not find a reason to examine and grow from our own experiences.

If we haven't endured great suffering personally, we have borne witness to it—“9/11” is a perfect example of this. If we acknowledge this fact, then maybe we can acknowledge that we are more connected to our patients than we once thought and that we have more to offer our patients in terms of their ability to adjust to their disability than we may have imagined. It is within the wrestling with suffering where meaning-making arises. Honoring, acknowledging, and appreciating human suffering (our own and that of others) is the cornerstone of adaptation. When we are mindful of this grappling with life's challenges, we can't help but be transformed, and a new normal ushers its way into place over and over again. Within the pains blossoms wisdom and insight, a deeper capacity to feel life deeply, maybe even to have our heart's broken on schedule, maybe even a capacity to wonder at it all and to act accordingly and with discernment.

Frank Ostaseski, after years of working in hospice and training hospice workers, in his book *The Five Invitations* offers these suggestions rooted in mindfulness practice, which are helpful pointers for therapists:

1. Don't Wait.
2. Welcome Everything, Push Away Nothing.
3. Bring Your Whole Self to the Experience.
4. Find a Place of Rest in the Middle of Things.
5. Cultivate Don't Know Mind.³³

AWARENESS OF PSYCHOLOGICAL ADJUSTMENT IN THE CLINIC, SOCIETY, AND CULTURE

Working with individuals with functional limitations requires that we cultivate a holistic and all-encompassing perspective: to visualize how they might best participate within their own homes and communities and in the context of their society and a given time. This is a dynamic and constantly evolving process. The clinician must develop

an intervention that will appropriately stimulate the individual and all their potential caregivers to maximize the potential for the highest-quality life possible. The skilled clinician initially evaluates the individual's physical and cognitive capabilities, depending on the type of functional limitations. The more subtle psychological aspects of the patient's ability to function need to be assessed at some level. These include the individual's support system and/or family network and the ability to adjust to the imminent changes in lifestyle. It would be a tragic situation for a clinician to ignore the individual's psychological adjustment or consider it to be less important in any way.^{19,34–37}

Livneh and Antonak³⁸ have introduced a consolidated way to look at adaptation as a primer for counselors, which should be examined by therapists. They use some of the same basic concepts, such as stress, crisis, loss and grief, body image, self-concept, stigma, uncertainty or unpredictability, and quality of life, to frame their approach. They also consider the concepts of shock, anxiety, denial, depression, anger and hostility, and adjustment in a format that is usable by the therapist.

Livneh and Antonak³⁸ mention that one of the aspects that the therapist must watch out for is a form of coping called *disengagement*. This style of coping may be demonstrated through denial or avoidance behaviors that can take many forms. It can result in substance abuse, blame, or just refusal to interact. Research regarding people with head injuries has demonstrated that if a premorbid coping style for a person was to use alcohol or other drugs, the patient may revert to these same styles of coping, which can result in poor physical and emotional rehabilitation.³⁹ It is important to help the individual out of this quagmire. The skills of a therapist are likely not enough to do this in the short time that the patient is in treatment, so a referral to social work, psychology, or psychiatry is recommended to help support the long-term process. It is still the therapist's job to understand the process of adjustment, the indications regarding how an individual is adjusting, as well as key concepts for how to engage with an individual who is adjusting. It is also essential for the clinician to build skills for how to set personal boundaries without numbing out, to build skills of caring for oneself deeply and on many levels, and to build a practice of extending self-compassion to oneself, so that the clinician is less likely to be overwhelmed by the process of adjustment and disability and has greater capacity to stay centered in the face of human suffering, adjustment, and growth.

In light of all this, it is still the primary job of the therapist to help promote and maximize the engagement in functional activities. These activities are behaviors that are goal oriented (patient, family, and therapist driven), demonstrating problem solving and information seeking and involving completion of steps to positively move forward into life with the disability and maximize independence (promoting function).

The rest of this section introduces the reader to some of the psychological change components that may be assessed and acknowledged. The last section will attempt to demonstrate possible ways that these components can be taken into account as an aspect of therapy.

Growth and Adaptation

The clinician must keep in mind the context from which the patient is coming. Just days or even hours ago the individual may have been going about daily life without difficulty. The trauma may be multifaceted: (1) physical trauma, (2) emotional trauma occurring to the individual's support system, and (3) trauma of each of these systems interacting (the support system trying to protect the individual, and the patient trying to protect the support system). The interaction of these multifaceted components of the trauma may lead to posttraumatic stress. Posttraumatic stress can happen anytime after the life-changing or traumatic event. The level of distress can become disabling in and of itself, and our medical system will label the response a "syndrome" if the level of distress becomes paralyzing. The posttraumatic stress

"syndrome" may be observed more often in women,⁴⁰ but because of cultural barriers it can be hidden in men. It happens more often when there has been a near-death situation.^{41,42} The patient may blame others, try to protect others, or be so self-absorbed that little else in the world may be seen or heard. It may be helpful to get psychological help for the individual early in therapy, even without the label of a "syndrome," if the level of distress is preventing optimal outcomes or creating obstacles in therapy.^{4,15,43–46} Keeping in mind that even the concepts of "optimal outcomes" and "obstacles in therapy" can dehumanize our patients and can become blocks in our own capacity as clinicians to bring our own humanity to the patient-therapist relationship. These are moral and ethical concerns that skilled clinicians need to remain vigilant of throughout our career working in our culture's industrialized systems of health care that seek a bottom line that can often be a financial one with fierce productivity standards.

One of the most important jobs the therapist does is to develop a trusting relationship with the patient. Through this relationship the individual can be guided to focus on the goals of therapy and work on a positive perspective about the future. One of the errors of the medical system is that of focusing on the disease outcomes and pathology and not on the person and their capabilities and helping boost the integrity and personal sovereignty of the individual as a whole person.¹⁹ If we focus solely on the loss, we may cause the individual to see only the injury, disease, or condition and nothing else. In a Veterans Administration hospital, spouses of people with spinal cord injuries formed a group in which the group's focus was on why the partners got married in the first place; the group never looked at the physical limitations as disabling. After a little while, people came to the conclusion that they did not marry their spouses for their legs and the fact that the legs no longer worked was not a major issue after all. This started the decentering from the medical disability model, and the focus started to be placed on the people and the families' future. If we can help patients focus on their functions and interests and not their dysfunctions, the effect of therapy after treatment will be much better. More work needs to be done to help patients see the potential they will have in the future to live their lives with the highest quality possible.^{35,47–51} The World Health Organization developed a model that differentiates the disease pathology model of medicine and focuses on individuals' activities in life and the ability to participate in those interactions. The therapy world has enthusiastically accepted this model, the International Classification of Functioning, Disability, and Health (ICF), and the professions of both occupational and physical therapy use it as a reference model for practice.

Focusing on how to participate, move, and function in the world is one of the keys to helping the patient and the family work toward its future.^{34,50,52–55} The therapist needs to help the patient focus on the direction of treatment objectives and demonstrate how therapy translates into meeting the patient's goals.^{19,56} To discover the patient's true goals, the therapist must gain the trust of the patient and establish sound lines of communication. Distrust from health professionals may obstruct the adjustment process and lead to negative consequences.⁵⁷ Whenever possible, the patient's support system should be enlisted to help establish realistic support for the patient and the goals of both the patient and the family. It has been found that if the patient trusts the health professional, the patient will be more adherent and will seek assistance when it is needed.^{58,59}

A New Normal

When we experience a decline in our ability to carry out our everyday routine tasks, regardless of the cause of our "disability," we may experience incredible degrees of despair. Many societies emphasize a very specific idea of what it means to be normal. At least in our modern,

North American model, there doesn't appear to be a great deal of flexibility in what this standard of normal is, regardless of one's cultural background. When an individual fails to live up to or no longer fits this norm, there can exist a tremendous amount of mental and emotional suffering. Because our bodies and minds are so intricately interconnected, our physical being is adversely affected by the mental and emotional anguish. On top of what the individual may already be experiencing physically, suddenly there is another layer of mental-physical anguish that is far too easily ignored, unappreciated, and unattended to by clinical professionals. However, once we are aware of the multifaceted potential for human suffering with regard to adjusting to a disability, we may be empowered to assist the individual with a non-linear, multifaceted approach. Researchers and theorists from various psychotherapy traditions have begun to explore the potential value of the therapeutic relationship by making direct references to different levels of validation as a means of demonstrating warmth, genuineness, empathy, and acceptance and reiterate how important it is for therapists to reflect back to the patient that their feelings, thoughts, and actions make sense in the context of their current experience and the cultural norms at large. In addition, the therapist articulates an expectation that the treatment collaboration will be effective in an attempt to convey hope and confidence in their ability to work together.⁶⁰

We can guide our patients in identifying a new normal for themselves, all the while allowing them and their support system to grieve the "loss" of the old normal. As the Harvard psychologist Ellen Langer described in her book *Mindfulness*, "if we are offered a new use for a door or a new view of old age [or disability], we can erase the old mindsets without difficulty."⁶¹ We can offer our patients a new view of themselves by showing them what they are capable of as they rebuild their lives. We can also help them honor and acknowledge what is present in this moment for them, we can help reflect back to them what they are capable of, and to appreciate their humanity and their wholeness as they are, without needing them to be any other way.

People who choose to go into this line of work and to be a part of the helping rehabilitation profession tend to be compassionate people. This is of course a wonderful quality to bring to our patients. At the same time, however, we need to be vigilant of the desire we may bring into our work with the underlying goal to take away another person's suffering. This kind of attitude to our work can bring about burnout and compassion fatigue. If we notice this underlying desire, it is helpful to just notice it as it is, maybe inquire about where we may have picked up this narrative, identify if it is useful to the situation, and letting it go. Let's consider this a bit more.

A woman who has lived with multiple sclerosis for over 30 years describes how the relief of suffering does not require restoring physical function to some perceived level of normality. Nor is she saying that our job is to relieve suffering. She states, "Suffering is relieved to the extent that patients can learn to integrate bodily disorder and physical incapacity into their lives, to accommodate to a different way of being" (p. 591).⁶² It may be that we can bring healing to ourselves, our patients, and our culture to appreciate the potential for a new narrative around our customary approach to suffering, which implies that in general we want relief from suffering and sometimes at significant costs. Maybe the new narrative we could foster is one where suffering does not need to be "relieved." We may wonder about who we are as people and health care practitioners, often bringing a narrative of "us" as clinicians, being the ones to take away or "relieve" someone else's suffering. Is this necessary or even helpful? What if we learned to approach our own suffering, our patient's suffering, and the suffering of the world with a view that it is to be honored and appreciated as a profoundly meaningful human experience, not to be disregarded or something to "get rid of"? There is potential within our suffering to

bring profound meaning to our lives. More recent research is demonstrating that when we wrestle with life's challenges or when we give ourselves the space to suffer during challenges and changes, these experiences can help us make meaning of our lives. The process of grappling with these difficulties and intensities, while holding ourselves and others with compassion and clarity, can bring new narratives we so desperately need in these times. So let us wonder together about the implications of this. Feelings of sadness, anger, despair, longing, and fear can all be appropriate responses to change. How might we hold space for and honor these human experiences? There are almost no role models for this way of being in the midst of most of our dominant systems of our industrialized existence, including our health care institutions, but we can always learn, and practicing mindfulness can foster this capacity in meaningful ways.

According to research by De Souza and Frank,⁶² their subjects with chronic back pain expressed regret at the loss of capabilities and distress at the functional consequences of those losses. They found that facilitating adjustment to "loss" was more helpful than implying the potential for a life free of pain as a result of therapeutic interventions. The word "loss" is in quotations here to recognize that the language we use to imply a certain kind of meaning on someone else's experience needs to be considered thoughtfully and held in awareness. Language is powerful, and it is important to recognize that it is possible for people to not experience their situation necessarily as a "loss" but consider the experience as a gift or both. Or we could say experiencing that loss comes with a gift.

There is a broad continuum of experience a human being may ascribe to their situation, and we need to be alert to our own biases about a person's potential experience and honor that and not need to impose our own biases and views upon their experience. How do we know what they may be experiencing? Well, we could ask them, with an open, curious awareness, "How is it for you now? What is this experience like for you?" So often in our modern North American culture we are taught to not show our pain and suffering, to numb and subjugate our experience. Through our own personal practice, integrating a mindful holding and honoring of our own human experiences, the griefs, the sadness, the fears, the joys, and the wonder, we become more capable of holding another's full human experience and not needing them to be different from what "it" is.

We can sense this capacity in each other. Consider this: you may know people in your life you feel safe sharing your deepest truth and feelings with and others you can sense are not fully capable of holding your pains and difficulties or your joys for that matter. As clinicians, we can develop and build our capacity to hold another person's experience as meaningful for them without needing them to sugarcoat or subjugate it for our sake to make us feel better.

Guiding the individual through practice and repetition of basic functional activities will allow the patient to identify for himself or herself how to live successfully in this world again and cultivate this "different way of being" in action, while participating in daily life. At the same time we can encourage our patients to mindfully plan for and visualize their future (see the practice section later) during specific times of their day so that their minds are not in constant worry mode or rehearsing, which can cause a great deal of anxiety about the future. We can assist our patients in using emotion-focused and problem-focused problem-solving strategies as they plan for their future, in the present moment, especially in a medical environment where shorter rehabilitation stays are the norm. And we can do all of this without needing their suffering or pain to go away and without needing them "to get on with it already" and "to adapt."

Without any need to apologize for their situation, just simply being with them in the moment in a nonjudgmental way and allowing them to

BOX 5.1 Practice: Mindful Planning and Visualization of Future

- Find a time when you are alone; you need only a few minutes every day for this practice.
- Allow this time to be specifically for future planning and visualization, not worrying.
- If you find yourself worrying about the future at other times during the day, acknowledge that there will be a specific time devoted to planning and visualizing. Worrying throughout the day will bring a great deal of mental anguish during times when you need to focus attention on an important task or rehabilitation intervention.
- Use a journal to record thoughts and ideas on paper so that the thoughts do not have to stay in the mind and be rehearsed. Write down concerns, your emotions, and feelings, as well as your desires and plans.
- Try to let go of planning during daily activities and tasks until the next scheduled mindful planning session, or, if necessary, allow this moment to be the next planning session but be sure to stop whatever else you are doing and be fully present in the planning process.

grieve (and honoring our own grief) can be a powerful tool for healing. Acknowledging the loss, pain, and the suffering may help patients move forward with their lives in a new way. “Acceptance [of what is] doesn’t, by any stretch of the imagination, mean passive resignation. Quite the opposite. It takes a huge amount of fortitude and motivation to accept what is—especially when we don’t like it—and then work wisely and effectively as best we possibly can with the circumstances we find ourselves in and with the resources at our disposal, both inner and outer, to mitigate, heal, redirect, and change what can be changed” (Box 5.1).⁶³

Societal and Cultural Influences

Culture, subcultures, and the culture and beliefs of the given family are all aspects of the patient that the therapist must be aware of.^{22,53,64–70} This concept gets into the beliefs about the world and maybe a belief about the cause of the disability or at least how the patient is viewing the disability. Asking “Do you notice any beliefs about why this happened?” can lead to an insightful experience. “Causes” may range from “things like this just happen,” “sometimes bad things happen to good people,” to “God is punishing me,” “I deserved it,” or even “life is against me.”

From an early age, people in our society are exposed to misconceptions regarding the disabled.^{71–74} If in the therapeutic environment, however, the patient and family have their misconceptions challenged constantly, they may start reformulating their concept of the role of the disabled person. As this process progresses, therapists and other staff can help make the expectations of the disabled person more realistic. Therapists can schedule their patients at times when they will be exposed to people adjusting to their disabilities. For example, use of individuals who have been successfully rehabilitated as staff members (role models) can help to dispel misconceptions that people with disabilities are not employable.^{75–77}

This process of adaptation to a new disability can be considered as a cultural change from a majority status (able bodied) to a minority status (disabled). Part of the adaptation process can be considered as an acculturation process, and the therapist can help facilitate this process.^{16,73,78,79}

The cultural background of the individual also contributes to the perception of disability and to the acceptance of the disabled person. Trombly and Radomski⁸⁰ state that perception and expression of pain, physical attractiveness, valuing of body parts, and acceptability of types of disabilities can be culturally influenced. One’s ethnic background can also affect intensity of feelings toward specific handicaps, trust of staff,⁸⁰ and acceptance of therapeutic modalities.^{81–85}

The successful therapist will be sensitive to the cultural values of the patient and will attempt to present therapy to the patient in the most acceptable way. For example, in the Mexican culture it is not polite to just start to work with a patient; rapport must first be established. Sharing of food may provide the vehicle to accomplish rapport. Thus the therapist might schedule the first visit with a Mexican patient during a coffee break. The therapist must remember that the patient may be the one who may have difficulty adjusting to the therapist and that the therapist may need to adjust to the patient, especially in the early stages of therapy.

Gaining trust is one of the crucial links in any meaningful therapeutic situation.^{59,86,87} Trust will create an environment that facilitates communication, productive learning, and exchange of information.^{76,87} Trust is important in all cultures and will be fostered by the therapist who is sensitive to the needs of the patient. This sensitivity is necessary with every patient but will be manifested in many different ways, depending on the background and needs of the individual in a therapy. A patient of one culture may feel that looking another person in the eyes is offensive, whereas in another culture refusal to look into someone’s eyes is a sign of weakness or lack of honesty (shifty eyed).⁸⁸ Thus, although it is impossible to know every culture or subculture with which the therapist may come into contact, the therapist must attempt to be sensitive to the background and needs of the patient. Even if the therapist knows the cultural norms, not every person follows the cultural patterns. Thus every patient needs to be treated as an individual in the therapeutic relationship with respect, dignity, and sovereignty. It should be the therapist’s job to be sensitive to the subtle nonverbal and verbal cues that indicate the level of trust in the relationship. The therapist will obtain this information by being open to the patient and their context, not open to a textbook. The patient is the owner of this information and will share it with everyone he or she trusts and those who care to ask. It is OK if we mess up sometimes; this is inevitable. Being human and working in diverse health care settings is dynamic and complex. Holding ourselves in compassion when this happens, learning from the situation, and (if it is called for) apologizing are essential.

Trust is often established in the therapeutic relationship through the therapeutic process of doing physical activities. For example, the act of working with a patient in transferring from the chair to the bed can either build trust or destroy the potential relationship. If the patient trusts the therapist just enough to follow instructions to transfer but then falls in the process, it may take quite some time to reestablish the same level of trust, assuming that it can ever be reestablished. This trusting relationship is so complex and involves such a variety of levels that the therapist should be as aware of attending to the patient’s security in the relationship as to the physical safety of the patient in the clinic.^{59,86} If the patient believes that the therapist is not trustworthy in the relationship, then it may follow that the therapist is not to be trusted when it comes to teaching and learning to participate in newly difficult activities of daily living (ADLs). If the patient does not know how to safely go about their daily activities and thus has not yet built trust in their body or their skill to navigate their ADLs, then lacking trust in the therapist will only compound the stress of the situation.^{59,86,89}

The patient’s culture may be unfamiliar to the therapist, even though both the clinician and patient may be from the same geographical region. A patient’s problems of poverty, unemployment, and a lack of educational opportunities^{77,87,90,91} can all result in the therapist and patient feeling that therapy will be unsuccessful, even before the first session has begun. Such preconceived concepts held by both parties may not be warranted and must be examined. These preconceived concepts can be more reflective of failure of rehabilitation than any physical limitation of the patient.

Cultural and religious values may also result in the patient feeling that he or she must pay for past sins by being disabled and that the disability will be overcome after atonement for these sins. Such a patient may not be inclined to participate in or enjoy therapy. The successful therapist does not assault the patient's basic cultural or religious values but may recognize them in the therapy sessions. If the therapist feels that the culturally defined problems are impeding the therapeutic process, the therapist may offer the patient opportunities to reexamine these cultural "truths" in a nonjudgmental way and may help the patient redefine the way the physical limitations and therapy are seen.⁹² Religious counseling could be recommended by the therapist, and follow-up support in the clinic may be given to the patient to view therapy not as undoing what "God has done" but as a way of proving religious strength. Reworking a person's cultural and religious (cognitive) structure is a sensitive area, and it should be handled with care and respect and with the use of other professionals (social workers and religious and psychological counselors) as appropriate.

The hospital staff can be encouraged to establish groups in which commonly held values of patients can be examined and possibly reframed or incorporated.^{16,92-98} Such groups can lead the patient to a better understanding of priorities and may help the person see the relevance of therapy and the need to continue the adjustment process. This can also prepare the patient to better accept the need for support groups after discharge. The therapist may be able to use information from such group sessions to adjust the way therapy sessions are presented and structured to make therapy more relevant to the patient's values and needs. Value groups or exercises⁹⁹ can be another means used by the therapist for evaluation and understanding of the patient.

Beliefs and values of cultures and families can play a profound role in the course of treatment. Such things as physical difficulties, which can be seen, are usually better accepted than problems that cannot be seen, such as brain damage that changed an individual's cognitive abilities or personality.¹⁰⁰ A person with a back injury may be seen as lazy, whereas a person with a double amputation will be perceived as needing help. At the same time, in some cultures a person who has lost a body part may be seen as "not all there" and should be avoided socially. Therefore being attuned to the culture and beliefs of the patient is imperative in therapy. The reader is encouraged to refer to texts on cultural issues in health care such as *Culture in Clinical Care* by Bonder, Martin, and Miracle¹⁰¹; *Cultural Competence in Health Care: A Practical Guide* by Rundle, Carvalho, and Robinson¹⁰²; and *Caring for Patients from Different Cultures* by Galanti¹⁰³ for more detailed discussions on how culture and beliefs affect health care.

Attachment and Evolving Sense of Self: Foundations of Adjustment

The persons we serve in rehab are fellow travelers on a human, developmental, and evolving journey through life—with its experiences, losses and gains, encounters, and opportunities and obstacles. Any treatment we provide is in the context of that journey as a "self" with its ongoing times of crisis, disequilibrium and chaos, reorganization, and integration and change. The therapist seeks to support the person in their current crisis or condition as well as accompany in service of that evolving meaning-making self. And it is helpful to understand where they are in their evolution as a self, not as an evaluation of their stage but as an understanding of their meaning-making.

As humans we are intrinsically, neurobiologically social. From the time of infancy attachment and development, a growing sense of self and other and of efficacy is gradually formed in the container of relationship with a primary caregiver. Burgeoning research on this primary biological, neurological social core process has shown how sense of other and self, relational constructs are developed and then

continually grown. We are evolved "in relation." It is the medium in which we learn and know self, other, and the world and adapt, grow, and evolve. Research has identified basic "good enough" caregiver qualities crucial to a healthy sense of self, and these core qualities in primary relations become internalized as part of growth and development. They can also be thought of as the qualities of a good container for growth and healing. Family, school, friendships, and groups may hold these qualities to greater or lesser degrees, and we need to consider their capacity to be containers.

The following are some basic qualities ideally present for an infant:¹⁰⁴

- Physical presence, eye contact, physical contact, consistency, reliability, and interest
- Protection
- Attunement
- Soothing and reassurance
- Expressed delight
- Unconditional support and encouragement
- Felt sense of safety
- Felt sense of comfort
- As the child develops, encouragement and support for inner and outer exploration

Diane Fosha¹⁰⁵ identifies these similar qualities as therapeutic holding:

- Empathic attunement
- Recognition, affirmation, validation, and valuing of patient's experience
- Expressed care, compassion, and concern
- Authenticity and encouragement
- Expressed delight

These all help undo the sense of being alone. It can be said that in general these are attributes from without and internalized within that help promote healing, integration, resilience, and growth. These are also functions of community that can be of primary support for patients, families, and caregivers.

Parents who have experienced obstacles in bonding with an infant born with severe illness or disability can access help and support in this area and also take hope that these are potentially areas of continued growth and healing. Health providers must all give primary support for bonding and the primary relationships. Promising research also shows that deficiencies in attachment can be healed and repaired throughout life with attention and support. No one has perfect experiences (see, among others, D. J. Brown, *Elliott Treating Attachment Disorders in Adults*).

The holding environment and secure-base experience are themselves corrective emotional experiences for patient in large part because they reduce or "undo" the patient's sense of being alone with her or his painful experience.¹⁰⁶

Persons undergoing new injury, insult, or conditions are often experiencing huge changes in perception, processing, and sense of self. They need support as they undergo an often long and slow process of reorientation, recalibration, and reintegration of a changing sense of self. In this regard, the therapist must be attuned to the present state as well as the long and wide view.

Respect for the current stage and state must be maintained while cultivating openings, opportunities, and seeds for adaptation and integration. Digestion of trauma and change cannot be forced. Healing and growth are a spiraling process with seeming backslides as well as gains. Mindfulness practice, where possible for patients, caregivers, and family, can offer experientially gained insight that promotes greater flexibility, acceptance, and perspective on change, identity, and sense of self over time. When experiencing crisis, the notion of a fixed identity dependent on good health, job and family roles, certain physical, mental, or other capacities can be shattered or injured. Much support, holding, and mirroring are

needed to both grieve real losses and validate the patient's experience and value. Many disciplines as well as community and personal networks have a potential role to play over time in supporting the person and their network of caring others who are experiencing their own losses and changes. As time goes on, support groups, consumer groups, community programs, chaplains, counselors, mindfulness groups, or individual support might eventually be incorporated. The trajectory of when a person or family is interested or willing to pursue some of these may vary greatly.

The Evolving Sense of Self: Growth Over the Life-Span

Background to circumstances of health, illness, and changes in abilities and circumstances is the great life project, what Robert Kegan calls the evolution of meaning,¹⁰⁷ the person's capacity to make sense of life in an adaptive manner, to "make whole." The spirit is always engaged in a progressive motion, in giving itself new form an endeavor that requires courage and involves losses and eventual gains. This constructive-developmental approach pays attention to the developmental ongoing activity of meaning-making constructing.

Meaning is in its origins, a physical activity, a social activity, a survival activity (in doing it we live). This evolving is the "primary human motion."

Processes of internalization are intrinsically related to the movement of adaptation.

—Kegan

Growth is a matter of both differentiation and reintegrating into new connection in a spiraling process, what Piaget calls "decentration," the loss of an old center, and what Kegan calls "recentration," the recovery of a new center.¹⁰⁸ We undergo a series of transformations and imbalances and rebalances, "hatching out" of one self and reforming a larger self and larger relationship with the world, with life, finding new states of equilibrium in the world, "between the progressively individuated self and the bigger life field." And this ongoing conversation with life "is marked by periods of dynamic stability or balance followed by instability and qualitatively new balance."¹⁰⁹ In each new stage, we are defending, surrendering, and reconstructing a center.¹¹⁰

Understanding this adaptive conversation forms a background of our understanding how to better serve patients in pain and transition. As humans, we have this process in common. We are fellow travelers in an evolving life project. We are engaged in growing a point of view. Kegan says, "This activity is about knowing and being, about theory-making and investments and commitments of the self. The same ongoing tension between self-preservation and self-transformation is descriptive of the very activity of hope itself."¹¹¹

Undoing Aloneness: The Need for Community, Friendship, Belonging.

From infancy on, it is essential to know that we exist in the heart and mind of another. This is our core relational need—to be recognized, seen, and known and to matter to one another. There are two powerful and profound yearnings in human existence and experience. One is unity: to be included, to be part of, close to, joined with, to be held, admitted, and accompanied. The other is a desire for agency and differentiation: to be independent, to have a unique and separate integrity, and to choose one's own direction.¹¹² There is an ongoing dynamic tension between these yearnings, and as we grow in development, we spiral through different balances leaning toward one or the other. We are increasing our understanding and differentiation as well as expanding our integration of the world and life. This very much models the experiences of mindfulness practice: that one is knowing, becoming more familiar increasing perception and specificity of

understanding self and experience, and simultaneously expanding the sense of an "I" to include more of life. A sense of safety is essential to this life enterprise of evolving stages of self and other and our construct of the world.

The good-enough "holding environment," described by Winnicott in infancy, is something that accompanies us throughout life. We live in a series of holding environments, in our history of embeddedness. They are the mediums that hold us and include us, and from which we differentiate. As Kegan says, "Your buoyancy or lack of it, your own sense of wholeness or lack of it, is in large part a function of how your own current embeddedness culture is holding you."^{113,114}

"Good enough" holding environments—as in infancy and beyond—are containers and mirrors to the self we are and a bridge to the self we are becoming, and a stable presence for the transition in between when one self with its evolutionary truce is gone and the organization of new meaning-making is in transition. Cultures of embeddedness are often inadequate in our society and modern way of life, especially in times of crisis and change. We need to really consider how to create or connect to these ongoing supports of continuity through change.

Mitigating a sense of aloneness and isolation aids healing and recovery. We share a common humanity, and we all take on different roles in life at different times. As social beings, we need to be connected. Humans can bear hardship with the feeling of being accompanied by others. Healing and living fully happen in relation to others. Illness, crisis, disability, and stress can easily lead to isolation and a negative spiral of effects. We need positive mirroring and authentic affirmation of strengths and value. We need to be included and belong, as well as be valued for our uniqueness and agency. We need to know we positively affect others. Some of the most effective community programs have started as tiny grassroots initiatives and have simply grown out an unmet need, which include the Cabrillo College Stroke Center (<https://www.cabrillo.edu/academics/strokecenter>) and the Shurig Center for Brain Injury Recovery (<https://www.schurigcenter.org>). Because there was such a big need, they often grew into established vibrant and funded programs over time. Having regular times to meet and share with others provides an important buffer for individuals, caregivers, and families.

In speaking to our need to live in the context of community, Kegan says, "among its most important benefits is its capacity to recognize a person, a marriage, a family, over time and to help the developing system recognize itself amid the losses and recoveries of normal growth." Healing communities can provide a safe support and serve to affirm and recognize individuals, acknowledge losses and growth, and value people. A crisis or illness with loss often includes a loss of how one creates meaning.¹¹⁵

The patient's loss and grief brought on by disability or injury can be experienced as the "dying of a way to know the world which no longer works, a loss of an old coherence with no new coherence immediately to take its place. And yet a new balance again and again does emerge . . . Still, it is a new life not a return or recovery. We will never restore the (old) balance—but there is a new balance that can be achieved. We are not going back, but we are coming through- to a new integration, a new direction."¹¹⁶

As therapists, we are accompanying and collaborating with the person in their meaning-making process when their process has been threatened. Fosha, et al, reminds therapists, "We are wired to heal, to right ourselves, to grow and transform. It is what neuroplasticity is about."¹¹⁷ Furthermore, "People have a fundamental need for transformation. We are wired for growth and healing. And we are wired for self-righting and resuming impeded growth. We have a need for the expansion and liberation of the self, the letting down of defensive barriers and the dismantling of the false self. We are shaped by a deep desire to be known, seen, and recognized, as we strive to come into contact with parts of ourselves that are frozen."¹¹⁸

We want to take note of the state of the person's vitality and life-force and notice areas of aliveness and obstacles to that life force. Areas of aliveness and wellness needed to be seen and felt, along with more difficult emotions. As Hildegard de Bingen noticed, the tendency of a living thing is to return to its essence after being wounded, and promoting aliveness and healing involve a lot of time to see who a person is.¹¹⁹ The long-range view of healing and resources for patients beyond our own contact is of primary importance. We want to encourage healthy social connectedness and hope to expand those possibilities.

Building Resilience: Felt Sense as an Underpinning for Positive Strengths and Neural Integration

Felt sense, a most basic way that we know our experience, is actually a skill that can be cultivated and used to support our more accurate and fully owned bodily perception, emotional knowing and regulation, and neural integration. Increasing capacity for felt sense—bringing attention in present time to the sensory sensations of the body—provides a way to anchor in the body and breath, self-regulate, and increase self-knowledge. Wellness can be described as a byproduct of our ability to tolerate our internal experience.¹²⁰ Having a stable caring environment along with mindful felt sense (an internalized holding) increases that capacity to be with our experience. Hendel and others refer to the body as the place of deep emotional knowing.¹²¹ It is an important stepping stone, increasing capacity for meta-cognition, a sense of insightful “knowing that you know” important to healing and growth. Felt sense is an important part of bringing attention and anchoring positive states in the body and thus wiring them into the brain.

As the qualities of the good enough caregiver (including how we care mentally and emotionally for ourselves) are the food for optimal brain development, in the same way the capacity to feel and sense and drink in positive states and experiences supports positive neuroplasticity in the service of adjustment and healing.^{122,123}

Bringing attention to one's experience and amplifying the positive felt experience make them more “known.” Gergely's research on marked expressivity, marked affectivity is mirrored with exaggerated content and tone so that the experience is “marked” as having happened, as important, and as belonging to the self.^{124,125} In other words, it is known, owned, and wired in the brain more effectively and with greater efficiency, a way that neuroplasticity is utilized for healing. This capacity is increasing the ability to receive positivity, making the most of it, and in the process building up strengths and capacities so the process becomes a self-enhancing loop.

The development of the capacity for felt sense and safety, is the doorway to digest emotions associated with suffering and release subconscious, adaptive action tendencies.¹²⁶ Fosha describes in her Accelerated Experiential Dynamic Psychotherapy model that all affective states, in an adequate holding environment, are seeds for deeply transformative experience and development. Understanding this important insight can orient us to highlight this holding environment and build it into the way we structure and enact therapeutic environments and experiences as a foundational support. Presence, being with, cultivating sensing, and mindfulness all affect the quality of the healing capacity.¹²⁷ Mindfulness and positive relational experiences of safety, being seen and known, heard, and acknowledged, grow areas of interconnectedness in the corpus callosum, hippocampus, and prefrontal cortex. These relational experiences can happen in ongoing groups and cultures of belonging. Another resource of patients with capacity to develop attention and for caregivers is classes in mindfulness, which in addition to other benefits mentioned, is protective against depression and depression relapse. A secondary condition resulting from brain injury or other neurological events can be clinical depression, which must be addressed by the care team.

Establishment of Self-Worth and Healthy Body Image

The true value of a human being is determined primarily by the measure and the sense in which he has attained liberation from the self.

—Albert Einstein

Self-worth is composed of many aspects, such as body image, sexuality, and the ability to help others and affect the environment. The body image of a patient is a composite of past and present experiences, familial and cultural influences, and the individual's perception of those experiences. Because body image is based on experience, it is a constantly changing construct. An adult's body image is substantially different from the body image of a child and will no doubt change again as the aging process continues. A newly disabled person is suddenly exposed to a radically new body, and it is that individual's job to assess the body's capabilities and develop a new body image. Because the therapist is at least partially responsible for creating the environmental experiences from which the patient learns about this new body, the therapist must be aware of the concept. In the case of an acute injury, the patient has a new body from which to learn and experience. The therapist can promote positive feelings as the therapist instructs the patient how to use this new body and to accept its changes.^{1,16,20,27,128,129}

Because in “normal” life we slowly observe changes in our bodies, such as finding one gray hair today and watching it take years for our hair to turn totally white, we have the luxury of slowly adapting to the “new us.” Change usually does not happen quite so slowly and “naturally” when trauma or a disease affects the nervous system. This sudden loss of function can create a void that only new experiences and new role models can fill.

The loss of use of body parts can cause a person to perceive the body as an “enemy” that needs to be forced to work or to compensate for its disability. In all cases the body is the reason for the disability and the cause of all problems. The need for appliances and adaptive equipment can create a sense of alienation and lack of perceived “lovability” resulting from the “hardness of the hardware.” People tend to avoid hugging someone who is in a wheelchair or who has braces around the body because of the physical barrier and because of the person's perceived fragility; a person with physical limitations is certainly not perceived as soft and cuddly.^{20,27,53,103,128} Both the perception that these individuals are not lovable and their labored movements can sap the energy of the disabled and discourage social interaction or life participation. To accept the appliances and the dysfunctional body in a way that also allows the disabled person to feel loved can be a significant challenge.

In the case of a person who will be disabled for the long term, such as the person with cerebral palsy or Parkinson disease, the therapist is attempting to teach the patient how to change the previously accepted body image to one that would allow and encourage more normal function. In short, the therapist has two roles. One role is to help lessen the disabled body image. The second is to teach a functional disabled body image to a newly disabled person. The techniques may be the same, but in both cases the patient will have to undergo a great amount of change. The person with a neurological disorder or neurologically based disability may assume that he or she will not be capable of accomplishing many things with his or her life. The therapist is in a unique position to encourage development of and maximize the patient's level of functional ability. The individual may then expect more of himself or herself. The newly disabled person must change the expectations; however, he or she has little concept of what is realistic to expect of this new body. At this point, role models can be used to help shape the patient's expectations. If the patient is unable to adjust to the new body and accept the body image and self-expectations, life may be impoverished for that individual. Pedretti¹³⁰ states that the patient with

low self-esteem often devalues his or her whole life in all respects, not just in the area of physical dysfunction.^{1,16,20,27,128,130}

One way the patient can start exploring this new body is by exploring its sensations and performance. Dr. Jon Kabat-Zinn developed a guided “body scan” meditation that can help individuals learn how to become more connected and in tune with the sensations of the body.⁶³ This kind of practice is about learning to pay attention to the body in a new way and can be very helpful in developing an accurate body image and improve self-awareness. For example, the patient with a spinal cord injury may also use the sensation of touch to “map out” the body to see how it responds.¹³¹ Including the whole body, encompassing the felt experience as part of sensory awareness, even though that may include unfamiliar sensations, numbness, and lack of sensation, is helpful in this regard. They may ask themselves the following questions: Is there a way to get the legs to move using reflexes? Can positioning the legs in a certain way aid in rolling the wheelchair or make spasms decrease? Such exploration will start the patient on the road to a self-informed and personally empowered evaluation of his or her abilities.

The therapist’s role is to maximize the patient’s perceptions of realistic body functioning. Exercises can be developed that encourage exploration of the body by the individual and, if appropriate, the significant partner. Functioning and building an appropriate body image will be more difficult if intimate knowledge of the new body is not as complete as before injury.⁹ The successes the patient experience in the clinical setting, coupled with the patient’s familiarity with his or her new body, will result in a more accurate body image and contribute to the patient’s feelings of self-worth.

The last aspect of self-worth is often overlooked in the health fields. This aspect is the need that people have to help others.¹³² People often discover that they are valuable through the act of giving. Seeing others enjoy and benefit from the individual’s presence or offering increase self-worth. Situations in which others can appreciate the patient’s worth may be needed. Unless the patient can contribute to others, the patient is in a relatively dependent role, with everyone else giving to him or her without the opportunity of giving back. Achieving independence, understanding common interdependence, and then reaching out to others, with therapeutic assistance if necessary, facilitate the individual’s more rapid reintegration into society. The therapist should take every opportunity to allow the patient to express self-worth to others through helping and giving back to their family and community.

The ability to expand one’s definition and experience of oneself is a key factor in adjusting to a disability. Expanding the experience of oneself in terms of all the roles and responsibilities one has or gently holding an experience of oneself that is so much greater than just the physical realm can help the individual comprehend the enormity of who he or she is. As humans, we have the capacity to understand how we are so much greater than just the job we once performed and so much greater than the role we once played. This practice can cultivate understanding of how complex our species is, it can humble us by acknowledging the vastness of our place within the universe and on this planet, and how much we have to offer the world (God knows the world certainly needs us), differently abled or not (see the journal activity in [Box 5.1](#)).

Sense of Control

Oh, I’ve had my moments, and if I had to do it over again, I’d have more of them. In fact, I’d try to have nothing else. Just moments, one after another, instead of living so many years ahead of each day.

—**Nadine Stair, 85 years old, Louisville, Kentucky**

In her poignant quote, Nadine Stair speaks to an understanding that we all have the capacity to choose how we will experience every given moment of our lives. There is so little in life that we actually have

control over and our dominant culture doesn’t teach what we do have control over, which is how we relate to every moment of our lives. We can intentionally choose to be present, and once we know this is so, we have control over our quality of attention, our level of attention, and our intention. So as humans we can develop these capacities and in doing so we build a greater and greater sense of self-control over our lives. While this sounds simple, it can be profoundly life changing and empowering on many levels. All the while we are exercising our choice to be intentionally present in a specific way and we are building neuroplasticity to choose every single time so that we will more likely be present when the going gets tough.

As Drs. Roizen and Oz stated in their book *You: The Owner’s Manual*, we can control our health destiny.¹³³ Although we can’t always control what happens to us (no matter how fit we are), there are some things we can control: our attitude, our determination, and our willingness to take our own health into our own hands.¹³³

Adjusting to a disability can make patients feel as though they have very little control over their lives; they may feel helpless, as though their health is in everyone else’s hands but their own. This feeling can cause incredible suffering and emotional anguish on top of their physical or cognitive disability. If we focus solely on treating the disability and ignore what may be going on for our patients mentally and emotionally, we may be creating even more suffering for them. Clinical professionals have the opportunity to guide their patients toward a new way of relating to their disability by focusing on what they do have control over as well as identifying ways in which they may relate differently to those situations over which they do not have control.

Dr. Jill Bolte-Taylor says this eloquently in a passage from her book:

I’ve often wondered, if it’s a choice, then why would anyone choose anything other than happiness? I can only speculate, but my guess is that many of us don’t exercise our ability to choose. Before my stroke, I thought I was a product of my brain and had no idea that I had some say about how I responded to the emotions surging through me. On an intellectual level, I realized that I could monitor and shift my cognitive thoughts, but it never dawned on me that I had some say in how I perceived my emotions . . . What an enormous difference this awareness has made in how I live my life.¹³⁴

“I had some say in how I perceived my emotions.” Let’s wonder out loud about this statement. As Dr. Bolte-Taylor describes, all of us have the choice to be in relation to the present moment fully, or we can allow our thoughts and emotions to “take us for a ride” as though we were on automatic pilot.¹⁰⁹ If we allow our minds and emotions to take over our experience of the present moment without any awareness or personal choice, we can feel powerlessness and be dragged along into rehashing our past events that led up to the disability, which can create more suffering and emotional anguish. We also may be rehearsing what our lives will be like without allowing the dust to settle, without waiting until we have a clearer picture of what implications the disability may have for us. An unacknowledged rehashing and rehearsing can create an incredible sense of lack of control over one’s life, which can lead to anxiety and depression.

Approximately 70% of our thoughts in any particular waking state can be considered to be daydreams, and they can often be unconstructive.¹³⁵ In an experience sampling method, Klinger and his colleagues found that “active, focused problem-solving thought”¹³⁶ made up only 6% of the waking state. According to Baruss, “it would make more sense to say that our subjective life consists of irrational thinking with occasional patches of reason”¹³⁵ while we are participating in our daily activities. Especially when one is participating in menial, basic self-care activities, our mind is most often in another place. For the most part,

our modern North American culture does not teach the skills of mindful, present moment awareness or emotional intelligence.

If an individual is frequently disconnected from the present moment, tending to unconsciously ruminate over negative past or future events, he or she may experience significant negative effects from this perpetual distraction. Unacknowledged rumination, absorption in the past, rehashing, or fantasies and anxieties about the future can pull one away from what is taking place in the present moment. Awareness or attention can be divided without conscious choice, such as when people occupy themselves with multiple tasks at one time or preoccupy themselves with concerns that detract from the quality of engagement with what is focally present, and this can increase a sense of disempowerment, anxiety, and depression.¹³⁷ Anxiety and depression can be signs of underlying problems that are unacknowledged. Anxiety and depression are not the problem in and of themselves.

Being sad and feeling depressed or anxious, for example, are completely appropriate responses to so many situations that ail us culturally, socially, ecologically, economically, politically, and personally. So we must be careful in our “diagnosis” of what ourselves or others may be experiencing and feeling and not necessarily labeling “the ailments,” the suffering, the strong emotional experiences as dysfunctional when the responses to those events or situations may be completely appropriate to the situation and may actually help bring meaning to one’s life, motivation, and emotion-focused problem solving, discernment, and skillful action.

On the other hand, according to Drs. Roizen and Oz,¹³³ emotions can cause high blood pressure, as well as disrupting the body’s normal repair mechanisms. Low-level, perpetual, and unacknowledged states of stress can also constrict our blood vessels, making it even harder for enough blood to work its way through the body. At the same time, stress is also shown to encourage bonding responses that actually work to bring people together in community (https://www.ted.com/talks/kelly_mcgonigal_how_to_make_stress_your_friend). Also called the “tend and befriend reflex,” stress can be our friend if we can change our relationship to stress, acknowledge it, honor it for the message it may be sending, and hold it gently in awareness. Learning relaxation techniques such as yoga and meditation can help us build the skills of awareness, clarity, and self-compassion to honor these strong emotions and feelings of stress in our bodies. Learning to allow and honor our human experience, learning how to relate to our feelings and emotions with clarity, discernment, and care is an essential process of learning how to be in skillful relationship to our feelings. Numbing and subjugating our feelings, as our modern North American culture often teaches, is not the answer.

However, we know now that all mind states affect our bodies profoundly whether we are feeling joy, wonder, and awe or jealousy, rage, and hopelessness—for example, a feeling of helplessness appears to weaken the immune system, yet joy and wonder release hormones associated with well-being.¹³³ We can teach ourselves and our patients to be mindful of and pay attention to our mind states, feelings, and thoughts during therapeutic intervention. In this way and with the skills of mindful awareness, we can encourage a greater sense of personal control and facilitate greater mental and emotional equilibrium and adjustment to the individual’s disability. According to a 2008 article by Ludwig and Kabat-Zinn in *JAMA*, “the goal of mindfulness is to maintain awareness moment by moment, disengaging oneself from strong attachment to beliefs, thoughts, or emotions, thereby developing a greater sense of emotional control, balance, and well-being.”¹³⁸

The key here is in the practice of loosening attachments or clinging to any specific mind state so that as we begin to notice mental phenomena, we can choose how we wish to respond. We can let go of the thought and focus our attention on the present moment at hand, or we

can hold the thoughts, emotions, and feelings in awareness. We can honor and appreciate our experience as it is without needing it to be any other way, or we can choose another thought or feeling or emotion altogether. Of course this sounds easy, but this takes practice and attitude of kindness, patience, compassion, and a specific kind of intention. One intention is to develop the capacity to build greater and greater degrees of awareness of the sensations of our bodies and to recognize and appreciate the messages of our bodies. Anat Baniel, in her book *Move into Life*, describes how research shows that the moment we bring attention and awareness to our body’s movements moment by moment, the brain resumes growing new connections and creating new pathways and possibilities for us.¹³⁹

According to a research study by Dr. Jon Kabat-Zinn¹⁴⁰ of the Stress Reduction Program at the Center for Mindfulness in Medicine, Health Care, and Society, the practice of mindfulness meditation used by chronic pain patients over a 10-week period showed a 65% reduction on a pain rating index. Large and significant reductions in mood disturbance and psychiatric symptoms accompanied these changes and were stable on follow-up. Another study looked at brain imaging and immune function after an 8-week training program in mindfulness meditation.¹⁴¹ The study demonstrated that this short program in mindfulness meditation produced demonstrable effects on brain and immune function. The results of a clinical intervention study by Brown and Ryan¹³⁷ showed that higher levels of mindfulness were related to lower levels of both mood disturbance and stress before and after the Mindfulness-Based Stress Reduction (MBSR) intervention. Increases in mindfulness over the course of the intervention predicted decreases in these two indicators of psychological disturbance. Evidence has indicated that those faced with a life-threatening illness often reconsider the ways in which they have been living their lives, and many choose to refocus their priorities on existential issues such as personal growth and mindful living.¹⁴²

These findings suggest that meditation may change brain function and immune function in positive ways. “Meditation,” as it is taught in this 8-week program, is simply an awareness and attention training: a way of learning how to pay attention in the present moment to our bodies, thoughts, and emotions, and coming to understand how our thoughts and emotions affect our bodies. It may sound simple but actually can be incredibly challenging due to our cultural conditionings. However, an instant stress reliever can be bringing awareness to the breath. Deep breathing can act as a mini-meditation, and from a longevity standpoint, it is an important stress reliever.¹³³ Shifting to slower breathing in times of tension can help calm us and allow us to perform, whether mentally or physically, at higher levels.¹³³

Another study, focused on Coping Effectiveness Training (CET), consisted of weekly 60-minute psychoeducational group intervention sessions focused on six topic areas and was adapted from the protocol Coping Effectively with Spinal Cord Injury.¹⁴³ The treatment protocol was structured to provide education and skill building in areas of awareness of reactions to stress; situation appraisal; coping strategy choice; interaction among thoughts, emotions, and behaviors; relaxation; problem solving; communication; and social support.¹⁴⁴ There was a significantly positive correlation between the learned coping strategies and the disabled individual’s ability to adjust in a healthy way.

Hope, Grief, and Spiritual Aspects to Adjustment for the Patient and Therapist

To feel the consequence of your absence is what awakens in you the ability to feel absence. Seeing the end of something precious to you gives you the chance of loving it well. Loving and grieving are joined at the hip, for all the beauty, soul, and travail that brings. Grief is a way of loving what has slipped from view. Love is a way

of grieving that which has not yet done so. We would do well to say this aloud for many days, to help get it learned: Grief is a way of loving, love is a way of grieving. They need each other in order to be themselves. You can learn how to be a faithful witness, to be wrecked on schedule, to put your grief in your carry-on bag together with your other treasured things.

Grief has to be learned, which means it has to be taught. Which means it is possible not to learn it. When we keep insisting on grief being a feeling, or a process that needs management and closure, we are talking about grief as an affliction, the same way we talk about dying. But something changes when we start seeing grief as a skill that needs learning, which is what it is. As a culture we are grief-impaired not because we don't have what we need to feel bad, but because we are grief-illiterate. We aren't taught to grieve; we are taught to handle grief, to resolve grief, to get on the other side of it.

—Stephen Jenkinson, from *Die Wise: A Manifesto for Sanity and Soul* (2015)¹⁴⁵

Through the process of grappling with great suffering, we have the potential to grow deeper levels of understanding of life, meaning, and purpose, and from this process and practice of navigating and wrestling with life's challenges, we come into contact with our own and shared humanity, the heartbreak that seems to be a perpetual part of being human in these times of personal, global, economical, political, cultural, and ecological crisis. Our capacity and willingness to show up for the heartbreak change how we are in relationship to ourselves, to our bodies, and to life itself. As clinical professionals we need to be more than just aware of this capacity, we need to be practitioners of it and model it in our lives and work. This is a process of developing a self-evident knowing and embodied experience of how our greatest sufferings can act as potential windows to great depth of meaning in the process of living with fresh eyes as we relate to ourselves and behave and act in the world differently and with a chosen narrative rather than a default one.

Experiences of transcendence can be considered a potential problem for developing these capacities, as we are often taught in this culture that numbing and subjugating one's experience is a sought after way of relating to difficulties, and we are provided with a plethora of opportunities and numbing devices to choose from, such as excessive busyness, sugar, industrialized food products, media, pornography, gambling, drugs, alcohol, and gaming, just to name a few. So it is possible that we could use spiritual practices as a way to numb ourselves when life becomes uncomfortable. However, with a strong mindfulness practice in development, practices of transcendence can provide a process that can help us create a new normal for ourselves, as transcendence can alter our culturally pervasive narratives and stories about how we are meant to relate to our lives, and we can get glimpses of other-than-human perspectives and broader, more encompassing meaning of our lives. Our North American culture narrative perpetuates a view of "the living" as able-bodied, with full-time-plus work that brings in an income so that we can be "independent" consumers and play the worshipful part on the stage of an epic global economy. Our physical body, our relationship to the physical-linear realm, and a clinging to all of "the stuff" are of utmost importance in this cultural narrative. Youthful health and appearance and the endless acquisition of more stuff are presented endlessly in our media culture. A great rupture in this narrative can happen when we sustain a fissure in our capacity to fulfill this pervasive narrative, which can cause us to suffer greatly.

As described by Dr. E. Cassel in the *New England Journal of Medicine*, "Transcendence is probably the most powerful way in which one is restored to wholeness after an injury of personhood. When experienced, transcendence locates a person in a far larger landscape. The

sufferer is not isolated by pain but is brought closer to a transpersonal source of meaning and to the human community that shares those meanings. Such an experience need not involve religion in any formal sense; however, in its transpersonal dimension, it is deeply spiritual."¹⁴⁶ Parker Palmer, a writer and teacher, describes it this way: "Traacherous terrain, bad weather, taking a fall, getting lost—challenges of that sort, largely beyond our control, can strip the ego of the illusion that it is in charge and make space for true self to emerge."¹⁴⁷ Eckhart Tolle describes how unnecessary suffering ensues when we are so completely identified with and hang our identities purely on form—physical form, thought form, and emotional form.¹⁴⁸ The more we are identified with and grasping to the physical realm of our human existence, without any recognition or acknowledgement of a realm beyond the human one, the more we suffer when our attachment to stuff or "form" becomes torn through disability or even death of all kinds. In Stephen Jenkinson's book *Die Wise*, he describes how our modern, North American, death-phobic culture is in part a product of this kind of obsession with the living and how we go to great lengths even to die, not dying.¹⁴⁵

So, it seems a paradox of sorts and a particular challenge to develop the capacity to both release our attachments to unconscious, hand-me-down narratives that can play out in our lives and in our beliefs about our lives and at the same time to open to our humanity as it relates to our capacity to wrestle with life-changing circumstances as well as (and maybe most importantly to) the simple, mundane acts of engaging with our daily lives with openness and curiosity. "For all of us, our willingness to explore our fears and to live inside helplessness, confusion, and uncertainty is a powerful ally. Acknowledging our repeated exposure to human suffering—our own and others'—and the seductive draw of numbness and melancholy that provides temporary escape is necessary if we are to be renewed."³² Dr. Santorelli goes on to say that "there is no way out of one's inner life, so one had better get into it."³² "On the inward and downward spiritual journey, the only way out is in and through."¹⁴⁷

Practice: Developing Attitudes of Willingness to Hold It All in Awareness

1. Become aware of the moments when "resistance to what is" or "clinging to what is" is or "not wanting this . . ." or "not wanting that . . ." is noticed. This may manifest itself as anxiety, sadness, fear, depression, powerlessness, or anger. All valid feelings to be noticed, honored, and acknowledged for the potential messages they bring. Feel the embodied experience of these feelings and emotions without needing them to be any other way keeping in mind that grief is not resistance; it's a valid response to real loss that may also have longing, yearning, as well as resistance/clinging associated with it. Sit quietly and be with the feeling holding in awareness with attitudes of curiosity, self-compassion, and gentleness.
2. As soon as anger arises (for example), notice how it manifests itself physically in the body. It may be tension in the muscles, a quickened or palpating heartbeat, or sweating. See if you can just allow it space to be experienced, acknowledged, and honored.
3. Note what the sensation feels like in the body without trying to make the moment different than it is. Acknowledge whatever is present in the moment. Note that we are not the anger, we are the awareness of it.
4. Focus awareness on the sensation of the breath as you hold the intense emotion in awareness. Sensing into the breath.
5. Note what the awareness does. Note what they emotion or feeling does. What challenges arose? How did you work with them? What did you learn about yourself? Journal any thoughts or feelings about the practice.

Dr. Jon Kabat-Zinn, in his book *Coming to Our Senses*, states, “It seems as if awareness itself, holding the sensations without judging them or reacting to them, is healing our view of the body and allowing it to come to terms, at least to some degree, with conditions as they are in the present moment in ways that no longer overwhelmingly erode our quality of life, even in the face of pain or disease.”⁶³

*Mystery surrounds every deep experience of the human heart: the deeper we go into the heart's darkness or its light, the closer we get to the ultimate mystery of God [the Universe].*¹⁴⁷

Religious and spiritual beliefs can be assistive in the process of adjusting to a disability. Johnstone, Glass, and Oliver highlight that religion and spirituality are important coping strategies for people with disabilities.⁶⁸ According to Dr. Jill Bolte-Taylor in her book *My Stroke of Insight: A Brain Scientist's Personal Journey*, “Enlightenment is not a process of learning but a process of unlearning.”¹³⁴ Western society rewards the skills of the “doing” left brain much more than the “being” right brain, which can significantly hinder our process of spiritual deepening. The focus of our lives becomes more about obtaining positions, roles, and “stuff.” We begin to identify ourselves with all of this when in reality the positions, roles, and things can be taken from us at any moment. “When we are obsessed with productivity, with efficiency of time and motion, and with projecting reasonable goals and making a beeline toward them, it seems unlikely that our work will ever bear fruit, unlikely that we will ever know the fullness of spring in our lives.”¹⁴⁷

There is a much deeper definition of ourselves that goes beyond all of the material possessions and the roles that we may ever play. According to Eckhart Tolle,¹⁴⁸ when forms that we identify with, that give us a sense of self, such as our physical bodies, collapse or are taken away, it can lead to a collapse of the ego, because ego is identification with “form.” When there is nothing to identify with anymore, who are we? When forms around us die, or death approaches, Spirit is released from its imprisonment in matter. We can finally understand that our essential identity is formless, spiritual.¹⁴⁸ Cultivating greater understanding of these concepts, developing an embodied experience of them ourselves, and delving more into the experience of spirit can provide a great deal of relief for all of us who are suffering.

There is a wonderful quote by former Secretary-General of the United Nations U Thant, as he describes how he envisions the spiritual:

Spirituality is a state of connectedness to life.

It is an experience of being, belonging and caring.

It is sensitivity and compassion, joy and hope.

It is harmony between the innermost life and the outer life or the life of the world and the life of the universe.

It is the supreme comprehension of life in time and space, tuning of the inner person with the great mysteries and secrets that are around us.

It is the belief in the goodness of life and the possibility for each human person to contribute goodness to it.

*It is the belief in life as part of the eternal stream of time, that each of us came from somewhere and is destined to somewhere, that without such belief there could be no prayer, no meditation, no peace, and no happiness.*¹⁴⁹

Spirituality is something that provides hope, connection with others, and reason or meaning of existence for many (if not most) people. It is amazing that the medical community has been slow to accept the power of spirituality because this is an area that gives meaning to so many people's lives. Spirituality has been linked to health perception, a sense of connection with others, and well-being.^{67,68,150–156}

The Western medical system was based on diagnosis of pathology and how best to cure disease, but there has been a slow but fruitful shift toward including a more holistic view of the healing process and prevention. The National Institutes of Health now has a National Center for Complementary and Alternative Medicine (<http://nccam.nih.gov>). Almost every major hospital and university in the country now has an integrative health center (e.g., <https://stanfordhealthcare.org/medical-clinics/integrative-medicine-center.html> and <https://oshercenter.org>). Although this small but steady shift in the focus of medicine has gained momentum, one of the dangers of the medical system is still the entrapment in pathology to the point where the patient may not see anything but his or her pathology. Spirituality can help the patient and the family to see that there is more to life than pathology, stimulate interaction with others, put the functional limitations in perspective, give meaning to life (and the disability), and give the person hope and a sense of well-being.^{67,68,150,152,153,157,158} This is what we all want for the patient and the family.

Adjustment Using the Stage Concept

Each person has his or her own coping style, and each should be allowed to be unique. Kerr¹⁵⁹ describes five possible stages of adjustment, but please hold these stages lightly as we can oversimplify human experiences and want to rush people along the stages if we feel like it's not quick enough for us, especially considering our dominant cultural view that we need to “move on” or “get on with it already,” and if we are not progressing through these kinds of stages, we might even get slapped with a diagnosis of depression or anxiety disorder etc.:

Shock: “This really isn't happening to me.”

Expectancy for recovery: “I will be well soon.”

Mourning: “There is no hope.”

Defense: “I will live with this obstacle and beat it.” “I am adjusted, but you fail to see it.”

Adjustment: “It is part of me now, but it is not necessarily a bad thing.”

In light of current research, it is important for the therapist to realize that these are not lockstep stages and are to be thought of as concepts to help with the understanding of common reactions of some individuals.^{160,161} Some individuals may settle in one stage for quite some time or may even skip stages altogether, whereas others may move through the stages quickly. This is an incredibly individual process.

Shock

The individual in shock does not recognize that anything is actually wrong. The patient may totally refuse to accept the diagnosis. The patient may even laugh at the concern expressed by others. This stage is altered when the person has an opportunity to test reality and finds that the physical or cognitive condition is actually limiting the ability to participate in functional activities.

Expectancy for Recovery

There is a dignity to acknowledging and grieving for what is lost. The patient in the stage of expectancy for recovery is aware that he or she is disabled but also believes that recovery will be quick and complete. The person may look for a “miracle cure” and may make future plans that require total return of function. Total recovery is the only goal, even if it takes a great deal of time and effort to achieve. Key signs of this stage are resentment of loss of function and the feeling that the whole body or mind is necessary to do anything worthwhile. The patient's ability and capability to take on reality of situation is going to be very individual in capacity and timing. Great sensitivity must be used in being authentic and also mindful of the state and condition of the patient. It cannot be overstressed that hope needs to be encouraged. Hope is

qualitatively different than having a wish or expectation. One can hope that life will have goodness and continue to unfold while having a disability. While one seeks healing and improvement and wishes for outcomes that specifically may not be either reachable or guaranteed.

This can all be a very gradual process on everyone's part, and often there are some great unknowns. Humans have natural protections, and sometimes systems under great stress cannot process too much too soon. Holding environments acknowledge where the person is while believing and promoting the next growth is of essence. In the case of an individual who has experienced a stroke or a brain injury, we know now that the brain is capable of repairing itself throughout a lifetime—though we need to be clear that we do not know how much recovery will occur, if any. This all depends on the severity of the damage and the lifestyle of the patient—for example, smoking, stress, and/or lack of participation in meaningful activity, all of which impede progress.

Mourning

During the stage of mourning the individual feels that all is lost, that he or she will never achieve anything in life. Suicide is often considered. The individual may feel that characteristics of the personality (such as courage or will) have also been lost and must be mourned as well. Thus motivation to continue therapy or the will to improve may be impeded. The prospect of total recovery may no longer be held, but at the same time there appears to be no other acceptable alternative. This feeling of despair may be expressed as hostility, and as a result therapists may view the individual as a “problem patient.” It is possible for a patient to remain at this stage with feelings of inadequacy, dependence, and hostility. However, it is also possible for therapeutic intervention to facilitate movement to the next stage by creating situations in which the patient may feel that “normal” aspirations and goals can be achieved. In this circumstance, normal would not include such “low-level” activities as dressing or walking; these are all activities that were taken for granted before the injury. Normal, though, would include performing the job the patient was trained to do. Such activities would also include playing with or caring for a child or family. This would be seen as self-actualization by Maslow.¹⁶²

Defense

The defense stage has two components. The first represents a healthy attitude in which the patient actually starts coping with the disability. The individual takes pride in his or her accomplishments and works to improve independence and become as “normal” as possible. The person is still very much aware that barriers to normal functioning exist and is bothered by this fact but also realizes that some of the barriers can be circumvented. This healthy stage can be undermined and possibly destroyed by well-meaning family, friends, and therapists who encourage the individual to see only the positive aspects and who do not allow the patient to examine feelings about the restrictions and barriers of the condition. Conditions that lead to the final stage of adjustment are the realization that the prior or “whole” body or mind is not needed to actualize his or her life goals and that needs can be actualized in other ways. A therapist should watch for opportunities to facilitate this transition. There is a fine line between hopelessness and hope of regaining function. Taking away any hope of regaining quality of life leads to helplessness and may take away the motivation for neuroplasticity within the patient's central nervous system. Thus helping the patient be realistic and reality oriented while not taking away hope is a skill all therapists need to cultivate.

The negative alternative during the defensive stage is the neurotic defensive reaction. The patient refusing to recognize that even a partial barrier exists to meeting normal goals typifies this. The patient may try to convince everyone that he or she has adjusted.

Adjustment

In the final stage, adjustment, the person sees the disability as neither an asset nor a liability but as an aspect of the person, much like a large nose or big feet. He or she is accepting what is to the degree they are able, not resisting what is. Functional limitation or inability to participate in any life activity is not something to be overcome, apologized for, or defended. Kerr¹⁵⁹ refers to two aspects or goals of this stage. The first goal is for the person to feel at peace with his or her god or greater power: the patient does not feel that he or she is being punished or tested. The second goal is for the patient to feel that he or she is an adequate person, not a second-class citizen. Kerr¹⁶³ believes that “[i]t is essential that the paths to those more ‘abstract goals’ be structured if the person is to make a genuine adjustment.” She also believes that it is the health care professional's job to offer that structure.

Acceptance or adjustment is at least as hard to achieve and maintain in life for the disabled person as happiness and harmony are for all people.¹⁶⁴ Adjustment connotes putting the disability into perspective, seeing it as one of the many characteristics of that person. It does not mean negating the existence of or focusing on the condition. Successful adjustment may be defined as a continuing process in which the person adapts to the environment in a satisfying and efficient manner. This is true for all human beings, able-bodied or disabled. There are always obstacles to overcome in attempting the goal of a happy and successful life.^{16,93,164,165}

People and circumstances change. Maintaining a balanced state of adjustment is not easy, especially for the person with limitations. I recall a woman who had achieved a relatively stable state of acceptance of her quadriplegic condition. One day she called in a panic because, as she saw it, she “wasn't adjusted anymore.” She had moved into a college dormitory and wanted to go out for a friendly game of football with her new friends but suddenly saw how physically limited she was. She had come to terms with her disability in a hospital and had never had to face this situation. After discussing this, she was able to put things into perspective and was able to talk over her feelings of isolation with her friends, who, without hesitation, altered the game to include her. Keeping a balanced perspective is a challenge in a world that changes constantly.

White¹⁶⁶ stated that without some participation, there can be no affecting the environment and thus no sense of self-satisfaction. Fine¹⁶⁷ and King¹⁶⁸ point out that without satisfaction from affecting the environment, reinforcement is insufficient to carry on the behavior, and the behavior will be extinguished. Thus satisfaction and performance must be linked. If the patient has not adjusted to his or her new body, however, little satisfaction can be gained from such everyday activities as walking, eating, or rolling over in bed.¹⁶⁹ To define adjustment on a purely performance basis is to run the risk of creating a “mechanical person” who might be physically rehabilitated but, once discharged, may find that he or she lacks satisfaction, incentive, and purpose. The psychological state of adjustment is what makes self-satisfaction possible.

Body Image

Self-care is never a selfish act—it is simply good stewardship of one of the greatest gifts I have been given, the gift I was put on this earth to offer to others. Anytime we can listen to true self and give it the care it requires, we do so not only for ourselves but for the many others whose lives we touch.¹⁴⁷

Self-care and body image are inextricably connected, and when we build the skills of caring for ourselves (and modeling this behavior for our patients), we affect how we relate to our bodies and we can heal our relationship to our bodies, and this affects how we think about our

bodies. Body image is an all-encompassing concept that considers how the person, and to some extent, the support systems view the person and roles that are expected to be assumed. Taleporos and McCabe²⁰ found that patients had negative feelings about their bodies and general negative psychological experiences after injury. Even when patients do not have disfigurements that are readily observable, they often still report changes in body image and negative feelings of self-worth.

Self-care is an important practice for our health, sense of self-worth, and well-being particularly when we are going through intense life experiences, and caring for ourselves on many levels can build a strong and resilient body image. Our culture often neglects self-care as an important part of building resilience and stress-hardiness, yet caring for oneself can significantly enhance our view of ourselves, especially when that view may be tested. Self-care can include eating food that is life-enhancing, getting adequate sleep, not saying yes to every activity or opportunity, participating in support groups and counseling services, getting a massage, spending time with friends and family who nourish us, and listening to our favorite music. As clinicians we can support our patients by encouraging them to establish self-care routines that support their resilience, health, and well-being.

Questions about any physical performance are within the domain of therapy. If the patient is asking for information regarding sex (e.g., positioning options), it is a subject that needs to be addressed in a respectful manner. If the questions are regarding fertility, capability, and the like, then these should be referred to an appropriate medical person. None of these questions should be discouraged or neglected, because this area is important for your patients' motivation and sexual health.^{170,171} It is important for the therapist to know that in spinal cord injury, fertility will generally not be impaired for a woman, but issues of lubrication before sex should be addressed by the appropriate person. Men may have erection problems and ejaculation issues, but these too can be addressed by the appropriate medical practitioner. It is now known that fertility in spinal cord-injured men may be possible and should not be ruled out.^{172,173–176}

Support System

Earlier literature hinted that partner relationships may be negatively affected by a member being disabled. Within the last few years, this concept has been questioned in regard to some disabilities such as adult-onset spinal cord injuries,¹⁷⁷ whereas pediatric spinal cord injury and other disabilities may result in relationship problems.^{178,179} It has been shown that adjustment and quality of life can be adversely affected by the physical environment being inadequate, thus making the person more dependent. The result of the dependence appears to be poor relationships.^{180–182} This can also be seen with the families in which a member has had a brain injury.^{183,184} In studies on muscular dystrophy, it was found that physical dependence is not the only variable that needs to be considered. Psychological issues need to be identified and considered as part of intervention.^{185,186} Recent literature has identified a number of elements that the patient and the family may need help to work on, such as “to assist them to develop new views of vulnerability and strength, make changes in relationships, and facilitate philosophical, physical, and spiritual growth.”¹⁸⁵ Turner and Cox¹⁸⁵ also felt that the medical staff could facilitate “recognizing the worth of each individual, helping them to envision a future that is full of promise and potential, actively involving each person in their own care trajectory, and celebrating changes to each person's sense of self.”¹⁸⁵ Man¹⁸⁶ observed that each family copes differently in relation to a brain-injured family member and that the family's structure should be explored to develop intervention guidelines. It has also been noted that health care professionals should view the situation from the family's perspective to approach and support the family's adaptation.¹⁸⁷ This

should be done to help the patient and the family accept the disability but at the same time help them keep the negative views of society in perspective.⁷¹ In general, it has also been found that family support is a significant factor in the patient's subjective functioning^{188,189} and that social engagement is productive.^{90,190} According to Franzén-Dahlin and colleagues,¹⁹¹ enhancing psychological health and preventing medical problems in the caregiver are essential considerations to enable individuals with disabilities to continue to live at home. Their research found that evaluating the situation for spouses of stroke patients was an important component when planning for the future care of the patient.

When working with children, it is important to realize that they often feel responsible for almost anything that happens in life, such as divorce, siblings getting hurt, or general arguments between parents. It is important that the therapist help the patient and the siblings realize that they are not responsible for the patient's condition. Part of this magical thinking that often appears is the concept that “bad things happen to bad people.” Thus the child may consider themselves as bad because a bad thing has happened, or the adult is bad just because the disease or trauma has occurred. It is important to be sensitive to this ideation and help dispel this maladaptive thought pattern because it is not true or productive for the patient, the siblings, parents, or spouses within a family and may cause further adjustment problems later in treatment. Siblings of the patient should be encouraged to see their roles as good siblings and should not be placed in the role of caretakers of a sibling with special needs. In this way, all children can grow naturally without any one of the children being overly focused on. At the same time, it is a fact of life that the disabled child will probably need physical assistance, therapy, increased medical care, and thus and more time devoted to him or her, and this is just a fact of life.

It should always be noted by the medical establishment that having a disability is expensive in ways that we are often not aware of. There are obvious medical costs of therapy, surgery, drugs, wheelchairs, or orthoses, but there are other costs such as the possibility of extra cost of transportation, catheters for urination, wheelchair maintenance, adaptive clothing, and the like that are continuing costs not covered by most insurance plans. These costs add up and contribute to the emotional costs and demands on the family. The significant others may feel the need to work more to have the money to cover such expenses, but then that person is not around to help out. This is but one of the many dilemmas that must be acknowledged for the support system of the disabled person. The family may be encouraged to contact groups such as the Family Caregiver Support Network (www.caregiversupportnetwork.org) to get information and assistance on such diverse topics as being a caregiver, legal and financial aid, and communications (this group tends to focus on the adult but still may be a wonderful aid). Such groups will give information to all who need it and help to empower the family. This takes the focus off of the medical condition and may help the family to gain a better, more balanced perspective on the condition.

Loss and the Family

In this chapter, the patient's support system is referred to as the *family*. The family may be composed of spouses, parents, children, lovers (especially in gay and lesbian relationships), friends, employers, or interested others such as church groups, civic organizations, or individuals. The people in the support system may go through the same stages of reaction and adjustment to loss that the patient does.^{1,9,167,192–194}

Family Needs

The family will, at least temporarily, experience the loss of a loved family member from the normal routine. During the acute stage, the family

may not have concrete answers to basic questions regarding the extent of injury, the length of time before the injured person will be back in the family unit, or possibly whether the person will live.

During this phase, the family network will be in a state of crisis.⁹ New roles will have to be assumed by the family members, and the “experts” will not even tell them for how long these roles must be endured. If children are involved, they will probably demand more attention to reassure themselves that they will remain loved. Depending on the child’s age, the child will have differing capabilities in understanding the loss (see the section on examination of loss). Each member of the family may react differently to bereavement, and each may be at a different stage of adjustment to the disability (see the section on adjustment). One member may be in shock and deny the disability, whereas another member may be in mourning and may verbalize a lack of hope. The family crisis that is caused by a severe injury cannot be overstated.^{99,193–196}

Role changes in the family may be dramatic.^{65,75,93,197–199} Members who have never driven may need to learn that motor skill; one who has never balanced a checkbook may now be responsible for managing the family budget; and those who have never been assertive may have to deal forcefully with insurance companies and the medical establishment.^{9,58,200,201}

The family may feel resentment toward the injured member. This attitude may seem justified to them because they see the person lying in bed all day while the family members must take over new responsibilities in addition to their old ones. In a study by Lobato, Kao, and Plante,²⁰² Latino siblings of children with chronic disabilities were at risk for internalizing psychological problems. The medical staff may not always understand the stress that family members are under and may react to the resentment expressed either verbally or nonverbally with a protective stance toward the patient. Siding with the “hurt” patient may alienate the family from the medical staff and may also drive a permanent wedge between family members. This long-term situation may undermine the compliance of family members’ involvement in home programs and, ultimately, the successful outcome of long-term intervention.

As clinicians, it may be at times that the only way we may be of service in certain situations is to be a compassionate witness to all that is unfolding in our own or in another person’s life. Holding the enormity of the situation in our awareness while staying grounded in our own embodied experience of the present moment is essential. It may be that all we can do is to be a nonjudgmental, engaged, curious listener and life-learner, allowing ourselves to be touched by the other person’s (or even our own) suffering. It may be that we are all starving for someone to just be present enough and grounded enough within themselves that they can bear witness to all that is unfolding on personal, communal, and global levels. This kind of listening is learned, and it is not taught in our dominant culture, so clinicians who wish to have this skill will have their work cut out for them to seek out this kind of learning experience. San Jose State University’s Mindfulness-Based Occupational Therapy Advanced Certificate program (open to all health care practitioners) and the Center for Mindfulness at the University of Massachusetts Medical School are both such places for this kind of specialized training. These authentic teachings are essential to this kind of way of being and relating to our lives and our work, and they can help us bring healing to an otherwise disembodied, disconnected, dysfunctional system of hierarchy and institutionalization.

Parental Bonding and the Disabled Child

The parental bonding process is complicated and is still being studied.⁴⁸ The process may start well before the child is even conceived. The parents often think about having a child and plan and fantasize about

future interactions with the child; after conception the planning and fantasizing increase. During the pregnancy the parents accept the fetus as an individual, and after the birth of the child the attachment process is greatly intensified. The “sensitive period” is the first few minutes to hours after the birth. During this time the parents should have close physical contact with the child to strongly establish the attachment that will later grow deeper.^{203,204} There is an almost symbiotic relationship between mother and child at this time: infant and mother behaviors complement each other (e.g., nursing stimulates uterine contraction, breast milk production, and oxytocin release). In the early stages of bonding, seeing, touching, caring for, and interacting with the child allow for the bonding process. When this process is disturbed for any reason, such as congenital malformations or hospital procedures for high-risk infants, problems may occur then and later.

When the parents are told that their child is going to be malformed or disabled, it is a profound shock if they were not informed in advance of the baby’s birth. The dream of a “normal” child is given up, and the parents must go through the loss or “death” of the child they expected before they can accept the new child. Parents often feel guilty. Shellabarger and Thompson²⁰⁵ state that parents often feel the deformed child was their failure.¹ The disabled child will always have a strong impact on the family, sometimes a catastrophic one.^{1,8,9,205,206} A study by Ha and colleagues²⁰⁷ found that compared with parents of nondisabled children, parents of disabled children experienced significantly higher levels of negative affect, poorer psychological well-being, and significantly more somatic symptoms. Older parents were significantly less likely to experience the negative effect of having a disabled child than younger parents.

In a study by Arnaud and colleagues,²⁰⁸ greater severity of impairment was found to not always be associated with poorer quality of life; in the moods and emotions, self-perception, social acceptance, and school environment domains, less severely impaired children appeared to be more likely to have poor quality of life. Pain was associated with poor quality of life in the physical and psychological well-being and self-perception domains. Parents with higher levels of stress were more likely to report poor quality of life in all domains, which suggests that factors other than the severity of the child’s impairment may influence the way in which parents report quality of life.

Parents must be encouraged to express their feelings and emotions, and they must be taught how to deal with the issues at hand. Techniques for accomplishing these goals are discussed in later sections.^{48,204,206}

The Child Dealing With Loss

If a parent is injured, the young child may experience an overwhelming sense of loss. Child care may be a problem, especially if the primary caregiver is injured. The child might feel deserted by the injured parent and may long for the attention of the remaining parent. This will increase the strain on all family members.⁶⁵

If the child is the patient, his or her life will have undergone a radical change: every aspect of the child’s world will have been altered. Loved ones, loved objects, and a sense of safe place will help restore the child’s feeling of security. It is of major importance to explain to the child in very simple terms what is going on and to allow the child the opportunity to express feelings both verbally and nonverbally. It is important to use play and art as the medium of communication for children.

The hospital setting is threatening to all people, but children are especially susceptible to loss of autonomy, feelings of isolation, and loss of independence. Senesac has stated that the severity of the disability is not as important a variable in the emotional development of the child as are the attitudes of parents and family.^{2,8} Parents must attempt to be aware of the child’s inability to understand

the permanence (or transience) of the loss of function.⁸ They will also need to help the child feel secure by bringing in familiar and cherished objects. A schedule should be established and kept to promote consistency. Play and art should be encouraged, especially types that allow the child to vent feelings and deal with the newness of the experience and the environment. Any procedures or therapies should be presented in a relaxed and playful way so that the child has time to think and to feel as comfortable as possible about the change. The parents may often need to be reminded to pay attention to the children in the family without disabilities during this acute stage.

The Adolescent Dealing With Loss

The adolescent is subject to all of the feelings and fears that other patients express. Adolescents are in a struggle to achieve autonomy, initiation, and independence, and they often are ambivalent about their feelings. When an adolescent is suddenly injured and has to cope with being disabled, it can be a massive assault on the individual's development.^{165,209} According to research conducted by Kinavey,⁵¹ findings imply that youth born with spina bifida face biological, psychological, and social challenges that interfere with developmental tasks of adolescence, including identity formation. Therapists are urged to direct intervention toward humanizing and emancipating the physical and social environment for youth with physical disabilities to maximize developmental opportunities and potential while fostering positive identity and initiation into adolescence and young adulthood. Our culture lacks structures in place that can help initiate a child through these monumental growth periods. Programs are recently being developed to provide a container for these kinds of rite of passage experiences to initiate our children into adulthood and beyond including programs for children experiencing catastrophic life difficulties, and most of them accept applications for scholarships for low-income families. As clinicians we can provide resources and encouragement related to the significance of experiences of initiations for youth, especially youth who may be experiencing crisis.

Kingsnorth and colleagues⁵⁰ stated that with advances in health care, an increasing number of youth with physical disabilities are surviving into adulthood. For youth to reach their full potential, a number of critical life skills must be learned. Specific learning opportunities are important, as youth with physical disabilities may be limited in the life experiences necessary to acquire these skills. Therapists are in the unique position of fostering these kinds of environments to encourage adolescents to engage in critical life skills such as emotion-focused and problem-focused problem solving, decision making, values-based intentional goal setting, critical thinking, mindfulness-based communication skills, assertiveness and self-advocacy, the establishment of healthy personal-boundaries, self-awareness, self-compassion, being/becoming a life-learner, and developing skills for resilience and stress hardiness. Life skills differ from instrumental daily living skill, though it is best to work on developing life skills in the midst of our daily lives so that our daily living skills (the activities required to function independently in the community including skills such as financial management, meal preparation, and navigating community) become catalysts for our personal growth and development.

Family Maturation

The family also has a maturational aspect. If the injured person is a child and if the family is young with dependent children at home, the adjustment may not be the problem that it would be for a family whose children are older. In the latter case, parents have begun to experience freedom and independence, and they may find adjusting to a restricted lifestyle difficult or even intolerable. They may have the feeling that they have already "put in their time" and "should now be free." If the disability interrupts the child's developmental process, future conflict

may arise because the parents may eventually expect retirement, relaxation, and freedom as our dominant North American culture teaches. Parents may feel guilty and try to repress this response.

The reverse may also be true. The parents may be feeling that the children have left them ("empty nest syndrome"), and they may be too willing to welcome a "dependent" family member back into the home. This may lead to excessive dependence or anger toward the parents on the part of the patient. All these factors need to be taken into consideration by the therapist when therapy is presented to the patient and family.

The therapist can develop a greater understanding of the patient and family by being aware of common human developmental patterns. These patterns identify some of the major processes of adjustment that need to be considered during the therapeutic process, but we need to understand that every person and family will have their own unique way of processing the circumstances, and we need to honor, acknowledge, and appreciate, and if we are fortunate enough to be open-minded enough to learn from, perspectives and ways of being and relating to life's challenges that may not be of our dominant North American culture.

Coping With Transition

Learning to suffer, wrestle with tragedy, and grapple with catastrophe is a skill set that we are not taught to any degree in our modern North American culture. In fact, we are systematically taught how to numb and subjugate challenging circumstances, and we are given ample opportunities to do so; this cultural training begins at an early age. Media, refined and processed highly addictive food products, excessive busyness and consumption, gambling, alcohol, drugs, pharmaceuticals, and others all constitute an epic part of our cultural experience across the life-span. We all participate in and perpetuate this system to some degree. The benefit, if there is such a thing, is that we can all tap into the experience of it ourselves, because we have our own embodied experience of how this feels and what this looks like in our daily lives.

We call it "Coping with Transition," with the subtle, undercurrent of meaning that "we need to just get over it already"—whatever *that* is. "Just cope, please, for all our sakes, so we don't have to be with the messiness of too much grieving, too much anger, or too much despair." The subtle message is, "It's just too uncomfortable for me, and I wasn't taught how to be in wise relationship to suffering, so please just get on with it so we can get on to meeting your goals so I can get paid for being a "good therapist" who helps their patients meet goals." Witnessing suffering, our own and that of others (including the planet-in the case of the 6th wave of extinctions; Kolbert, 2014),²¹⁰ makes us all uncomfortable because we were born into and trained to be suffering-phobic, strong-emotion phobic, and death-phobic. So it is likely you will notice this in yourself. We all need to learn, on the job, with training in mindfulness under our belts, to develop a new relationship to suffering, where we can become engaged, compassionate witnesses to what is unfolding.

Without this skill development, we may be more likely to have our own present-moment experience co-opted by another's to the degree that we dissociate and fall back on the standard cultural narratives we've learned since childhood. With the developing skills of learning how to be in relationship to the messiness of life's human (and otherwise) tragedies, we can learn to stay grounded and rooted in our being, all the while being present to and in some level of acceptance of what needs to be seen and heard and witnessed without needing to numb or subjugate our experience. Begin a process of learning how to be a compassionate witness to your own suffering, your own emotions, and your own embodied experiences. This is the only way that you will be able to support someone through the trauma of catastrophic, life-changing circumstances. If you haven't already, engage in mindfulness training as soon as possible and begin.

With all of this in mind, in the acute stages of a family member's injury, we can support the family in grappling with the crisis at hand by bearing witness to their experience without needing to change it in any way and just noticing what comes up for you personally as you notice and listen to all that is unfolding. During this phase (that can take any length of time), the family must first be allowed the space to cope, in their own way, with the emotional impact of what is happening with a loved one. When we force our views that our patient's grief or anger or any other strong emotion must be overcome, we may be engaged in perpetuating dysfunctional North American cultural conditioning or what Dr. Robert Masters calls *spiritual bypassing*.

*Spiritual bypassing, a term first coined by psychologist John Welwood in 1984, is the use of spiritual practices and beliefs to avoid dealing with our painful feelings, unresolved wounds, and developmental needs. It is much more common than we might think and, in fact, is so pervasive as to go largely unnoticed, except in its more obvious extremes.*²¹¹

In a previous version of this chapter, you will see a standard narrative of the stages of coping listed. It helps to know the literature that is out there around these kinds of stages, but they may be more useful if we hold them lightly and in perspective of the larger cultural narrative around coping that we are all complicit in perpetuating. For example, Brammer and Abrego²¹² have developed a list of basic coping skills that they have broken into five levels. In the first level, the person becomes aware of and mobilizes skills in perceiving and responding to transition and attempts to handle the situation. In the second level, the person mobilizes the skills for assessing, developing, and using external support systems. In level three, the person can possess, develop, and use internal support systems (develop positive self-regard and use the situation to grow). The person in level four must find ways to reduce emotional and physiological distress (relaxation, control stimulation, and verbal expression of feelings). In level five, the person must plan and implement changes (analyze discrepancies, plan new options, and successfully implement the plan). Using this model, the therapist and family can evaluate the coping skill level of the family. The therapist and staff are often prompted to promote movement toward the next level of coping with the transition. The stages listed are not the problem in and of themselves. The problems arise when we begin forcing or manipulating our patients, however good our intentions, "to move on already," and we might even work to try to move them on to the next stage, as previously described. This is a pervasive problem we have all been privy to; it is applauded as an integral part of the health care system and way of doing things, and so it helps to hold this reality and realization with gentleness and self-compassion.

Another complex challenge we face as clinicians is encouraging a balanced perspective about disability. One consequence of hospitalization in managing the care of a newly disabled person is that the hospital staff can often focus on the disability rather than on the individual's strengths.^{77,193,213} Centering on the disability can lead to a situation in which patient, family, and staff see only the functional limitations and not the potential ability of the patient.

Decentering from the loss of function and holding the whole person of view are important and will be examined further in this chapter. If the family relationship was positive before the disability and if the patient is cognitively intact, then the focus can be directed toward the relationship's strengths as well as toward the patient's and family's individual cognitive and emotional strengths.⁹² In the initial acute stage of adjustment, crisis intervention may help the family use its strengths and at the same time deal with the situation at hand.

To adequately grapple with the crisis at hand, in the context of shortened hospital stays, the therapist can encourage the family to do the following:

1. Be encouraged to focus on (rather than deny) the crisis caused by the disability; acknowledge and explore the situation to stimulate emotion-focused and problem-focused problem solving; identify and work through doubts of adequacy, guilt, and self-blame; identify and honor the grief process; gently notice and hold in awareness any anticipatory worry; be offered instruction in mindfulness skills to assist in building skills of stress-hardiness, resilience, and self-compassion and basic information and education regarding the crisis situation; and be helped to create a bridge to resources in the hospital and in the community for support and to see their own family and community as potential resources.^{49,214–217}
2. Be helped to remember how they have dealt successfully with crises in the past and to implement some of the same strategies in the present situation.

Work with the family as a unit during crisis to help strengthen the family and facilitate more positive attitudes toward the patient. These attitudes by the family will improve the patient's attitudes or feelings toward the injury and hospitalization.^{93,199,218–221} Encouraging family-unit functioning in this situation can decrease the amount of regression displayed by the patient. If the family is encouraged to function without the patient, however, more damage than good may be done.^{1,165}

TREATMENT VARIABLES IN RELATION TO THERAPY

Skilled therapy intervention focuses on maximizing participation in functional activities, participation in life, and behavioral change. Livneh and Antonak¹⁶⁰ promote the following activities for the health professional:

1. Assisting patients to explore the personal meaning of the disability. "Training patients to attain a sense of mastery over their emotional experiences." A way of doing this would be to help the patient look at his or her thoughts, emotions, and mental formations with clarity and discernment and to put them into perspective. Mindfulness training can be particularly helpful with this skill.
2. Providing patients with relevant medical information. "These strategies emphasize imparting accurate information to patients on their medical condition, including its present status, prognosis, anticipated future functional limitations, and when applicable, vocational implications." This may be done by helping the patient and family access resources such as PubMed (www.ncbi.nlm.nih.gov/pubmed) online or find medical references in the library. Education about the condition of disability for patient, family, friends, teachers, and others can be essential for assisting communication, understanding, supportive behaviors, and realistic expectations. For example understanding specifics of communication deficits common to aphasia, cognitive processing, perception, stimulation tolerance, attention, distractibility, or social pragmatics can ease the way for successful communication, relations, and tasks. In some cases, the patient may be able to be the one to take charge of educating others about a condition and needs; in other cases an advocate will fill that role. Some neurological conditions may increase lability, impulsivity, volatility, distractibility, etc., and both the patient and supportive others can learn to work with this as possible. Familiarity and knowledge are a form of empowerment. Interdisciplinary referral, consultation and collaboration among speech, counseling, social work, educators, occupational and physical therapies, and involved support systems are called for. The more effective the teamwork and collaboration, the more successful is the reinforcement of interventions and strategies

for recovery. Caregiver education and support is another important focus.

3. Providing patients with supportive family and group experiences. “These strategies permit patients (usually with similar disabilities or common life experiences) and, if applicable, their family members or significant others, to share common fears, concerns, needs, and wishes.” This can be done in rather unobtrusive ways such as scheduling patients with the same disability at the same time so that they meet in the waiting room or while doing group mat activities. Another option is hiring individuals with limitations who are health care professionals and can discuss and role model positive behaviors and answer relevant questions from the patient’s perspective. Remember that patients are all potential teachers for you as well as other patients.
4. Teaching patients adaptive coping skills for successful community functioning. “These skills include assertiveness, interpersonal relations, decision making, emotion-focused and problem-focused problem solving, suffering-literacy, emotion-literacy, creating values-based narratives to live by, discernment when it comes to dysfunctional cultural messages perpetuated by the dominant North American narratives, stigma management, and time management skills.” This would entail role-playing disturbing situations that may occur in the community, such as an able-bodied person asking why the patient is in a wheelchair; preaching to the wheelchair user because he or she must have offended God in some way—otherwise the person would not be in a wheelchair; or telling a woman that it is such a shame that she is disabled because she is so good looking and could have found a man if it were not for the disability.

ROLE OF THE THERAPEUTIC ENVIRONMENT

Whenever possible in therapy the functional activity should be presented and structured to promote empowerment, problem solving, and adjustment. Adjustment and adaptation to life form a dynamic process that allows for the person to interact with life in a way that encourages the person to find meaning and purpose in life (Fig. 5.1).^{17,81,222–225} This section examines issues the therapist and staff should know to create a therapeutic environment that will facilitate psychological adjustment

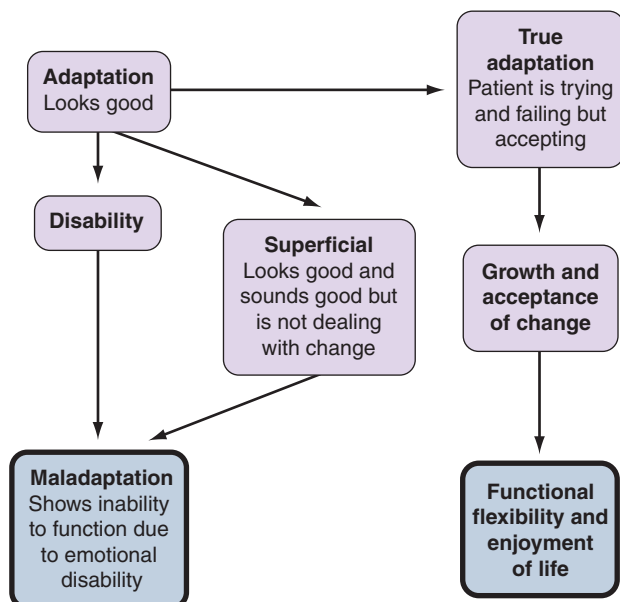

Fig. 5.1 Possible Directions of the Adaptive Process.

and independence of the patient with activity limitations. We all know there is increasing pressure to meet goals quickly due to shorter hospital stays, so keeping this in mind will help us maintain a human perspective as we navigate these institutionalized structures that we do not have much say over. With this in mind, the physical and the attitudinal environment of the treatment facility plays a major role in the way the patient views the services that are rendered and their desire to build rapport with the treatment team.

Recall a time before you became a member of the medical community. Think about how you experienced doctors wearing their white coat uniforms, keep in mind how you experienced the unfamiliar smells of the hospital, how busy it all seemed, and how puzzling the secret medical language and the medical technology and devices were. It all seemed overwhelming then, and it still is to newcomers, especially newly admitted patients and their families. The hospital usually appears impersonal,²²⁶ sterile, monotonous, and confusing, and all personal status accumulated outside the hospital means little on the inside.

The therapist needs to take the setting into account when engaging with patients. The environment can be altered in a variety of ways. Therapy staff could wear street clothes, decorate the department or hospital with posters and lively colors, and allow patients to bring some personal items into the hospital.

The nature of the therapy process can often lead the therapist to see only the disability and not the person—as occurs, for example, when a patient is referred to by his or her disability rather than by name. This stereotyping of those with disabilities can lead the therapist to concentrate on the lack of abilities rather than on the strengths of the patients, and it reduces the patient to the disease. The real danger is that the patient and family will also start to focus on the functional limitations of the patient and feel that their family relationship is now permanently altered. The accuracy of this perception may have to be evaluated as part of the adjustment process. The wife of a man with paraplegia said with a sudden burst of insight, “I didn’t marry him for his legs—this doesn’t change the relationship.” Often so much attention is directed toward the disability that tunnel vision develops. One way to try to get a better perspective is to look at the bigger picture. A variety of questions can be asked that may help the therapist gain greater insight into the patient as a person (Box 5.2).

After the therapist is aware of the strengths of the patient, these strengths may be capitalized on therapy to help the patient realize them and build confidence. Patients often reported that they were not complimented in therapy and especially that they never received feedback that their bodies were desirable²²⁷ or that they were doing things correctly.^{11,77,228} A logical thought by the patient is, “If the therapist cannot see anything desirable about me, and the therapist deals with the individuals with similar problems all the time, then there must not be anything good about me.” Positive, sincere comments to the patient and family can add a motivational factor to treatment that may have been missing.^{77,220}

Providing opportunities to be outdoors can help patients cultivate a sense of connection with something that is larger than themselves. At the most basic level there is more oxygen outside, and in general the air is fresher than indoors. “And looking at a faraway horizon or sky can help us gain needed perspective on our small world, bounded by our bodies and our lives.”²²⁹

The last and possibly the most important aspect in creating an environment that will foster growth and adjustment in the patient is a staff whose members are well adjusted and aware of their own personal needs. Just as coping skills are necessary for the patient, the staff, too, must actively engage in skills that build stress hardiness and resilience as well as self-compassion and mindfulness. The therapist must also engage with his or her own personal reactions to the sometimes devastating situations others are experiencing.^{77,220,230} For example, exposure to such situations, without having built the skills and know-how to acknowledge

BOX 5.2 Reflection Questions to Help Gain Insight into the Patient as a Person

The following questions can be considered by therapist:

- What would this person be doing if he or she did not have this condition?
 - What is stopping the person from reaching these goals now?
 - What are his or her positive traits?
 - What has this person been doing for a living, how has he/she been in the world, how has this person contributed to life?
 - What will this person do for a living?
 - What has this person done for enjoyment, and what might this person do in future?
 - How will this person bring others enjoyment?
 - What would this person be doing if there was no disability?
 - How is the disability stopping the person from actualizing their goals? (These are the goals that can be worked on.)
- Similar questions can be asked of the patient to explore ways of helping the patient have a meaningful life, and the therapist could choose from among these questions to orient a discussion:
- What skills are you needing/wanting to address now?
 - What are you needing/wanting to address in therapy now?
 - What important things would you be doing now if there were no barriers?
 - What activities or forms of productivity were you involved in before, and which were important to you?
 - Which of these things do you still do?
 - What if anything is preventing you from doing these things now?
 - What adjustments might enable you to participate in these activities?
 - What kind of balance do you want in your life among self-care, work, recreation, family time, time with others, rest, spiritual life?
 - How does this condition currently affect your being a lover of life, family, significant other, and so on?
 - Consider an important life goal or meaningful activity, and what a new approach might be.
 - How much different would your life look if it were not for this condition?
 - Are any of the above changed or prevented by your condition, and if so how?

one's own emotional landscape, the capacity to honor and stay grounded within one's own experience, and to identify when one needs somatic-integrated psychotherapy. Staff needs to care for their own mental and emotional well-being to be able to be in skillful relationship as workers on the front lines of incredible human suffering. This emotional energy needs to be engaged skillfully so that the energy does not turn into dysfunction within the staff interaction or become a destructive force for the patient.

To decrease the possibly destructive nature of unacknowledged or unappreciated emotions and feelings, the staff should be made aware of their own coping styles, and they should be allowed to express their reactions in a positive, supportive group. Group meetings can be useful in providing a container for the community of practitioners to express, honor, and acknowledge challenges that may arise. This is not a psychotherapy session (although psychotherapy may be warranted in some situations) but rather an opportunity to problem solving, express feelings, and to be heard and acknowledged as a community. These sessions can make use of the four elements of crisis intervention mentioned in the previous section as well as information from others.²²⁰ The staff can use these sessions to better understand their various reactions and responses to stress and explore their coping styles.^{198,220,231,232} Ideally, this knowledge of coping styles and stress reduction will decrease staff burnout and aid the staff to help patients and their families engage with stress more skillfully.^{165,228–232} MBSR developed out of the University of

Massachusetts Medical School's Center for Mindfulness is a course series that is recommended for health care practitioners wanting to build their own skills for stress hardiness, resilience, and emotional intelligence. MBSR courses held in most hospitals, universities, and communities can be found online at www.umassmed.edu/cfm/mbsr.

The need to have a staff that is supportive is of paramount importance because the attitude of rehabilitation personnel has emerged as one of the chief motivating factors in rehabilitation.^{1,93,163} In fact, the use of humor has been found to be assistive in the process of adjustment. In a study by Solomon,²³³ aging well was related to aspects of humor. It seemed to affect aging well through its relationship with perceived control. Physical health, satisfaction with housing, and relationships with family and friends were also positively influenced by humor.

We have already explored the complex circumstances that we live in a suffering-phobic culture and that learning to be in skillful relationship to our own and another's suffering, grief, and despair is essential for the work we do as therapists, but what about the value of distracting oneself when we just need to do so? Of course, in fact, one suggestion by McCreddie and Wiggins²³⁴ is that stress can be coped with through distraction, which lessens the negative physical effects of stress. Humor is also known to have a number of potential benefits in relation to interpersonal skills or social support.²³⁵ Specific aspects such as empathy, intimacy, and interpersonal trust have all been positively correlated with a sense of humor and subsequently with interpersonal relationships. According to McCreddie and Wiggins,²³⁴ a degree of rapport with the patient is necessary before humor should be used, and humor should be used only after a level of empathy, caring, and competence has been clearly demonstrated. This interaction of therapy and societal interactions explain why the World Health Organization model went from a disability or handicap model to a model of functional ability and participation in life. Although the International Classification of Diseases (ICD-9 or ICD-10) deals with physicians and disease categories, therapy clearly separates itself into a clear model that stresses the strength of an individual and his or her potential to participate in and have quality of life (<https://www.who.int/classifications/icf>).

Rogers and Figone¹⁶⁹ developed the following suggestions that could benefit the therapist when trying to create a supportive environment:

1. It is helpful to use the same staff member to develop the relationship and provide continuity of care.
2. Concerned silence is most appreciated, although pushing is sometimes necessary.
3. Staff members should anticipate the need to repeat information graciously.
4. Cumbersome, hard-to-repair adaptive equipment should not be used after discharge.
5. Give patients responsibility so that they feel they have some control over therapy.
 - a. The patient should be allowed to pick his or her own advocate from the team.
 - b. The patient should be given a choice of activities (e.g., which exercise comes first).
 - c. Health care professionals should avoid placing the patient in an inferior status.
6. Personal matters are better discussed with staff members with whom the patient has developed a relationship.^{2,215}
7. Willingness to allow the patient to try and fail is more helpful than controlling the patient.

Bolte-Taylor¹³⁴ developed "forty things I needed the most" during her rehabilitation for her stroke. Here are a few:

1. I am not stupid, I am wounded. Please respect me.
2. Come close, speak clearly, repeat yourself if necessary, and enunciate.

3. Approach me with an open heart, slow your energy down, and take your time.
4. Be aware of what your body language and facial expressions are communicating to me.
5. Make eye contact with me, encourage me.
6. Honor the healing power of sleep.
7. Protect my energy. No talk radio, TV, or nervous visitors! Keep my visitations brief.
8. Speak to me directly, not about me to others.
9. Clarify for me what the next step or level is so I know what I am working toward.
10. Celebrate all of my little successes. They inspire me.

CONCEPTUALIZATION OF ASSESSMENT AND TREATMENT

Assessment

The one component that weaves through all of Rogers and Figone's¹⁶⁹ seven points is the need for the therapist to be involved with the patient in a therapeutic relationship—that is to develop a sense of where the patient is coming from. To know where the patient is coming from is to be aware of and sensitive to the person's total psychosocial frame of reference.^{2,215}

The therapist who knows his or her own beliefs, reference points, and prejudices can evaluate whether an assessment result or treatment sequence reflects the patient's needs and values or those of the therapist. In the first half of this chapter, some assessments were discussed that could be summarized into the following three major components:

1. Preinjury
 - a. Values and prejudices (value systems, culture, and prejudices) of the patient and family members before the injury
 - b. Developmental stage of the patient and family members
 - c. Cognitive level of the patient and family members
 - d. Ability of the patient and family members to handle crisis
2. Components to be evaluated leading to adjustment
 - a. Loss and grief process for the patient and family members
 - b. Adjustment process for the patient and family members
 - c. Transitional stages for the patient and family members
 - d. Role changes for the patient and family members
 - e. Age or cognitive level of patient and family members^{9,165,215,236}
 - f. Sexual adjustment for the patient and spouse
3. Techniques used to elicit adjustment and independence
 - a. Crisis intervention strategies
 - b. Letting the patient and family take control
 - c. Expression of emotion, both verbally and nonverbally
 - d. Emotion-focused and problem-focused problem solving
 - e. Role playing
 - f. Praise
 - g. Education
 - h. Support groups

Once an assessment has been made of the patient and family members' stages of psychological adjustment, the patient's occupational history and roles, and their preinjury attitudes and beliefs, a treatment protocol can be established. This protocol will need to incorporate steps toward stage change and possibly attitudinal change. Because these changes require learning on the part of the patient and family, an environment that optimally facilitates these changes need to be established.^{9,76,93,99,182,197,237–239}

Therapy can be seen as a form of education in which the patient and the patient's family are taught how the patient could care for and optimally function with his or her body. However, the education process is not limited to the physical aspects of therapy. The patient is also

encouraged to experience, view, and wonder about their body and the experience of disability and to begin to articulate their needs and be given the opportunity to make decisions for themselves whenever possible. If the staff is nonverbally telling the patient and the family that the patient is not capable of making decisions and is not capable of being independent, it follows that the patient may indeed feel dependent and incapable of making decisions. Giles¹⁹⁸ and others^{194,198,237,240,241} stated that there was an inverse relationship between independence and distress. Distress causes further anxiety and decreases the learning potential of the patient. Thankfully, there are many ways for the therapist to encourage resilience, stress-hardiness, adaptation, and independence on the part of the patient and his family.

Specific Therapeutic Interventions

“Engagement in leisure-like activities may not only help people feel better in the immediate context of coping with rehabilitation treatments, but may help sustain coping efforts as individuals learn to live with ongoing functional limitations.”²⁴²

Problem-Solving Process

The family unit, including the patient, should be encouraged to take active control over as much of the patient's care and decision making as possible.^{19,22,53,195,198,236–238,240,241,243–245} This can be done in every phase of the rehabilitation process. A family conference with the rehabilitation staff should actively involve the patient and family in all stages of planning and treatment, up to and including discharge. The family (including the patient) should be briefed ahead of time to prepare questions that they want answered or problems that need to be addressed. Rogers and Figone¹⁶⁹ report that conferences with family members that excluded the patient engendered suspicion^{2,198}; therefore if the patient is capable, the patient may educate the family in regard to what is happening in the hospital and in rehabilitation. Conversely, family involvement facilitates and shortens the rehabilitation process and encourages reintegration into the community.^{8,194,237,241} The family can also be educated regarding the side effects and interactions of medication with publications such as the *Physicians' Desk Reference*.²⁴⁶ Later in the rehabilitation process, the patient and family can be encouraged to arrange transportation services, find and evaluate housing, and supervise attendant care. All these activities allow the patient and the family to be more in control of the environment and thus feel independent.

In the context of one-on-one therapy, giving choices can foster patient responsibility and independence. Making a decision about the order of treatment activities (such as on which side of the bed to transfer out of or which direction to roll one's wheelchair first) can give the individual a sense of self-worth that can continue to grow. This can cultivate a belief by the patient and family that they are strong, with basic needs that can be respected and met. Moving out of the role of the victim, the patient begins to exercise responsibility and to take action, such as applying for extended health benefits or getting a second consultation when an important medical decision needs to be made. If the patient and family start to realize that they do not have to be a casualty of the medical establishment and if they find ways to control what they can within the medical establishment,^{93,222,247} they are better able to discard the role of victim.

The steps of crisis intervention, which were mentioned in the previous section, can be used to help the family understand and analyze their needs in the crisis situation. Once the family has discerned that they may be discovered that they are in crisis, they will then be able to draw upon strategies and skills that they can use to overcome present and future problems.

Our dominant cultural way of coping with difficulty primarily deploys problem-based problem-solving strategies, yet emotion-focused

problem solving is a skill that can be developed and can be an important element in the process of adjusting to a disability, and the therapist can use these techniques to help the patient and family gain intentional, values-based planning to enhance independence and a sense of control over the situation.^{19,53,194,198,237,238,240,241,243,244}

Rather than having the patient learn how to accomplish each specific activity, the patient or family can be encouraged to think through the process from the problem to the solution and to accomplishment of the task. To achieve this activity analysis, the patient would have to know the basic principles behind the activity¹⁶⁹ and may then be responsible for educating the family. An example of this would be a transfer from the wheelchair to the toilet. If the therapist simply has the patient memorize the steps in the task, the patient or family members will not necessarily be able to generalize this procedure to a transfer to the car. If the patient learns the principles of proper body mechanics, work simplification, and movement, the patient or family member may be more able to generalize this information to almost any situation and solve problems later when the therapist is unavailable.²⁴⁰ Rogers and Figone¹⁶⁹ have noted that although the patient and family may fail at times during these trials, the therapist should let them be as independent and responsible as possible: let them try it their way, even if they are not successful the first time.

Pictures or slides of a restaurant, movie theater, or public building can be used to facilitate discussion and problem solving by the family unit when analyzing potential architectural barriers in the environment. Thus in the future when the family is presented with a problem or a barrier, they will have the resources to overcome it rather than be devastated by it.

Role playing in combination with support groups can also be used to defuse potentially painful situations and operate independently. While the patient is still in the safe environment of the rehabilitation setting, simulations of incidents can be created for them to practice problem solving with supervision to help anticipate potential situations. They can be asked what they would do when a stranger (possibly a child) approaches the patient and asks why he or she is in a wheelchair or is disabled, or what they would do when a waiter asks the family member to order for the disabled patient. All of these situations are potentially devastating for all involved; however, if role playing and support groups are used in advance to help all members of the family (patient included) to satisfactorily handle and feel in control of the situation, the family will not be as likely to be traumatized by a similar occurrence. The result is that the family will not be as inclined to be overwhelmed by social situations and will be able to socialize in a much freer, more gratifying way.^{78,80,248,249}

Cognitive-behavioral therapy has been used for patients and spouses with success.^{94–96} Psychosocial support groups have been called for throughout the literature.^{92,214,217,224,237,250–252} Throughout the therapeutic process, the patient and the family need to be praised frequently, and credit needs to be given for the gains made by the patient and family members. Granted, the therapist may have engineered the gains, but the family and patient are the ones who need the reinforcement. As Bolte-Taylor¹³⁴ suggested, celebrate all of the little successes—they can help inspire the patient and their family. Through gratifying experiences the family will unite to overcome the disability. They need to know that they can survive in the world without having the medical staff constantly there to solve the family's problems. In short, they need the strategies and resources that will allow them to be independent outside the medical model.

Yet another way to encourage independence can be applied to working with parents of disabled children.¹³ The parents should be educated about normal and abnormal growth and development, including physical, cognitive, and emotional growth, so that the family can maintain some perspective and objectivity about their child's various levels.^{8,92,224}

The parents can then better understand the needs of those children with disabilities and those without in the family. Armed with this knowledge, the parents and children will be less likely to be frustrated with unreal expectations or unreal demands. Education for the parents could take place at local colleges, online, at the hospital, or even in a parent's group.

Support Systems

Groups are often used to increase motivation, provide support, increase social skills, instill hope, model our humanity, and help the patient and family realize that they are not the only ones who have a disabled family member. This will help the patient and family establish a more accurate set of perceptions about the disabled individual and allow for greater independence of the patient and family.^{1,9,93,161,249,253} Problem solving can be encouraged, and value systems can be clarified and bolstered. Patient or family support groups, including healthy peer groups, can be used to relieve pressure that might otherwise be vented in therapy. Lawrie Williams, a mother of two daughters who experienced serious medical challenges, is the author of a series of articles about parental roles in family-centered care. One article in particular highlights the role parents can play in helping other families through parent-to-parent support programs. Williams first experienced the support of another parent when one of her daughters was young, and later realized she could use her own experiences professionally. For the past 6 years, Williams has been the coordinator of the Parent Support Program at the Center for Children with Special Needs, Children's Hospital and Regional Medical Center in Seattle, Washington.²⁵⁴

Livneh and Antonak¹⁶⁰ found that in a chronic-care ward family involvement helped the patient and the family improve their status. Schwartzberg²³⁷ and Schulz¹⁵⁴ and others^{1,99,132,236,255–257} have reported great success in the use of support groups with individuals who had brain damage. Support groups can also be used to educate the patient about the patient's disability to increase independence.^{1,194,236,241,258,259}

Kreuter and colleagues²⁵⁹ and Taanila and colleagues^{13,258} found that independent physical functioning and knowledge about one's condition were exceedingly important in moving through the phases of the rehabilitation process.^{76,222,253,260} A guide to facilitating support groups has been published by Boreing and Adler,²⁶¹ and it has been found to be useful, especially by laypeople establishing such groups.^{76,93,99,194,237,258–262}

The Adult Patient With Brain Damage

The adult patient with brain damage and the needs of the family will be specifically, yet briefly, explored here. Brain damage can affect the cognitive, perceptual, emotional, social, and neurological systems of the individual and can be incredibly disruptive and catastrophic to the patient's and family's lives. When a person sustains a brain injury and is hospitalized, emotional support for the family (patient included) is the primary need to be met initially. The therapist should attempt to convey warmth and a caring attitude, especially during the family's initial contacts.²⁶³ Typical complaints about the acute period involve impersonal hospital routines and lack of definite information about the patient's status.^{13,93,217,264} Unfortunately, definitive information is usually not available at the earliest stages.

Later the family must deal with the physical changes in the patient's body; what may be even more injurious to the family are the psychological, cognitive, and social changes in the patient.^{1,8,9,16,18,19,250} People with cerebrovascular accidents have been found to be more clinically depressed than orthopedic patients are. The libido²⁵¹ and the emotional systems are also affected.^{76,214} It has further been shown that persons who survive a cerebrovascular accident or other impairment and who have a full return of function do not return to normal life because of a

lack of social and emotional skills.^{1,9,93,161,249,253} Families of cerebrovascular accident victims have also reported that social reintegration is the most difficult phase of rehabilitation.²⁶⁵ Lack of socially appropriate behaviors has been one of the most troublesome complaints of people who deal with the person with a traumatic brain injury. Therapists may be able to help alter this difficulty by encouraging appropriate behavior and by structuring therapy situations to provide opportunities for the patient to practice appropriate behavioral and social interaction skills. A technique called *dialectical behavioral therapy* has been used with people with mental health disorders, and it appears to be a promising approach. One study by Miller and colleagues²⁶⁶ found significant reductions in suicidal symptoms; the most highly rated skills included distress tolerance and mindfulness skills. The goals of a dialectical behavioral therapy program designed for individuals with mild traumatic brain injury include decreasing the individual's self-defeating behaviors and cognitions, cultivating understanding of the individual's abilities and impairments, and increasing behavioral and cognitive skills that will lead to a greater sense of self and feelings of self-esteem. The program is designed to improve each patient's ability to accept his or her life as it is and function independently.²⁶⁷

Better follow-up care needs to be implemented when dealing with the adult with brain damage.^{1,99,132,236,255–257} In some areas there are outpatient, privately funded programs that can help support the brain-injured individual and his or her family on discharge from hospital settings. These resources must be recommended for follow-up care as needed.

It may not be possible for the patient and family to constantly come to the clinic for support and follow-up, but Skype or Zoom conversations can be scheduled on a periodic basis, or the exchange of text messages and emails can also be used. With the increased availability

of online video conferencing capabilities, follow-up may be performed online by patients living in rural areas. In-person or online conferencing support groups are being used increasingly to facilitate patient and family adjustment and accommodation to disability, as well as reentry into the community.^{1,16,93,220,227,236,258,268}

CONCLUSION

The practice area of neurological rehabilitation and the implications of our work in fostering and supporting our patients and patients in the process of learning how to be in relationship to disability is an extraordinarily complex and encompassing practice. We all have, as a part of our own humanity, experiences of adaptation and adjustment through our life-spans to draw from and as therapists. We are given unlimited opportunities to bring our own humanity to bear in this dynamic and humbling work. It may be that beyond the intensifying productivity standards and potential for cynicism and burnout that is increasingly becoming a reality of our work. There is a well of insight, wisdom, and compassion we can draw from to cultivate and develop as clinicians. Our practice, with the support of community, is in seeking out opportunities to build our own inner and outer resources of support, strengthening our capacity to remain centered, modeling qualities of reciprocity, connection, and self-care to the best of our abilities in the therapeutic relationship, all the while sustaining the course even in the midst of challenging circumstances.

Acknowledgment

The present authors and editors would like to thank Gordon U. Burton PhD, OTR/L for his significant contribution on this chapter in the previous edition of the text.

CASE STUDY 5.1 Putting Evaluations and Techniques Into Practice

Diane, a divorced 42-year-old woman with a college-age daughter, was happily employed as a junior high art teacher when she had a left hemorrhagic CVA resulting in right spastic hemiplegia and motor speech impairment. She had right-handed dominance prior to the stroke. She is in grief over the losses of her job as a teacher and her accomplished art skills that relied on her dominant hand. She is devastated and angry about these losses and the difficulties ahead. She is experiencing fear and stress about how she will manage financially and practically. Connecting with other patients in similar circumstances is very important to her. The value and authenticity of this sharing is acknowledged by members of the team. A very independent person, Diane still wants to work. She hopes to learn to drive an adapted car in the future, pending thorough evaluation and training. She wants to live as independently as possible and be able to participate in all those activities that brought meaning, purpose, and joy to her life. Diane's friends, colleagues, and siblings have been supportive. Her daughter took a semester off from college and will be returning to school in a few months.

Treatment

What is key here is the manner of proceeding in collaboration, with therapists looking for opportunities within the therapy experience to listen and reflect what is being discovered and for gains to acknowledge. Diane has been participating in occupational therapy and physical therapy treatments working to treat spasticity, learning methods to decrease tone, and using splinting. Mindful sensing and breathing are incorporated into the treatment as well as reporting nuances of awareness of felt experience: familiarizing, being aware of, and owning the experience of the body as it is in the moment. All kinds of feelings of grief, strangeness, and frustration may arise throughout treatment sessions. Her goal in PT is to progress to walk independently with walker and quad cane and to transfer safely. She is working with the speech therapist on motor speech and

swallowing techniques. Currently her speech is labored but understandable. Diane is working with OT on dressing using nondominant L side assistive devices, and she is learning one-handed kitchen skills with assistive methods and devices. Spasticity, pain, and therapy appointments are all physically, mentally, and emotionally fatiguing.

Initially Diane will participate in peer-support groups to foster mental and emotional processing of her situation, to work with processes of acceptance, adjustment, and coping, and to provide an atmosphere to cultivate relationships, bonding, a sense of belonging, build resources for resilience, and enhance inner and outer resources such as emotion-focused problem solving, mindfulness, and building a sense of community and connectedness.

The current treatment plan is to collaborate with Diane to plan and implement energy conservation strategies and break down very sizable goals into workable steps. She has high hopes, and it will be important to keep steps incrementally achievable, to recognize small gains, and to honor the challenge and work involved so that the healing and rebuilding processes are not overwhelming. This can be an opportunity to explore mutuality, interdependence, and independence in the context of community.

The treatment team is collaborating with Diane to explore interests, strengths, and needs to address potential job or job-training possibilities. While there are new restraints, there are also deepening capacities growing out of these challenging circumstances. The OT and Diane will work together to problem solve what adaptations, support, and stamina issues need to be considered. While Diane has great grief over losing her dominant hand for art work, OT will invite alternative approaches with her nondominant hand, offering participation in art activities. This exploration will need to be sensitive to Diane's capabilities and perhaps allow a new approach, one following her lead, permission to experiment in a new medium with no agenda other than doing something new,

Continued

CASE STUDY 5.1 Putting Evaluations and Techniques Into Practice—cont'd

and engage in a creative process using her nondominant hand and thus different brain engagement.

The medical social worker, in communication with the rehab team, will be working with Diane and support persons to assess finances, services, and access to resources for her goals. She will also be referred to vocational rehab

counseling once she feels more stabilized in her daily functioning and has a realistic picture of her activity tolerance and fatigue. The rehab team contributes to vocational rehab assessment. There is discussion of exploring the future possibility of canine companions, which Diane has heard about and is very interested in.

Abstract: This chapter provides the reader a comprehensive discussion of the process of adaptation and adjustment of an individual with a neurological condition. The chapter will explore elements and complexities of the grief process and how the mourning process is impacted by our dominant cultural narratives and potential biases. This chapter also explores the role

of mindfulness, resilience, coping, emotion-focused problem solving, significance of inner and outer resources, community, and learning styles into the process of adaptation and potential impacts on treatment.

Keywords: Adaptation, grief, mindfulness, emotion-focused problem solving, inner and outer support systems, community, and resilience

Differential Diagnosis of the Patient With a Neurological Condition

John D. Heick and Rolando T. Lazaro

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify the difference between differential diagnosis for medical screening, and differential diagnosis for diagnosis of impairments, activity limitations, and participation restrictions.
2. Analyze the concept of body system and subsystem screening to be used with patients with unknown or known preexisting neurological dysfunction.
3. Develop a mechanism for body system screening to be used with patients with preexisting neurological dysfunction.
4. Analyze the significance and importance of performing a medical screening for all patients who interact in a therapeutic environment with clinicians.

KEY TERMS

causational systems interaction
medical screening

patient referral
review of systems

INTRODUCTION

The term *differential diagnosis* means different things to different clinicians. In this text the term will be used to answer the question that all therapists should ask themselves when they are performing the initial evaluation of a patient: Does the patient present a condition that is within the scope of physical or occupational therapy practice that the clinician can treat? If the answer is no, then the clinician has two choices. The first is to continue to manage the patient to work on those issues that can be improved with physical or occupational therapy intervention AND refer the patient to another health care provider that can help identify and treat the other condition the patient may have. The other option is to refer the patient out to another health care practitioner who is capable of diagnosing and managing the presenting condition.

This initial process of differential diagnosis is performed by the clinician while doing a thorough history and neurological examination to rule out serious neurological conditions and rule in the patient's condition. In this case, the patient likely presented with multiple "red flags," which are signs and symptoms that act as warnings to alert the therapist to investigate further. In the case that a patient does have a serious neurological condition, therapists need to appreciate that clusters of tests or clusters of red flag signs and symptoms are most useful to identify serious neurological conditions and that the reliance on only one test or positive red flag sign or symptom is not as conclusive to the decision making process for the clinician.

Evidence has suggested that identifying clusters of several red flags improves the sensitivity or specificity of a condition. For example, Raison and colleagues¹ found that combining asking a patient about bowel

and bladder disorders and asking the patient about saddle paresthesia and identifying two positive answers to these red flags improved the specificity to 0.92 in those patients whose magnetic resonance imaging (MRI) confirmed spinal cord compression. Kollensperger and colleagues² found that clustering red flags for confirming multiple system atrophy, a condition that mimics Parkinson disease, resulted in a specificity increase to 98.5%, sensitivity to 84.2%, positive predictive value to 96%, and negative predictive value of 92.7% when clustering 2 out of 6 red flag categories.

In the neurological examination, one sign or symptom that appears as a red flag does not mean that the examination is stopped and does not mean that there is complete certainty of predicting the cause; it just increases the probability of that condition. For example, an upgoing plantar response to the Babinski test as the one positive test is considered to be a reliable marker for upper motor neuron lesion. If the clinician identifies the red flag and stops the neurological examination on the patient at that point in time, the clinician might miss the other potential positive tests or signs and symptoms that would help to clarify the patient's diagnosis. Simply stated, red flags are used as warning signs to alert the therapist to investigate further and consider the complete examination. Red flags may occur through multiple approaches that are specific to the setting. Red flags may come from questioning the patient. Yet Premkumar and colleagues³ recently reported that individual red flag questions were not as effective as clusters of red flag questions, albeit in patients with low back pain. Red flags may also come as objective findings or positive neurological tests. Evidence continues to build on the compilation of red flag questions and red flag objective findings and the use of clinical decision rules to assist therapists in differentiating one condition compared to another.

Evidence suggests that clustering of red flag questions and tests improves the probability of the specific condition, but this has not been explored as well with neurological conditions as it has with orthopedic conditions. After the physical examination, the next step is to evaluate the results of the examination. This systematic approach helps the therapist to identify clusters of positives and thus form clinical patterns that are consistent with specific diagnoses.

The neurological examination should be performed systematically every time. When considering a direct access primary care clinic where physical therapists work, there may be an increased probability of patients coming in with serious conditions that warrant immediate referral to another health care provider. These could be potentially life threatening and include conditions such as stroke or a patient with progressive neurological system decline such as in transverse myelitis. Transverse myelitis may initially present with low back pain and paresthesias, and rapidly progress to weakness in the extremities and bowel and bladder incontinence. In many situations like this example, this may involve additional tests and measures that the patient has to undergo to rule out conditions and ultimately identify the condition. In the multiple practice settings where occupational and physical therapists work, therapists may have a variety of resources to assist in identifying conditions, such as referral sources to assist in ordering blood work or imaging for therapists who work in the hospital, emergency department, or settings that are in close proximity to a physician, nurse practitioner, or physician's assistant. On the other side of the spectrum, many therapists have little to no resources available to them to assist in identifying conditions, such as in school settings.

In those settings that have a variety of resources, such as the ability to quickly receive blood work or imaging, therapists must form relationships across disciplines to understand how to facilitate this process and advocate for their patients. Understanding neuroanatomy and how neurological conditions present is pivotal to improving clinical decision making and facilitating the right test for the patient with a neurological condition. For example, a patient with a suspected stroke that presents at a direct access clinic may present with a specific clinical pattern that helps the therapist conclude the location of the deficit. Anterior circulation deficits may be anterior cerebral or middle cerebral artery presentations. Anterior cerebral artery strokes in a patient may present with lower extremity weakness more than upper extremity weakness, whereas middle cerebral artery strokes present with contralateral hemiparesis and speech deficits. Posterior circulatory deficits could likely be seen in a patient presenting with vertigo, dizziness, altered mental status, or visual field deficits. By knowing this, therapists can assist with imaging requests that correspond to the patient's clinical presentation. For example, anterior circulatory strokes are easier to catch by head computed tomography (CT).⁴ Middle cerebral artery strokes are best identified with noncontrast head CT with angiography. Head CT with angiography can be used to identify diffuse atherosclerosis and has an odds ratio of 23.6 for ischemic stroke identification. CT angiography with the addition of noncontrast head CT increases the specificity to 88% and sensitivity to greater than 70%.⁴ Small lesions such as transient ischemic attacks are hard to identify on CT, with a sensitivity of only 12%. Posterior circulatory lesions require MRI to identify (sensitivity 80%, specificity 95%).⁴

In all settings, the therapist starts with the initial examination which includes taking a thorough history, including an investigation of the patient's medical history, presenting complaints, and a systems review (Box 6.1). In terms of differentially diagnosing the patient in the outpatient setting, a review of systems (Box 6.2) is done by ensuring that a questionnaire that asks about body systems is completed by the patient, and the therapist reviews these questions with the patient to make sure the patient understands. Fig. 6.1 is an example of an intake

BOX 6.1 Systems Review Checklist

SYSTEMS REVIEW (note if subjective or objective information: note as impaired or not impaired)

- Cardiovascular and Pulmonary Not impaired Impaired
- Blood Pressure: _____
 - Edema
 - Heart Rate _____
 - Respiratory Rate _____
- Integumentary Not impaired Impaired
- Integrity
 - Scars
- Musculoskeletal Not impaired Impaired
- Gross ROM WNL
 - Gross Strength WNL
 - Gross Symmetry: Symmetrical
- Height: _____
- Weight: _____
- Neuromuscular Not impaired Impaired
- Gross Balance
 - Gross Gait
 - Gross Locomotion
 - Gross Transfers
 - Gross Transitions
 - Motor Function (control, learning)
- Communication, Affect, Cognition, Learning Not impaired Impaired
- Age-appropriate Communication
 - Orientation × 4
 - Emotional/behavioral responses
- Language:
- Preferred Language: _____
 - English verbal comprehension

form/medical history questionnaire that includes items for systems review and review of systems. In the inpatient setting, by contrast, a systems review and review of systems is initiated by performing a chart review to investigate the patient's medical history followed by a physical examination of the patient. For example, in a patient with a chief complaint of inability to walk secondary to a middle cerebral artery stroke, it would be important to take their vital signs, scan their integumentary system for signs and symptoms of arterial and venous compromise, as well as to perform a complete neurological examination. A review of systems is also necessary to determine which other body systems may be pathological—whether related or not to the primary diagnosis. This history and the findings of the physical examination will lead to a diagnosis that may necessitate additional tests and measures, which may include laboratory tests or imaging that the patient needs a referral to receive. Especially in the care of the patient with a neurological condition, the therapist needs to be certain of the decision of treat, treat and refer, or refer. The identification of a condition that implicates the central nervous system after the examination of the patient, when the patient is sent to the therapist with a different

BOX 6.2 Review of Systems

When conducting a general review of systems, ask the patient about the presence of any other problems anywhere else in the body. Depending on the patient's answer you may want to prompt him or her about any of the following common signs and symptoms* associated with each system:

General Questions

- Fever, chills, sweating (constitutional symptoms)
- Appetite loss, nausea, vomiting (constitutional symptoms)
- Fatigue, malaise, weakness (constitutional symptoms)
- Excessive, unexplained weight gain or loss
- Vital signs: blood pressure, temperature, pulse, respirations, pain, walking speed
- Insomnia
- Irritability
- Hoarseness or change in voice, frequent or prolonged sore throat
- Dizziness, falls

Integumentary (Include Skin, Hair, and Nails)

- Recent rashes, nodules, or other skin changes
- Unusual hair loss or breakage
- Increased hair growth (hirsutism)
- Change in nail beds
- Itching (pruritus)

Musculoskeletal/Neurological

- Joint pain, redness, warmth, swelling, stiffness, deformity
- Frequent or severe headache
- Change in vision or hearing
- Vertigo
- Paresthesias (numbness, tingling, "pins and needles" sensation)
- Change in muscle tone
- Weakness; atrophy
- Abnormal deep tendon (or other) reflexes
- Problems with coordination or balance; falling
- Involuntary movements; tremors
- Radicular pain
- Seizure or loss of consciousness
- Memory loss
- Paralysis
- Mood swings; hallucinations

Rheumatological

- Presence/location of joint swelling
- Muscle pain, weakness
- Skin rashes
- Reaction to sunlight
- Raynaud phenomenon
- Change in nail beds

Cardiovascular

- Chest pain or sense of heaviness or discomfort
- Palpitations
- Limb pain during activity (claudication; cramps, limping)
- Discolored or painful feet; swelling of hands and feet
- Pulsating or throbbing pain anywhere, but especially in the back or abdomen
- Peripheral edema; nocturia
- Sudden weight gain; unable to fasten waistband or belt, unable to wear regular shoes
- Persistent cough
- Fatigue, dyspnea, orthopnea, syncope

- High or low blood pressure, unusual pulses
- Differences in blood pressure from side to side with position change (10 mm Hg or more; increase or decrease/diastolic or systolic; associated symptoms: dizziness, headache, nausea, vomiting, diaphoresis, heart palpitations, increased primary pain or symptoms)
- Positive findings during auscultation

Pulmonary

- Cough, hoarseness
- Sputum, hemoptysis
- Shortness of breath (dyspnea, orthopnea); altered breathing (e.g., wheezing, pursed-lip breathing)
- Night sweats; sweats anytime
- Pleural pain
- Cyanosis, clubbing
- Positive findings during auscultation (e.g., friction rub, unexpected breath sounds)

Psychological

- Sleep disturbance
- Stress levels
- Fatigue, psychomotor agitation
- Change in personal habits, appetite
- Depression, confusion, anxiety
- Irritability, mood changes

Gastrointestinal

- Abdominal pain
- Indigestion; heartburn
- Difficulty in swallowing
- Nausea/vomiting; loss of appetite
- Diarrhea or constipation
- Change in stools; change in bowel habits
- Fecal incontinence
- Rectal bleeding; blood in stool; blood in vomit
- Skin rash followed by joint pain (Crohn disease)

Hepatic/Biliary

- Change in taste/smell
- Anorexia
- Feeling of abdominal fullness, ascites
- Asterixis (muscle tremors)
- Change in urine color (dark, cola-colored)
- Light-colored stools
- Change in skin color (yellow, green)
- Skin changes (rash, itching, purpura, spider angiomas, palmar erythema)

Hematological

- Change in skin color or nail beds
- Bleeding: nose, gums, easy bruising, melena
- Hemarthrosis, muscle hemorrhage, hematoma
- Fatigue, dyspnea, weakness
- Rapid pulse, palpitations
- Confusion, irritability
- Headache

Genitourinary

- Reduced stream, decreased output
- Burning or bleeding during urination; change in urine color
- Urinary incontinence, dribbling

Continued

BOX 6.2 Review of Systems—cont'd

- Impotence, pain with intercourse
- Hesitation, urgency
- Nocturia, frequency
- Dysuria (painful or difficult urination)
- Testicular pain or swelling
- Genital lesions
- Penile or vaginal discharge
- Impotence (males) or other sexual difficulty (males or females)
- Infertility (males or females)
- Flank pain

Gynecological

- Irregular menses, amenorrhea, menopause
- Pain with menses or intercourse
- Vaginal discharge, vaginal itching
- Surgical procedures
- Pregnancy, birth, miscarriage, and abortion histories
- Spotting, bleeding, especially for the postmenopausal woman 12 months after last period (without hormone replacement therapy)

Endocrine

- Change in hair and nails
- Change in appetite, unexplained weight change
- Fruity breath odor
- Temperature intolerance, hot flashes, diaphoresis (unexplained perspiration)
- Heart palpitations, tachycardia
- Headaches
- Low urine output, absence of perspiration
- Cramps
- Edema, polyuria, polydipsia, polyphagia
- Unexplained weakness, fatigue, paresthesia

- Carpal/tarsal tunnel syndrome
- Periarthritis, adhesive capsulitis
- Joint or muscle pain (arthralgia, myalgia), trigger points
- Prolonged deep tendon reflexes
- Sleep disturbance

Cancer

- Constant, intense pain, especially bone pain at night
- Unexplained weight loss (10% of body weight in 10–14 days); most patients in pain are inactive and gain weight
- Loss of appetite
- Excessive fatigue
- Unusual lump(s), thickening, change in a lump or mole, sore that does not heal; other unusual skin lesion or rash
- Unusual or prolonged bleeding or discharge anywhere
- Change in bowel or bladder habits
- Chronic cough or hoarseness, change in voice
- Rapid onset of digital clubbing (10–14 days)
- Proximal muscle weakness, especially when accompanied by change in one or more deep tendon reflexes

Immunological

- Change in skin or nail beds
- Fever or other constitutional symptoms (especially recurrent or cyclical symptoms)
- Lymph node changes (tenderness, enlargement)
- Anaphylactic reaction
- Symptoms of muscle or joint involvement (pain, swelling, stiffness, weakness)
- Sleep disturbance

referring diagnosis, is important to verify as soon as possible. This will aid in recognition of a specific diagnosis and lead to a more accurate prognosis. One way to think about a systems review is that it directs the therapist on whether to investigate that system. For example, in the patient that presents with a middle cerebral artery stroke and left neglect, the therapist needs to be concerned about the integumentary system, especially of the left upper extremity if the patient has a lesion of the dorsal column medial lemniscus tract.

The therapist organizes the history and physical examination (including tests and measures) findings into clusters, syndromes, or categories. In the neurological examination, therapists identify clusters of findings that suggest the presence of disease or an adverse drug event and warrant communication with a physician. The therapist then considers using the World Health Organization (WHO) International Classification of Functioning, Disability and Health (ICF) model⁵ to examine the influences of both internal and external factors to the patient's health. The ICF framework classifies the health components of function and disability. The ICF framework focuses on the three perspectives that influence the patient: body, individual, and society. By reflecting on these influences, therapists can then pair outcome measures that correctly identify how these three perspectives influence the individual with a neurological condition.

DIFFERENTIAL DIAGNOSIS: MEDICAL SCREENING

The *Guide to Physical Therapy Practice*⁶ clearly describes the therapist's responsibility to refer patients with health concerns to other practitioners (Fig. 6.2). In the practice of treating patients with neurological conditions, many times the therapist needs to refer the patient back to the physician. This usually occurs due to the patient's sudden changes in mental and/or physical status. This may also be associated with a recent exacerbation of symptoms such as pain, weakness, numbness, dizziness, falls, or confusion. Therapists may also detect signs or symptoms not related to the patient's primary neurological condition but instead related to a comorbidity or a medication side effect. The systems review and review of systems may reveal a need to refer the patient for a dermatological, cardiovascular, or other system involvement not related to their primary neurological condition that requires attention by a physician (Fig. 6.3).

As a health care professional and especially in a direct access clinic, it is the therapist's duty to screen the patient within their scope of practice. In screening the patient the therapist may (1) identify signs and symptoms consistent with existing medical conditions, (2) identify signs and symptoms suggesting that an existing medical condition may be worsening, (3) identify neurological

Personal History					
Have you ever had:					
• Anemia	Yes	No	• Chronic bronchitis	Yes	No
• Epilepsy/seizures	Yes	No	• Emphysema	Yes	No
• Fibromyalgia/myofascial pain syndrome	Yes	No	• GERD	Yes	No
• Hepatitis/jaundice	Yes	No	• Gout	Yes	No
• Joint replacement	Yes	No	• Guillain-Barré syndrome	Yes	No
• Parkinson's disease	Yes	No	• Hypoglycemia	Yes	No
• Polio/postpolio	Yes	No	• Peripheral vascular disease	Yes	No
• Shortness of breath	Yes	No	• Pneumonia	Yes	No
• Skin problems	Yes	No	• Prostate problems	Yes	No
• Urinary incontinence (dribbling, leaking)	Yes	No	• Rheumatic/scarlet fever	Yes	No
• Urinary tract infection	Yes	No	• Thyroid problems	Yes	No
			• Ulcer/stomach problems	Yes	No
			• Varicose veins	Yes	No
For Women:					
History of endometriosis	Yes	No			
History of pelvic inflammatory disease	Yes	No			
Are you/could you be pregnant?	Yes	No			
Any trouble with leaking or dribbling urine?	Yes	No			
Number of pregnancies _____			Number of live births _____		
Have you ever had a miscarriage/abortion?	Yes	No			
General Health					
1. I would rate my health as (circle one):	Excellent	Good	Fair	Poor	
2. Are you taking any prescription or over-the-counter medications? If yes, please list: _____	Yes	No			
3. Are you taking any nutritional supplements (any kind, including vitamins)	Yes	No			
4. Have you had any illnesses within the last 3 weeks (e.g., colds, influenza, bladder or kidney infection)?	Yes	No			
If yes, have you had this before in the last 3 months?	Yes	No			
5. Have you noticed any lumps or thickening of skin or muscle anywhere on your body?	Yes	No			
6. Do you have any sores that have not healed or any changes in size, shape, or color of a wart or mole?	Yes	No			
7. Have you had any unexplained weight gain or loss in the last month?	Yes	No			
8. Do you smoke or chew tobacco?	Yes	No			
If yes, how many packs/pipes/pouches/sticks a day? _____ How many months or years? _____					
9. I used to smoke/chew but I quit.	Yes	No			
If yes: pack or amount/day _____ Year quit _____					
10. I would like to quit smoking/using tobacco.	Yes	No			
11. How much alcohol do you drink in the course of a week? (One drink is equal to 1 beer, 1 glass of wine, or 1 shot of hard liquor) _____					
12. Do you use recreational or street drugs (marijuana, cocaine, crack, meth, amphetamines, or others)?	Yes	No			
If yes, what, how much, how often? _____					
13. How much caffeine do you consume daily (including soft drinks, coffee, tea, or chocolate)? _____					
14. Are you on any special diet?	Yes	No

Medical/Surgical History

- Have you ever been treated with chemotherapy, radiation therapy, biotherapy, or brachytherapy (radiation implants)? Yes No
If yes, please describe: _____
- Have you had any x-rays, sonograms, computed tomography (CT) scans, or magnetic resonance imaging (MRI) or other imaging done recently? Yes No
If yes, what? _____ When? _____ Results? _____
- Have you had any laboratory work done recently (urinalysis or blood tests)? Yes No
If yes, what? _____ When? _____ Results (if known)? _____
- Any other clinical tests? Yes No
Please describe: _____
- Please list any operations that you have ever had and the date(s):
Operation _____ Date _____
- Do you have a pacemaker, transplanted organ, joint replacement, breast implants, or any other implants? Yes No
If yes, please describe: _____

Work/Living Environment

- What is your job or occupation? _____
- Military service: (When and where): _____
- Does your work involve:
 - Prolonged sitting (e.g., desk, computer, driving)
 - Prolonged standing (e.g., equipment operator, sales clerk)
 - Prolonged walking (e.g., mill worker, delivery service)
 - Use of large or small equipment (e.g., telephone, forklift, computer, drill press, cash register)
 - Lifting, bending, twisting, climbing, turning
 - Exposure to chemicals, pesticides, toxins, or gases
 - Other: please describe _____
 - Not applicable; none of these
- Do you use any special supports:
 - Back cushion, neck cushion
 - Back brace, corset
 - Other kind of brace or support for any body part _____
 - None; not applicable

History of falls:

- In the past year, I have had no falls
- I have just started to lose my balance/fall
- I fall occasionally
- I fall frequently (more than two times during the past 6 months)
- Certain factors make me cautious (e.g., curbs, ice, stairs, getting in and out of the tub)

I live:

- Alone With family, spouse, partner
- Nursing home Assisted living Other _____

manifestations that suggest an acute or life-threatening crisis, and (4) identify signs and symptoms suggestive of the presence of an occult disorder or medication side effect. This medical screening has always taken place within the clinical framework of physical therapist (PT) practice, but as direct access practitioners, this screening must become more comprehensive, requiring outcome measures and documented evaluation results. Fig. 6.4 is an example of an examination scheme that leads into a clinical decision to treat the patient, to treat *and* refer the patient, or to refer the patient. This figure suggests referring the patient may also include the decision to refer the patient to another practitioner (e.g., dietician, social worker, clinical psychologist) for services such as wellness clinics that encourage participation in movement activities to maintain gains experienced in therapy or once the patient has reached a plateau in rehabilitation. The following material focuses on the components of this scheme most directly related to the medical screening process leading to a patient referral.

Identifying Patients' Health Risk Factors and Previous Conditions

Owing to the considerable overlap in symptomatic presentation of impairment-related conditions and those requiring physician examination, identifying existing health risk factors for occult diseases is important. Numerous factors have an effect on the patient's risk for compromised health status, including age, sex, race, occupation, leisure activities, preexisting medical conditions, family medical history, medication usage (over-the-counter and prescription drugs), tobacco use, and substance abuse or the interaction of some of these conditions.

Of these, a personal history of a current or recent medical condition, current medication use, and a positive family history (e.g., mother and aunt with a history of breast cancer, father diagnosed with prostate cancer at the age of 58 years) are the most relevant risk factors for the potential presence of an occult condition. For example, the history of a previous episode of depression significantly increases the risk of a second episode compared with the risk that someone who has never had an episode of depression will have his or her first such episode.⁷ The greater the number of existing risk factors, the more vigilant the therapist should be for the presence of warning signs suggestive of disease and the more extensive the other medical screening components will need to be. Those increased risk factors, whether within one system or multiple systems, can lead to clinical behaviors that are the summation of the systems problems and their interactions that affect movement. Physicians should be able to depend on the therapist to recognize these interactive symptoms and refer the patient back to either the referring physician or to another specialist.

There are different methods to collect this medical history and patient profile information, including a review of the medical record and use of a self-administered questionnaire, depending on the practice setting and patient population. Fig. 6.1 is an example of a self-administered questionnaire that could be completed by the adult patient, a family member, or a caregiver. A quick review of this information should occur, if possible, before the patient interview is begun. The therapist will have a head start in organizing the history and physical examination, knowing what to prioritize and at least initially what parts of the examination can be deemphasized.

Affirmative answers to previous or current illness questions should direct the therapist to consider what the potential impact may

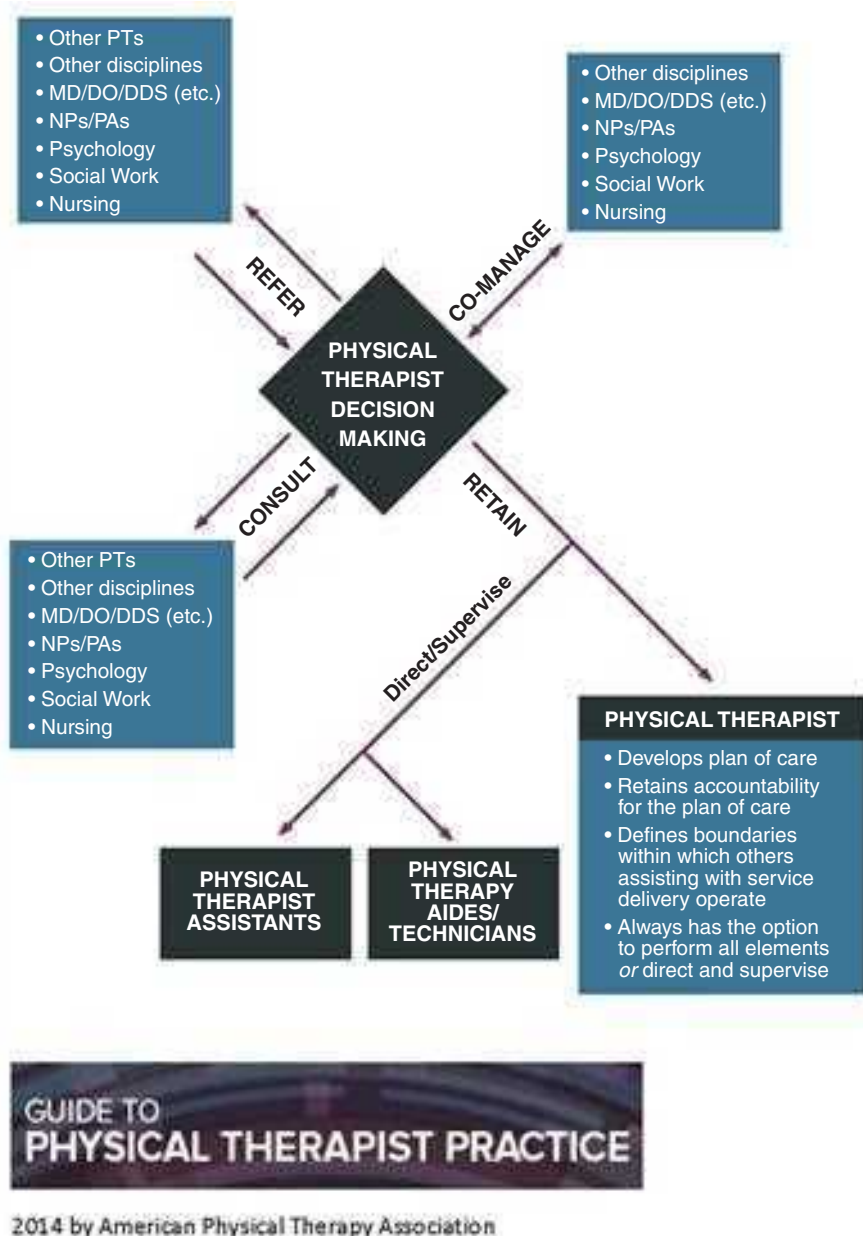

Fig. 6.3 The Physical Therapist Decision Making Process. (Reprinted from <http://www.apta.org>, with permission of the American Physical Therapy Association. © 2019 American Physical Therapy Association. All rights reserved.)

be on the patient's symptoms, choice of examination and interventions, rehabilitation potential, and risk for additional illness. For example, the presence of existing chronic kidney disease (e.g., renal failure) should alert the therapist to numerous potential complications including patient fatigue, weakness, and impaired concentration, all of which could interfere with rehabilitation efforts. Chronic renal failure is also marked by paresthesia and muscle weakness, which could mistakenly be associated with other neurological conditions. Renal osteodystrophy is yet another complication associated with chronic renal failure. The concern for compromised bone density should direct the therapist to use techniques that carry a reduced risk of skeletal injury. A series of follow-up questions for the affirmative answers will assist the therapist in determining the relevance

(if any) of each item (see Fig. 6.5 for examples of follow-up questions for selected information categories).

Symptomatic Investigation of Functional Restriction

The chief presenting symptoms or limitation in activity typically provides the reason for therapy services being sought and can provide the initial warning sign(s) of potential medical issues needing to be addressed. Despite pain not typically being the chief complaint of many patients with primary neurological conditions, a relatively mild pain is often the initial complaint associated with a serious pathological condition; a dull diffuse ache is often the initial presenting complaint associated with tumors of the musculoskeletal system.⁸ This relatively minor complaint may easily be overlooked by therapists working with

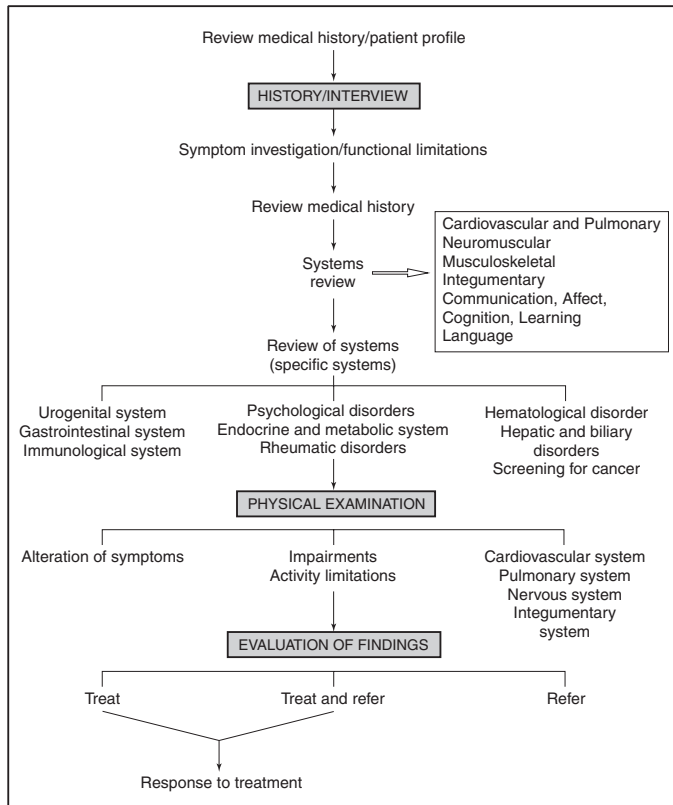

Fig. 6.4 Examination scheme that leads into a clinical decision to treat the patient, to treat *and* refer the patient, or to refer the patient. (Modified from notes from course by W.G. Boissonault, 1998 as published in Umphred DA, Lazaro RT, Roller ML, Burton GU. *Umphred's Neurological Rehabilitation*. 6th ed. St. Louis, MO: Elsevier; 2013.)

Medical History Follow-Up Form	
1. Have you EVER been diagnosed as having the following condition(s)?	
Heart condition	<input checked="" type="radio"/> Yes <input type="radio"/> No
Follow-up questions:	
• Describe your heart condition?/What is your heart condition?	
• Current problem or previous problem and now fully resolved?	
• If a current problem	
-Which doctor is following you for this condition?	
-When is your next follow-up visit?	
-What symptoms do you experience when your heart problem acts up?	
-How do you treat your problem if it's acting up?	
-How does your heart problem interfere with your daily activities/lifestyle?	
-Has the MD placed you on any restrictions owing to your heart problem?	
2. Has anyone in your immediate family (parents, sister[s], brother[s]) ever been treated for any of the following:	
Cancer	<input checked="" type="radio"/> Yes <input type="radio"/> No
Follow-up questions:	
• Who in your family has the history of cancer?	
• What type of cancer?	
• At what age were they diagnosed?	
• What is their current health status?	
• Does anyone else in your family have cancer?	

Fig. 6.5 Potential follow-up questions for affirmative answers on the self-administered questionnaire. (From W.G. Boissonault course notes, 1998 as published in Umphred, Lazaro, Roller, et al. *Umphred's Neurological Rehabilitation*. 6th ed. St. Louis, MO: Elsevier; 2013.)

patients who have neurological involvement and signs and symptoms (e.g., weakness, numbness) that are much more debilitating and cause more functional limitations than the pain complaints. Although investigating pain complaints may not be the initial priority for therapists, at a later visit such questioning is very important, especially if the pain continues, increases in intensity, shifts, or enlarges its region with no causation. Effective medical screening involves the interpretation of a patient's description of symptoms, functional limitations, and the corresponding physical examination findings. Descriptions of symptoms associated with neuromusculoskeletal impairments (loss or abnormality of physiological, psychological, or anatomical structure or function) generally reveal a fairly consistent and predictable pattern of onset and change over a defined period of time. In addition, the neurological and musculoskeletal impairments noted during the physical examination should match with the functional limitations described by the patient or the caregiver. If these expectations are not met, it does not necessarily mean the patient has cancer or an infection, but doubt should be raised on the therapist's part whether therapy is indicated.

Patients many times are not aware that presenting signs and symptoms suggest a condition better addressed by a physician as opposed to a PT or an occupational therapist (OT). For example, a 67-year-old male patient had a cerebrovascular accident 6 months ago with resultant mild residual left hemiplegia. At the time of discharge from rehabilitation services, he was independent in all activities of daily living, but residual left upper extremity weakness remained. When visiting his internist for a routine checkup, he complained that over the prior 3 weeks he had lost some functional skills and was having difficulty with self-care. The physician then referred the patient to the therapy clinic for evaluation and treatment. The patient states he has been less active and just needs some help regaining his motor function. During the patient interview he states that he is experiencing a deep, dull, aching sensation in the lower lumbar spine and right buttock. He assumes it has developed as a result of his inactivity and thus saw no reason to bother the physician with this problem. As the patient continues to describe his difficulties, he also notes a constant deep ache in the right shoulder that he relates to increased use of his right arm to compensate for the left arm weakness. The physical examination of the low back, pelvis, and right shoulder reveals that the existing symptoms do not vary with active or passive range of motion, resisted testing, or postural holding. In addition, quantity of motion is normal for these regions and motor programming appears intact. At this point the therapist cannot explain the symptoms from an impairment standpoint; therefore depending on other examination findings, including the patient profile and medical history, communication with the internist may be warranted.

Symptom Pattern

Aspects of the patient's chief complaint other than symptom location are very relevant to the process of differential diagnosis, in particular a description of how and when the symptoms changed over a defined period of time. Complaints of pain, paresthesia, and numbness associated with primary musculoskeletal conditions typically change in a consistent manner over a 24-hour period. The patient will report that the symptom intensity increases with the assumption of specific postures such as left side lying or sitting or with specific activities such as walking, driving, or 2 hours of computer work. Conversely, patients typically can relate paresthesia or pain relief with avoiding certain postures or activities, the assumption of certain postures, wearing an arm sling, and so on. Night pain investigation also falls under this subcategory of patient data. Pain that wakes an individual from sleep and for which changing positions in bed does not provide relief is more concerning than if the pain is positionally related. If the pattern of symptom aggravation and alleviation is that there is no consistent

pattern, such as pain that comes and goes independently of the patient's posture, activities, or time of day; night pain is the patient's most intense pain; or paresthesia or pain moves from one body region to another inconsistently with common pain referral patterns or identified medical conditions, then the therapist should consider if the patient is a candidate for physical or occupational therapy.

In general, when symptoms such as weakness or numbness associated with primary neurological conditions are investigated, the 24-hour reference point to assess symptom change is not realistic. Except for an acute onset or exacerbation, these symptoms tend not to fluctuate that quickly with change in posture or position. Understanding the pathogenesis of primary neurological disorders will allow for detection of symptom change unusual for the patient. This will lead to follow-up questions to determine whether this change may represent a medically serious condition. Similarly, a change in the biomechanical alignment of a joint (e.g., the shoulder) may immediately alter the patient's pain response, indicating a direct relationship between musculoskeletal imbalance in joint stabilization and gravitational pull, for which therapy would be appropriate.

History of Symptoms

The therapist must also scrutinize the patient's report of the onset of the symptoms. Pain and paresthesia or numbness associated with neuromusculoskeletal impairments typically can be related to trauma, either on a macro or a micro level, or to a medical event such as a cerebrovascular accident. More often than not it is repetitive overuse or cumulative trauma that leads to tissue breakdown and inflammation. Patients with neurological impairments resulting in postural abnormalities and abnormal movement patterns are at risk for such conditions. If a patient's symptoms are truly insidious, meaning not related to macro or micro trauma, or there has not been a significant change in activity level that reasonably accounts for the complaints, the therapist should again be concerned about the source of the symptoms. A worsening of symptoms such as numbness, weakness, spasticity, or swelling associated with an existing medical condition should be investigated by the therapist with the same scrutiny. The therapist always needs to ask, "Is there a reasonable explanation for the worsening?" An increase in the intensity of the complaints or the involvement of additional body regions could signal a progression of the disease.

Review of Systems

By design, *review of systems* screening allows the therapist to detect symptoms secondary (and potentially unrelated) to the reason therapy has been initiated.⁹ The review of systems allows for a general screening of body systems for symptoms suggesting the presence of an adverse drug reaction, occult disease, or worsening of an existing medical condition. Suspicions of any of these scenarios would warrant communication with a physician. A set of sample checklists of symptoms and signs for each body system that can be used by the PT during the patient interview can be found in [Box 6.2](#). To keep the checklists manageable in length, the therapist should investigate presenting complaints and symptoms and the patient's medical history before the review of systems. For example, on review of the cardiovascular and peripheral vascular systems associated with heart conditions, important items appear to be omitted, such as chest pain, claudication, a history of heart problems, hypertension, high cholesterol levels, and circulatory problems. If symptoms have already been investigated by use of a body diagram, the therapist would already know whether the patient has chest pain. If symptom change (aggravation or alleviation) over a 24-hour period has already been investigated, the therapist would know whether claudication is an issue. Finally, if the patient's medical history has already been discussed, the therapist would know whether heart problems, hypertension, or circulatory problems existed.¹⁰

All of the checklists in [Box 6.2](#) need not be used for every patient. The location of symptoms will direct the therapist in deciding which checklists should be included in the initial examination. [Fig. 6.6](#) and [Table 6.1](#) can be used to link pain location with visceral systems that could be the source of the complaints. [Table 6.2](#) provides a summary of potential pain locations and diseases of the pulmonary, cardiovascular, gastrointestinal, and urogenital systems. Other symptom characteristics can also alert the therapist to the possible involvement of the endocrine, nervous, and psychological systems. Symptoms, including pain and paresthesias that come and go irrespective of posture, activity, or time of day and that appear to move among the various body regions, can be associated with these systems as well as the visceral systems. In addition to the identification of the location and characteristics of symptoms, a patient's medical history will also help the therapist decide which systems to screen. A positive medical history, such as a heart problem, would direct the therapist to investigate the patient's condition, including possible use of the cardiovascular and peripheral vascular checklist as well as the questions listed in [Box 6.2](#). The therapist also needs to be aware of the medications taken by the patient to medically manage these pathological conditions. Similarly, therapists need to be able to analyze how the drugs potentially affect functional movements and functional loss. Often, that means a therapist must have a working professional relationship with a clinical pharmacist. Use of a general health checklist (see [Box 6.2](#)) can assist the therapist in prioritizing the inclusion of the checklists in the systems review checklists box during the initial visit. The symptoms noted in this checklist can be associated with disease of most of the body's systems, as well as with systemic disease and adverse drug events.

If the patient or caregiver (on the patient's behalf) replies "yes" to any *review of systems* question, the therapist must determine whether there is a reasonable explanation for the complaint, whether the physician is aware of the complaint, and, if so, whether the complaint has worsened since the patient last saw the physician. When the given explanation is not satisfactory, the physician is unaware of the

TABLE 6.2 Linking Pain Patterns and Visceral Systems

Pain Location	Visceral Systems
Right shoulder (including shoulder girdle)	Pulmonary Cardiovascular Gastrointestinal
Left shoulder (including shoulder girdle)	Cardiovascular Pulmonary
Upper thoracic or midthoracic spine	Cardiovascular Pulmonary Gastrointestinal
Lower thoracic and upper lumbar or midlumbar spine	Peripheral vascular Pulmonary Gastrointestinal Urogenital
Lumbopelvic region	Gastrointestinal Urogenital Peripheral vascular

complaint, or the symptom is worsening, communication with the physician is warranted. Similarly, most physicians look at direct causation: complaint to disease. Therapists need to look at system causation because we see the end result of the combinations of the problems: disease, maturation, environmental factors, and other nondisease causations. All the checklists do not need to be covered during the initial visit. If the patient says “no” for each of the general health items, the patient’s health history is uneventful, and the therapist is comfortable with the description of the chief complaints (including pattern and onset), then the therapist can proceed with the evaluation of specific impairments and functional limitations with some confidence that therapy interventions are very likely appropriate. The review of systems then takes a lower priority. The result is that the therapist could decide to delay the use of the appropriate systems review checklists until the patient’s second or third visit. If the patient answers “yes” to general health items and has an inconsistent pain pattern, the appropriate review of systems then takes a higher priority and should be covered during the initial visit.

Musculoskeletal System

Box 6.3 provides the checklist for the musculoskeletal system. The general health checklist also provides a level of screening for conditions of the musculoskeletal system, as with all other body systems. Infections, metastatic cancers, and rheumatic disorders (e.g., rheumatoid arthritis) are problems associated with this system. Identifying patient risk factors for these conditions is a key for recognizing when to be suspicious. For example, those at highest risk for musculoskeletal

BOX 6.3 Musculoskeletal System Screening

- Insidious onset of symptoms
- Atypical pain pattern (aggravating or alleviating factors)
- Night pain (progressive and/or nonpositional)
- Early morning stiffness lasting longer than 30 to 60 min
- Inadequate relief of symptoms with rest or rehabilitation
- Inability to alter symptoms during the physical examination
- Lack of impairments that match patient’s functional limitations
- Atypical physical examination findings (e.g., masses, unexplained atrophy, or weakness)

cancers are those (1) over the age of 50 years and under 20 years, (2) having a previous history of cancer (e.g., breast, lung, prostate, thyroid, and kidney—the most common cancers to metastasize to the axial skeleton), (3) having a positive family history of cancer, and (4) having had exposure to environmental toxins. Those individuals at highest risk for musculoskeletal infections report or demonstrate (1) current or recent infection (e.g., urinary tract, tooth abscess, skin infection), (2) history of diabetes with use of large doses of steroids or immunosuppressive drugs, (3) elderly age, and (4) spinal cord injury (SCI) with complete motor and sensory loss.¹¹ Last, the primary risk factors for rheumatoid arthritis include (1) female sex, (2) age (peak 30 to 40 years, and (3) positive family history.¹²

The other category of musculoskeletal conditions for which therapists need to be vigilant is fractures. The pain and deformity associated with most sudden-impact, traumatic fractures make for an obvious presentation. However, trauma sufficient to cause a fracture may not be so obvious in a patient with decreased bone density. Lifting a gallon of milk, experiencing a mild slip or bump, or trying to open a window that is stuck may be sufficient to cause a fracture in a patient with a history of chronic renal failure, multiple sclerosis, rheumatoid arthritis, hyperparathyroidism, gastrointestinal malabsorption syndrome, and long-term corticosteroid, heparin, anticonvulsant, and cytotoxic medication use. The most common locations for such fractures include vertebral bodies, the neck of the femur, and the radius. Observation of posture and body position may provide a clue that something may have changed structurally. For example, with vertebral compression fractures the thoracic kyphotic curve may be accentuated, accompanied by a very pronounced apex of the curve that was not present before. With femoral neck fracture the lower extremity is often positioned in external rotation and appears shortened compared with its counterpart.¹³

Causing potential confusion for the clinician are diseases (especially in the early stages) of the musculoskeletal system, which may mimic mechanical musculoskeletal conditions. The patient may report a specific event or time of onset of symptoms, and a pain pattern of increasing pain with weight bearing on the involved extremity over time and lessening relief of pain with assumption of non-weight-bearing positions—all typical findings with impairment-driven symptoms. The therapist may also be able to provoke symptoms during the physical examination as the involved bony area is mechanically loaded. When the history and physical examination findings are evaluated, an unusual finding or pattern will emerge, or the patient will not respond to treatment as expected, making the therapist step back and consider alternative hypotheses regarding the origin of patient symptoms, especially if the risk factors listed earlier are present.

Integumentary System

Screening of the integumentary system is not typically based on the presence or absence of pain, paresthesia, or numbness. As with the nervous system, some degree of screening of the integumentary system occurs with every patient regardless of the presenting diagnosis. Skin cancer has the highest incidence of all the cancers,¹⁴ and therapists generally see a number of exposed body areas during the postural

BOX 6.4 Skin Lesion Screening—Pathological Characteristics

- Multivariant color
- Black or blue-black color
- Irregular borders
- Nondistinct (“fuzzy”) borders
- Size: 6 mm or larger in diameter
- Asymmetrical shape
- Friable tissue
- Ulcerations
- Evolving (changing size, shape, color)

assessment and regional examination that make up the physical examination. In fact, as noted in Fig. 6.4, screening the skin begins during the patient interview. During the interview the therapist can be looking at areas of exposed skin such as the face, neck, arms, and feet. As with screening of the other body systems, the therapist’s goal is not to identify a melanoma or differentiate squamous cell and basal cell carcinoma but simply to identify skin lesions with atypical presentations. Once the patient has been referred to the physician, disease will be ruled out or diagnosed. Box 6.4 can be used to assess any mole or other skin marking. The items noted are atypical for a benign lesion, more suggestive of a pathological condition.¹⁵ Selected items from Box 6.4 have been highlighted, resulting in an acronym—*A* (asymmetry), *B* (borders), *C* (color), *D* (diameter), and *E* (evolving)—that has been used to educate the public for self-screening.¹⁶ If the therapist notes any of these findings and the patient reports a recent change in the size, color, or shape of the lesion, and that a physician has not looked at the lesion, a referral would be warranted.

Besides skin lesions, abnormal general skin color can be a manifestation of a number of conditions. Table 6.3 summarizes abnormal skin color changes. Occasionally, some of the most obvious abnormalities are the most difficult to note when one is so focused on items more directly related to therapeutic intervention.

Nervous System

As with the integumentary system, the nervous system is screened to a degree for all patients. The systems review provides a very gross, general screening of the nervous system. The therapist should be vigilant for the presence of any of these items in all patients during the initial and subsequent visits. For patients with preexisting findings from this checklist, the therapist must be vigilant for a worsening of the observed abnormalities. Covering the items in the nervous system checklist should add little time to the therapist’s initial examination. Assessing for facial asymmetries and tremors can take place during the interview. Observation of balance, movement patterns, and muscle atrophy can occur while watching the patient ambulate into the examination area, during the interview, and as the patient changes positions during the physical examination. Last, impaired mentation may become apparent during the interview or the physical examination as the patient struggles to appropriately answer questions or follow directions. Case Studies 6.1 and 6.2 illustrate the importance of this general screening.

CASE STUDY 6.1

A 55-year-old elementary school teacher was referred with a diagnosis of C5 to C6 and C6 to C7 degenerative disk disease. Her chief complaint was pain in the posterior cervical region and reports of neck weakness. Functionally, the patient’s primary concern was her increasingly difficult time making it through her workday. She taught first-grade students, so much of her workday was spent with her neck and trunk in a forward flexed position. The patient

believed that this persistent flexion posturing was a significant factor for the worsening of her symptoms as her workday progressed. As the patient interview continued, the physical therapist observed tremor of the patient’s right hand and forearm. When questioned about the observed tremor, the patient stated it started about 4 months ago. When further questioned, she admitted the tremor appeared to be getting worse, but since it did not interfere with her

Continued

CASE STUDY 6.1—cont'd

activities, she did not mention it to her physician. No other significant neurological findings were noted. After the initial examination was completed, the therapist collaborated with the patient to develop goals and a plan of care related to the complaints of neck pain and weakness. The therapist also discussed his concern about the tremor and requested permission from the patient to call the patient's primary care physician (who is also the referring physician) so he can communicate his finding of resting tremor. The physician facilitated a referral of the patient to a neurologist who diagnosed the patient with Parkinson disease. In this example, differential diagnosis

revealed the presence of a new symptom (tremor of the right hand) that was not consistent with the medical diagnosis of degenerative disk disease. This symptom triggered the decision by the therapist to continue with physical therapy management and refer the patient back to the physician for that specific clinical sign, which led to the additional diagnosis of Parkinson disease. The patient was medically managed with medications for Parkinson disease, and she was also referred to physical therapy for further examination and management of impairments, activity limitations, and participation restrictions related to Parkinson disease.

CASE STUDY 6.2 Written by Brian Moore, PT, DPT, NCS

The patient was a 57-year-old Hispanic male who was referred to physical therapy for an episode of low back pain that occurred two weeks ago. He worked as an auto body technician but had not returned to work at the time of initial evaluation. Past medical history included recurrent episodes of low back pain and controlled hypertension and hypercholesterolemia. During the initial interview the patient reported two falls that occurred in the last 3 months due to tripping, once while walking across a parking lot and the other during a walk with his wife. He reported weakness in the right lower extremity and muscle twitching in the right lower extremity.

Pertinent physical therapy examination findings included the following:

Normal strength and range of motion in the upper extremities

Pain on palpation in the paraspinal muscles

Deep tendon reflexes were present and symmetrical except for the Achilles tendon reflexes, which were exaggerated and symmetrical

The therapist concluded that the clinical findings were consistent for a symptom modulation rehabilitation approach to address recurrent back pain with the patient presenting with a directional preference into extension. Following 8 weeks of treatment to improve movement control and optimize function, the patient's report of low back pain had resolved. However, the patient reported worsening weakness in the right leg, with weakness in the left lower extremity in addition to symptom complaints of cramps and stiffness in bilateral lower extremities. Due to the worsening in functional status, the patient was referred back to the patient's primary care physician. The patient was then referred to a neurologist due to the clear neurological signs of bilateral lower extremity weakness.

The patient presented to the neurologist 2 months following the end of the episode of care with the physical therapist. He was no longer able to rise from a chair to stand without assistance and required assistance from his wife to maintain his balance while walking. The patient was diagnosed with amyotrophic lateral sclerosis (ALS), given the presence of upper motor neuron (UMN) and lower motor neuron (LMN) signs found on physical examination and electrodiagnostic testing. Results of the neurological examination, laboratory, and imaging findings were important to exclude other motor neuron disorders that mimic the presentation of ALS, including progressive demyelinating disorders of the peripheral nervous system (chronic inflammatory demyelinating polyneuropathy) and central nervous system (multiple sclerosis) in addition to paraneoplastic syndrome, cervical myelopathy, Lyme disease, human immunodeficiency virus, and syringomyelia. Individuals with neuromuscular disorders may go years living with a progressive disorder in a pre-symptomatic phase prior to symptoms emerging such as tripping while walking or slurring of speech (i.e., dysarthria). Following the emergence of initial symptoms there is a worsening of the presentation that may manifest as weakness in the lower extremities or slurred speech. Such symptoms progress over the course of months to years. Depending on the speed of the progression and presence of clear neurological signs, individuals may go 4 to 16 months before referral to a neurologist.¹⁷ In this case the physical therapist decided to continue treatment then referred the patient to a physician because of worsening symptoms that do not seem to be consistent with the initial diagnosis of low back pain.

TABLE 6.3 Abnormal Color Changes of the Skin

Color Change	Physiological Change	Common Causes
White, pale (pallor)	Absence of pigment or pigment changes Blood abnormality Temporary interruption or diversion of blood flow Internal disease	Albinism, lack of sunlight Anemia, lead poisoning Vasospasm, syncope, stress, internal bleeding Chronic gastrointestinal disease, cancer, parasitic disease, tuberculosis
Blue (cyanosis)	Decreased oxygen in blood (deoxyhemoglobin)	Methemoglobinemia (oxidation of hemoglobin), high blood iron level, cold exposure, vasomotor instability, cerebrospinal disease
Yellow	Jaundice, excess bilirubin in blood, excess bile High levels of carotene in blood (carotenemia)	Liver disease, gallstone blockage of bile duct, hepatitis pigment (conjunctivae are also yellow) Ingestion of food high in carotene and vitamin A
Gray	High level of metals in body	Increased iron, bronze-gray; increased silver, blue-gray
Brown (hyperpigmentation)	Disturbances of adrenocortical hormones	Adrenal pituitary Addison disease

BOX 6.5 Depression Screen

Depressed or irritable mood
 Psychomotor agitation or retardation
 Apathy
 Sleep disturbance
 Weight gain or loss
 Fatigue
 Feelings of worthlessness
 Impaired concentration
 Suicidal ideation (recurrent)
 Recent loss of family member

Depression. Depression is a commonly encountered mental health disorder.^{7,18–20} The systems review checklists in **Box 6.5** contain items the therapist can use to help make the decision to refer a patient for consultation. For the first eight items on the depression checklist, concern should be raised when the therapist detects four or five of the items present daily for a minimum of 2 weeks and resulting in the patient having difficulty functioning at home, work, or school, socially, or in rehabilitation. Of the four or five items, one of them should be depressed or irritable affect or apathy. An exception to the 2-week time frame is during periods of bereavement. When people are faced with a significant loss, it is not uncommon for them to experience a number of the checklist items as they work through the grieving process.⁷ It is reasonable for these people to experience these symptoms for up to 2 months. A neurological event such as a cerebrovascular accident could easily trigger a major clinical depressive disorder, and the depression could significantly impede rehabilitation progress. The therapist may be in a position to facilitate a psychological consultation.

Clinicians must screen the general adult population for depression. The two-item (PHQ-2) and nine-item Patient Health Questionnaires (PHQ-9) are validated tools for depression screening. According to recommendations by the US Preventive Services Task Force (USPSTF) and American Academy of Family Physicians, the PHQ-9 or a clinical interview must be performed if PHQ-2 was found to be positive for depression.²¹

Suicide. Considering that approximately 15% of people with true major clinical depression commit suicide,⁷ therapists need to be vigilant for warning signs that the patient may be considering this action. See the suicide screening shown in **Box 6.6** for a list of warning signs. Once the patient acknowledges suicidal ideation, follow-up questions would be appropriate to investigate the patient's plan and how readily available the resources are regarding the reported method of attempt. This is all-important information to be reported when the therapist contacts the physician. Therapists should be very familiar with their facility's "suicide protocol or procedure" in terms of what information should be collected from the patient and who should be contacted.

BOX 6.6 Suicide Warning Signs

History of major clinical depression, chemical dependency, schizophrenia, or previous suicide attempt
 Expressions of hopelessness
 The sense that the patient is "giving up"
 An abrupt improvement in patient mood

PHYSICAL EXAMINATION

In addition to this discussion of observation screening for the integumentary and nervous systems, other screening principles are associated with the physical examination. The therapist should have expectations of physical examination findings based on the existing medical diagnosis and data from the history. There should be a correlation between the described activity limitations and the noted impairments. A patient's complaint of right shoulder pain would be expected to increase or decrease in intensity with palpation, movement assessment, or special tests. The inability to alter a patient's complaints and the lack of neuromusculoskeletal impairments one would expect with a particular medical diagnosis should raise concern about the source of the symptoms.

The *Guide to Physical Therapy Practice* describes the systems review, in part, as a brief or limited examination of the anatomical and physiological status of the cardiovascular and pulmonary, integumentary, musculoskeletal, and neuromuscular systems, as well as the assessment of communication, learning, and affect. For the purposes of this chapter the discussion will focus on assessment of height and weight and assessing heart rate and blood pressure. Being overweight or obese can significantly increase the risk of development of a number of serious conditions. Using patient height and weight to calculate body mass index (BMI) can be a valuable measure to identify patients who may need a dietary consultation to prevent disease states or minimize morbidity associated with current illnesses.

Resting blood pressure and pulse rate and rhythm are also important values to be routinely measured. A 30-second monitoring period after a 2- to 5-minute rest period is recommended to obtain baseline rate values.²² Resting blood pressure values can also provide important screening information. As with assessing pulse rate, resting blood pressure should be assessed after a 5-minute rest period. Variations from the normative values may lead therapists to additional assessment of the vascular system and the central autonomic nervous system and then to a patient referral.

Examination Summary

For many patients a single red flag finding does not warrant a referral, but a cluster of history and physical examination findings does increase disease probability to the point where a referral is indicated. Two examples that are germane to a number of individuals with neurological conditions are deep vein thrombosis (DVT) and pulmonary embolus (PE). DVT affects approximately 2 million individuals in the United States annually, making it the third most common cardiovascular disease.^{12,23} Approximately 50% of those with a DVT are asymptomatic in early stages. Clinicians are challenged to identify patients at greater risk for this condition who do not have the obvious signs and symptoms of calf pain, swelling, and redness. The revised Wells Clinical Decision Rule (CRD) determines whether the patient is "likely" or "not likely" have DVT, and is recommended in outpatient settings (**Table 6.4**). It should be noted that there is an increased risk of DVT in the population of patients with SCI because of hypercoagulability, changes in the epithelial structure of the blood vessels, and decreased blood circulation.²⁴

Similarly for PE, a clinical decision rule exists for screening (**Table 6.5**). PE is associated with high morbidity and mortality, highlighting the critical nature of timely detection. Hull describes PE as one of the "great masqueraders" of medicine because of the often nonspecific presenting symptoms and signs.²⁵ Wells and colleagues estimate that 50% of PEs go undiagnosed.²⁶

Clinician concern regarding the possibility of a DVT and/or a PE being present would warrant urgent communication with the patient's physician.

TABLE 6.4 Revised Wells Clinical Decision Rule for Deep Vein Thrombosis

Clinical Presentation	Score
Previously diagnosed DVT	1
Active cancer (within 6 months of diagnosis or receiving palliative care)	1
Paralysis, paresis, or recent immobilization of lower extremity	1
Bedridden for >3 days or major surgery within the previous 12 weeks	1
Localized tenderness in the center of the posterior calf, the popliteal space, or along the femoral vein in the anterior thigh/groin	1
Entire lower extremity swelling	1
Unilateral calf swelling (>3 cm larger than uninvolved side)	1
Unilateral pitting edema	1
Collateral superficial veins (nonvaricose)	1
An alternative diagnosis is as likely (or more likely) than DVT (e.g., cellulitis, postoperative swelling, calf strain)	-2
Total points	
Key: ≥ 2 : DVT likely; < 2 : DVT unlikely.	
Medical consultation is advised in the presence of low probability and medical consultation is required with moderate or high score	

DVT, Deep vein thrombosis.

RESPONSE TO TREATMENT

Frequently the therapist will decide referral of the patient to a physician is not warranted and will proceed to determine whether physical therapy is warranted or no intervention recommended. As treatment is initiated and progresses, the therapist must remain vigilant for the appearance of symptoms and signs discussed throughout this chapter. In addition, correlating subjective and objective changes as treatment progresses will help the therapist decide whether further intervention is warranted or whether referral back to the physician or other health care practitioner is appropriate. For example, if a patient reports a significant improvement or worsening, one would expect the therapist to note a corresponding change in posture, movement ability, palpatory findings, or neurological status. If the expected correlation between patient report and physical examination findings is not found, the therapist should begin considering that therapy may not be warranted. A careful review of systems and symptom investigation is necessary.

CONCLUSION

If all diseases manifested with a high fever, coughing up blood, and blood in the urine, the medical screening process would be a simple one. Unfortunately, many diseases initially manifest with subtle complaints, intermittent symptoms or mild pain, stiffness, subtle weakness or paresthesias, or acute dementia. If these complaints are brought to a physician's attention by the patient, they often are not severe enough to warrant extensive diagnostic testing. Many patients or family members simply ignore symptoms or physiological changes, rationalizing that everything is okay, the family member is just old, or he or she simply does not like to see physicians or is too busy. All of the scenarios can account for patients with occult disease seeing therapists. The fact that PTs and OTs tend to spend a moderate amount of time with patients over a period of weeks or months can facilitate the detection of subtle manifestations. In addition, as therapists develop rapport with patients and family members, information may be shared that they were uncomfortable disclosing initially. Always remember that acute dementia is never normal and is reflective of an acute problem rather than simply of aging.

The responsibilities of the PT and OT related to screening for symptoms and signs that indicate the involvement of another health care practitioner are clearly stated in the *Guide to Physical Therapy Practice*. The process associated with differential diagnosis allows for the appropriate medical screening yet keeps therapists within their scope of practice. The therapist simply communicates to the physician the list of clinical findings. The physician will determine whether new or additional medical tests are needed to rule out or diagnose specific diseases. Facilitating the timely referral of patients to physicians is an important role for therapists working within a collaborative medical model. It is this model that best serves the needs of our patients. For additional information related to the medical screening process, the readers are directed to the *Goodman's Differential Diagnosis* 6th edition textbook (Elsevier) and several other texts available in the market.

With changes in health care delivery and physicians also being asked to see more patients in less time, it is critical that all health care practitioners include an adequate medical screening component to their examinations. If quality-of-life issues are truly an important component of health care delivery, then medical screening will continue to be a professional expectation and responsibility placed on each PT and OT. Because consumers are accessing therapeutic services through more direct means, that responsibility will remain and grow

in importance as part of both professions' education and practice. Over the next few years the roles of PTs and OTs will continue to evolve in the arena of primary care. Medical screening performed by the therapist will guide patients to a physician and could become a key component of maintaining the health and quality of life of that consumer.

In the future another choice will have to be considered as part of the role of a movement specialist. The results of differential diagnosis assessments may determine that neither a medical referral nor therapeutic intervention itself is appropriate. In this situation, the patient might benefit from community activities but would not need a movement specialist, especially if the physician also has determined that medical intervention is not necessary.

ACKNOWLEDGMENT

The chapter authors would like to thank Dr. William Boissannault and Dr. Darcy Umphred for their excellent work in developing this chapter

in the fifth and sixth editions of the text. Their work was particularly important at that time, when physical therapists were defining their roles related to diagnosis by a physical therapist, differential diagnosis and screening for possible medical conditions.

REFERENCES

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 26 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Abstract: This chapter introduces the reader to the concept of differential diagnosis of the patient with a neurological condition. After reading the chapter, the reader should be able to distinguish between differential diagnosis for medical screening, and differential diagnosis of impairments, activity limitations, and participation restrictions. The reader will be able to analyze the concept of system and subsystem

screening to be used with patients with known or unknown preexisting neurological dysfunction. This chapter emphasizes the importance of performing a medical screening for all patients who interact in a therapeutic environment with occupational or physical therapists.

Keywords: medical screening, patient referral, review of systems, differential diagnosis

Examination and Evaluation of Functional Movement Activities, Body Functions and Structures, and Participation*

Deborah S. Diaz

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Differentiate the medical diagnosis made by the physician from the diagnosis made by a movement specialist.
2. Identify the differences among activity limitations, participation restrictions, and impairments in specific body structure and function.
3. Choose appropriate examination tool(s) from each category of the International Classification of Functioning, Disability and Health model.
4. Identify resources used to analyze the usefulness and psychometric properties of outcome measures
5. Evaluate the results of the examination to establish a physical therapy diagnosis that drives intervention planning.

KEY TERMS

activity limitations
evaluation
examination

impairments
participation restrictions

INTRODUCTION

People who experience neurological disease or dysfunction are often cared for by therapists (physical therapists [PTs] and occupational therapists [OTs]) who are experts in the assessment of and treatment of movement disorders. Movement therapists' (PT and OT) role in working with patients with neurological dysfunction is to address the impact of the condition on the patient's functional status and ability to engage in society. The neurological examination is a process used by therapists to determine the implications of a neurological condition on patients' ability to perform important functional activities. The results gleaned from a neurological examination inform therapists about the movement diagnosis, prognosis, long-term and short-term goals, and plan of care. The neurological exam is performed in part or whole throughout the episode of care to document patient progress and stimulate changes in the plan of care.

Whether the neurological condition is recent/acute or long-standing/chronic, movement therapists must first screen their patients on two levels. First, a medical screening exam is important to answer the question, "is my patient sufficiently medically stable that it is safe to proceed with the examination?" If the therapist notes "red flags," meaning the patient's medical condition is unstable and requires immediate and, in some cases, emergent care, treatment from a physician or other health care provider is warranted. When the patient is deemed medically stable, movement therapists must determine appropriateness for therapy and ask, "Am I the appropriate professional to address this patient's limitations in light of his/her goals and preferences?" If the answer to this question is "no," the movement therapists must refer the patient to the appropriate professional for the most suitable care.¹

When the patient is deemed both medically stable and appropriate for therapy, the neurological examination commences. Ideally, the neurological examination begins with a review of the medical record, which can inform the therapist about the following: (1) onset and cause of the condition, (2) comorbid conditions, (3) social context (meaning family and work responsibilities), (4) home environment, (5) avocations, and (6) patient age. This information should help the therapist to formulate questions for the subsequent patient interview and plan the objective evaluation.

A framework for clinical decision making regarding comprehensive examination in the movement therapies is the International Classification of Function developed by the World Health Organization (see Chapter 1). There are numerous tools available to measure the impact of neurological conditions at each of the levels of the International Classification of Functioning, Disability and Health (ICF), Body Function and Structure Impairments, Activity Limitations and Participation Restrictions. All tests and measures of each of these levels must be rigorously tested for their psychometric or clinometric properties (validity, reliability, sensitivity, specificity, etc.). Throughout the neurological examination, movement therapists should frame the data they plan to gather and the results they find into the levels of the ICF.

Therapists can use several tools to assess patient status after neurological damage. Multiple body function and structure impairments may contribute to an impaired ability to perform functional activities. Therapists select measurement tools that address specific sensory, motor, or cognitive systems which contribute to activity performance.

Activity measures specifically assess patient functional performance of activities of daily living objectively. These tools typically rate

*Videos for this chapter are available at studentconsult.com.

performance on an ordinal or interval scale, which provides the opportunity to measure progress or decline. Although the change in score on a performance measure is objective and reflects decline or improvement in function, it is not possible, simply from the score, to know the cause of this change. The clinician must hypothesize the most likely cause at the body function and structure level and specifically examine the impairment to confirm or deny the hypothesis. In many cases a combination of body function and structure impairments contribute to scores on activity performance measures.

A third category of assessment addresses participation outcome measures (OMs) that are designed to assess a client's involvement or restriction in domestic, community, social, and civic life situations. Most often these measures address the client's perspectives regarding the impact of the neurological condition upon quality of life, interpersonal interactions, and quality of involvement in domestic, community, social, and civic life situations.

To evaluate the results of the neurological examination at the body function and structure, activity and participation levels must be synthesized by the therapist to proceed to the meaningful next steps. Therapists must critically evaluate the results to establish the client's diagnosis, prognosis, and plan of care while considering the individuals' goals and preferences.² In addition, the neurological examination is an ongoing, repetitive process throughout the episode of care. The therapist must constantly assess the patients' health status to identify evidence of recovery or decline. As the patient recovers the ability to perform more complex movement activities, therapists must consider further assessment at the body function and structure level, as well as the activity level. It may be that changes at the body function and structure level contribute to improved function and interventions should change to reflect this improvement.

In addition, improvement in activities may require a different measurement tool because the patient's recovery goes beyond the capability of the measure to document change. In other words, the assessment tool may have a ceiling effect to which the patient outperforms. In all cases, the rigor and intensity of therapy interventions must morph to require continual and significant effort on the patient's part.

History and Systems Review

The first encounter with a patient begins with a history of the present illness in which the patient reports the experience surrounding the onset and sequelae of the condition. During the interview, the therapist gathers information including the patient's perspective on the onset and course of the current condition, comorbid conditions, social context, meaning family and occupation responsibilities, home environment, avocations, and age. The therapist attends to information that is different from or in addition to the medical record. It is imperative that the therapist fully understands as a result of this subjective assessment, the patient's primary concerns, goals, and priorities for this episode of care.²⁻⁴

During the interview, while the therapist listens attentively, she or he also observes how the patient moves and interacts. Important physical details to note include, eye contact, facial symmetry, posture, and movement of the extremities and trunk. In addition, to screen for impairments in cognition, speech production, perception, and aphasia, the therapist should attend to the patient's clarity and coherence of speech and whether the patient attends to all parts of the environment.

Upon concluding the history and review of systems, the therapist notes the important objective tests and measures to gather next. The therapist should, based on the patient's stated goals and priorities, identify both functional activities to assess and the body function and structure impairments that likely contribute to movement dysfunction. The therapist should have a plan for completing this part of the neurological examination in the most efficient yet thorough manner.

Tests and Measures

Ideally, this phase of the examination begins with the observation of functional activity that reflects the patient's stated goals. During movement analysis of these functional activities, the therapist notes the qualities of movement that vary from neurotypical movement without neurological pathology. Although visual observation is important, it is vital that the examiner use assessment tools that are objectified and quantifiable to track change over time. Please refer to the section on "Choosing the best appropriate examination tool," found later in this chapter, for several lists of relevant tests and measures used in physical therapy practices.

TESTS OF ACTIVITY AND FUNCTIONAL PERFORMANCE

Measures at the activity level quantify patient functional status ranging from balance skills to walking ability and other tasks important to everyday function. Tests of skills at the activity level may range from a single item that documents a narrow set of skills to multidimensional tests used to discern the elements of an activity that are most problematic and require skilled therapeutic interventions. Those activity measures that include a single or small set of skills may be used to assess client ability generally. These tests are quick and easy to perform and can screen out those who do not require in-depth study and screen in those with more significant involvement. At the other end of the Activity assessment spectrum are multiple item tests. These multiple item tests are more time consuming but test more skills that might be overlooked when using shorter assessments. One way to consider these is that a short tool can screen for general problems, whereas the multiple-item tests provide information in more detail and can be used as a follow-up to the short, single-item tests. For example, the Timed Up and Go (TUG) test is an excellent measure that predicts risk for falls in many populations. People who score below a "cut-score" on the TUG test are at higher risk for falling. But which dimension(s) of balance should a therapist devote time and attention to minimize the fall risk? One might consider follow-up testing using a multidimensional balance assessment like the Berg Balance Scale, the Fullerton Advanced Balance Scale, or the Mini-Best Test. From these multi-item tests, a clinician can deduce which elements of balance that the client needs to work on the most.

Outcome scales for functional tests may be found in ordinal format (e.g., Functional Independence Measure [FIM], Barthel Index, Katz Index of Independence in Activities of Daily Living). Each has its unique point value and range, varying from a two- to three-point scale (e.g., Tinetti Performance-Oriented Mobility Assessment [POMA]) to a seven-point scale (e.g., FIM). A few tools supply ratio scale data (e.g., the TUG test, Functional Reach Test, and measures of gait velocity). Test data presented in ratio scale format will more clearly show incremental changes, thereby facilitating the comparison of pretherapy to posttherapy performance.

TESTS OF BODY FUNCTIONS AND STRUCTURES

After identifying problems with the performance of functional activities, the clinician then focuses on body functions and structures that likely contribute to difficulty in daily activities. Consistent with the ICF model, the intent is to identify which body systems or subsystems are intact and functioning normally and those systems that could be optimized as the patient works to maximize functional tasks and participate in life. Identifying which body systems and subsystems that are not normal may lead the clinician to surmise the likely cause of the functional loss.

Impairment is defined as the loss or abnormality of physiological, psychological, or anatomical structure or function at the organ system level.⁵ The clinician must distinguish between primary impairments and secondary impairments. Primary impairments are a direct consequence of the client's specific disease or pathological condition. Secondary impairments are changes in the structure and function of body systems that could have many causes. Secondary impairments may result from unaddressed primary impairments after the onset of the neurological condition, modified movement patterns after onset resulting in stress or compromise to a body structure or function, normal aging, disuse, repetitive strain, lifestyle, and many more. Secondary impairments may be premorbid. In this case an impairment that did not interfere with activities and skills prior to onset may now interfere with moving adaptively after onset. For instance, someone with a C6 spinal cord injury must have full elbow extension and significant shoulder external rotation to passively lock the elbows for transfers and prop sitting. Prior to the injury, a slight elbow flexion contracture may go undetected, but afterward, the consequences are dire, prohibiting the individual from transferring independently.

Moreover, the clinician must remember that, although functional limitations are usually caused by a combination of specific impairments, it is possible that impairments may not contribute to specific functional problems for some clients. If this is the case, the clinician should decide whether these impairments, if left uncorrected, will result in the development of activity limitations or other complications later. Simultaneously, the patient must be a part of this discussion to prioritize which impairments to address given the patient's goals.

The ultimate goal of any therapeutic intervention program is to maximize the client's health and wellness. Measuring progress toward these goals is critical.

Clinicians are challenged with selecting and administering examination tools that reflect the patient's health, wellness, and response to therapeutic interventions. Examination tools that assess activity limitations typically require a lot of change to be clinically significant. Clinicians should document baseline performance of the functional activity and repeat the performance assessment at regular intervals. However, during rehabilitation programs, therapists address patients' activity limitations and impairments of body systems that contribute to functional problems. It is reasonable to expect short-term improvement in impairments prior to small change in functional tasks and activities.

Box 7.1 illustrates impairments that may be seen in patients/clients with movement disorders caused by neurological dysfunctions. These impairments are further classified as those that are within the central nervous system and those that are outside the central nervous system and result from interaction with the environment. These impairments are further discussed in detail in various sections of this book.

Range-of-motion (ROM) testing is one example of a common neuromusculoskeletal system examination procedure. Clinicians depend heavily on ROM measurements as an essential component of their examination and consequent evaluation process. It is imperative that the data obtained from this procedure be reliable. It has been suggested that the main source of variation in the performance of ROM testing is the method used. Standardizing methods and procedures will improve the reliability of the data gathered.⁶

An impairment in ROM can be the result of other body system impairments. ROM measurements may be used to determine the effect of tone, balance, movement synergies, pain, and so forth on the neuromuscular system and ultimately on behavior. Most important, the clinician needs to remember that the ROM needed to perform a functional activity is more critical than "normal," anatomical, biomechanical ROM values and must be considered when labeling and

BOX 7.1 Identification and Classification of Impairments

Impairments Within the Central Nervous System

1. Tone and reflexes
2. Synergies (volitional or reflexive)
3. Sensory integration and organization
4. Balance and postural control
5. Speed of movement
6. Timing
7. Reciprocal movement
8. Directional control, trajectory, or pattern of movement
9. Accuracy
10. Emotional influences
11. Perception
12. Cognition, memory, and ability to learn
13. Levels of consciousness

Impairments Outside of the Central Nervous System and Interaction With the Environment

1. Range of motion
2. Muscle strength or power production
3. Endurance
4. Cardiac function
5. Circulatory function
6. Respiratory function
7. Other organ system interactions
8. Hormonal and nutritional factors
9. Psychosocial factors

measuring impairments. For example, full ROM in the shoulder is seldom needed unless activities of daily living, work, or leisure activities require it, such as performing a tennis serve or reaching overhead to paint a ceiling. When needed for specific tasks, goniometric measurements of ROM are appropriate, but at other times a functional range measurement may be sufficient.

Muscle strength testing is another commonly used examination procedure. Clinicians use various methods of quantifying strength including "traditional" manual muscle testing (MMT) and the use of a dynamometer. As with ROM, strength should be correlated with the patient's functional performance. Again, the clinician may find a client to have $\frac{3}{5}$ strength in the shoulder flexor muscle groups or find grip strength to be 35 kg, but the more important question should be "What does this mean in terms of the client's ability to perform activities of daily living, and/or can he use that power in a functional activity?" The clinician is also advised to make the distinction between muscle strength and muscular endurance as it relates to function. A client may have sufficient lower-extremity strength and power to get up from the seated position; however, this does not necessarily mean that the client has muscular endurance to perform the task repeatedly during the day as part of normal everyday activities.

The status of the cardiac, respiratory, and circulatory systems significantly affects a client's functional performance. Blood pressure, heart rate, and respiration give the clinician signs of the patient's medical stability and the ability to tolerate exercise. The clinician may also obtain the results of pulmonary function tests for ventilation, pulmonary mechanics, lung diffusion capacity, or blood gas analysis after determining that the client's pulmonary system is a major factor affecting medical stability and functional progress. Various exercise tolerance tests also attempt to quantify functional work capacity and serve as a guide for the clinician performing cardiac and pulmonary rehabilitation.

A client who has difficulty performing activities of daily living and who has neurological impairments in the central motor, sensory, perceptual, or integrative systems needs to undergo examination procedures to establish the level of impairment of each involved system and to determine if and how that system is contributing to the deficit motor behaviors. Functional evaluation tools used may include the FIM, the Barthel Index, the Tinetti POMA, or the TUG test. The results of these tests will help to steer the clinician toward the most useful impairment tools to use to evaluate limitations in the various body systems. Impairment tools may include the Modified Ashworth Scale for spasticity, the Upright Motor Control Test for lower-extremity motor control, the Clinical Test of Sensory Interaction on Balance (CTSIB), or the Sensory Organization Test (SOT) for balance and sensory integrative problems, or computerized tests of limits of stability on the SMART EquiTest, among others.

The clinician is also advised to investigate the interaction of other organs and systems as they relate to the patient's functional limitations. For example, electrolyte imbalance, hormonal disorders, or adverse drug reactions may explain impairments and activity limitations noted in other interacting systems.

TESTS FOR PARTICIPATION AND SELF-EFFICACY

In ICF terminology, *participation* is defined as an individual's involvement in a life situation. Domestic life, interpersonal interactions and relationships, and community, social, and civic life are some examples of aspects of participation that can be examined for each individual. *Participation restriction* is the term used to denote problems that individuals may experience in involvement in life situations. When considering participation, it is important to obtain the individual's perception of how the medical condition, impairments, and activity limitations affect his or her involvement in life and community. Therefore many of the tests for participation and self-efficacy are in self-report format. The Activities-specific Balance Confidence (ABC) Scale, Short Form 36 (SF-36), and Dizziness Handicap Inventory (DHI) are examples of tests that can be used to gather information under this domain. These tests allow an individual to assess his or her health quality of life after an incident that affected activity and participation.

CHOOSING THE APPROPRIATE EXAMINATION TOOL

Selecting appropriate OMs is key in clinical decision making, documenting patient change over time and in response to interventions, justifying payment for skilled therapy, and communicating with the health care team, including the patient. Deciding which OMs to use can be a daunting task. One repository of OMs in rehabilitation is the Rehabilitation Measures Database found at the Shirley Ryan Ability Lab (<https://www.sralab.org/rehabilitation-measures>). A brief search of this database using the term "neurologic physical therapy outcome measures" returned more than 400 assessments. This large amount is clearly overwhelming for clinicians looking for assessments for their patients. Some mechanism for organizing outcomes must be used to make wise selections. One useful organizing tool is the aforementioned ICF model in which the clinician can choose measures based on whether they assess limitations in Body Structure and Function, Activity, or Participation. However, categorizing more than 400 measures into these categories is still daunting. In 2006 the American Physical Therapy Association (APTA) in partnership with the Research Section of the APTA formed the Evaluation Database to Guide Effectiveness (EDGE) Task Force in an attempt to standardize OMs and distill them to a core set.⁷

The Academy of Neurologic Physical Therapy (ANPT) formed multiple diagnosis-specific EDGE Task Forces that provided recommendations for measures by level of the ICF, patient, practice setting, utility in research, and entry-level physical therapy education. There are currently six EDGE documents available on the ANPT website (www.neuropt.org) that include StrokEDGE,⁸ MS EDGE,⁹ Traumatic Brain Injury EDGE,¹⁰ Spinal Cord Injury EDGE,¹¹ Parkinson Disease,¹² and Vestibular Disorders.¹³ The EDGE Task Forces' recommendations for PT education are divided into OMs that "students should learn to administer" and those "students should be exposed to." Combining the recommendations from each EDGE Task Force and eliminating redundancy, graduates of PT education programs should know how to administer 52 different OMs and be exposed to an additional 55 OMs, making 107 OMs in neurological patient/client management courses alone. The specific EDGE Task Force recommendations are included in [Appendix 7.A](#).

In July of 2018, the Journal of Neurologic Physical Therapy and ANPT identified a core set of OMs for neurological rehabilitation.⁷ The authors used the Consensus-based Standards for the selection of health Measurement Instruments (COSMIN) checklist to examine the literature related to OMs in neurological rehabilitation. Their criteria were that each measure could be applied to patients at different levels of acuity, with varied neurological conditions and in different practice settings. Nine action statements were addressed with the first six addressing specific activities necessary for function on a daily basis. The seventh addressed documentation, whereas eight and nine made recommendations for using the core set of OMs and their results. The Action Statements and the associated OMs are included in [Appendix 7.B](#).

Another way to approach assessment tools is to categorize them by the type of information that the clinician and patient seek. Those heavily involved with clinical practice may find this type of organization most valuable for their particular circumstances as they could easily identify possible tests and measure to use based on a particular patient problem or presentation that they would like to closely monitor for progress. Please refer to [Appendix 7.C](#).

Moreover, there are OMs that are specifically valuable for the pediatric population. A list of the more common OMs can be found in [Appendix 7.D](#).

For all measures, the reader is referred to the Rehabilitation Measures Database (search "Rehabilitation Measures Database") for the most recent data and literature for each measure.

The ability to choose the appropriate examination tool(s) for a particular client will depend on several factors:

1. The client's current functional status (ambulatory vs. nonambulatory)
2. The client's current cognitive status (intact vs. confused or disoriented)
3. The clinical setting in which the person is being evaluated for treatment (acute hospital, rehabilitation, outpatient, skilled care, or home care)
4. The client's primary complaints (pain vs. weakness vs. impaired balance)
5. The client's goals and realistic expectation for recovery, maintenance, or prevention of functional loss (acute injury, chronic problem, or progressive disease process)
6. The type of information desired from the test (e.g., if the test is discriminative or predictive). The reader is encouraged to read the two articles on "outcome measures in neurological physical therapy practice"^{20,21} published in the *Journal of Neurologic Physical Therapy* for a detailed discussion on this subject.
7. The psychometric properties of the test on the specific patient population/diagnosis
8. The ability of the test to detect significant change over time

The evaluator should select examination tools that address three objectives: first, to measure the client's primary problems (activity limitations, impairments, and participation restrictions); second, supply outcome values necessary for setting realistic treatment goals in collaboration with the client and family; and third, to plan efficient and effective intervention strategies.

Many of the examination tools that measure a client's ability to perform functional activities have been accepted as valid, reliable, and useful for the justification of payment for services rendered. The number of activity limitations and the extent of the client's participation limitation are often reasons why an individual either has access to therapy services directly or is referred by a medical practitioner. For this reason, the third-party payers expect to receive reports concerning positive changes in the client's functional status to justify therapeutic services. The initial list of functional or activity limitations or participation restrictions helps the therapist to determine the extent of, expectations for, and direction of intervention, but it does not determine why those limitations exist. The answer to this question is critical in the evaluation process. Examination tests and procedures that identify specific system and subsystem impairments help the therapist to determine causes for existing participation and activity limitations. These tools must be objective, reliable, and sufficiently sensitive to provide needed communication to third-party payers to explain the subsystem's baseline progress during and after the intervention. These tools should also supply explanations for residual difficulties in the event that the functional problems themselves do not demonstrate significant objective change or show progress within the time frame estimated.

Examination Process in Practice

The following case scenario synthesizes the clinical examination and evaluation process used by PTs and OTs.

Assume that a clinician has been called in to examine a client who has sustained an anoxic brain injury during heart surgery. The client's cognitive ability is within normal limits, and he is highly motivated to get back to his normal activities. He is retired; he loves to walk in the park with his wife and to go on birdwatching experiences in the mountains with their group of friends. The clinician must select which functional tests to use to obtain an objective initial status and target the client's problems. Currently the client requires assistance with all gross mobility skills and is demonstrating difficulty balancing in various postures and performing activities of daily living. Results of functional testing reveal that the client demonstrates significant limitations, requiring moderate assistance in the activities of coming to sit, sitting, coming to stand, standing, walking, dressing, and grooming. Assume that the client also displays impairment limitations in flexion ROM at the hip joints caused by both muscle and fascia tightness and hypertonicity within the extensor muscle groups. He has compensated to some degree and is able to perform bed mobility independently. Upper extremity motor control is within normal limits, and thus the client is capable of performing many activities of daily living as long as his lower trunk and hips are placed in a supportive position and hip flexion beyond 90 degrees is not required. The client has general weakness from inactivity, and power production problems in his abdominals and hip flexor muscles owing to the dominance of extensor muscle tonicity. Once he is helped to stand, the extensor patterns of hip and knee extension, internal rotation, slight adduction, and plantarflexion are present. He can actively extend both legs after being placed in flexion, but he is limited in the production of specific fine and gross motor patterns. Thus a resulting balance impairment is present owing to the inability to adequately access appropriate balance strategies caused by the presence of tone, limb synergy production,

and weakness in the antagonists to the trunk and hip extensors. Through the use of augmented intervention, the client is noted to possess intact postural and procedural balance programming; however, both functions are being masked by existing impairments. The decision is made to perform impairment measures, including assessments of ROM at the hip, knee, and ankle joints; the ability to produce strength in both the abdominal and hip flexor muscle groups; and volitional and nonvolitional synergic programming, balance, and posture, and volitional control over muscle tone. The demand on ROM, power production, and specific synergic programming will vary according to the requirements of the functional activities performed.

Using a clinical decision-making process, the clinician will conclude that the impairments that are being targeted to measure will vary from one functional activity to the next. For instance, if this client is demonstrating difficulty rising from a chair, the target impairment may be quantified with a ROM measurement. This same ROM impairment may also contribute to problems with moving about the base of support in functional sitting. The clinician makes the determination as to the extent to which the impairment interferes with each functional problem for that particular client.

These objective measurements help the clinician to explain which outcomes would be expected to be achieved first and why. These measurements are recorded as part of intervention charting and help to objectively demonstrate that the client is improving toward functional independence. They also give an indication of what the client still needs to reach the desired outcome, the rate of learning that is taking place, and an estimation of recovery time that is still required. These objective measurements give to the clinician and the client a better avenue to discuss expectations with family members, other medical practitioners, and third-party payers. In this example, assume that, after intervention, functional ROM in the hip was achieved. However, this improvement did not result in an improvement in the activity problems because synergic programming prevented adequate hip flexion during one or more functional activities. Understanding and measuring the difference between lack of ROM as a result of muscle or fascia tightness versus lack of range from abnormal synergic patterning helps the clinician to communicate why a client is successful in one activity and may still need assistance in another.

Scores obtained from tests of activity, participation, and impairments supply statistically important measurements that can then be used to discuss the limitations placed on the therapeutic environment by fiscal intermediaries. Therapists must be clear when documenting the initial status and the target status for clients so that the recommended intervention and length of stay may be justified.

When making a determination of the potential impact of an intervention on improving a client's problems, clinicians must remember that a key factor in this process of examination and evaluation is the acceptance of the movement dysfunction or impairment by the client. A mobility problem or impairment may be clearly identified by a functional test or impairment test; however, the client may deny that the problem even exists. Acceptance of the problems by the client and a willingness to change are critical to the client's adherence to the intervention strategy.

As mentioned earlier, the identification of potential impairments was done after functional testing to streamline the examination process. After performing the functional examination, the therapist postulated that the client might have impaired motor control, muscle weakness, sensory deficits, pain, and decreased endurance that may have been causing the functional limitations. MMT revealed lower-extremity strength of $\frac{1}{5}$ in both ankle motions, $\frac{2}{5}$ in both knees, and $3-5$ in both hips. Upper extremities tested as $\frac{1}{5}$ finger flexors (incomplete

grip), $\frac{2}{5}$ wrist motions, and 3+/5 in both elbow motions. Shoulder and trunk strength were within functional limits for all motions. Sensory testing indicated absent touch and proprioceptive sensations from the foot to the knee of both lower extremities, with impaired sensation from the thighs to the hips. Both hands and wrists tested absent to touch and proprioception, with the elbows and shoulders testing intact. The client's endurance was limited to short bouts of activity (3 to 5 minutes), with rapid muscular and cardiovascular fatigue. The presence of these impairments helped to explain the resultant functional limitations tested earlier.

In terms of standardized functional tests, the multidisciplinary FIM could give insight into this patient's ability to function in multiple domains and categories. Baseline scores on the Berg Balance Scale could be collected because this client is expected to regain further function in balance and postural control as recovery from the condition occurs. As the client regains strength and peripheral sensory ability, he may be able to perform the TUG test and the 10-Meter Walk Test. These functional assessments paint a better picture of what the client can and cannot do, as well as provide a way to measure functional progress in various activities throughout rehabilitation.

Because the patient's prior status included enjoying walks in the park with his wife and birdwatching experiences in the mountains with friends, it is important to keep in mind that the patient likely desires to return to these activities that relate to his role as husband and friend. The clinician is encouraged to add measures of satisfaction with life and to link the outcome assessment results to goals to return to walks in the park and bird watching in some format.

CASE STUDY 7.1^a

The patient is a 30-year-old man who was referred to outpatient physical therapy after a 1-week stay in an acute care facility following an exacerbation of relapsing-remitting multiple sclerosis (MS). His height was 2.05 m (6 feet 9 inches), and his weight was 133.81 kg (295 pounds). The patient was first diagnosed with MS 4 years ago. He developed optic neuritis during the exacerbation and was treated with corticosteroid pulse therapy. The patient's past medical history included depression, gastroesophageal reflux disease, migraine headaches, and hyperlipidemia. After being diagnosed with MS, the patient had to stop working. Before the most recent hospitalization, the patient lived with his sister in a single-story home with five stairs to enter with a railing. At that time he was able to ambulate independently without an assistive device and to complete all activities of daily living without any assistance.

An outpatient physical therapy initial examination was conducted 1 week after the patient was discharged from the hospital. He reported that he was using a wheelchair to get to and from appointments, and inside his home. He was alert and oriented to person, place, and time, although responses were delayed and speech was slightly slurred. There were no complaints of pain, and the patient stated that fatigue and temperature had not affected him.

Several tests of functional movement activities were performed first. The patient was able to roll to the right and left with minimal assistance, with rolling to the right being less difficult for the patient. He needed supervision to move from supine to sitting.

The patient required moderate assistance to perform a sit-to-stand transfer. He was able to ambulate five steps with a front-wheeled walker (FWW) and moderate assistance of one person.

After examination of the patient's functional movement activities, several tests of body function and structures were then administered. Passive range of motion for all joints in both upper and lower extremities was within normal limits. The patient presented with $\frac{3}{5}$ (fair) strength of the right upper and lower extremities and good ($\frac{4}{5}$) strength of the left upper and lower extremities during MMT. Light touch and superficial pain sensations tested intact from C4 to S2 dermatomes bilaterally.

Sitting balance was scored as $\frac{3}{4}$ (good) because the patient was able to accept moderate challenges. Standing static balance was 10+/-4 (poor plus); the patient was able to maintain balance with handheld support and occasional minimal assistance.

Observational gait analysis was performed, and impairments in gait included the following: decreased step length bilaterally, wide base of support, decreased weight bearing through the right lower extremity, and lack of toe-off. It was also noted that ataxic type movements were present with ambulation.

The Gait Abnormality Rating Scale (GARS) was performed, and the patient scored a $\frac{32}{48}$, indicating increased fall risk. The Tinetti Performance-Oriented Mobility Assessment (POMA) was also administered. The patient scored $\frac{9}{28}$, indicating a high risk for falls. Several tests were performed using the Natus Balance Master. The sit-to-stand test showed that the patient had difficulty maintaining balance immediately after rising and had more weight on his left lower extremity. The results were abnormal, based on the norms for the patient's gender and age. Next, the weight-bearing squat test was done. During this test the patient was not able to maintain equal weight through bilateral lower extremities, with the patient bearing weight more on the left side. The patient then performed the limits of stability test, which revealed an inability to lean his center of gravity (COG) over his right lower extremity, or forward onto his toes. The patient then performed the rhythmic weight-shift test; he was not able to complete the forward-backward component of the rhythmic weight-shift test without falling, and he also had difficulty with directional control and velocity during lateral weight shifting.

Last, tests for participation and self-efficacy were administered. The Activities-specific Balance Confidence (ABC) Scale questionnaire was given to the patient to assess the patient's balance self-efficacy. The patient had a score of 20%, indicating a low level of physical functioning. He scored 10% on being able to bend down, pick a slipper up off the floor, and reach for a can on a shelf at eye level with the use of an FWW.

The data collected at initial examination revealed limitations in functional performance resulting from impairments in balance, gait, strength, and motor control, giving the therapist the various movement diagnoses that reflected problems. Intervention frequency and duration was set at three times per week for 8 weeks. The prognosis that the patient would be able to ambulate independently in the community with an assistive device in 8 weeks was good, given the patient's willingness to participate in physical therapy, positive outlook, family support, and positive response to medical interventions. The plan of care that was developed focused on improving activity limitations such as transfers and gait and impairments such as weakness and imbalance. The expected outcomes were set to be achieved in 8 weeks, and anticipated goals were set to be achieved in 4 weeks.

^aCase study modified from Larsen-Merrill J, Lazaro R: Use of the NeuroCom balance master training protocols to improve functional performance in a person with multiple sclerosis. *J Stud Phys Ther Res* 21:1–16, 2009.

Summary of Recommendations From the Evaluation Database to Guide Effectiveness (EDGE)

Abstract: This chapter introduces the reader to the examination process. This chapter emphasizes the selection of appropriate tools to most accurately capture the patient's strength and weaknesses to be able to determine the best course of therapeutic intervention, and to track progress following therapy.

Keywords: activity limitations, impairments, evaluation, examination, participation restrictions

Interventions for Individuals With Movement Limitations

Rolando T. Lazaro, Myla U. Quiben, and Sandra G. Reina-Guerra

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Appreciate the complexity of motor responses and discuss methods used to influence body.
2. Analyze the similarities and differences among interventions that address impairments in specific body systems, and functional training.
3. Identify the role of augmented feedback in neurological interventions.
4. Select appropriate intervention strategies to optimize desired outcomes.
5. Analyze variables that may both positively and negatively affect complex motor responses and a patient's ability to perform functional activities and participate in the community.
6. Discuss interventions in neurorehabilitation with regards to current evidence, clinical implications, and considerations for utility.
7. Consider the contribution of the patient/client, available support systems, research evidence, neurophysiology, and the best practice standards available to optimize outcomes.

KEY TERMS

augmented intervention
evidence-based practice

functional training
intervention for impairments

Before discussing therapeutic interventions, the therapist must identify the learning environment within which the patient/client will perform tasks/activities. That environment is made up of the therapist and the patient/client, all internal body control mechanisms of the patient/client, and the external restraints and demands of the environment. Although this text focuses on relearning functional movement, the reader must always consider many factors that influence the patient/client management, including how other organs or body systems will be affected by or will affect the therapeutic outcome, both during and after rehabilitation, in relation to long-term quality of life. An examination and evaluation are performed before intervention to establish movement diagnoses. A physical therapy diagnosis must link impairments at the body structure and function level to activity limitations and participation restrictions, as well as provide a prognosis of the patient's/client's potential for functional improvement. Personal factors, such as motivation, family support, financial support, patient values, and cultural biases, must be considered as part of the prognosis.¹⁻³ Therefore the physical therapy diagnosis and prognosis guide the selection of intervention strategies. This text addresses interventions for patients/clients with movement system dysfunction associated with nervous system impairments. Prognostic accuracy and appropriate goal setting require clinical reasoning to distinguish if a specific activity limitation is due to an acute event or if the limitation has developed over a lifetime as a result of small traumas and adjustments to life.

Both the American Occupational Therapy Association (AOTA) and the American Physical Therapy Association (APTA) have developed standards of professional practice to guide therapists in the patient/client management process.^{2,3} "The body of online tools to support

evidence-based practice is growing, including diagnosis-specific interventions. Some tools are open access such as the Physiotherapy Evidence Database (PEDro)⁴ while others require professional membership.^{5,6} Through the use of current evidence-based practice of sensorimotor processing, motor control, motor learning, and neuroplasticity theories and body systems models, the therapist must determine the inherent motor control and learning flexibility the patient demonstrates while executing functional activities and participating in life. This chapter and text cannot establish for the reader the exact treatment sequence that should be used for every patient but presents an example of a decision making pathway in [Box 8.1](#). Functional goals must be established that lead to the patient's/client's ability to participate within his or her environment and whenever possible lead to or maintain the quality of life desired by the patient/client. Before beginning any intervention, the therapist must determine the treatment strategies that will be used to help the patient/client attain the desired functional outcomes. The specific environment used by the therapist to optimize patient performance will depend on the functional level and amount of motor control exhibited by the patient. In some cases the therapist may be constrained to use the existing environment and will need to modify it to meet the intent of the therapeutic session. The following classifications can be used to document the specific role of the therapist within the intervention session:

Functional training: Practice of a functional skill that is meaningful, goal directed, and task oriented. Patients will experience errors and self-correct as the program becomes more automatic and integrated. An example would be gait training on a tile surface, rugs, inclined surfaces, compliant surfaces such as grass, and so on, to practice ambulation.

BOX 8.1 Treatment Strategy Categories**Compensation Training**

Use of an assistive device or orthotic to compensate for a permanent impairment or lost body system function.

Substitution Training

Teaching the patient to use a different sensory system or muscle(s) group to substitute for lost function of another system. An example of sensory substitution might be teaching the patient to use vision to substitute for an impaired vestibular system or somatosensory system for balance function. Substitution within the motor system might be teaching hip hiking to substitute for lack of dorsiflexion of the ankle during swing phase of gait.

Habituation Training

Activity-based provocation of symptoms with the goal of symptom reduction with repetitive practice. An example would be teaching head movement to a patient who has a chronic labyrinthitis and severe nausea with any head movement.

Neural Adaptation

Driving changes in structure and function of the central or peripheral nervous system with repetitive, attended practice. This category would be considered neural plasticity. This category of treatment strategy takes the greatest repetition of practice and requires a strong desire by the individual to gain the functional ability and realize the potential of the central nervous system to change.

Intervention for impairments: Treatment focus is on correcting an impairment in the body system with interventions such as muscle strengthening, stretching, sensory training, endurance training.

Whether the intervention approach is via functional training or intervention for impairments, the clinician may use *augmented feedback* strategies to optimize the patient's response to the intervention strategy. The external feedback received by the patient (auditory, visual, kinesthetic, tactile, etc.) will limit the response patterns (e.g., reducing degrees of freedom, reduction or enhancement of tone) for successful performance of the desired movement. Examples of these are provided in the later portion of this chapter.

Patients/clients with central nervous system (CNS) damage often benefit from a combination of interventions from the above categories. An example of this might be the early phase of partial body weight supported treadmill training (BWSTT), where a therapist or assistant guides the patient's/client's leg during swing and stance phases while the body harness supports a proportion of the patient's/client's total weight (augmented feedback) to maintain balance and decrease the power needed to generate a more typical gait pattern. This augmented intervention is done in a functional pattern within an environment that perturbs the patient's/client's base of support. This perturbation moves each foot reciprocally backwards and the body forward, triggering a stepping reaction. In the case of an individual after a cerebrovascular accident (CVA), one leg will still respond normally, thus helping to trigger a between-limb reciprocal stepping action of the involved leg. In the case of bilateral involvement, both legs may need placement, requiring more external assistance. The intent of the intervention is to correct an impairment, leading to functional training to trigger normal motor programs necessary for gait. Simultaneously, augmented training done by a therapist includes manual assistance in the direction and rate of stepping, and placement of the involved leg throughout the gait cycle. In

this previous example, therapists need to make sure they are aware of the patient's center of gravity and do not move the foot before it should be at "push off" during the gait cycle. When selecting from a variety of treatment interventions, it is important for the therapist to consider that each intervention comes with different strategies and rationales that contribute to the expected outcome. All interventions should address the needs of the patient and must consider any emotional and cognitive restraints. Because these intervention strategies can be used simultaneously and in various combinations, it is important for the clinician to determine how and why the outcomes were influenced by the intervention. Without understanding the interactions of intervention methods and the outcome, treatment effectiveness and future clinical decision making remain unpredictable, and unique practice patterns and pathways are hard to identify with consistency.⁷ A conscientious clinician knows how and why the decisions are made along the intervention pathway, communicates this rationale clearly, and leaves a legacy of effective patient/client care. The reader must remember that intervention encompasses multiple interactive environments where intervention decisions are often made moment by moment during any treatment period. The challenge to the clinician is to determine what is being done, why it is working, how to continue its effectiveness, and how to assess/measure the progress of the successful intervention. The clinician must also determine how to empower the patient/client (emotionally, cognitively, and motorically) to participate in the intervention with inherent, automatic mechanisms that lead to fluid, flexible, and functional outcomes that are independent of the therapist and not purely exclusive to the environment within which the activity is occurring. The efficacy of a specific treatment is often yet unestablished in the laboratory and research literature; therefore the patient's/clinician's thoughtful choice of interventions and outcome measures is the first step in determining treatment effectiveness. Once efficacy has been established through larger controlled studies within the clinical environment, researchers can begin to tease out separate variables and establish efficacy as part of evidence to justify clinical decision making.

HISTORY OF DEVELOPMENT OF INTERVENTIONS FOR NEUROLOGICAL DISABILITIES

In the mid-1900s the interventions by physical therapists (PTs) and occupational therapists (OTs) were separate. In general, PTs worked on gross motor activities, with specific emphasis on the lower extremities and the trunk, whereas OTs worked on the upper extremities and fine motor activities. Both professions focused on daily living skills, with those involving the arms falling within the domain of the OT and those involving the legs falling within the domain of the PT. Activities that required gross motor skills such as sitting, coming to stand, walking, walking with assistive devices, and running fell within the purview of the PT, whereas grooming, hygiene, and eating were the responsibility of the OT. Currently, this approach is not as commonly practiced owing to the understanding of motor learning, neuroplasticity, and motor programming and control. In the past, it was also accepted that the PT worked on specific system problems such as weakness, inflexibility, lack of coordination, and voluntary control, whereas the OT worked on functional activities integrated within the environment (such as dressing) and the patient's emotional needs and desires (occupational expectations). According to the terminology of the mid- to late 20th century, PTs were trained to identify and correct impairments that caused functional limitations, whereas OTs were trained in activity analysis and treatment that identified and optimized the functional activities that resulted from the impairments. Few clinicians seemed to focus on the sequential or interactive aspect of lack of function with

specific impairments. Thus, after the onset of a stroke, the PT would strengthen and evaluate range of motion (ROM) of the leg and trunk, whereas the OT would encourage the patient to try to functionally use the arm. Both therapists hoped the patient would accept responsibility for continued improvement through practice. What both professions discovered was that the patient generally did not regain normal motor control. The patient may be able to walk and move the shoulder, but the movement strategies were generally stereotypical, were abnormal in patterns, and took tremendous effort by and energy from the patient to perform. Over time, patients lost the motivation to even try, and thus what had been gained through therapy may have been lost from lack of practice once they got home. There was also minimal recovery of functional hand use, often because of the tremendous effort a patient had to use to move the shoulder to place the hand somewhere. Once that effort had been used, the tightness and increased tone in the hand prevented functional use. Although measurable, functional, independent skills as were achieved, typical movement patterns and motor control were rarely restored, and quality of life was clearly affected for the patient and family.

During the decade or two before the 1960s, clinicians began to question the traditional therapeutic intervention strategies. Several renowned clinicians^{8–32} in neurological rehabilitation pioneered the development of new concepts that allowed basic science to infiltrate the clinical arena. The intervention strategies of Jean Ayers, Berta Bobath, Signe Brunnstrom, Margaret Johnstone, Susanne Klein-Vogelbach, Margaret Knott, Dorothy Voss, and Margaret Rood, among others, became popular. Colleagues observed these master clinicians and could easily see that the “new” interventions were much more effective and provided better outcomes than previous interventions. Each approach focused on multisensory inputs introduced to the patient in controlled and identified sequences. These sequences were based on the inherent nature of synergistic patterns^{8,24,33,34} and motor patterns observed in humans^{8,10,35} and lower-order animals³⁶ or a combination of the two.^{22,24} Each method focused on the individual patient, the specific clinical problems, and the availability of alternative treatment approaches within an established framework. Some of these approaches focused on specific neurological medical diagnoses. The treatment emphasis was then on specific patients and their related movement disorders. Children with cerebral palsy and head injuries^{10,26,31} and adults with hemiplegia^{11,12,24,35} were the three most frequently identified medical diagnoses associated with these approaches.

The timeline and evolution of clinical practice and research in the therapy professions can be derived in great part by understanding the products of a series of conferences, currently known as the STEP Conferences.³⁷ A summary of the four STEP conferences follows in this section to give the reader contextual perspective of present day intervention strategies for prevention of primary and secondary impairments, the choice and application of predictive measures, strategies to enhance patient participation, and ongoing research to examine exercise-induced brain plasticity.

Beginning in 1968 at Northwestern University with NUSTEP, and most recently in 2016 at the University of Ohio for IV Step, master clinicians and academics along with research scientists of the day have come together to try to (1) identify the commonalities and differences between therapeutic approaches, (2) integrate and use the neuroscience of the day to explain why these approaches worked,³⁸ and (3) promote the translation of new knowledge into clinical practice. Parallel to the STEP conferences, most dogmatism no longer persists with respect to territorial boundaries between PTs’ and OTs’ perceived ownership of a certain body systems or treatment approaches; this as result of the adoption of a systems model when looking at impairments, activity limitations, and participation in life interactions.³⁹

Since the 1970s, substantial clinical attention has also been paid to children with learning and language difficulties.^{8,16,40} Now these concepts and treatment procedures have been applied across the age spectrum for all types of medically diagnosed neurological problems seen in the clinical setting (refer to section Intervention Strategies of this text). This expansion of the use of any of the methods for any pathological condition manifested by insults from disease, injury, or degeneration of the brain seems to be a natural evolution given the structure and function of the CNS and commonalities in system problems and activity limitations that take the individual away from participating in life.

Since the II Step Conference in 1990, the boundaries for interventions began blurring. Intervention approaches such as proprioceptive neuromuscular facilitation (PNF) were then integrated into the care of patient’s with orthopedic problems and patients with neurological impairments. Currently, few universities within the United States teach separate sections or units on specific approaches but rather teach students to identify impairments, when and how these interfere with functional activities, and what body systems may contribute to activity limitations or participation restriction.

For example, assume that a patient/client with hemiplegia exhibited signs of a hypertonic upper-extremity pattern of shoulder adduction, internal rotation, elbow flexion, and forearm pronation with wrist and finger flexion. Brunnstrom¹¹ would have identified that pattern as the stronger of her two upper-extremity synergies. Michels,²⁴ although using an explanation similar to Brunnstrom’s to describe the pattern, would have elaborated and described additional upper-extremity synergy patterns. Bobath would have asserted that the patient/client was stuck in a mass-movement pattern resulting from abnormal postural reflex activity.³³ Although the conceptualization of the problem certainly determined treatment protocols, the pattern all three clinicians would have worked toward was shoulder abduction, external rotation, elbow extension, forearm supination, and wrist and finger extension. The rationale for the use of this pattern within an intervention period would vary according to the philosophical approach. One clinician might describe the pattern as a reflex-inhibiting position (Bobath).³⁴ Another would describe the pattern as the weakest component of the various synergies (Brunnstrom),¹¹ whereas still another might identify the pattern as producing an extreme stretch and rotational element that inhibited the spastic pattern (Rood).²⁸ How those master clinicians sequenced treatment from the original hypertonic pattern to the opposite pattern and then to the goal-directed functional pattern would vary. Some would facilitate push-pull patterns in the supine and side-lying positions and rolling. Others would look at propping patterns in sitting or at weight-bearing patterns of patients in the prone position, over a ball or bolster, or in partial kneeling. All have the potential of improving the functional pattern of the upper extremity and modifying the hypertonic pattern. One method may have been better than the others given a particular patient, but in truth, improved patient performance may have stemmed not from the method itself but rather from the preferential CNS biases of the patient and the variability of application skills among the clinicians themselves. That is, when a therapist intentionally uses specific augmented feedback to modulate the motor system’s response to an environment but does not identify the other external feedback present within that environment (e.g., lighting, sound, touch, environmental constraints), therapeutic results will vary. Because of variance, efficacy of intervention is often questionable, although the effectiveness of that therapist may be easily recognized.

Because of the overlap of intervention strategies and the infiltration of therapeutic management into all avenues of neurological dysfunction, various multisensory models were developed during the early 1980s.^{16,41–44} These have continued to evolve into acceptable methods

in the current clinical arena. Although these models attempted to integrate existing techniques, in reality they have created a new set of holistic treatment approaches. In July 2005, the III STEP conference⁴⁵ was held in Utah to again bring current theories and evidence-based practice into the current clinical environment. The history of the three STEP conferences demonstrates the evolution of evidence-based practice from the first conference, where basic science was the only evidence to justify treatment, to the second conference, where evidence in motor learning and motor control began to bring efficacy to intervention. By the time the third conference was held, the research in neuro/movement science regarding true efficacy within practice and the reliability and validity of our examination tools set the stage for standards in practice.⁴⁶ No proceedings from that third conference were published, but over the preceding years, articles covering most of the presentations had been published in *Physical Therapy*. The ultimate goal would be to develop one all-encompassing methodology that allows the clinician the freedom to use any method that is appropriate for the needs and individual learning styles of the patient as well as to tap the unique individual differences of the clinician. Although intervention currently is based on an integrated model, the influence of third-party payers, the need for efficacy of practice, and time constraints often factor into the therapist's choice of intervention. Visionary and entrepreneurial practice ideas that have the potential to be effective will always be a challenge to future therapists. Those ideas generally originate within the clinical environment and not the research laboratory. For that reason, clinicians need to communicate ideas to the researcher, and then those researchers can develop research studies that test the established efficacy or refute that effectiveness. Few researchers are master clinicians, and few clinicians are master researchers; thus collaboration is needed as the professions move forward in establishing evidence-based practice.

Today's therapists have replaced many of the existing philosophical approaches with patient-centered therapeutic interventions. Patient performance, values and preferences, available evidence, and the expertise of the clinician often play key roles in the clinical decision making process. Control of the combination of movement responses and modulation over specific central pattern generators or learned behavior programs will allow the patient opportunities to experience functional movement that is task oriented and environmentally specific. With goal-directed practice of the functional activity, neuroplastic changes, motor learning, and carryover can be achieved.⁴⁷ With a better scientific basis for understanding the function of the human nervous system, how the motor system learns and is controlled, and how other body systems, both internal and external to the CNS, modulate response patterns, today's clinicians have many additional options for selection of intervention strategies.^{48–57} Whether a patient would initially benefit best from neuromuscular retraining, functional retraining, or a more traditional augmented or contrived treatment environment is based on the specific needs identified during the examination and evaluation process.

No matter what treatment method is selected by a clinician, all intervention should focus on the active learning process of the patient. The patient should never be a passive participant nor should the patient be asked to perform an activity when the system problems only create distortion or demonstrate total lack of control of the desired movement. With all interventions requiring an active motor response, whether to change a body system impairment such as by increasing or reducing the rate of a motor response, modulate the tonal state of the central pattern generators and learned motor behaviors, or influence a functional response during an activity, the patient's CNS is being asked to process and respond to the external world. That response needs to become procedural and controlled by the patient without any

augmentation to be measured as functionally independent. In time, the ultimate goal is for the patient to self-regulate and orchestrate modulation over this adaptable and dynamic integrated sensorimotor system in all functional activities and in all external environments.

A problem-oriented approach to the treatment of any impairment or activity limitation implies that flexibility and neural adaptation are key elements in recovery. However, adaptation should not be random, disjointed, or non-goal oriented. It should be based on methods that provide the best combination of available treatment alternatives to meet the specific needs of the individual. Development of a clinical knowledge bank enables the therapist to match treatment alternatives with the patient's impairments, activity limitations, objectives for improved function, and desired quality of life. A therapist no longer bases treatment on identified approaches, although specific aspects of those approaches may be treatment tools that will meet the patient's needs and assist him or her in regaining functional control of movement. Intervention is based on an interaction among basic science, applied science, the therapist's skills, and the patient's desired outcomes.^{52–55,58–60} In most cases, multiple intervention strategies must be included, but the therapist needs to be able to identify why those selected treatments will lead to system improvement, as well as documenting those findings using reliable standardized and acceptable clinical methods and terminology. These intervention strategies must be dynamic yet also understandable and repeatable. As new scientific theories are discovered, new information must be integrated to continue to modify treatment approaches.

INTERVENTION STRATEGIES

Functional Training

Functional training is a method of retraining the motor system using repetitive practice of functional tasks in an attempt to reestablish the patient's/client's ability to perform activities of daily living (ADLs) and participate in specific life activities. This method of training is a common and popular intervention strategy used by clinicians owing to the fact that it is a relatively simple and straightforward approach to improving deficits in function. A system problem such as weakness in the quadriceps muscle of the leg can be treated by muscle strengthening in a functional pattern that can be easily measured. Because of its inherent simplicity, functional training is sometimes misused or abused by clinicians. Most patients with neurological deficits have multiple subsystem problems within multiple areas, which forces the CNS to use alternative movement patterns to try to accomplish the functional task presented. If the therapist accesses a motor plan such as transfers but allows the patient to use programs that are inefficient, inappropriate, or stereotypical, then the activity itself is often beyond the patient's ability. The patient may learn something, but it will not be the normal program for transfers. This activity often leads to additional problems for the patient.

The intricate relationship of body system problems, impairments, and functional limitations that decrease participation in the rehabilitation process are discussed. Functional training can be implemented once the clinician has identified the patient's activity limitations. The clinician must first answer the questions: "What can the individual do?" "What limitations does the patient have when engaging in functional activities in his or her daily environments?" "Are there motor programs that are being used to substitute for typical motor function?" and "Can the therapist use functional training to improve body system problems within the context of the functional skill?" Once the therapist develops an understanding of the potential reasons for activity limitations and can alleviate the substitution and compensation for the deficit, functional tasks should be identified and practiced.

Effect of Functional Training on Task Performance and Participation

The main focus of functional training is the correction of activity limitations that prevent an individual from participating in life. However, through repetitive practice of functional tasks and gross motor patterns, many of the patient's impairments can also be affected. For example, if a therapist practices sit-to-stand transfers with a patient in a variety of environments and performs multiple repetitions of each type of transfer, not only can learning be reinforced, but the patient can also gain strength in the synergistic patterns of the lower extremities that work against gravity to concentrically lift the patient off of the support surface and eccentrically lower him or her down. Weight bearing through the feet in a variety of degrees of ankle dorsiflexion during transfer training will effectively place the ankles in functional positions. The act of standing also helps the trunk and neck extensors to engage in postural control. Varying the speed of the activity during the treatment can stimulate cerebellar adaptation to the movement task. Moving from one position to another with the head in a variety of positions stimulates the vestibular apparatus and may assist in habituating a hypersensitive vestibular system, allowing the patient to change body positions without symptoms of dizziness, resulting in a higher quality of life. Repetitive practice also affects the vasomotor system and may assist in habituating postural hypotensive responses.

Functional training should access the patient's highest level of independent and uncompensated movement—this is often challenging. For example, early gait training for patient's with acute stroke may take place in artificial environments, such as within parallel bars. If the therapist providing the training is not cognizant of the quality and goal of the patient's postural control and body movement, the patient may use a dysfunctional, inefficient motor program. An example outcome of prolonged, ineffective gait training within the parallel bars can be seen in a patient with CVA who relies heavily on the nonparetic upper extremity for support on one bar, resulting in the next compensation of forward trunk lean, then hip retraction and knee hyperextension on the hemiparetic limb during single limb stance phase. If this misuse of functional training is not recognized, the patient may have long-lasting dysfunctional use of both the upper and lower extremity.

Instead, the astute therapist will use strategies to help the patient to safely and gradually explore appropriate movement strategies, provide the patient with a variable practice environment for walking (e.g., out of the parallel bars), and ultimately improve the plasticity of the patient's nervous system during recovery. Functional training is the best method of intervention when the patient has some motor abilities with limitations such as limited ROM or inadequate muscle power from disuse. Functional training will use existing abilities until fatigue sets in, which may be after only one or two repetitions. Increasing the repetitions and/or the power necessary to complete the tasks will lead to functional improvement. An intervention approach in the early 1990s that evolved as an offshoot of functional training was labeled *clinical pathways*. These pathways were established by health care institutions to improve consistency of management of patients who met specific medical diagnostic criteria. It has been proven that the implementation of these pathways reduces variability in clinical practice and improves patient outcomes.⁶¹ Health care practitioners also became aware that some individuals do not fall into these pathways and need to be treated according to the specific clinical problems that the patients were presenting.

Selection of Functional Training Strategies

What is the "ideal" procedure for effectively and efficiently using functional training as a treatment intervention? First, it is suggested

that the clinician identify and select procedures that will use the patient's strengths to regain lost function and correct system limitations—"What can the individual do?" The clinician is also advised to avoid activities that may be too difficult and elicit compensatory strategies that may result in the development of abnormal, stereotypical movement and potentially create additional impairments. An example of this is using transfer training when the patient is unable to perform the task with some element of success. Once in a situation where the patient fails to perform the task, the patient uses approaches to prevent from falling, not activities that allow the patient to safely transfer. The therapist's decision regarding what functional patterns or activities to practice, and in what order, will depend on several factors. The therapist must choose functional activities that are necessary for the patient to perform independently or manage with less help before being discharged home. For PTs, safe transfers and ambulation are generally the focus of functional training. For OTs, independent bathing, dressing, and feeding are major foci. Yet both PTs and OTs also need to be sensitive to the activities that the patient or the patient's family want to improve to enhance the quality of life for everyone involved in the person's case. The ability to get in and out of a car might be the most important activity due to frequent trips to the physician's office and the primary caregiver's limited abilities to physically assist.

It is suggested that the clinician modify or "shrink" the environment to allow normal motor programs to run. An example of this might be to limit the ROM an individual is allowed while performing a rolling pattern. The therapist may opt to start this movement with the patient in a side-lying position. The amount of patient movement may be even further limited by the therapist stabilizing the patient's hips by using the therapist's one leg in kneeling position against the patient's posterior pelvis and the therapist's other leg in half-kneeling position with the top leg of the patient over the therapist's half-kneeling leg. In this way, the individual's body can be totally controlled by the therapist; the patient can be encouraged to roll the upper part of his trunk both backward with the arm reaching back and then forward with the arm coming across the body toward a weight-bearing pattern on the hand. The therapist can change the rate of movement and also use his or her knees to control the range that the patient is allowed. The environment can be progressively "enlarged" to allow the patient/client to perform the activity in a functional context. Although this narrowing of the functional environment would be considered a contrived environment and must not be recorded as functional as defined in a functional or activities-based examination, it may allow the nervous system the opportunity to control and modify the motor programs within the limitations of its plasticity at the moment. This therapeutic technique could be used within a functional training environment or may fall into an augmented treatment approach category, given an individual who has neurological problems that prevent normal movement.

The goal of therapy is to move toward functional training as quickly as the patient's motor system can control the movement. As learning and repetition assist the CNS in widening the response pattern during a functional activity, the patient's ability to respond to variance within the environment will enlarge and assist in gaining greater independence. An example of this application of functional training might be asking a patient/client to perform a stand-to-sit transfer. The patient is first guided down to sitting onto a large gym ball, a high-low table, or a stool that allows the patient to sit only one-fourth to one-half of the way down before returning to stand. As the patient develops increased strength and balance and improved control over abnormal limb synergies and tone in this pattern, then a smaller gym ball or a lower point on a high-low table

can be used. Finally, the patient is asked to sit down onto a ball/mat or chair that results in sitting with the hips and knees at 90 degrees. Once the patient can sit down and return to a vertical position, the next task will be to sit down, relax, and then stand up. When this task is done easily, the patient will be functionally able to move from standing to sitting and to reverse the movement pattern to sitting to standing.

Although many clinicians understand the importance of running motor tasks within an appropriate biomechanical, musculoskeletal, and sensorimotor window in which the patient has the ability to perform procedures functionally, it may be argued that in many cases this particular type of treatment strategy is simply not possible in a real-world situation. For example, given the current health care environment, if the patient is given a limited number of visits to achieve the desired outcome, the clinician may conclude that there is no choice but to “allow as many degrees of freedom as possible” or, in other words, to “force the window open” no matter the abnormal movement patterns used or the limitations in independent functional control that they may produce.

In summary, the clinician should first identify and emphasize the patient’s strengths and use those strengths to efficiently and effectively achieve functional change. Next, the clinician must prioritize activities that need to be addressed; the choice of what activities to emphasize during therapeutic training always poses a dilemma to therapists. One should keep in mind that, although several skills may be learned by training them simultaneously, it may make more sense to concentrate on the safe performance of one or two necessary functional tasks rather than having the patient end up being able to perform multiple tasks that require considerable outside assistance for safety. The need to work functionally on additional activities may also be an opportunity for the clinician to request additional therapy visits for the patient/client, arguing that there is a reasonable expectation that more intervention would result in a greater increase in function and a greater decrease in the risk for potential injury than if the intervention were not continued. The use of valid and reliable functional outcome measures becomes critically important in case management. These tools objectively measure the effect of the intervention, help to predict the potential risks if the therapy is not continued, and ultimately aid in the justification to continue therapeutic intervention.

One important variable that has clearly been identified with respect to functional training is “task specificity.”^{50,62–70} Although it is important that a patient be independent in as many ADLs as possible, often the therapist, the patient, and the family need to prioritize which activities are most important to the quality of life of the patient. If walking into the mountains to do “birdwatching” is one important goal to the patient, then creating an environment that would closely resemble the environment of that activity is crucial. Similarly, practice within that environment is a key to successful carryover. If the patient wants to walk into the mountains and the family expects the patient to walk into his or her old job, a therapist must accept that motivation will drive behavior and task specificity will drive learning. Carryover into any other functional activity such as walking into the office building to go back to work may not be the motivating factor that will guide that individual’s desire to perform that motor task. Whether the patient ever goes back to work is not the variable that should be used as part of the motivational environment for task-specific gait training geared to walking in the mountains and is not a decision for which the therapist is responsible. Therapists need to elicit the most important activities for the patient and use the specificity of that task to optimize motor learning and functional recovery.

CASE STUDY 8.1 Functional Training: Ambulation

Teaching a patient to ambulate can be approached in many ways. Assume that the objective for a particular session is ambulation. First, the patient may be asked to ambulate in the parallel bars using the upper extremities to assist in forward progression of the movement to decrease fear and to assist in maintaining balance. Once the patient can perform this ambulatory activity, the therapist might decide to progress the patient’s ambulation by introducing a walker, which has four points of support. Ambulating with the walker will again increase power production in the legs and create an environment of safety for the patient. Once walking with the walker can be performed at various speeds and distances, the therapist may advance the activity to using two canes, then one cane depending on the patient’s balance, coordination, and need. While the patient is practicing ambulating with cane(s), he may also be walking supported on a treadmill to increase endurance, velocity of gait, and power. Once the patient can ambulate safely with a cane, the therapist may decide to transition to walking without any assistive devices. Again, the patient may first be asked to walk on a treadmill while holding on with his arms until he feels safe walking and no longer needs an assistive device. The therapist could transition to ramps, obstacles, uneven ground, and so on. All these activities would require the individual to begin with functional control. All the activities are focused on regaining independence in the functional activity of walking, using repetitive practice. Training can continue with or without an assistive device, with consideration that a device itself will usually limit the environments within which a patient can ambulate independently.

Intervention for Impairments

The therapeutic examination results in the identification of activity limitations and possible body system and subsystem impairments that are causing the functional movement disorders. Directly addressing these system impairments is another intervention strategy that involves the intervention for impairments with the expectation that improving these will result in a corresponding improvement in function. For example, when a patient has the inability to stand up without assistance (activity limitation) and the clinician determines the cause to be lower-extremity weakness, an appropriate approach may be to strengthen the lower extremities. Numerous studies have shown the effectiveness of addressing impairments directly in improving the functional performance of individuals with neurological conditions such as cerebral palsy,^{71,72} stroke,^{73–81} multiple sclerosis,^{82–87} Parkinson disease,^{88–92} and other neuromuscular diagnoses.^{93–104} Considering the previous case, the strengthening interventions should reflect the task and the environment within which the impairment was identified. The clinician should attempt to create a training situation so that the patient may be able to run the necessary motor programs with all the required subsystems in place. For example, training sit-to-stand with weakness in the hip and knee extensors is much less likely to automatically result in the improvement of sit-to-stand function if the therapist begins the activity in sitting, where generation of extension is most difficult, than if the strengthening training was performed with repetition of practice starting in standing and going to sit and back again to stand. By decreasing the degrees of freedom of the eccentric control of the hips and knees when going from stand to sit, the functional training activity has turned into specific impairment training. The therapist can ask the patient to eccentrically lengthen the extensors only in a limited range and then concentrically contract back to standing. As the power increases, the degrees of freedom can also be enlarged until the patient is able to complete the task of stand to sit while simultaneously regaining the sit to stand pattern.

In pure impairment training, a patient might also be asked to straighten the knee when sitting or to extend the hip when prone. These three exercises have the potential of training impaired strength, but only the first example forces the training within a functional pattern. Similarly, the therapist could train the sit-to-stand pattern using various seat heights that encompass many of the components that force the use of normal movement synergies and postural control, using the environment in which that activity is typically performed, versus performance of strengthening exercises against resistance in an open chain exercise program.

The decision to treat the impairments causing the activity limitations or to correct the functional problems themselves is influenced by many factors. One critical factor is the therapists' ability to isolate the cause of the atypical movement pattern. Different impairments may potentially contribute to atypical movement; thorough movement analysis and testing should elicit the impairments that contribute most to movement dysfunction and that should be targeted during interventions. It would appear that for certain tasks to be completed the patient must possess the "threshold amount" of basic movement components required for the task. Task specificity within this limited environment will result in more meaningful changes in function.

Augmented Therapeutic Intervention

Some treatment alternatives require little if any hands-on therapeutic manipulation of the patient during the activity. For example, the patient practices transfers on and off many support surfaces with standby guarding only. The patient self-corrects or uses inherent feedback mechanisms to self-correct error to refine the motor skill. This ultimate empowerment allows each individual to adapt and succeed at self-identified and self-motivated objectives first with augmented intervention and finally without any assistance. Often, allowing the patient to attempt movement without assistance enables the therapist to evaluate what components of the task the patient can control and what components are not within the patient's current capabilities, especially if normal, fluid, efficient, and effortless movement is the desired outcome. In some cases, the therapist may use hands-on skills or augmented aids such as BWSTT, which would substitute for many aspects of the environment and allow the patient to succeed at the task—but the control and feedback during the activity would be considered augmented feedback and fall into that classification.

Augmented techniques make up a large component of the therapist's specific interventions tool box. Augmented training may be done as part of a functional, task-specific activity but could also be administered in nonfunctional positions, depending on therapeutic goals. In augmented training the therapist may use a piece of equipment to be part of the patient's external environment for the patient to succeed at the task. For example, in BWSTT a harness is used to take away the demand of gravity on the limbs during gait and the demand of the postural trunk and hip muscles for stability. Before the therapist or the patient can consider the movement as independent, those aspects must be removed from the environment. In the previous example, the individual needs to transition from maximal body weight support during ambulation to not needing any external support during ambulation. The patient must assume *total ownership* of the functional responses. Then and only then has independence been achieved. At that time, functional retraining can be used with the intent of enlarging the environmental parameters to allow for maximal independence. Augmented techniques are often the early choices for treatment of patients who have neurological insults. It cannot be emphasized enough that once the patient has the ability to perform without augmented

methods and does so in functional, efficient ways, those augmented techniques need to be selectively eliminated.

Once a clinician has chosen to augment the clinical environment, the patient needs to learn efficient motor behaviors within the limitations of that environment. The patient influences the therapist's decision making strategies by selecting inefficient or ineffective motor responses to a given task demand. If the response is effortless, efficient, and noninjurious to any part of the body and meets the patient's expectations and goals, then the therapist knows the strategies selected were effective even if the therapist augmented the intervention. If the movement itself is available to the patient, then there is a high probability that the patient will be able to regain that movement control, regardless of the need for early augmentation to achieve the skill. If the response does not meet the desired goal for any reason, then the therapist must determine why. Often, it is because the therapist did not identify the correct body system impairments. Which solution is best may be more patient than approach dependent. Fig. 8.1 summarizes the use of these intervention approaches as a roadmap for neurological rehabilitation.

The clinician has little basis for decision making without a comprehensive understanding of the neurophysiological mechanisms of (1) the various techniques introduced to modify input, (2) where that information will be processed and how that might affect motor output, (3) prior learning and the ability for new learning, and (4) the patient's willingness and motivation to adapt.

The number of available augmented feedback techniques is almost infinite. This section presents an overview of a classification system that can be used to help the reader develop a greater understanding of why certain responses occur and why the selection of certain techniques is appropriate and should positively affect the desired motor responses. This section focuses on intervention strategies that have been accepted, have been used within the traditional Western health care model, and are efficacious. There are other classification systems a clinician might use when analyzing movement problems seen in patients with neurological dysfunction. For example, a therapist may see in a patient a problem primarily with tone, such as hypertonicity, hypotonicity, rigidity, dystonia, flaccidity, intentional and nonintentional tremors, ataxia, and combinations of or fluctuations in the total movement strategies. Given this specific classification schema, one still uses the available treatment strategies or uses an input modality that may modify the specific tone problem that was causing the movement dysfunction.

The primary goal of this section is to help the reader develop a classification system based on the primary input modality used when introducing an augmented treatment technique to facilitate a sensory system and provide feedback to the CNS to help a patient learn or relearn motor control.

When the primary input system for a technique is identified, at no time do we suggest that it is the only input system affected. For example, when a proprioceptive technique is introduced, tactile cutaneous receptors are also simultaneously firing. If there is a "noise" component (such as with vibration or tapping with the fingers), then auditory input has been triggered as well. There is evidence that a given sensory modality may "cross over" or fuse with a completely different modality, helping in the synthesis of motor responses. In addition, there is evidence that the principles of neuroplasticity are applicable across modalities (e.g., auditory, visual, vestibular, somatosensory). Sometimes responses occur in a modality that does not appear to be related. For example, olfaction may improve tactile sensitivity of the hand. This concept is called *cross-modal training* or *stimulation*.^{105,106} Yet, a classification schema based on a primary modality promotes

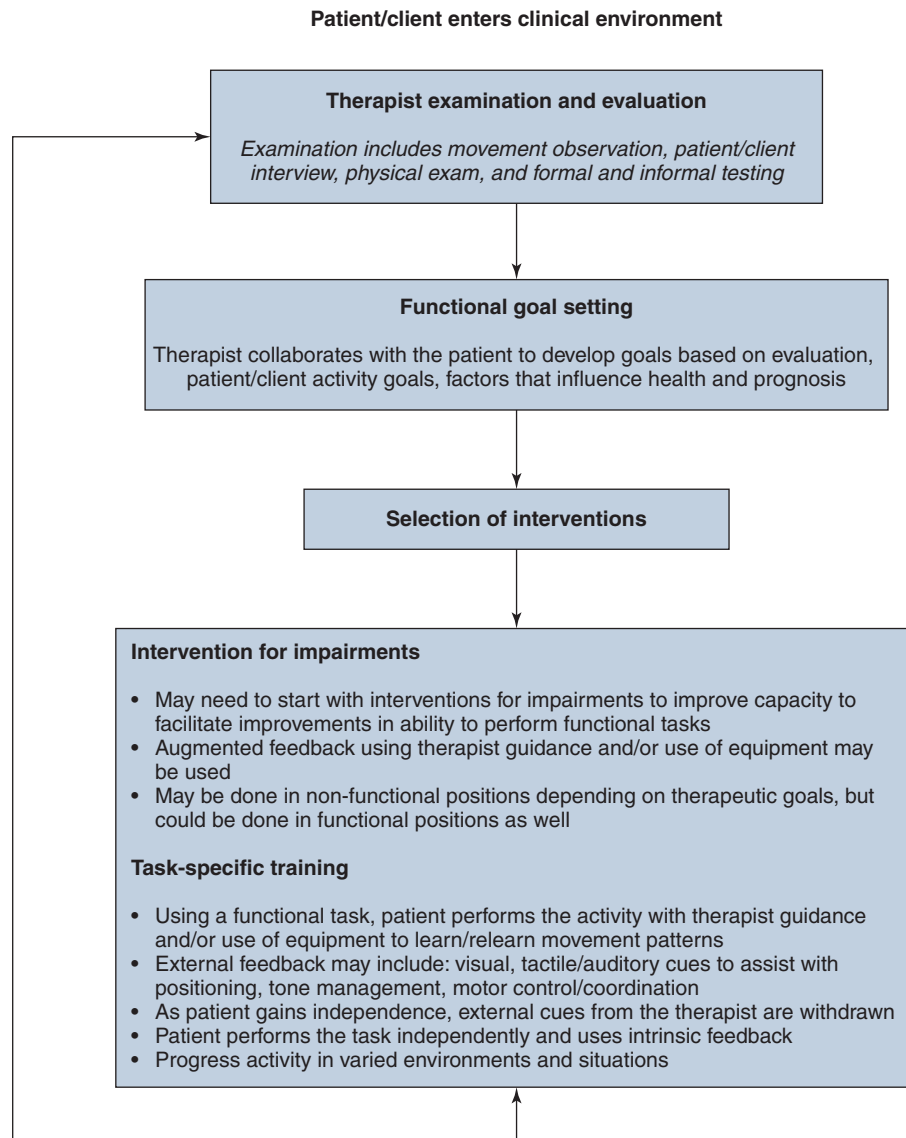

Fig. 8.1 Roadmap for Neurological Rehabilitation. (Modified from the original work of Jan Davis, OTR, San Jose State University.)

logical problem solving because the therapist can select from available treatment procedures that theoretically provide similar information to the CNS and help in the organization of appropriate motor responses. The motor system and its various motor programmers adapt to the environment to achieve functional motor output toward a goal. Both external and internal feedback are critical for adaptation and change. External feedback in this chapter is considered a mechanism to help the patient's CNS optimally learn and adapt. Obviously, as the patient learns, internal feedback will allow the person to run feedforward motor programs without the need for external feedback for control. External feedback will, it is hoped, be used only when the outside surrounding needs the feedforward program to change to adapt to a new environment (refer to the Chapter 3 section on motor learning). Therapists must realize that even if the primary goal may be to facilitate or dampen a motor system response, diverging pathways may also connect with endocrine, immune, and autonomic systems. According to motor control theory, the clinical picture is a consensus of all interacting body systems (see Chapter 3). Research tools are not yet available

to measure those systems interacting simultaneously, although functional magnetic resonance imaging (fMRI) studies are beginning to help researchers and clinicians identify what happens to the nervous system with input from the environment and how that information is processed. Efficacy using reliable and valid measurement tools must then be based on outcomes, with an understanding of the best available scientific knowledge as a rationale for why the outcome is present.

This classification system is based on identified input, observed responses, current research on the function of the CNS, and the various systems involved in the control and modification of responses. An understanding of normal processing of input and its effect on the motor systems helps the clinician to evaluate and use the intact systems as part of treatment. Research with fMRI is currently allowing greater insight into specific brain regions that are being used during various cognitive and motor activities.^{107–122} Yet the specific interactive nature of multisensory input, memory, motivation, and motor function is still unknown. When the response to certain stimuli does not help the patient select or adapt a desired motor response, then the classification

schema for augmented input provides the clinician with flexibility to select additional options. This can be done by spatially summing input, such as using stretch, vibration, and resistance simultaneously, or temporally summing input, such as increasing the rate of the quick stretch or increasing the time between inputs to give the system ample time to respond.

Many factors can influence motor behavior, such as the methods of instruction, the resting condition of the nervous system, synaptic connections, cerebellar or basal ganglia or cortical processing, retrieval from past learning, motor output systems, or internal influences and neuroendocrine balance. Its clinical implications become clearer if the therapist retains a visual image of the patient's total nervous system, including afferent input, intersystem processing, efferent response, and the multiple interactions on one another. At any moment in time, multiple stimuli are admitted into a patient's input system. Before that information reaches a level of primary processing, it will cross at least one if not many synaptic junctions. At that time the information may be inhibited, excited, changed or distorted, or allowed to continue without modification. If the information is at the first synapse, the patient will have no sensation. If it is inhibited at the thalamus, again the patient will not perceive sensation, but that does not mean other areas of the brain will not be sent that information, because sensory information is also sent to a variety of areas after that initial synapse. Research studies have found that sensory input information may even affect gait and other movement patterns even if the patient has no perception of the input.^{123,124} If the input is changed, then the processing of the input will vary from the one normally anticipated. The end product after multiple system interactions will be close to, will be farther away from, or will seem to have no effect on the desired motor pattern. Furthermore, sensory processing can take place at many segments of the nervous system. Although the CNS is not hierarchical, with one level in total control over another, certain systems are biased to affect various motor responses. At the spinal level the response may be phasic and synergistic. Brain stem mechanisms may evoke flexor or extensor biases, depending on various motor systems and their modulation. Cerebellar, basal ganglia, thalamic, and cortical responses may be more adaptive and purposeful.¹²⁴⁻¹²⁷ Thus the therapist must try to discern where the input or the feedback is being affective or short circuited.

Remembering input as a possible option for intervention will always allow the therapist to differentiate the same five alternatives—no response, facilitating (heightening), inhibiting (dampening), distorting, or normal processing. These alternatives can occur anywhere in the system at synaptic junctions. Finally, motor output is programmed and a response is observed. If the response is considered normal, the clinician assumes that the system is intact with regard to the use and processing of the inputs. If the response is distorted or absent, little is known other than there is a lack of the normal processing somewhere in the CNS or an insufficient amount of input was used. One way to differentiate motor problems from problems with other systems is to use other functional activities that have programs similar to the body system program identified as impaired. If a program, such as posture, demonstrates deficiencies in one functional pattern, then the therapist must determine if it is also deficient in other patterns. If the postural motor problem affects all motor performance, then the therapist had determined that a motor program deficit exists and will have to determine how to correct that problem. If, on the other hand, the program runs smoothly and effortlessly when certain demands are taken away, such as resistance from gravity, position in space, need for quick responses, and so forth, then it may be that the problem is within another subsystem such as cognition, perception, the biomechanical system, or the cardiopulmonary system or is a power-production

problem that can be corrected by slowly increasing the demand on the postural system through repetitive practice using various additional input interventions. Differentially screening motor impairments as pure CNS motor problems (muscle recruitment, firing rate, balance) versus problems with another system (perception of vertical) becomes critical in a managed-care system that funds only a certain number of treatment sessions. Once normal processing has been identified, understanding of deficit systems and potential problems can be analyzed more easily. To reiterate, this requires awareness of the totality of the individual (i.e., the patient's personal preference of stimuli and the uniqueness of processing and internal influences). A systems model requires simultaneous processing of multiple areas, with interactions being relayed in all directions. A patient's CNS and peripheral nervous system (PNS) are doing just that, and the therapist must develop a sensitivity toward the patient as a whole while interacting with specific components. With input from the patient and family, it is the therapist's responsibility to select methods most efficacious and effective for each patient's needs in relation to that person's specific neurological problems. This viewpoint, based on a variety of questions, leads to a problem-oriented approach to intervention. Because the output or response pattern is based on α motor neuron discharge and thus extrafusal muscle contraction, the *first question* is posed: what can be done to alter the state of the alpha motor neuron pool or motor generators? *Second*, what input systems are available, either directly or indirectly, that will alter the state of the motor pool? *Third*, which techniques use these various input systems as their primary modes of entry into the CNS? *Fourth*, what internal mechanisms need modification or adaptation to produce a desired behavior response from the patient? *Fifth*, which input systems are available to alter the internal mechanism and what outcomes are expected? *Sixth*, what combination of input stimuli will provide the best internal homeostatic environment for the patient to learn and rehearse a more optimal response pattern? For example, assume that a patient with a residual hemiplegia resulting from an anterior cerebral artery problem has a hypertonic lower extremity that produces the pattern of extension, adduction, internal rotation of the hip, extension of the knee, and plantarflexion inversion of the foot. The answers to the first two questions are based on the knowledge that the proprioceptive and exteroceptive systems can drastically affect spinal central pattern generators and that these input systems are intact at spinal, brain stem, cerebellum, and thalamic levels and may even project to the cortex.

Appropriate selection of specific techniques will provide viable treatment alternatives. Awareness that a patient's/client's response pattern is an inherent synergistic pattern leads to a better understanding of the clinical problem. Knowing that the patient/client is unable to combine the alternative patterns, such as hip flexion with knee extension needed for the late stage of swing phase through the early aspects of stance phase during gait, the therapist can use the other inherent processes to elicit these and other patterns. BWSTT is an example of an augmented treatment intervention in which the clinician assists the patient to place the leg and foot with each step while the apparatus controls balance and posture to provide an experience of normal gait while requiring the patient to have only the strength to manage partial body weight.¹²⁸⁻¹³³ Finally, techniques such as combining standing and walking with the application of quick stretch, vibration, or rotation, or having the patient reach for a target or follow a visual stimulus while walking, provide a variety of combinations of therapeutic procedures to help the patient learn or relearn normal response patterns. Furthermore, combining techniques gives the clinician a choice of various procedures and promotes a learning environment that is flexible, changing, and interesting. The therapist must, again, make the transition from applying contrived therapeutic

procedures during functional tasks to allowing the patient to practice the task without the therapist interceding and without external feedback.¹³⁴ In that way the patient uses inherent feedback to self-correct feedforward motor programming and then to continue running the appropriate movement strategies.

Proprioceptive System Integration of Stretch, Joint, and Tendon Receptors

Proprioceptive training is proposed to benefit somatosensory and sensorimotor function through cortical reorganization that occurs in response to repetitive active or passive movement. Proprioception¹³⁵ as an input system has a direct effect on program generators at the spinal level.¹³⁶ However, because of its importance in motor learning and motor adaptation to new or changing environments, proprioception also has significant connections to the cortical and cerebellar neural networks. Its divergent pathways have synapses within the brain stem, diencephalon, and spinal system. Proprioceptive input can potentially influence multiple levels of CNS function, and all those levels can potentially modulate the intensity or importance of that information through many different mechanisms.^{136,137} Proprioceptors are found in three peripheral anatomical locations: the stretch receptors, the tendon, and the joint. The afferent receptors responsible for relaying sensory information through those sites are discussed in the following subsections.

Muscle stretch receptors

Stretch. Stretch, quick stretch, and maintained stretch are all sensory input systems that use the stretch receptors in the muscles and heighten the motor pool.^{138–140} Stretch simultaneously heightens both the muscle response to that stretch and potentially heightens the sensitivity of the agonistic synergy. It will also lower the excitation of the antagonistic muscle and those muscles that are part of the antagonistic synergy. Stretch information will be sent to higher centers for sensory integration and perception. The cerebellum uses this incoming feedback to maintain and/or regulate motor nuclei in the brain stem that will influence the state of the α and γ motor neurons. This allows for cerebellar feedforward regulation (refer to Chapter 19). There are many ways to apply stretch to the muscles. The therapist can use (1) the hands and their respective muscle power to apply a stretch, (2) a manual weight system of some sort that maintains the stretch through the range, (3) a suspension system such as used in Pilates exercises, (4) the patient's own body weight against gravity, (5) a complex robotic system that computerizes the amount of stretch depending on the individual's specific data, or many other creative ways to apply stretch to muscle fibers within the belly of the muscle tissue. As stated previously, stretch can also be applied to the antagonist muscle or muscle synergy to dampen agonist function. Thus stretch can be used to enhance tone in the agonist or to decrease tone of the agonist through the antagonist. The therapist should always remember that even though a response may not look obvious, as long as the peripheral nerves and motor neurons within the spinal system are intact, these approaches will change the state of the motor pool.

Table 8.1 lists a variety of treatment procedures believed to use proprioceptive input from the muscles as a primary mode of sensory stimulation. The varying intensity, amount of tension, or rate of the stimuli, in addition to the original length of the muscle before application of the stimulus, will determine its firing. Remember, afferent information is projecting to many areas above the spinal system, and the result will be regulation or modulation, ultimately affecting activity.¹³⁶

Resistance and strengthening. Resistance is often used to facilitate intrafusal and extrafusal muscle contraction. Resistance can be applied manually, mechanically, and by the use of gravity. Resistance recruits more motor units in the target muscles. Although muscles can contract both in an isometric and an isotonic fashion, most

TABLE 8.1 Treatment Suggestions Using Proprioceptive Input from the Muscles

1. Resistance
2. Quick stretch to agonist
3. Tapping: tendon and/or muscle belly
4. Reverse tapping: gravity stretches; tapping agonist into shortened range
5. Positioning (range)
6. Electrical stimulation
7. Pressure or sustained stretch
8. Stretch pressure
9. Stretch release
10. Vibration: facilitatory frequency for small vibrator, relaxation for total-body vibration
11. Gravity as a prolonged stretch
12. Active motion

contractions consist of a mixture of the two. Certain muscle groups, such as the flexors, benefit from isometric exercise, as well as isotonic exercise in both eccentric and concentric modes. Under normal circumstances, the flexors are used for repetitive or rhythmical activities. The extensors, on the other hand, usually remain contracted in an effort to act against the forces of gravity. Therefore the extensor groups benefit best from isometric and eccentric resistance.¹⁴¹

When resistance is applied to a voluntary muscle, spindle afferent fibers and tendon organs fire in proportion to the magnitude of the resistance. Resistance is more facilitative to an isometrically contracted muscle than in an isotonic contraction.⁴⁰ As isometric resistance is increased or continued, more motor units are recruited, thereby increasing the strength of extrafusal contraction.²⁹ Eccentric isotonic contraction refers to the lengthening of muscle fibers with resistance added to the distal segment, as in lowering the arms while holding a heavy weight. Eccentric contraction uses less metabolic output and promotes strength gains in less time.²⁹ Resistance is an important clinical treatment and has been used and will continue to be used by clinicians within multiple treatment philosophies over the next millennium.^{11,22,28,32,71,142–148} The complexity of neural adaptation after resistive exercises may lead to a different training environment depending on age, athletic status, and specific body system deficits.¹⁴⁹ Combining resistive training with guided imagery or other types of adjunct interactions has conflicting results.^{149–151} Yet there are still questions regarding optimal resistive training, in particular, the parameters of load and work frequency,^{152,153} and whether one resistive technique is better than another.^{154,155} Research certainly has shown that resistance training does enhance functional abilities across age groups,^{145,156,157} but¹⁵⁸ again the specific resistive training techniques are often not identified. The terms *resistive training*, *weight training*, and *strength training* are often used synonymously, and thus specifics are yet to be identified in the research. How all these uses of resistive exercises will play out in the future is up to future researchers in the field of movement science. Very costly high-technology tools have been added to aid in resistive training.^{159,160} Given the needs of individuals after neurological insults, cost becomes a major factor, and finding creative and cost-efficient ways to apply resistance may become a common research question in the future.

Tapping. Three types of tapping techniques are commonly used by therapists. Tapping of the tendon is a fairly nondiscriminatory stimulus. Physicians use this technique to determine the degree of stretch sensitivity of a muscle. A normal response would be a brisk muscle contraction. Because of the magnitude of the stimulus and the

direct effect on the α motor neuron, this technique is not highly effective in teaching a patient to control or grade muscle contraction.¹⁶¹ Instead, tapping of the muscle belly, a lower-intensity stimulus, is more satisfactory. Reverse tapping is a less frequently described technique, but it can be used. The extremity is positioned so gravity promotes the stretch, instead of the therapist manually tapping or actively inducing muscle stretch. Once the muscle responds, the therapist taps or passively moves the extremity to help the muscle obtain a shortened range. An example of reverse tapping would be tapping the triceps muscle when the patient is bearing weight on the extended elbow and actively trying to achieve full elbow extension. Timing of this technique is important. Gravity quickly stretches the triceps. If the timing follows the quick stretch to the extensor, then the flexors will be dampened and active extension more likely a motor response. If the therapist taps the elbow toward extension when the flexors' motor neurons are sensitive, then those flexor muscles may respond to the stretch and contract, taking the arm farther into flexion.

Positioning (range). The concept of submaximal and maximal range of muscles is highly significant to clinical application. Bessou and colleagues¹⁶² monitored the neuronal firing of muscle spindles at different ranges of motion. Upper motor neuron lesions can alter the sensitivity of the spindle afferent reflex arc fibers by not using presynaptic inhibition to normally dampen incoming afferent activity.¹⁶³ Therefore ROM should be carefully assessed on an individual basis, particularly in a patient with an upper motor neuron lesion, to determine the maximal or submaximal range for an individual. Therapists always need to determine whether the difference between optimal range and functional ROM is different. If a patient will never need to use full ROM, then spending long periods of time trying to stretch a shoulder or hip to end-range of tissue mobility may not be the best decision with regard to intervention. Therapists also need to carefully evaluate excessive range resulting from hypermobility and hypotonicity. In those situations, external support of the affected joint or limb needs to be considered in all functional positions in order to prevent complications such as pain.^{164–166}

Stretch pressure. The muscle belly is the stimulus focus of stretch pressure. The therapist slowly applies pressure to the muscle belly. It is used to decrease or release tone in the target muscle, allowing for the (temporary) recovery of voluntary movement.^{105,167} Generally this type of stimulus is applied and maintained for a period of time (e.g., 5 to 10 seconds). It is not a quick stimulus and may be using the tendon organ to dampen tone. This type of pressure technique is also used in a variety of complementary approaches (see Chapter 39).

Stretch release. This technique is performed by placing the fingertips over the belly of larger muscles and spreading the fingers in an effort to stretch the skin and the underlying muscle. The stretch is done firmly enough to temporarily deform the soft tissue so the cutaneous receptors and Ia afferent fibers may produce facilitation of the target muscle. It is easy to determine quickly whether the response is efficacious by just feeling and looking at the response of the patient.

Manual pressure. Manual pressure can be facilitatory when it is applied as a brisk stretch or friction-like massage over muscle bellies. The speed and duration at which the manual pressure is applied determine the extent of recruitment from receptors. Paired with volitional efforts, manual pressure can lead to motor function and, with repetition, motor learning.

Vibration. There are two types of vibratory methods used therapeutically. The first deals with the use of a handheld vibrator to facilitate Ia receptors to enhance agonistic muscle contraction in hypotonic muscles or to facilitate Ia receptors of antagonistic muscle fibers to inhibit hypertonic agonists. Currently the use of vibration to facilitate Ia responses within specific muscle function has been used to show

how proprioception can be used to alter upright standing.^{168,169} The second type of vibratory method is a total-body vibration to facilitate postural tone and balance and is applied through the feet in a standing position.^{170–173}

Bishop^{174,175} wrote an excellent series of articles on the neurophysiology and therapeutic application of vibration in the 1970s. High-frequency vibration (100 to 300 Hz or cycles per second) applied to the muscle or tendon elicits a reflex response referred to as the *tonic vibratory response*. Tension within the muscle will increase slowly and progressively for 30 to 60 seconds and then plateau for the duration of the stimulus.¹⁷⁶ Some researchers found that at cessation of the input the contractibility of the muscle was enhanced for approximately 3 minutes.^{176,177} The discrepancy in the research may reflect the way the individual is using the input, both from a direct effect on the motor generator and from supraspinal modulation over the importance of the input, which may affect the overall learning and plasticity of the CNS. To facilitate hypotonic muscle, the muscle belly is first put on stretch, and then vibratory stimuli are applied.¹⁷⁸ To inhibit a hypertonic muscle, the antagonistic muscle could be vibrated.^{174,178} The use of vibration can be enhanced by combining it with additional modalities such as resistance, position, and visually directed movement. Vibration also stimulates cutaneous receptors, specifically the pacinian corpuscles, and thus can also be classified as an exteroceptive modality.¹⁷⁹ Because of its ability to decrease hypersensitive tactile receptors through supraspinal regulation, local vibration is considered an inhibitory technique (it is also discussed later in the section on exteroceptor-maintained stimulus).

Amplitude or amount of displacement must also be considered when vibration is analyzed as a modality. It has been reported that high amplitude causes adverse effects, especially in patient's with cerebellar dysfunction.¹⁷⁵ Vibration is not recommended for infants because the nervous system is not yet fully myelinated and the vibration might cause too much stimulation. The reader is also cautioned about using vibration over areas that have been immobilized because of the underlying vascular tissue potential for clotting. Vibration on or near these blood vessels could dislodge a clot, causing an embolism. Vibration also needs to be used cautiously over skin that has lost its elasticity and is thin (e.g., that in older persons) because the friction itself from the vibration can cause tearing. The therapist must always keep in mind the environment and the functionality of an intervention procedure. The use of vibration may assist the patient in contractions and somatosensory awareness, but it is an unnatural way to facilitate either system and thus needs to be removed as part of an intervention as soon as the patient demonstrates some sensory awareness and/or volitional control over a movement component.

Within the past decade, the use of vibration of specific muscle groups of the neck has been studied to determine its effect on upright standing and the interaction with and without eyes open.^{168,169} These studies showed that by vibrating specific muscle groups, those muscles would actively contract and change the position of the head in space but that with eyes open the effect was minimized in relation to global postural control. A similar study examined the effect of vibration on various muscles within the lower extremities and how that affected various postural responses.^{180,181} These researchers found that different frequencies affected different muscle groups. The one consistent thing all studies have shown is that vibration does facilitate Ia muscle fibers, which in turn affect muscle contraction of the agonist receiving the vibration. Other sensory systems can assist or override the effect of vibration, but that is because of supraspinal influence over motor generators.

Total-body vibration is currently being used to determine if it affects motor performance. Studies have shown that whole-body

vibration can enhance motor performance in high-level athletes performing sprints and jumps,^{170,171} as well as improve trunk stability, muscle tone, and postural control in individuals after stroke while in geriatric rehabilitation.¹⁷³ Its application for individuals with neurological dysfunction is inconclusive.^{182,183} Studies specifically directed toward the elderly again show promise, but further research is needed for specificity.^{184–186} Future research will need to determine the effect of total-body vibration when introduced to all populations of individuals with neurological dysfunction.¹⁸⁷ At that time, both amplitude and magnitude will need to be identified to replicate studies. Total-body vibration certainly falls under primarily proprioception but also could be classified under combined proprioceptive techniques or multisensory classification techniques because the input affects the muscle spindles, the joints, the vestibular system, and possibly the auditory system with the low frequency noise. And every time vibration is applied, the skin receptors will initially fire although most will adapt quickly to prolonged use of any stimuli.

The tendon. The tendon receptors are specialized receptors located in both the proximal and the distal musculotendinous insertions. In conjunction with the stretch receptors, the tendon plays an important role in the mediation of proprioception.^{136,137,188–193}

The principal role of the tendon is to monitor muscle tension exerted by the contraction of the muscles or by tension applied to the muscle itself. Research has demonstrated that the tendon is highly sensitive to tension and acts conjointly with the stretch receptors to inform higher centers of continuing environmental demands to modulate or change existing plans; these higher centers in turn regulate tonicity and the state of the motor pool.^{46,136} The tendon (Ib) signals not only tension but also the rate of change of tension and provides the sensation of force as the muscle is working.¹⁸⁸ A fundamental difference between the tendon organ and the stretch receptors is that the stretch receptors detect length, whereas the tendon monitors tension and force. The stretch receptors regulate reciprocal inhibition, whereas the tendon modulates autogenic inhibition. Table 8.2 lists a variety of treatment approaches using the tendon to inform higher centers regarding needed changes and regulation over spinal generators.

Maintained stretch to the tendon organ. Maintained stretch to a muscle has the potential for triggering the tendon organ if tension is great enough. Once the maintained stretch fires the tendon organ, autogenic inhibition of the same muscle occurs. A therapist will feel a release of the agonist muscle, allowing for elongation of the contractile components. Simultaneously, the tendon organ's sensory neurons will facilitate motor neurons to the antagonist muscle, thus heightening its sensitivity and potential for activity. This is the technique used when a joint has developed range restriction. The clinician always needs to differentiate whether the tightness found within the joint is caused by compensatory muscles considered *movers* protecting injured postural muscles beneath or by tightness just from positioning, disuse, or fear.

Inhibitory pressure. Pressure has been used therapeutically to alter motor responses. Mechanical pressure (force), such as from cones, pads, or the orthokinetic cuff developed by Blashy and Fuchs,¹⁹⁴

provided continuously is inhibitory. That pressure seems most effective on tendinous insertions. It is hypothesized that this deep, maintained pressure activates pacinian corpuscles, which are rapidly adapting receptors. A variety of researchers have studied these receptors and their relationship to regulating vasomotor reflexes,¹⁹⁵ modulating pain,^{196–200} and dampening other sensory system influence on the CNS.^{177,199}

This inhibitory pressure technique also works when pressure is applied across the longitudinal axis of a tendon. The pressure is applied across the tendon with increasing pressure until the muscle relaxes. Constant pressure applied over the tendons of the wrist flexors may dampen flexor hypertonicity and elongate the tight fascia over the tendinous insertion.

Pressure over bony prominences has modulatory effects. A common example is pressure on the medial aspect of the calcaneus, which dampens plantarflexors and allows contraction of the lateral dorsi-flexor muscles. Pressure over the lateral aspect of the calcaneus also dampens calf muscles to allow for contraction of the medial dorsi-flexor muscles.²⁸ Localized finger pressure applied bilaterally to acupuncture points has been shown to relieve pain and reduce muscle tone.^{200–204} This technique has also been found to be particularly effective when used in a low-stimulus environment and when combined with deep breathing. This combination of pressure (manually applied), environmental demands (low), and parasympathetic activity (slow, relaxed breathing) illustrates various systems interacting together to create the best motor response. The real world requires the patient to respond to many environmental conditions while relaxed or under stress. Thus once a patient begins to demonstrate normal adaptable motor responses, the therapist needs to change the conditions and the stress level to allow the patient to practice variability. As described, this practice should incorporate motor error, especially error or distortions in the plan, yet still achieve the desired goal. As the patient self-corrects, greater demand and variability should be introduced.²⁰⁵

Joint receptor approximation. Approximation of the joint mimics weight bearing and facilitates the postural extensor system, and thus use of the treatment technique is thought to improve balance.²⁰⁶ Gravity creates approximation and its greatest force is produced down through the body in vertical postures. Approximation should help to stabilize any joint that is in a load-bearing situation by eliciting coactivation of the muscles around the joint in question. In standing, gravity creates approximation down through the entire spine, hips, knees, and ankles. When in a prone position on elbows, the load goes down again through the upper spine while simultaneous going down through the shoulder girdles of both arms. If a therapist increases that load by adding pressure down through the joints in question, then an augmented intervention has been added to the therapeutic environment. Using weight belts around the waist or a weighted vest on the trunk can facilitate the postural coactivation needed during standing or walking.^{207–209} At times, approximation can be used to heighten normal postural tone while simultaneously dampening excessive tone in the other leg. For example, patients/clients who have CNS insult often have an imbalance in function within the two lower extremities. This can be very frustrating for the therapist because bringing the patient to standing to assist in regaining normal postural extension of one leg triggers the other into a strong extensor pattern, causing plantarflexion and inversion of that foot. One way to use approximation in treating both legs simultaneously might be to first bring the patient from sitting onto a high-low mat. Then the therapist can raise the mat high enough that the patient can be lowered into standing on the normal-functioning leg. At the same time the patient's other leg can be bent at the knee, and that knee placed on a stool or chair. This allows

TABLE 8.2 Treatment Suggestions Using Proprioceptive Input From the Tendon

1. Extreme stretch
2. Deep pressure to tendon
3. Passive positioning in extreme lengthened range
4. Extreme resistance: more effective in lengthened and shortened range
5. Deep pressure to muscle belly to put stretch on tendon
6. Small repeated contractions with gravity eliminated

approximation down through the entire leg that is in standing position while approximating the trunk, hip, and knee of the other leg in the kneeling position. The therapist can work on standing and weight shifting in one leg while dampening abnormal tone in the kneeling leg. As the kneeling leg starts to regain postural coactivation in its hip, postural function will often be felt in the knee and ankle.

Traction and distraction. One or more joints are distracted by a force that causes it or them to separate or pull apart, similar to the swing phase of the leg during ambulation or the arms in a reciprocal pattern to each leg. This distraction of the joint receptors also puts stretch on the muscles, which combines to facilitate the pattern into which the limb is moving. Simultaneously, distraction dampens the antagonistic movement pattern, which allows the agonist movement to continue. A therapist will often use manual traction to get relaxation of hyperactive extensor muscles or for limited mobility.²¹⁰ Often therapists do not think of the traction when applying resistance to a limb. For example, a mistake made is placing ankle weights to facilitate limbs that are ataxic. Ataxia is an imbalance in coactivation and smooth movement of both agonist and antagonist muscle groups.²¹¹ The weight itself slows down the excessive movement by the resistance. However, weight on the ankle creates traction that will facilitate only the flexor group and often creates an additional imbalance in the ataxic leg.²¹² When the weights are removed, the patient often is more ataxic. **Table 8.3** lists a variety of treatment approaches using the joints to facilitate or inhibit motor output.

Combined proprioceptive input techniques. Many techniques succeed because of the combined effects of multiple inputs to the proprioceptive system of stretch, joint, and tendon receptors. Some of these combined techniques described in this section include ballistic movements; total-body positioning; PNF patterns; postexcitatory inhibition (PEI) with stretch, range, rotation, and shaking; heavy work patterns; Feldenkrais (see Chapter 39)^{213–215}; and manual therapy.^{23,198,216}

Ballistic movement. Ballistic movements are characterized by muscle contractions that occur in very high velocities over a short period of time. They are effective because of their combined proprioceptive interaction. The patient/client is asked to quickly initiate a movement, such as shoulder flexion while prone over a table with the arm hanging over the side. This component is volitional, but the patient then maintains a passive role. As the patient relaxes, the movement patterns become automatic. The physiology behind the automatic movement is easy to understand. As the muscle approaches the shortened range, the amount of ongoing γ afferent activity decreases. Thus both the agonist α motor neuron bias and the inhibition of Ia and II receptors of the antagonistic α motor neurons decrease. Simultaneously, the antagonistic muscle is being placed on more and more stretch. This stretch, as well as the lack of inhibition on the

antagonistic α motor neurons, will encourage the antagonistic muscle to begin contraction and reverse the movement pattern. The tendon organs also play a key role in ongoing inhibition. As the muscle approaches the shortened range and tension on the tendon becomes intense, the tendon organ increases its firing, thus inhibiting the agonistic muscle in the shortened range while facilitating the antagonistic muscle. This technique is highly movement oriented, and the traction applied by gravity to the shoulder joint while swinging the arm further facilitates the movement. These ballistic movements are part of the program generators within the spinal system that facilitate reciprocal movements of the limb. As the patient performs the movement, there is little need for conscious attention to drive the movement; it will run automatically. The role of the Ib fibers during this open chain or movement pattern is definitely different from its role in a closed chain or weight-bearing environment.¹⁸⁹ Supraspinal influence over programmed activity also plays a role in the effectiveness of this treatment.²¹⁷ The specific rationale for why ballistic movements have functional carryover may be explained by recent research into cerebellar function and the importance of mechanical afferent input in regulation of movement (see Chapter 19).

The clinician using this technique must exercise caution. ROM can easily be obtained through ballistic movement. Consequently, the clinician must always determine before therapy the reasons for specific clinical signs and whether the total problem will be corrected through an activity such as a ballistic movement. This is the diagnostic responsibility of the professional. If one component of the problem is alleviated, such as limitation of range, while other components are ignored, this can be a dangerous technique. If the lack of range is a result of muscle splinting because there is lack of postural tone or joint stability, then ballistic movement has the possibly increasing the problem. For example, assume that the rotator cuff muscles are slightly torn and the movers of the shoulder are superficially splinting to prevent further tearing. Ballistic movement that causes relaxation of more superficial muscles will place more responsibility for shoulder stabilization on the rotator cuff muscles and may increase the tear on the rotator cuff muscles causing increased pain.

Total-body positioning. Total-body positioning implies the use of positioning and gravity to dampen afferent activity on the α motor neurons and thus cause a decrease in tone, or relaxation.²¹⁸ Currently, the rationale for why relaxation of striated muscle occurs after this treatment implies that the effect of the flexor reflex afferents is being dampened by a combination of input and interneuronal activity. These changes in the state of the muscle tone will not be permanent and will revert to the original posturing unless motor learning and adaptation within the central programmer occur simultaneously. Thus, for this treatment to effect permanent change, a large number of systems need modification. This modification can be augmented by techniques that facilitate autogenic inhibition, reciprocal innervation, labyrinthine and somatosensory influences, and cerebellar regulation over tone.²¹⁹ Changing the degree of flexion of the head also alters vestibular input and the state of the motor pool. But again, the patient's CNS needs to be an active participant and will ultimately determine whether permanent learning and change are programmed.

Proprioceptive neuromuscular facilitation. To analyze and learn the principles, techniques, and patterns that constitute PNF, a total approach to treatment, refer to the texts by Adler and colleagues,²²⁰ Voss,²²¹ and Sullivan and colleagues.³² This approach is used extensively for patients with musculoskeletal and neuromuscular problems, with research on this method encompassing more populations with lower motor neuron and musculoskeletal problems than upper motor neuron lesions.^{149,216,222–230} When proprioceptive techniques are packaged in specific movement patterns, it may be referred to as PNF. When individual

TABLE 8.3 Treatment Suggestions Using Proprioceptive Input From the Joints

1. Manual traction (distraction) to joint surfaces to facilitate joint motion
2. Manual approximation (compression) to joint surfaces to facilitate cocontraction or postural holding
3. Positioning: gravity used to approximate or apply traction
4. Weight belts, shoulder harnesses, and helmets to increase approximation
5. Wrist and ankle cuffs to increase traction
6. Wall pulleys, weights, manual resistance
7. Manual therapy²³
8. Elastic tubing to provide compression during movement

proprioceptive techniques are discussed alone, the specific sensory function is being acknowledged, and these techniques can be integrated into many rehabilitation intervention strategies.

Postexcitatory inhibition with stretch, range, rotation, and shaking. The concept of PEI is based on the action potential or electrical response pattern of a neuron at the time of stimulation and on the entire phase response until the neuron returns to normal. At the time of stimulation, the action potential will build and go through an excitatory phase. The neuron then enters an inhibitory phase or refractory period during which further stimulation is not possible. This is referred to as the *PEI phase* or *postsynaptic afferent depolarization*.¹⁰⁵ These phase changes are extremely short and, in normal muscle, asynchronous with respect to multiple neuronal firing. In a hypertonic muscle, more simultaneous firing occurs. When the muscle is lengthened, and thus tension is created, more fibers will be discharged. It is hypothesized that if the hypertonic muscle is placed at the end of its spastic range and a quick stretch is applied and held, then total facilitation followed by total inhibition will occur because of PEI. As the inhibition phase is felt, the therapist can passively lengthen the spastic muscle until the facilitatory phase sets in repolarization. At that time the clinician holds the lengthened position. Increased tone will ensue, followed by inhibition and continued lengthening. Holding the range (not allowing concentric contraction during the excitatory phase) is critical. If the muscle is held as the tone increases, the resistance and stretch are then maximal and probably further facilitate the inhibitory phase.

Rood's heavy work patterns. Rood's concepts of cocontraction in weight-bearing positions such as on elbows, on extended elbows, kneeling, and standing blend with current concepts of motor learning. Concepts explain the rationale why postural holding in shortened range for periods of time are valid interventions. Rood stressed the need for patients to work in and out of those shortened ranges to gain postural control and to practice directing the limbs during both closed and open chain activities.

Feldenkrais. The Feldenkrais concepts^{213,214} of sensory awareness through movement place emphasis relaxation of muscles on a stretch, including distracting and compressing joints for sensory awareness. Both techniques reflect combined proprioceptive techniques. Taking muscles off the stretch slows general afferent firing and thus overload to the CNS. Compression and distraction of joints enhance specific input from a body part while simultaneously facilitating input of a lesser intensity from other body segments. This combined proprioceptive approach enhances body schema awareness in a relaxed environment. It also integrates empowerment of the patient by use of visualization and asking for volitional control. (See Chapters 27 and 39 for additional information.)

Exteroceptive or Cutaneous Sensory System

Differentiation of receptor site as augmented intervention. Humans have many different types of tactile receptors. Some are superficial, and others are deep within the layers of the skin. These receptors have been identified within the chapter on motor learning. Their use as augmented intervention strategies is discussed in the following section.

A list of treatment techniques using the exteroceptive (tactile) input system as their primary mode of entry can be found in Table 8.4. Interventions that use cutaneous stimuli include neutral warmth, light touch, and maintained pressure, among others. Specific stimuli for the varied receptors and the expected responses to cutaneous stimuli are presented in the table.

Treatment alternatives using the exteroceptive system. The function of the exteroceptive system is to inform the nervous system

TABLE 8.4 Suggested Treatment Procedures Using Cutaneous Stimuli

Quick Phasic Withdrawal

1. Stimulus
 - a. Pain
 - b. Cold: one-sweep with ice cubes, Rood quick ice
 - c. Light touch: brush (quick stroking), finger, feather
2. Response
 - a. Stimulus applied to an extensor surface: elicits a flexor withdrawal*
 - b. Stimulus applied to flexor surface: may elicit flexor withdrawal or withdrawal from stimulus into extension

Prolonged Icing (Repetitive Icing Should Be Used With Caution Because of Rebound Effect)

1. Stimulus
 - a. Ice cube
 - b. Ice chips and wet towel
 - c. Bucket of ice water
 - d. Ice pack
 - e. Immersion of body part or total body
2. Response: inhibition of muscles below skin areas iced

Neutral Warmth

1. Stimulus
 - a. Air bag splints
 - b. Wrapping entire body or individual body part with towel
 - c. Tight clothing such as tights, fitted turtleneck jerseys, Lycra clothing
 - d. Tepid water or shower
2. Response: inhibition of area under which neutral warmth was applied

Light Touch, Rapid Stroking

1. Stimulus
 - a. Light intermittent tactile stimulus to an identified dermatome-motome interaction area
2. Response: facilitation of muscle(s) related to the stimulus area

Maintained Pressure or Slow, Continuous Stroking With Pressure

1. Stimulus
 - a. Slowly rubbing the target area with a towel
 - b. Wearing Lycra or spandex clothing
2. Response: sensory receptor adaptation and decrease in afferent firing

*Response: adaptation of many cutaneous receptors to stimulus, thus decreasing exteroceptive input, decreasing reticular activity, and decreasing facilitation of muscles underlying stimulated skin.

about the surrounding world. The CNS will adapt behavior to coexist and survive within this environment. Although many protective responses are patterned within the motor system, these patterned responses can be changed or modulated according to momentary inherent chemistry, attitude, motivation, alertness, and so on. Different from some of the other treatment approaches, the function of the exteroceptive input system is not reflexive but rather informative and adaptable.

Quick phasic withdrawal. The human organism reacts to painful or noxious stimuli at both conscious and unconscious levels. If the stimulus is brief and of noxious quality, it will elicit a protective reaction of short duration with use of the long-chain spinal reflex loops. Simultaneously, afferent impulses ascend to higher centers to evoke prolonged emotional-behavioral responses. Stimuli such as pain, extremes in temperature, rapid movement, light touch, and hair

displacement are the most likely to cause this reaction by activating free nerve endings. These stimuli are perceived as potentially dangerous and communicate directly with the reticular-activating system and nonspecific thalamic nuclei. These structures have diffuse interconnections with all regions of the cerebral cortex, autonomic nervous system (ANS), limbic system, cerebellum, and motor centers in the brain stem. Research has shown that children who exhibit hyperactive withdrawal reactions also develop negative emotional reactivity and show significantly more avoidance behavior and in time show right frontal asymmetry.²³¹ These alerting stimuli have been linked to motor seizures in critically ill patients.²³² As indicated by these research studies, therapists need to be aware of these potential responses, especially in patients with severe neurological insult that has resulted in a lower level of consciousness. These low-functioning patients cannot express their feelings nor how their nervous system is reacting to the input. Thus therapists need to be very aware of any motor response a patient may express and try to avoid using stimuli that might trigger these avoidance behaviors.

From observance of the behavior of patient's with chronic neuropathic pain, withdrawal responses seem to become habitual and may be associated with somatosensory (S1) remapping²³³; thus some individuals may have difficulty with discriminating benign stimuli from potentially injurious stimuli. When any movement or touch is perceived as painful, the challenge to both therapist and patient is to agree on the therapeutic dose of a certain intervention and particular session. Therapists need to gain trust, and one way is to not elicit a lot of pain during treatment. Patient responses to pain induced during treatment such as exercise and manual therapy range can from increased patient resistance to joint and overall body movement to a complete loss of trust in the practitioner. Alami and colleagues completed a small study of patients/clients who experienced pain induced by exercise and mobilization (PIEM) during physical therapy and found that patient's desire preintervention education about pain, their particular pain response, and how a physical therapy plan of care can be adapted according to their pain intensity.^{233a}

There are some real therapeutic limitations to using stimuli that "load" the spinothalamic system. A painful stimulus will be excitatory to the nervous system and produce a prolonged reaction after discharge.

Because light touch has both a protective and a discriminatory function, techniques such as brushing or stroking the skin with a soft brush have the potential of informing the CNS about (1) texture, object specificity, and error in fine motor responses or (2) danger (eliciting a protective response). If a protective response is triggered, the specific withdrawal pattern will depend on a variety of circumstances. If the stimulus is applied to an extensor surface, then a flexor withdrawal will be facilitated. If the stimulus is placed on a flexor surface, one of two responses occurs. First, the patient might withdraw from the stimulus, thus going into an extensor pattern. Second, the stimulus may elicit a flexor withdrawal and cause the patient to go into a flexor pattern. Which pattern occurs depends on preexisting motor programming bias as a result of positioning and the predisposition of the patient's CNS. Both responses would be considered normal. The condition or emotional state of the nervous system and whether the stimulus is considered threatening also determine the sensitivity of the response, again reinforcing the systems' interdependence. These responses are protective and do not lead to repetition of movement or motor learning. For that reason, along with the emotional and autonomic reactions, a phasic withdrawal to facilitate flexion or extension is not recommended as a treatment approach unless all other possibilities have been eliminated.

Short duration, high-intensity icing. Cold is another stimulus that the nervous system perceives as potentially dangerous. The use

of ice as a stimulus to elicit desired motor patterns is an early technique developed by Rood and was referred to as *repetitive icing*. An ice cube is rubbed with pressure for 3 to 5 seconds or used in a quick-sweep motion over the muscle bellies to be facilitated. This method activates both exteroceptors and proprioceptors and causes a brief arousal of the cortex. This method can produce unpredictable results. Although initially a phasic withdrawal pattern generator response will be activated immediately after the reflex has taken place, the "rebound" phenomenon deactivates the muscle that has been stimulated and lowers the resting potential of the antagonistic muscle.²³⁴ Therefore a second stimulus to the same dermatome-myotome neural network may not elicit a second response. However, because of reciprocal innervation, the antagonistic muscle may effect a rebound movement in the opposite direction. Icing may also cause prolonged reaction after discharge because of the connections to the reticular system, limbic system, and ANS. Thus the ANS would be shifted toward the sympathetic end. Too much sympathetic tone causes a desynchronization of the cortex.²³⁵ Although the resting state of the spinal generator may be altered briefly, if the heightened state persists, the cause is most likely fear or sympathetic overflow (see Chapter 4). This state is destabilizing to the system and most likely will not lead to any motor learning. Because of unpredictable response patterns to Rood's repetitive icing, this technique is seldom used.

The therapist is cautioned not to use short-duration, high-intensity icing to the facial region above the level of the lips, to the forehead, or to the midline of the trunk. These areas have a high concentration of pain fibers and a strong connection to the reticular system.^{13,236}

Ice should not be used behind the ear because it may produce a sudden lowering of blood pressure.²³⁷ The therapist should also avoid using ice in the left shoulder region in patients with a history of heart disease because referred pain from angina pectoris manifests itself in the left shoulder area, indicating that the cold stimulus might cause a reflexive constriction of the coronary arteries.²³⁸ In addition, the primary rami located along the midline of the dorsum of the trunk have sympathetic connections to internal organs. The cold stimulus may alter organ activity and perhaps produce vasoconstriction, causing increased blood pressure and reduced blood supply to the viscera.^{239,240}

Brief administration of ice can have beneficial effects if the nervous system's inhibitory mechanisms are in place. For instance, in children with learning disabilities or adults with sensorimotor delays, the application of ice to the palmar surface of the hands will cause arousal at the cortical level because of the increased activity of the reticular activating system. This arousal response presumably produces increased adrenal medullary secretions, resulting in various metabolic changes. Therefore icing should be used selectively. If the patient has an unstable ANS, icing should be eliminated as a potential sensory modality.²⁴¹

Prolonged use of ice. Physicians have used therapeutic cold for the treatment of individuals with high fever and/or intracranial pressure with the intent of reducing the body temperature or brain swelling to prevent brain damage.²⁴² This procedure is done with cooling pans or blankets. Whole-body cryotherapy has been used to reduce inflammation and pain and overcome symptoms that prevent normal movement. This type of therapy consists of the use of very cold air maintained for 2 minutes in cryochambers. A recent study looked at this type of therapy for injured athletes. It was found that the procedure did not cause harm to the individual.²⁴³ This approach does not seem realistic for use in occupational or physical therapy clinics.

A variety of approaches that incorporate prolonged icing techniques have been used in therapy clinics for decades. The PNF approach may be the most common.²² Inhibition of hypertonicity or²⁴⁴ pain is the goal for the use of any of these methods. With prolonged cold, the neurotransmission of impulses, both afferent and efferent, is

reduced. Simultaneously the metabolic rate within the cooled tissue is reduced (see Chapter 30). Caution must be exercised with regard to the use of this modality. However, for effective treatment results, the patient (1) should be receptive to the modality, (2) should be able to monitor the cold stimulus (sensory deficits should not be present), and (3) should have a stable autonomic system to prevent unnecessary adverse effects of hypothermia. Research of the past decade has consistently shown that cryotherapy is an effective tool for reducing pain and has helped individuals regain integration of axial musculature after neurological insults.^{245–248} Individuals of all ages seem to respond similarly, which allows therapists to use this therapeutic tool across generations.²⁴⁹

Ice immersion of the contralateral limb was used decades ago to get a reflexive decrease in temperature in the affected limb. It was believed that this intralimb reflex was an effective way of treating pain without directly treating the limb, and recent research has validated that belief.²⁵⁰

Ice massage is another form of prolonged icing and is often used to treat somatic pain problems.²⁵¹ It is also used over high-toned muscles to dampen striated muscle contractions. Caution must be used when eliminating pain without correcting the problem causing pain. For example, if instability causes muscle tone and pain, then icing might decrease pain while causing additional joint instability and potential damage. The end result would be an increase, not a decrease, in pain and motor dysfunction.

Maintained stimulus or pressure. Because of the rapid adaptation of many cutaneous receptors, a maintained stimulus will effectively cause inhibition by preventing further stimuli from entering the system. This technique is applied to hypersensitive areas to normalize skin responses. Vibration used alternately with maintained pressure can be highly effective. It should be remembered that these combined inputs use different neurophysiological mechanisms. It is often observed that low frequency–maintained vibration is especially effective with learning-disabled children who have hypersensitive tactile systems that prevent them from comfortable exploration of their environment. When children themselves use vibration on the extremities, their hypersensitive systems seem to normalize and they become receptive to exploring objects. If that exploration is accompanied by additional prolonged pressure, such as digging in a sandbox, the technique seems to be more effective because of the adaptive responses of the nervous system.

Maintained pressure approaches using elastic stockings, tight form-fitting clothing (e.g., wet suits, expanded polytetrafluoroethylene [Gore-Tex] biking clothing), air splints, and other techniques can be incorporated into a patient's daily activity without altering lifestyle. The use of TheraTogs in children with various hyperactivity conditions has become an accepted therapeutic tool. They add some resistance, some support, and maintained pressure.²⁵² TheraTogs have also been shown to be effective in assisting individuals with hemiplegia to regain abductor control.²⁵³

In this way, patients can self-regulate their systems, allowing greater variability in adapting to the environment. Owing to the multisensory and multineuronal pathways used when peripheral input is augmented, traditional linear, allopathic research on human subjects is extremely difficult to design or measure with control, but outcome studies demonstrating efficacy are possible. Initially, efficacy confirmed by observation was acceptable. Concrete evidence is still scarce; repeat studies with use objective measures are needed.

Light discriminatory touch. Once an individual can discriminate light touch both for protection and for discriminatory learning, a lot of therapeutic tools become available to the therapist. Using boxes with an opening so the individual can insert a hand and arm but

cannot see what is inside, a patient can work on discriminating textures, objects, letter, numbers, and so on while working on higher-order processing. Once this touch has been integrated, the patient can also use light touch to determine balance, position in space, and various other types of perceptual tasks.²⁵⁴

Vestibular System

Vestibular treatment techniques. The vestibular system is a unique sensory system, critical for multisensory functioning, making it a viable and powerful input modality for therapeutic intervention. Any static position and any movement pattern will facilitate the labyrinthine system; therefore vestibular function and dysfunction play a role in all therapeutic activities. To conceptualize vestibular stimulation as spinning or angular acceleration minimizes its therapeutic potential and also negates an entire progression of vestibular treatment techniques.^{15,44,255–257} Linear movements in horizontal and vertical postures and forward-backward directions occur early in development and should be considered one viable treatment modality. These movements seem to precede side-to-side and diagonal movements, which are followed by linear acceleration and end with rotational movements. All these movements can be done with assistance or independently by the patient in all functional activities. It is important to remember that the rate of vestibular stimulation determines the effects. A constant, slow, repetitive rocking pattern, irrespective of plan or direction, generally causes inhibition of total-body responses via the α motor neuron but not the spindles,²⁵⁸ whereas a fast spin or fast linear movement tends to heighten both alertness and the motor responses. Again, the vestibular mechanism is only one of many that influence the motor system. Thus the system interaction must be constantly reassessed.

As already indicated, constant, slow, repetitive rocking patterns, irrespective of plane or direction, generally cause inhibition of the total-body responses. Yet any stimulus has the potential of causing undesired responses, such as increased or decreased tone. When this occurs, the procedure should be stopped and reanalyzed to determine the reason for the observed or palpated response. For example, assume that a patient, whether a child with cerebral palsy, an adolescent with head trauma, or an adult with anoxia, exhibits signs of severe generalized extensor hypertonicity in the supine position. To dampen the general motor response, the therapist decides to use a slow, gentle rocking procedure in supine position and discovers that the hypertonicity has increased. Obviously, the procedure did not elicit the desired response and alternative treatment is selected, but the reason for the increased hypertonicity needs to be addressed.

It is possible that the static positioning of the vestibular system is causing the release of the original tone and that through increasing of the vestibular input the tone also increases. It may also be that the facilitatory input did indeed cause inhibition but the movement itself caused fear and anxiety, thus increasing preexisting tone and overriding the inhibitory technique. Instead of selecting an entirely new treatment approach, a therapist could use the same procedure in a different spatial plane, such as a side-lying, prone, or sitting position. Each position affects the static position of the vestibular system differently and may differentially affect the excessive extensor tone observed in the patient. The vertical sitting position adds flexion to the system, which has the potential of further dampening extensor tone. This additional inhibition may be necessary to determine whether the slow rocking pattern will be effective with this patient. It would seem obvious that if a vestibular procedure was ineffective in modifying the preexisting extensor tone, then use of a powerful procedure, such as spinning, would be inappropriate. Selection of treatment techniques should be determined according to patient needs and disability. Patients either

with an acoustic tumor that perforates into the brain stem or with generalized inflammatory disorders may be hypersensitive to vestibular stimulation, whereas other patients, such as a child with a learning disability, may be in need of massive input through this system. Heiniger and Randolph⁴⁴ and Farber^{15,105} present in-depth analyses of various specific vestibular treatment procedures commonly used in the clinic. The literature clearly establishes the causation of one vestibular imbalance, dizziness, for all age groups.^{259–262} Certainly individuals can have vestibular problems and will present themselves as being dizzy or hypersensitive to movement of the head.

General body responses leading to relaxation. Any technique performed in a slow, continuous, even pattern will cause a generalized dampening of the motor output.²⁶³ During handling techniques, these procedures can be performed with the patient in bed, on a mat while horizontal, sitting at bedside or in a chair, or standing. The movement can be done passively by the therapist or actively by the patient. Carryover into motor learning will best be accomplished when the patient performs the movement actively, without therapeutic assistance. In a clinical or school setting, a patient who is extremely anxious, hyperactive, and hypertonic may initiate slow rocking to decrease tone or feel less anxious or hyperactive. The reduction of clinical signs allows the patient to sit with less effort and to be more attentive to the environment, thus promoting the ability to learn and adapt.

It is the type of movement, not the technique, which is critical. The concept of slow, continuous patterns is used in Brunnstrom's rocking patterns¹¹ in early sitting, in PNF mat programs, and in therapeutic ball exercise programs; the use of these patterns can be observed in every clinic. Although the therapist may be unaware of why Mr. Smith gets so relaxed when slowly rocked from side to side in sitting, this procedure elicits an appropriate response. The nurse taking Mr. Smith for a slow wheelchair ride around the hospital grounds may do the same thing. Once the relaxation or inhibition has occurred, the groundwork for a therapeutic environment has been created to promote further learning, such as learning of ADL skills. The technique in and of itself will relax the individual but not create change or learning.

Pelvic mobilization techniques in sitting use relaxation from slow rocking to release the fixed pelvis. This release allows for joint mobility and thus creates the potential for pelvic movement performed passively by the therapist, with the assistance of the therapist, or actively by the patient. This technique often combines vestibular with proprioceptive techniques, such as rotation and elongation of muscle groups, which physiologically modify existing fixed tonal response through motor mechanisms or systems interactions. Simultaneously, slow, rhythmic rocking, especially on diagonals, is used to incorporate all planes of motion and thus all vestibular receptor sites to get maximal dampening effect, whether directly through the vestibulospinal system or indirectly through the cerebellum and reticular spinal motor system. The same pelvic mobility can be achieved by placing the patient (child or adult) over a large ball. The ball must be large enough for the patient to be semiprone while arms are abducted and externally rotated, and the legs relaxed (either draped over the ball or in the therapist's arms). Again, this position allows for maintained or prolonged stretch to tight muscles both in the extremities and in the trunk while doing slow, rhythmical rocking over the ball. The pelvis often releases, and the patient can be rolled off the large ball to stand on a relaxed pelvis preliminary to gait activities. A word of caution must be given regarding use of a large ball for relaxation. It is much easier to control the ball when someone is assisting that control from the opposite direction (in front of the patient). If slow rocking is done and the therapist is keeping his or her voice monotonous for further relaxation, the individual assisting will also relax. One author has had family members fall asleep and slowly or quickly fall to the floor.

Techniques to heighten postural extensors. Any technique that uses rapid anteroposterior or angular acceleration of the head and body while the patient is prone will facilitate a postural extensor response. Scooter boards down inclines, rapid acceleration forward over a ball or bolster, going down slides prone, and using a platform or mesh net to propel someone will all facilitate a similar vestibular response of righting of the head with postural overflow down into the shoulder girdle, trunk, hips, and lower extremities. Rapid movements while on elbows, on extended elbows, and in a crawling position can also facilitate a similar response. Depending on the intensity of the stimulus, the response will vary. In addition, the patient's emotional level during introduction to various types of stimuli may cause differences in tonal patterns. Clinical experience has shown that facilitatory vestibular stimulation promotes verbal responses and affects oral-motor mechanisms. Children with speech delays will speak out spontaneously and respond verbally.

Because facilitatory vestibular stimulation biases the sympathetic branch of the ANS, drooling diminishes and a generalized arousal response occurs at the cortical level. Therefore the appropriate time to teach adaptive rehabilitative techniques is after vestibular stimulation.²⁶⁴

Facilitatory techniques influencing whole-body responses. Tactile, vestibular, and proprioceptive inputs also assist in the regulation of the body's responses to movement.^{40,105} As stated previously, the vestibular system, when facilitated with fast, irregular, or angular movement, such as spinning, not only induces tonal responses but also causes massive reticular activity and overflow into higher centers. Thus increased attention and alertness are often the outcome. The tracts going from the spinal cord, brain stem, and higher subcortical structures must be sufficiently intact to permit the desired responses from this type of input. If a lesion in the brain stem blocks higher-center communication with the vestibular apparatus, then massive input may cause a large increase in abnormal tone. The therapist needs to closely monitor any distress or ANS anomalies.²⁶⁵

Autonomic Nervous System

The ability to differentiate tone created by emotional responses versus tone resulting from CNS damage is a critical aspect of the evaluation process. Emotional tone can be reduced when stress, anxiety, and fear of the unknown have been reduced. This is true for all individuals. The patient with brain damage is no exception. Six treatment modalities²⁶⁶ that normally produce a parasympathetic or decreased sympathetic (flight or fight) response are as follows:

1. Slow, continuous stroking for 3 to 5 minutes over the paravertebral area of the spine
2. Inversion, eliciting carotid sinus reflex along with other somatosensory receptors (refer to the discussion of vestibular system earlier in the chapter)
3. Slow, smooth, passive and active assistive movement within a pain-free range (refer to Maitland grade II movements)²³
4. Deep breathing exercises
5. Progressive muscle relaxation
6. Cranial sacral manipulation (see Chapter 39)

When pressure is applied to both the anterior and posterior surfaces of the body, measurable reductions may be recorded in pulse rate, metabolic activity, oxygen consumption, and muscle tone.^{237,267} These pressure techniques are identified as an intricate part of the many intervention approaches such as therapeutic touch,^{27,238} Feldenkrais,^{213–215,268} Maitland,²³ massage,^{269,270} and myofascial release.^{9,202,271–273} Although not verbally identified, other techniques (e.g., neurodevelopmental treatment [NDT],^{34,35} Rood,^{32,44,105} Brunnstrom,¹¹ and PNF³²) also place an important emphasis on the response of the patient to the therapist's touch.

Treatment Alternatives Using the Autonomic Nervous System

Slow stroking. Slow stroking over the paravertebral areas along the spine from the cervical through lumbar components will cause inhibition or a dampening of the sympathetic nervous system. The technique is performed while the patient is in the prone position. The therapist begins by stroking the cervical paravertebral region in the direction of the thoracic area, using a slow, continuous motion with one hand. Usually a lubricant is applied to the skin, and the index and middle fingers are used to stroke both sides of the spinal column simultaneously. Once the first hand is approaching the end of the lumbar section, the second hand should begin a downward stroking at the cervical region. This maintains at least one point of contact with the patient's skin at all times during the procedure. The technique is applied for 3 to 5 minutes—and no longer—because of the potential for massive inhibition or rebound of the autonomic responses.^{40,263} It is also recommended that at the end of the range of the last stroking pattern, the therapist maintain pressure for a few seconds to alert both the somatic and visceral systems that the procedure has concluded. Eastern medicine recognizes the importance of the ANS in total-body regulation to a greater extent than Western medicine does. The concepts of meridians and acupressure and acupuncture points are all intricately intertwined with the ANS (see Chapter 39). For that reason, a technique such as slow stroking would potentially interact with meridians and does extend over the row of acupuncture points referred to as *shu points* and relates to visceral reflexes connecting smooth muscle and specific organ systems. It is believed that this continuous, slow, downward pressure modulates the sympathetic outflow, causing a shift to a parasympathetic reaction or relaxation. Whether a result of the pressure on the sympathetic chain, some energy pressure over meridian points, a pleasant sensation, or something unknown, slow stroking does elicit relaxation and calming.^{44,105} Patients/clients with large amounts of body hair or hair whorls are poor candidates for this procedure because of the irritating effect of stroking against the growth patterns and the sensitivity of hair follicles.

Slow, smooth, passive movement within pain-free range. Increasing ROM in painful joints is a dilemma frequently encountered by therapists caring for a patient with neurological damage. Having the patient communicate the first perception of pain and then moving the limb in a slow, smooth motion toward the pain range may elicit a variety of behaviors. In patients with fear and guarding, one strategy is for the therapist to stop the motion at the patient's stated point of pain, then retreat back into a pain-free area, or "safety range," then approach again, possibly with a slight variation in rotation or direction: often the patient will relinquish the safety range with improved comfort. The second finding is that if the motion toward the pain range is slow, smooth, and continuous, then frequently much of the range that was initially painful becomes pain free. The hypothesis is that slow, continuous motion is critical feedback for the ANS to handle imminent discomfort. The slow pattern provides the ANS time to release endorphins, thus modifying the perception of pain and allowing for increased motion. If the therapist stabilizes the painful joint and prevents the possibility of that joint going into the pain range, rapid, oscillating movements can often be obtained within the pain-free range. This maintains joint mobility and often, as an end result, increases the pain-free range. This technique is not unique to the treatment of individuals with neurological problems; it is often used as a manual therapy procedure.^{202,274,275} Furthermore, one can move slowly into a range that actually shortens muscles. If held for 30 seconds, the muscle that is too short can relax, promoting greater motion in the opposite direction. This can be called *strain-counterstrain*—inhibiting firing by maintaining a position of active insufficiency, making the muscle too short.

Manual therapy^{23,143,276–279} can be used to describe the pain and joint changes occurring at the joint level. As the fields of orthopedics and neurology merge into one system,²¹⁶ with the brain acting as an organ controlling the entire system and its components, the question of whether the pain reduction is centrally or peripherally triggered may be an important one. The answer is probably both. For example, thumb pain can increase the sensation of the nervous system to the point that even cutaneous and proprioceptive receptors act as nociceptors.

Maintained pressure. As discussed earlier, pressure has been a common technique in neurological rehabilitation. Farber¹⁵ discusses a variety of techniques that facilitate a reduction of tone or hyperactivity. Pressure to the palm of the hand or sole of the foot, to the tip of the upper lip, and to the abdomen all seem to produce this effect. The pressure need not be forceful, but it should be firm and maintained.²⁸⁰ This same technique is defined as inhibitory casting when applied through the use of an orthosis (see Chapter 32).

Progressive muscle relaxation. Progressive muscle relaxation is practiced during both meditation and treatment approaches such as Feldenkrais.^{268,280,281} These methods of relaxation tend to trigger parasympathetic reactions, which in turn slow down heart rate and blood pressure and trigger slow, deep breathing (see Chapters 16 and 39). The Alexander technique has also been shown to cause relaxation while simultaneously increasing postural tone.²⁸²

Treatment considerations using olfactory, gustatory, auditory, and visual systems. Boxes 8.2 to 8.5 present a summary of treatment considerations using the olfactory, gustatory, auditory and visual,

Combined multisensory approaches. Although all techniques have the potential to be multisensory, the specific mode of entry may focus on one sensory system, as already described, or it may target two or more input modalities along with automatic motor programming.

BOX 8.2 Treatment Considerations Using the Olfactory Sense

Smell evokes different responses by means of the limbic system's control over behavior. Pleasant odors, such as vanilla or perfume, can evoke strong moods. Unpleasant odors can facilitate primitive protective reflexes, such as sneezing and choking. Sharp-smelling substances such as ammonia can elicit a reflex interruption of breathing.^{283,284}

- Odors such as vanilla and banana have been used to facilitate sucking and licking motions.^{285,286}
- Ammonia and vinegar have been used clinically to elicit withdrawal patterns and increase arousal in semicomatose patients.²⁸⁷
- When odors are used as a stimulant, the therapist must be aware of all behavior changes occurring within the patient. Arousal, level of consciousness, tonal patterns, reflex behavior, and emotional levels all can be affected by odor.
- Odors such as body odor, perfumes, hairspray, and urine can affect the patient's behavior although the smell was not intended as a therapeutic procedure. Some patient's, especially those with head traumas and inflammatory disorders of the central nervous system, often seem to be hypersensitive to smell. In these cases the therapist needs to be aware of the external olfactory environment surrounding the patient and to make sure those odors that are present facilitate or at least do not hinder desired response patterns.²⁸⁸
- There may be a cultural sensitivity to various smells that would suggest a cultural learning linked with emotional responses to smell.^{289–291} Therefore if a therapist is going to use smell as part of therapy, identification of the individual's prior likes and dislikes is very important. Family members and close friends will be the best people to consult in order to get this information.
- Because of limited research in this area, caution must be exercised to avoid indiscriminate use of the olfactory system.

BOX 8.3 Treatment Considerations Using the Gustatory Sense

- Gustatory input is generally used as part of feeding and prefeeding activities. The oral region is sensitive not only to taste but also to pressure, texture, and temperature. For that reason, feeding would be classified as a multisensory technique that uses gustatory input as one of its entry modalities.
- Specific input modalities are based on the combined taste, texture, temperature, and affective response pattern (i.e., both a banana and an apple may be sweet, yet the textures vary greatly). When mashed, both fruits may have a pudding-like texture, yet the patient's emotional response may differ. Disliking the taste of banana but enjoying apple may cause startling differences in the patient's response during a feeding session.

BOX 8.4 Treatment Considerations Using the Auditory System

- Because of the complexity of the auditory system, a potentially large number of types of input modalities exists. Although some of them might not be considered traditional therapeutic tools, they are nonetheless techniques that affect the central nervous system (CNS). Some treatment alternatives focus on the following:
 - Quality of voice (pitch and tone)²⁹²
 - Quantity of voice (level and intensity)²⁹³
 - Affect of voice (emotional overtones)^{294,295}
 - Spatial and temporal sound (how fast a stimulus occurs, and how frequently)²⁹⁶⁻³⁰⁰
 - Extraneous noise (sound)³⁰¹
 - Auditory biofeedback³⁰²⁻³⁰⁸
 - Language³⁰⁹
 - Volume, level, and affect of voice³¹⁰⁻³¹²
 - Auditory perception³¹³⁻³¹⁵
- The therapist's voice can be considered one of the most powerful therapeutic tools. The emotional inflections used by the clinician certainly have the potential to alter patient response.^{294,295} Knowing which emotional tone best coincides with a patient's need at a particular moment may come with experience or sensitivity to others' unique needs.
- The varying level of sound or extraneous noise in a clinical setting can at times be overwhelming. Timer alarms, messages over loudspeakers, conversations, computers, printers, or a child crying all are encountered in the clinical environment, and all could be occurring simultaneously. Patients with CNS damage may not have the ability to filter sensitivity to all these intermittent noise sensations.³⁰⁷
- Decreasing auditory distracters or sudden noises can drastically improve the patient's ability to attend to a task or to succeed at a desired movement.^{316,317}
- Music is used for encouraging not only motor function but also memory^{318,319} and socialization.³²⁰⁻³²² Rhythmic sound perceived as an enjoyable sensation certainly has the effect of creating motor patterns in response to that rhythm.
- Auditory biofeedback is generally thought of as a procedure in which sound is used to inform the patient of specific muscle activity.^{306,308} The level or pitch may change in relation to strength of muscle contraction or specific muscle group activity.

As stated before, [Table 8.5](#) categorizes a variety of treatment techniques that are clearly multisensory. The therapist, analyzing how the summated effect of the combined input and automatic responses influences patient performance, gains direction in anticipating treatment outcomes in terms of the problem-solving process. Because the potential

BOX 8.5 Treatment Considerations Using the Visual System

- Any light, no matter the degree of complexity, has the potential to affect a patient's central nervous system (CNS). That input not only reaches the optic cortex for sight recognition and processing but also projects to the brain stem and to the cerebellum through the tectocerebellar tract. Simultaneously, these afferents activate the reticular-activating and limbic spinal generators through the tectospinal tract.^{263,323}
- The five categories of visual-system treatment alternatives should not be considered fixed, all-inclusive, or without overlap. The first three categories (color, lighting, and visual complexity) are common everyday visual stimuli. Combined, they make up the visual world.
 - Colors. Cool colors, a darkened room, and monotone color schemes all seem to have an inhibitory effect. In contrast, intermittent visual stimuli, bright colors, bright lights, and a random color scheme seem to alert the CNS and have a generalized facilitatory effect.³²⁴⁻³²⁶
 - Lighting. Patients may find that the high-frequency flutter of fluorescent lamps to be irritating and causes distraction. The types of visual stimuli that may cause seizures and are seen by patients within rehabilitation settings include computers, video games, television, and venetian blinds.³²⁷ For that reason, any change in lighting should alert the clinicians to watch for changes in their patients' behavior.
 - Visual Complexity. The visual system is the primary spatial sense for monitoring moving and stationary objects in space.^{328,329} When brain damage occurs, the ability to identify objects, localize them in space, pick them out from other things, and adapt to their presence may be drastically diminished.²³⁹ Because of the distractibility of many patients, reducing the visual stimuli within their external space can help them to cope with the stimuli to which they are trying to pay attention. Using rooms that have been stripped of such stimuli as furniture and pictures can reduce not only distractibility but also hyperactivity and emotional tone.

TABLE 8.5 Examples of Treatment Modalities/Techniques Using Combined Sensory Input Systems

Sweep tapping ³³⁰
Brunnstrom rolling (hand) ⁴³
Raimiste sign ⁴³
Stretch pressure ³³⁰
Digging in sand, and so on
Gentle shaking ³³⁰
Prone activities over ball ^{54,330,331}
Sitting activities on ball ⁵⁴
Mat activities
Resistive exercises: resistive rolling; resistive patterns: PNF ³³²⁻³³⁴ ; resistive gait ³³⁵ ; isokinetics ^{336,337} ; wall pulleys; rowing ⁴³
Feeding ^{54,93,330} : maintained pressure: walking to back of tongue; resistive sucking (straw, Popsicle); use of textures (peanut butter, applesauce); maintained pressure to top lip
Inverted TLR ^{330,338}
Touch bombardment ³³⁰ : tactile discrimination in sand, etc.; pool therapy
Joint compression more than body weight ^{339,340}
Throwing and catching: balloon; heavy ball
Variance in movement: quick action directed by vision; postural activities in front of mirror; therapist using voice command to assist patient with movement
High-level movements: walking on a balance beam; trampoline activities (running, jumping, skipping)

PNF, Proprioceptive neuromuscular facilitation; TLR, tonic labyrinthine reflex.

combinations of multisensory input classification are enormous, only a few examples of combinations are included in the text to illustrate the process a clinician might use when classifying a new technique or a new approach to intervention. When clinicians select augmented treatment interventions to help a patient as part of somatosensory retraining or functional retraining or to establish a procedural program, the basic science understanding behind the clinical decision helps to develop questions for future research, determine a prognosis regarding outcomes, and rationally explain why or why not an intervention was effective. Prioritization of which techniques to continue using must be based on understanding and integration of neurophysiological mechanisms, learning environments, concepts of motor learning and control, and what motor impairment or body system problems are affecting functional performance and on the patient's and family's needs, motivations, and goals. A simple rule a therapist might follow would be to take away the least natural technique first. That technique would be the most artificial or contrived. An example using only one sensory system might help to clarify this point. For example, a therapist might assist a patient with elbow flexion during a feeding pattern by (1) vibrating the biceps, (2) quickly tapping the biceps, or (3) quickly stretching the biceps a little beyond midrange by using gravity. The first option would be the least natural and obviously the least socially acceptable. The third option is the most natural and closest to what might occur in the real environment in which the patient will need to function. Remember, these contrived techniques are used to assist patients who cannot control or perform the motor programs or functional activities without assistance or who need assistance in learning to modulate motor control for greater functional adaptability. If the therapist added verbal feedback or music, as well as asking the patient to visually look at the target, the example would become multisensory.

Within the following section are examples of combined multisensory approaches that might be used to augment sensory feedback to obtain a better environment for regaining functional control.

Sweep tapping. Sweep tapping is usually used to open a hypertonic flexor-biased hand. Many isolated techniques, such as sweep tapping¹⁰⁵ or rolling,¹¹ would be considered primarily proprioceptive-tactile in sensory origin. During sweep tapping, the clinician first uses a light-touch sweep pattern over the back of the fingers of one of the hands. This stimulus is applied quickly over the dermatome area that relates to muscles the patient is being asked to contract. Second, the therapist applies some quick tapping over the muscle belly of the hypotonic muscle. The first technique is tactile and believed to stimulate the reflex mechanism within the cord to heighten motor generators and increase the potential for muscle contraction of the hypotonic muscle or to dampen the hypertonic flexors. The second aspect, tapping, is a proprioceptive stimulus used to facilitate afferent activity within the muscle spindle of the extensors, thus further enhancing the patient's potential for muscle contraction. At the same time the patient will be asked to voluntarily activate the extensor motor system, which then automatically augments tactile, proprioceptive, and auditory input with functional control.

Taping. Taping procedures normally used in peripheral orthopedic muscle imbalances and pain have the same potential for patients with neurological problems. This adaptation would be a modification of both splinting and slings. Research has been done to demonstrate efficacy of taping to offset peripheral instability in individuals with neurological system impairments.^{253,341-345} The concepts and ideas remain that taping has implications when treating individuals with neurological problems. Taping hypotonic muscle groups into a shortened range should effectively reduce the mechanical pull of gravity on both the muscle groups and joints and prevent the CNS from

developing the need for compensatory stabilization or hypertonicity. If hypertonicity is the result of peripheral instability, then taping a hypertonic muscle into its shortened range should stabilize the peripheral system and eliminate the need for the CNS to create the hypertonic pattern. On the other hand, taping can also be used to heighten information about proprioception and joint position, providing feedback to avoid hyperextension or hypermobility of a joint. This is especially true when there is an imbalance of intrinsics and extrinsics in the hand.

Oral-motor interventions. There are more research articles available on specific oral-motor dysfunctions in patients with neurological problems³⁴⁶⁻³⁵¹ than on interventions. These are studies using fMRI of the CNS during oral-motor activity, but the transition to intervention again is limited.^{352,353} Systematic reviews of potential oral-motor interventions are even fewer.³⁵⁴

When dealing with oral-motor intervention, the complexity of combined proprioceptive-tactile input becomes enhanced by adding another sensory input, such as taste. Implementation of one of a variety of feeding techniques clearly identifies the complexity of the total input system. When taste is used, smell cannot be eliminated as a potential input, nor can vision if the patient visually addresses the food. The following explanation of feeding techniques is included to encourage the reader to analyze the sensory input, processing, and motor response patterns necessary to accomplish this ADL task. The complexity of the interaction of all the various systems within the CNS is mind boggling, but if the motor response is functional, effortless, and acceptable to the patient and the environment, then the adaptation should be facilitated after attended repetitive behaviors.

Several feeding techniques have been developed in the past by master clinicians such as Mueller,³⁵⁵ Farber,¹⁰⁵ Rood,²⁸ and Huss.²⁶³ These techniques were not easily mastered or understood through reading alone. Competence in feeding techniques is best achieved through empirical experience under the guidance of a skilled instructor. Currently, some evidence base for implementation of feeding techniques or related motor activities can be found in the literature.^{55,356,357}

The facial and oral region plays an important role in survival. Facial stimulation can elicit the rooting reaction. Oral stimulation facilitates reflexive behaviors, such as sucking and swallowing. Deeper stimulation to the midline of the tongue elicits a gag reflex. These reactions and reflexes are normal patterns for the neonate. When these reactions and reflexes are depressed or hyperactive, therapeutic intervention is a necessity. Oral facilitation is an important treatment modality for infants and children with CNS dysfunction. Therapeutic intervention during the early stages of myelination can be crucial to the development of more normalized feeding and speech patterns.

Similarly, adults with neurological impairment often have difficulty with oral-motor integration. Problems with swallowing, tongue control, and hypersensitive and desensitized areas within the oral cavity and also with mouth closure or chewing are frequently observed in adults with CNS damage.^{346,347}

Before basic feeding techniques are implemented, clinicians need to understand how the CNS and PNS work collaboratively with the musculoskeletal system to control and perform these complex oral-motor functional movements.^{136,358,359} Feeding therapy is preceded by observation and examination. With a pediatric patient, the therapist should observe breathing patterns while the patient is feeding, to determine whether the child can breathe through the nose while sucking on a nipple. In addition, the child's lips should form a tight seal around the nipple. Formal assessments should include functional assessments, developmental milestones, and behavioral manifestations. Medical charts and results from neurological examinations should be consulted for baseline data.

Postural mechanisms can influence feeding and speech patterns in patient's with neurological dysfunction.^{31,357,360} A patient with a strong extensor pattern may have to be placed in the side-lying, flexed position to inhibit the forces of the extensor pattern. The ideal pattern for feeding is the flexed position, which promotes sucking and oral activity. Basic reflexes such as rooting, sucking, swallowing, and bite and gag reactions should be elicited and graded in children and evaluated in adults. The head needs to be in slight ventriflextion to pull in the postural stabilization of the neck and tongue. This is necessary to effectively facilitate programs that provide functional swallowing and control of foods by the tongue.

The facial region and the mouth have an extraordinary arrangement of sensory innervation. Therefore oral techniques must be used with utmost care. Anyone who has visited the dentist can attest to the feeling of invasiveness when foreign objects are placed in the mouth. With this in mind, the therapist should begin each treatment session by moving the autonomic continuum toward the parasympathetic end. Activation of the parasympathetic system should lower blood pressure, decrease heart rate, and, more important, increase the activity of the gastrointestinal system. Neutral warmth, the inverted position, and slow vestibular stimulation should help to promote parasympathetic "loading." Another approach that is applicable to feeding techniques is the application of sustained and firm pressure to the upper lip. An effective inhibitory device is a pacifier with a plastic shield that applies firm pressure on the lips. Perhaps this is why a pacifier is a "pacifier." Adults can acquire resistive sucking patterns with a straw and plastic shield and achieve the same results.

Sometimes children or adults are not cooperative and will not open their mouths.^{361,362} Rather than the mouth being pried open, the jaw is pushed closed and held firmly for a few seconds. On release of the pressure, the jaw reflexively relaxes. The receptors in the temporomandibular joint and tooth sockets may be involved in the production of this response.

A common problem seen in neurologically impaired infants and adults with head trauma is the "hyperactive tongue," which is often accompanied by a hyperactive gag reflex. To alleviate this problem, the receptors have to be systematically desensitized. The technique called *tongue walking* has met with clinical success.^{15,44} It entails using an instrument such as a swizzle stick or tongue depressor to apply firm pressure to the midline of the tongue. The pressure is first applied near the tip of the tongue and progressively "walked back" in small steps. As the instrument reaches the back of the tongue, the stimulus sets off an automatic swallow response. The instrument is withdrawn the instant the swallow is triggered. This technique is repeated anywhere from 5 to 30 times a session, depending on individual responses.

Another technique, which might be called *deep stroking*, is used to either elicit or desensitize the gag reflex. Again, an instrument such as a swizzle stick is used to apply a light stroking stimulus to the posterior arc of the mouth. The instrument should lightly stretch the lateral walls of the palatoglossal arch of the uvula. Normally, the palatoglossal muscle elevates the tongue and narrows the fauces (the opening between the mouth and the oropharynx). Just behind the palatoglossal arch lies another arch, called the *palatopharyngeal arch*. Normally, this structure elevates the pharynx, closes off the nasopharynx, and aids in swallowing. Touch pressure to either arc incites the gag reflex. This touch pressure should be carefully calibrated. A hyperactive gag reflex may be best diminished by prolonged pressure to the arcs, whereas light, continuous stroking may be more facilitatory in activating a hypoactive gag reflex. A child or adult who has been fed by tube for extended periods of time will often have both hypersensitive reactions in various parts of the oral cavity and hyposensitive areas in other

locations. This problem needs to be assessed to formulate a complete picture of the patient's difficulties.

The use of vibration over the muscles of mastication appears to be physiologically valid. Muscle spindles have been identified in the temporal and masseter muscles.⁴² Selected use of vibration on the muscles of mastication enhances jaw stability and retraction. For protraction to be facilitated, the mandible is manually pushed in.¹⁰⁵

To promote swallowing, some therapists use manual finger oscillations in downward strokes along the laryngopharyngeal muscles and follow up with stretch pressure. Ice is beneficial as a quick stimulus to the ventral portion of the neck or the sternal notch. In addition, chewing ice chips provides a thermal stimulus to the oral cavity and a proprioceptive stimulus to the jaw and teeth; it also increases salivation for swallowing.

It is recommended that a therapist work closely with a colleague who has experience working with functional feeding before independently beginning to work with patient's. The possible complications that might develop with individuals aspirating food cannot be overemphasized.³⁶³

The therapist can quickly realize that feeding as a proprioceptive, tactile, and gustatory input modality is extremely complex and often incorporates other sensory systems. Breaking down the specific approaches into finite techniques helps the clinician to categorize each component and then reassemble them into a whole. The job of dividing and reassembling the parts becomes more and more difficult as the number of input systems enlarges.²³⁸

Head and body movements in space. Proprioceptive and vestibular input is one of the most frequent combination techniques used by therapists. In fact, patient success in almost all therapeutic tasks depends on the coordinated input of these two sensory modalities.

If the head is moving in space and gravity has not been eliminated from the environment, vestibular and proprioceptive receptors will be firing to inform the CNS whether it should continue its feedforward pattern or adapt the plan because the environment no longer matches the programmed movement. Depending on the direction of the head motion and the way gravity is affecting joints, tendons, and muscles, the specific body response will vary according to the degree of flexibility within the motor system. Bed mobility, transfers, mat activities, and gait all incorporate these two modalities. Although all these functional movements can be performed without these feedback mechanisms, the CNS cannot adapt effectively to changing environments without input from these systems. For that reason alone, a thorough examination of the integrity of both systems and the effect of their combined input seems critical if any ADL is to be used as a treatment goal.

The use of a large ball or a gymnastic exercise ball can be classified under the category of proprioceptive-vestibular input. Many activities can be initiated over a ball. When a child or adult is prone on a ball, righting of the head can often be elicited by quickly projecting the child forward while the therapist exerts control through the feet, knees, or hips. If the weight of the head is greater than the available power, then a more vertical and less gravitationally demanding position can be used. As the head begins to come up, approximation of the neck can be added. Vibration of the paravertebral muscles might also assist. Rocking forward or bouncing the patient who is weight bearing on elbows or extended elbows will facilitate postural weight-bearing patterns through the two identified sensory input systems. Having a patient sitting on a therapy ball doing almost any exercise will require vestibular and proprioceptive feedback for appropriate adaptive responses to be made. The combination seems to play a delicate role in the maintenance of normal righting and the equilibrium response so important in functional independence.

A trampoline, balance board, or similar apparatus has the potential to channel a large amount of vestibular-proprioceptive input into the patient's CNS. In fact, a trampoline is so powerful it can often overstimulate the patient and cause excitation or arousal in the CNS.

The trampoline and balance board are generally used to increase balance reactions, orient the patient to position in space and to verticality, and increase postural tone. A patient with poor balance, poor postural tone, or inadequate position in space and verticality perception may be justifiably fearful of these apparatuses because of the rate, intensity, and skill necessary to accomplish the task. Because fear creates tone and that tone may be in conflict with the motor response from the patient, caution must be exercised with either modality. (See Chapter 21 for further discussion of the interactions of sensory systems and balance.)

Gentle shaking. A specific technique of gentle shaking can be listed under a combined vestibular, muscle spindle, and tendon category. This technique is performed while the patient is in a supine position and the head ventrified in midline. The head is flexed 35 to 40 degrees to reduce the influence of the otoliths and unnecessary extensor tone through the lateral vestibulospinal tract. This flexed position should be maintained throughout the procedure. The therapist places one hand under the patient's occiput and the other on the forehead. Light compression is applied to the cervical vertebrae. This technique activates the deep-joint receptors (C1 to C3) and muscle spindles in the neck along with the vestibular mechanism, which in turn connects with the cerebellum and motor nuclei with the brain stem. If the technique is performed slowly and continuously in a rhythmical motion, total-body inhibition will occur. If the pattern is irregular and fast, facilitation of the spinal motor generators will be observed.

Any one of these techniques can be implemented as a viable treatment approach in considering vestibular-proprioceptive stimuli. The selection of an approach or a method will depend on patient preference, patient response, the clinician's application skills, and the need for therapeutic assistance.

Innate Central Nervous System Programming

The responses of the PNS and CNS to various external stimuli determine the individuality of an organism and its survival potential within the environment. As organisms become more and more complex, the types of external stimuli and the internal mechanisms designed to deal with that input also increase in complexity. As the CNS develops structurally and functionally, inherent control over responses to certain common environmental stimuli seems to be manifested. Different areas of the motor system play different roles in the regulation of motor output. No area is dominant over another. Each area is interdependent on both the input from the environment and the intrinsic mechanisms and function of the nervous system.

As mentioned earlier, the PNS is intricately linked to the CNS and vice versa. Damage to one could potentially alter the neuropathways, their function, and ultimately behavior anywhere along the dynamic loops. Nevertheless, although researchers currently emphasize the dynamic interactions of all components,^{364–371} clinicians have observed for decades different motor problems when different areas of the brain are damaged. Thus when individuals with neurological damage are discussed, it seems paramount to identify inherent synergy patterns available to humans, especially if those patterns become stereotypical and limit the patient's ability to adapt to a changing environment.

The authors do not recommend or discredit the use of any stereotypical or patterned response as a treatment procedure. Acknowledging the presence and stressing the importance of knowing how these motor programs affect patients' functional skills are important. With-

out this knowledge, therapists working with either children or adults with CNS dysfunction limit their understanding of the normal CNS, the normal motor control mechanism and its components, and the interactive effect of all systems on the end product: a motor response to a behavioral goal.

To conceptualize a systems model, the reader must replace the hypothesis of a stimulus response-based concept of reflexes²⁶⁷ with a theory of neuronetworks that may be more or less receptive to environmental influences.³⁷² That sensitivity is modulated by a large number of interconnecting systems throughout the CNS and by the internal molecular sensitivity of the neurons themselves. Specific motor patterns seem to be organized or programmed at various levels or areas within the CNS. These synergies or patterned responses are thought to limit the degrees of freedom available to programming centers such as the basal ganglia and cerebellum^{14,219} and to enable more control over the entire body. Having soft-wired, preprogrammed, patterned responses allows organizing systems to activate entire sequences of plans and modify any components within the total plan. Modification and adaptation then become the goal or function of the motor system in response to both internal and external goal-directed activities. The specific location of soft-wired programs is open to controversy, as is the complexity of programming at any level within the CNS. Recognizing that these neuronetworks exist with or without external environmental influences would suggest that patterns can and will present themselves without an identified stimulus. In the past, when an external influence was not correlated with an identifiable stereotypical motor pattern, it was referred to as a *synergy*. When a stimulus was identifiable, the entire loop was called a *reflex*. Reflexes and preprogrammed, soft-wired neuronetworks such as walking are interactive or superimposed on one another to form the background combinations for more complex program interactions. This superimposed network may encompass spinal and supraspinal coactivity, which makes it difficult to specify a level of processing. The exact control mechanisms that regulate the specific pattern may again be a shared responsibility throughout the nervous system, thus providing the plasticity observed when disease, trauma, or environmental circumstances force adaptation of existing plans, as discussed in the neuroplasticity section.

When specific patterned responses are observed, the reader must always hold simultaneously the interaction of all other motor programming options. In this way the therapist can easily conceptualize the variations within one response and the reason why, under different environmental and internal constraints, the motor response pattern may show great variations within the same general plan. Similarly, the expected motor response may not be observable, although it would seem appropriate and anticipated. The clinician must remember that the more complex the action (e.g., rolling compared with dressing compared with playing hockey), the greater the need for integration and coordination over pattern generators. Similarly, the more complex the desired action (especially in new learning), the greater the potential for needed perceptual-cognitive and affective interactions and the greater the potential for gratification and also for failure.

Certain patterned responses or neuronetworks might be considered more simplistic or protective in function. These patterns were once thought to be hard-wired spinal reflexes. It is now known that these reflexes, as well as complex pattern generators, exist at the spinal level and that their responses affect brain stem, cerebellar, and cortical actions. These centers simultaneously affect the specifics of the spinal neuronetwork responses.^{123,124,373} With patients/clients who have low functional control over the spinal or brain stem motor networks, identifying existing patterns, optional patterns as a response to environmental demands, and obligatory patterns not within the control of the

patient's intentional repertoire of patterns becomes a critical evaluative component before prognosing or identifying the most appropriate interventions.

Recognizing specific patterns and how those patterns and others might affect functional movement or positional patterns has clinical significance. For instance, a child with spastic cerebral palsy shows extension and "scissoring" when the pads of the feet are stimulated. Sometimes the extension pattern is so strong that the child will arch backward. Sustained positions that oppose pathological patterns are believed to elicit autogenic inhibition. Contraction-relaxation techniques also work on the autogenic inhibition principle.²²

Just as afferent input can be used to alter tone and elicit movement, it can also become an obstacle when the therapist tries to coordinate complex movement patterns. The human palmar and plantar grasp patterns are often thought of as reflexive patterns, as seen in a newborn.^{374–376} A persistent grasp pattern is a common occurrence in children and adults with a CNS insult. This dominant grasp is often reinforced by the patient's own fingers and frequently prevents functional use of the hand. If a withdrawal pattern is elicited every time a patient is touched, the patient not only will be unable to explore the environment through the tactile-proprioceptive systems but also will experience arousal by the influence of the cutaneous system over the reticular activating system. Severe agitation could likely be a behavioral outcome from such a persistent reflex.

As with any treatment procedure, a clinician should determine whether the technique will help the patient to obtain a higher level of function. The clinician must learn to recognize not only specific patterns but also what combinations of responses of pattern generators would look like. If the reader overlaid the map of the pattern generators for any combination of programs, a complex neuronetwork would result. To some it would verify chaos theory, and to others it would verify the end result of multiple systems interacting. The neuronetwork complexity of multiple input can be overwhelming. Thus a therapist must always be observant of the specific behavioral response and the moment-to-moment changes in behavior during a treatment session, even if the specific neuronetwork is not understood.

The clinician needs to observe whether the specific patterned response is (1) triggered by afferent input, (2) triggered by volitional intent, or (3) activated without environmental input including position in space or cortical intent. In the third case, the entire motor system needs to be evaluated to determine which portion might be modulating the observable behavior. Differentiating these motor components will help in selecting appropriate examination tools, making the movement diagnosis, prognosing, and selecting interventions.

Holistic Treatment Techniques Based on Multisensory Input

As already mentioned, a variety of accepted treatment methods exist. Each approach focuses on multisensory input introduced to the patient in controlled and identified sequences. These sequences are based on the inherent nature of synergistic patterns,^{8,33} the patterns observed in humans^{8,10,377} and lower-order animals,³⁶ or a combination of the two.^{22,31} Each method focuses on the total patient, the specific clinical problems, and alternative treatment approaches available within each established framework. Certain methods have traditionally emphasized specific neurological disabilities. Cerebral palsy in children^{10,26,31,378–380} and hemiplegia in adults^{11,12,24,34,381,382} are the two most frequently identified. In the past two decades, substantial clinical attention has been paid to children with learning difficulties.^{15,40,383–385} Yet the concepts and treatment procedures specific to all the techniques have been applied to almost every neurological disability seen in the clinical setting. This expansion of the use of each method seems to be a natural evolution because of the structure and function of the

CNS and commonalities in clinical signs manifested by brain insult. Literature in occupational and physical therapy management of individuals with various other neurological problems has also enriched therapists' identification of efficacious interventions, as well as those that should be removed from the toolbox.^{386–391}

Additional Augmented Interventions: Current Focus

Four augmented therapeutic intervention approaches that have become accepted over the past decade are (1) body weight supported treadmill training (BWSTT), (2) constraint-induced movement therapy (CIMT), (3) imagery (discussed in the section on the visual system) and virtual reality, and (4) robotic training. Each is discussed as a separate intervention philosophy, but the reader must remember that these are *augmented intervention* programs. Before an individual would be considered functionally independent, the patient must be able to perform the functional activity in a natural environment, such as ambulation within a home setting or eating using the more involved extremity without having the unaffected extremity restrained. A fourth augmented intervention approach, robotics, will also be presented briefly within this chapter to illustrate how therapists and patients have the capabilities to interface with new and sophisticated technology. The reader is also referred to Chapter 38 for more in-depth detail. One additional augmented approach, the Accelerated Skill Acquisition Program (ASAP), has been described here. This approach is currently undergoing, and research is still needed to establish efficacy. This approach is impairment oriented, emphasizes bimanual activities, and focuses on active, patient-centered collaboration reinforced with self-management and self-efficacy.^{392–395} This approach emphasizes attended, repetitive task practice progressing in difficult situations and meets the principles for neuroplasticity.

Body weight–supported treadmill training. Over the past decade, BWSTT has been accepted within the therapeutic community as an alternative approach to teaching gait training for individuals with CNS damage and residual motor dysfunction. Students are introduced to the treatment procedures and potential sequences from total dependence to independence of the patient. Colleagues take continuing education courses to learn to position and drive the various motor components of the gait program while using BWSTT. Both a vertical support (harness) or air-distributed positive pressure to unweight the body and a treadmill are combined for BWSTT. The treadmill perturbs the feet backward or shifts the center of gravity forward, and the ground reaction forces are reduced by the support. The clinical environment unloads the CNS's need to (1) provide protection from falling; (2) trigger and control an effective and efficient postural system reaction; (3) reflexively drive the power stepping reaction necessary to perform upright ambulation; (4) control the balance strategy of stepping to prevent falling; (5) facilitate rhythmic, symmetrical, bilateral stepping; and (6) have a cognitive interface with the various motor programs necessary to run this functional activity. The treadmill perturbation of the lower limb into extension facilitates the transfer of weight to the forefoot. This forward translation forces the feet backward and optimizes the stepping reaction forward. If the moving treadmill is not a sufficient stimulus to trigger a step, this component can be controlled by one or two therapists, depending on whether it is a unilateral or bilateral problem. If the patient does not step, has a delayed stepping response, or steps effectively with only one foot, the therapist(s) can help to initiate the desired response at the patient's feet. The rate of movement or speed of the treadmill can also be controlled, as well as the length of time spent on the affected leg. This treadmill strategy may encourage more symmetrical and faster gait speed in patients after stroke³⁹⁶ and with Parkinson disease^{397–399}

compared with standard physical therapy. This control by the therapist helps to facilitate a patient's response even if it is slow or inadequate for normal over-ground ambulation. The question remains whether this type of augmented therapeutic intervention does create the best environment to empower the patient to learn or relearn normal locomotion after a neurological insult.

The literature is mixed with regard to this question. The literature supports BWSTT for individuals with incomplete spinal injury,³⁹⁰ older adults with Parkinson disease,³⁹¹ and some individuals after stroke,^{132,392} but other literature suggests that BWSTT is equivalent to or maybe less effective than over-ground gait training with a PT,^{400,401} and still other researchers report that there is no difference among different forms of ambulation training.⁴⁰¹ With the literature so inconsistent, the clinician could be confused as to the effectiveness of BWSTT and whether this type of augmented intervention should even be considered. One primary problem with the research literature is the great variance in training and the identified variables selected by researchers within their respective studies.^{130,402,403–405} The following are examples of potential variables:

- Walking speeds
- Amount of body weight supported
- Frequency of training
- Length of training
- Aerobic levels of training
- Type of unweighting
- Type and severity of the patient's neurological dysfunction
- Presence of hypertonicity
- Age of patient
- Time since injury
- Level of independence
- Assistance needed during ambulation

There have been some excellent systematic reviews of BWSTT in the literature that help to identify many of the reasons the literature seems so inconsistent.^{130,406} The research indicates that the two populations of individuals who most often benefit from use of BWSTT are people with incomplete spinal cord injuries and individuals post stroke. Another problem in BWSTT research is that the harness systems can be uncomfortable at 20% to 30% unweighting.⁴⁰⁷ Thus, as stated, the huge number of possible variables and functional ways to measure outcomes using BWSTT or other types of training along with BWSTT has led to confusion in the literature.^{401,402,405,408,409} Even with all the confusion regarding these variables, this form of augmented intervention seems to show promise as a protocol for gait training. Future research studies will still need to determine which patients, their degree of motor involvement, the optimal dosage, the time after insult, the best combination of other interactive interventions (e.g., pharmacological, robotic), the specific type of gait impairments, and where within the gait cycle the patient's would most likely benefit from this type of augmented intervention. It is important to continue to obtain evidence to more precisely define the practice guidelines for BWSTT. As has been shown in the past, new treatment ideas gain popularity and become standards of practice without the rigor of establishing an evidence-based practice.^{40,45,410,411}

Constraint-induced movement therapy. CIMIT (or CI therapy) is a type of intervention for individuals with motor system limitations with the aim of reducing the impact of upper limb functional limitations after a stroke. Major components of CIMIT include the restraint of the less impaired limb, behavioral strategies, and supervised practice of functional tasks.

The restraint or immobilization of the less impaired limb and resultant forced use of the affected limb for prolonged periods varies

from 6 hours to more than 10 hours per day across the literature. Patients typically participate in 6 to 7 hours of therapy a day; in addition, this training is reinforced in home activities and ADLs.^{412–415} A hand mitt or sling is used to constrain the use of the unaffected upper limb while the affected limb is engaged in a forced-use, mass practice of meaningful motor tasks.

Supervised practice of functional tasks is structured to challenge the capacities of the patients. The therapist-patient ratio is typically 1:1, with the therapist present to give tactile and verbal feedback and instruction, along with assistance for the desired skill training. Daily practice lengths vary across literature; early studies implemented 6 hours of practice per day, with more recent studies describing 1 to 2 hours per day using a modified CIMIT program.

The focus of CIMIT is on shaping behavior to improve functional use of the impaired upper limb.^{416,417} Behavioral strategies, such as shaping and adherence logs, are used to promote transfer of training to daily activities. Patients typically keep a daily treatment diary to document the amount and intensity of therapeutic intervention and the amount of time spent wearing the mitt or sling each day for the duration of the intervention.⁴¹⁴

CIMIT and the learned nonuse theory are based on deafferentation experiments in monkeys done by Dr. Edward Taub.^{418,419} Taub and colleagues proposed that the inability to move and use the paretic upper limb may arise, in part, from "learned nonuse."⁴²⁰ Early primate studies demonstrated that if the upper limb was surgically impaired by dorsal rhizotomy to disrupt afferent input to the sensory cortex, the animal stopped using the limb for function. Active mobility was restored by immobilizing the intact upper limb for several days while training the animal to use the affected limb.⁴²⁰ The results indicated that the inability to use the impaired limb may be a learned behavioral response.

CIMIT is based on the theory that impairment in hand and arm function in patients after a stroke is compounded by learned nonuse of that affected upper extremity, which leads to a physical change in the cortical representation of the upper limb in the primary sensory cortex.⁴²¹ Learned nonuse develops in the early stages after a stroke in humans as the patient compensates for difficulty using the impaired limb by increasing reliance on the intact limb. This compensation has been shown to hinder recovery of function in the impaired limb.⁴¹² The first report of CIMIT for hemiparesis in humans was by Ostendorf and Wolf in 1981.⁴²² Since then, investigations have demonstrated the effectiveness of CIMIT with individuals who have residual upper-extremity weakness as the result of an upper motor neuron lesion.^{422–432} CIMIT has been shown to be an effective therapy in persons with chronic stroke who have sufficient residual motor control to benefit from the exercises,^{423–425,430,433–437} in brain-injured patients,^{438,439} in children with hemiplegic cerebral palsy,^{414,416,440–443,444} and in patients with Parkinson disease.⁴⁴⁵ The CI therapy approach has also been used successfully for the lower-limb rehabilitation of patients with stroke hemiparesis, incomplete spinal cord injury, and fractured hip.⁴²⁶ Other diverse chronic disabling conditions, including nonmotor disorders such as phantom limb pain and aphasia, may also benefit from CIMIT.⁴²⁶

The criteria for the inclusion of subjects in most CIMIT research studies have focused on voluntary movement ability in the involved upper extremity.^{412,416–419,421–433,437} These criteria included the ability to start from a resting position of forearm pronation and wrist flexion and actively extend each metacarpal-phalangeal and interphalangeal joint at least 10 degrees and extend the wrist at least 20 degrees through a ROM.⁴³⁴ It is estimated that approximately 20% to 25% of the population of patients with chronic stroke with residual motor deficit meet this motor criterion.⁴¹⁵

Not all patients with hemiparesis have been found to benefit from CIMT. It has not been shown to be beneficial for patients with severe chronic upper-extremity hemiplegia after a stroke.⁴⁴⁶ Attempts to include individuals who did not meet the minimal motor criteria (at least 10 degrees of finger extension and 20 degrees of wrist extension) have failed to demonstrate significant or lasting functional improvements in the involved upper extremity after CIMT.^{426,446}

The criteria associated with successful therapeutic components of CIMT therapy are (1) restraint of the unaffected arm with a mitt, sling, or glove for 90% of waking hours for a 2- to 3-week period; and (2) therapeutic sessions with physical and occupational therapy in which patients concentrate on intense, repetitive task training of the more affected upper extremity for 8 hours a day.³ These same criteria have been identified as challenges to CIMT. Wearing a mitt or sling for 90% of waking hours is very restrictive. Similarly, therapy sessions of 6 hours per day for 2 weeks very intensive and is burdensome for the patient and caregivers. The application of CIMT to real-life clinical environments presents challenges, including the time and physical demands on therapists, the cost to the patient, and the resources required during rehabilitation. This limits its cost-effectiveness and overall effect.⁴¹² Many patients in the acute rehabilitation setting do not qualify for CIMT on the basis of limited motor function.⁴¹² CIMT, by its nature, can prove to be difficult, frustrating, and intense, and progress can be slow. It will create beneficial effects only if all participants put in the time and effort to make it successful.⁴¹⁴ Many subjects who have been presented with the opportunity to participate in CIMT programs and studies have refused because of the intense practice schedule and the necessity of the restrictive device.⁴⁴⁷ Therapists have also voiced concerns about patient adherence and safety.⁴⁴⁷ Although it has been shown to be effective in laboratory research, CIMT may have limited practicality in some clinical environments.⁴⁴⁷ Techniques were modified to address these concerns resulting in modified CIMT (mCIMT); the restriction on the less affected limb was limited to 5 hours per day (Page et al., 2013).⁴⁴⁸

Subjects with chronic stroke hemiparesis who have participated in CIMT rehabilitation programs have demonstrated significant gains in functional use of the stroke-affected upper extremity as measured by the Motor Activity Log,⁴¹⁵ significant reductions in motor impairment on the upper-extremity motor component of the Fugl-Meyer Test,⁴⁴⁶ and more efficient task performance as measured by the Wolf Motor Function Test.^{449–453} Fine motor improvements have also been measured with use of the Grooved Pegboard Test and other dexterity tests.^{412,421} These improvements in impairment and function have been shown to persist at follow-up evaluations up to 2 years after training.^{421,432,444,452} Individuals participating in CIMT studies have demonstrated improvements in the amount of use and quality of movement in the more involved upper extremity and carryover of skills from the clinic to real-world activities.^{414,422–424} This functional improvement may be significant even if the patient has previously participated in a conventional rehabilitation program.⁴⁵⁴ Recent systematic reviews and meta-analyses identified a multitude of outcome measures from those initially mentioned that primarily looked at upper extremity function. Outcome measures identified in the recent systematic reviews on CIMT include the Functional Independence Measure (FIM),^{455,456,457,459} Barthel Index (BI),^{455,456,459} Action Research Arm Test (ARAT),^{455,456,457} Motor Assessment Scale (MAS),⁴⁵⁵ Stroke Impact Scale (SIS) participation,⁴⁵⁹ quality of life (QoL),⁴⁵⁸ and ADLs.⁴⁵⁸

The question of when to begin CIMT after a stroke has not yet been definitively answered. CIMT has been applied to patients with subacute strokes. This early use of CIMT is based on the hypothesis that earlier intervention may prevent learned nonuse and may have a

greater impact on overall function. Investigators have found no adverse effects of CIMT in the subacute phase and only slightly greater improvement in motor function of the affected upper extremity.⁴⁶⁰ There is some evidence from animal studies to suggest that if CIMT is introduced too early (e.g., 24 hours post stroke), it may be detrimental and potentially harmful to humans. It may cause an increase in the size of the cortical lesion. This is based on studies of “forced overuse” in animals.^{461–464} Kozłowski and colleagues⁴⁶⁴ found that early forced overuse of the affected limb within the first 7 days after a sensorimotor cortex lesion impeded motor recovery of the affected limb and enlarged lesion volume. Bland and co-workers⁴⁶¹ also forced overuse of the affected forelimb immediately after a focal cortical middle cerebral artery stroke, which increased the lesion size and impaired motor recovery. The relative risks and benefits of “acute” CIMT and its optimal timing remain to be determined.⁴¹²

The neurophysiological mechanisms that are believed to underlie the treatment benefit of CIMT include overcoming learned nonuse and plastic brain reorganization.^{454,465} Studies have confirmed that CIMT produces use-dependent cortical reorganization in humans with stroke-related paresis of an upper limb.^{424,432,465,466} However, there is some question as to whether the improvements in upper-extremity motor function after CIMT are a result of the reduction of learned nonuse or of overcoming a sense of increased effort during movement.⁴²¹ Thus task-specific, goal-oriented training with the affected limb might be similarly beneficial, even without the constraint of the less affected side.

Neuroimaging studies such as transcranial magnetic stimulation (TMS), fMRI, and electroencephalography^{325,421} have been used to provide cortical evidence of neuroplasticity and cortical changes after CIMT.^{414,427,432,467} These studies have validated that massed practice of CIMT produces a massive use-dependent cortical reorganization. This change increases the area in which the cortex is involved during voluntary movements of an affected limb, even in patients with chronic stroke.^{412,468}

The utility of CIMT depends on several factors including economic considerations, limitations of the practice setting, and the cognitive and physical status of the patient. Less intense practice schedule models^{467,469,470} and combining CIMT with pharmacological interventions or robotic assistance may help to increase its effectiveness and decrease costs without sacrificing the benefits.^{412,471} Studies are underway to determine if massed task-specific practice without constraint can be equally beneficial.^{472,473} Systematic reviews and meta-analysis^{455–459} demonstrate improvements in upper-extremity movements during functional activities. Interestingly, evidence is limited on the improvements in quality of life and independence in ADL from intense CIMT. mCIMT, developed to address concerns on burden of such an intensive therapy, has demonstrated significant improvements in upper limb movements and independence in ADLs.⁴⁵⁹ Despite improvements noted with CIMT and mCIMT, further research is needed to understand the mechanisms that lead to improvements and the most effective functional activities. The evidence on CIMT, along with evidence on task-related training, posit that task-related training of functional activities with behavioral strategies is an effective, feasible approach to the rehabilitation of the upper limb after stroke.

Robotics, gaming, and virtual reality (see Chapter 38). The most recent augmented intervention procedures involve the use of technology to regain control over functional movement. The use of robotics,^{474–477} virtual reality,^{478–481} and gaming^{482–485} in the clinical environment continues to gain popularity as technology for gaming and virtual reality continue to be more affordable, and their applications are becoming more widespread. A thorough discussion of these technologies can be found in Chapter 38.

With the improvements and expansion of computational approaches and faster and more powerful computers, different types of robotic technologies have been tested in neurorehabilitation.⁴⁸⁶ Advantages identified to robotic devices in rehabilitation include the ability to provide consistent practice for patients to help decrease variability; decrease therapist burden with decreased hands-in clinical time and provide practice outside of the therapy sessions; and present another mechanism for quantitative examination and tracking of outcomes. The ability to deliver high-dosage and high-intensity training⁴⁸⁷ has been noted to be the most important advantage of robotic technology in rehabilitation. Robot-assisted training aims to provide intensive practice of repetitive, stereotyped, and functional movements with reduced therapist burden.

Systematic reviews and meta-analyses on robot-assisted training have shown mixed results. In a randomized controlled trial (RCT) that incorporated robotic therapy in an intensive task-specific practice of the upper limb,⁴⁸⁸ the group that completed an 8-week robotic training performed better than the comparison group on the Fugl-Meyer Assessment (FGA). The improvements were small and of weak significance, which bring into question the clinical relevance. Furthermore, improvements were not retained in follow-up assessments at 16 and 34 weeks. Participants in the conventional therapy group continued to improve during the follow-up sessions, suggesting that functional training may be of better value. A review of 12 RCTs in multiple stages of stroke⁴⁸⁹ showed that robotic therapy is not more effective than conventional therapy for upper limb

recovery, but when added to conventional therapy, significant improvements were seen in motor recovery of the of the upper extremity. With the costs in human training and robotic device and its limited efficacy, robotic devices are more an adjunct to therapy rather than the primary method of intervention.

The evidence on robotic therapy is variable and difficult to generalize given the heterogeneity of the robotic devices, the participants' characteristics, and the variety of the study designs in the literature. At this time, the role of robot-assisted training for stroke rehabilitation is more of an adjunct to therapy versus replacement to conventional therapy. Further developments on robotic technology may improve the efficacy and costs associated with robotic devices. For this approach to be an essential part of neurorehabilitation and a standard therapeutic modality, further studies with larger populations that demonstrate superior efficacy in motor recovery, that provide functional benefits above and with conventional therapy, and that offer realistic economic feasibility are substantially needed.

Summary of augmented intervention strategies. As with many interventions, the therapist may need to start with augmented approaches to reduce impairments and/or gain functional movement in a controlled environment. As the patient demonstrates improvement in this narrow window of movement or function, the clinician could then increase the challenge with the goal of optimizing functional performance and improving quality of life. A summary of the augmented intervention strategies that facilitate neuroplasticity can be found in [Box 8.6](#).

BOX 8.6 Summary of Intervention Strategies to Facilitate Neuroplasticity

There are many different intervention strategies to use when working with patients with neurological problems. These interventions need to be matched to the needs of the individual patient and be consistent with the patient's goals and objectives. All the intervention strategies should be goal directed and repeated with attention to both the input mechanisms (motivation, sensory) and the output mechanisms (movement). The input and output mechanisms are multifactorial, and they also involve all components of the sensory, emotional, sensorimotor, and motor systems. Although evidence is increasing about the benefit of learning-based activities, research is still needed to help define more precisely when intervention should occur, how intense the intervention should be, how much repetition is needed, how long the learning-based activities need to be continued and spaced, how specific the training needs to be, how quickly behaviors can be progressed and the magnitude of gradation needed, how to keep patients interested, motivated, and compliant in learning, and the magnitude of interference in learning relative to depression, stress, and loss of self-esteem. The intervention strategies can be broadly classified as follows:

1. General body responses leading to quieting of the nervous system^{11,263}
 - a. Slow rocking in a rocking chair or hammock.
 - b. Slow anterior-posterior, horizontal, or vertical movements (chair, hassock, mesh net, swing, ball bolster, riding in a carriage, glider chair).
 - c. Rotating equipment such as a bed, chair, stool, hammock, or therapeutic or gymnastic ball (e.g., rhythmical bouncing).
 - d. Slow linear, undulating movements, such as in a carriage, stroller, wheel-chair, or wagon.
 - e. Wrapping up tightly before rocking (e.g., roll self in sheet; put both arms inside tight tee shirt).
 - f. Listening to quiet music or natural environmental sounds (e.g., waves).
 - g. Repeating activities listed above first with eyes open and then closed.
2. Techniques to heighten postural righting reactions¹³⁶
 - a. Rapid or unexpected anterior-posterior or angular acceleration.
 - i. Scooter board: pulled or projected down inclines.
 - ii. Prone over ball: rapid acceleration forward.

- iii. Platform or mesh net: prone.
- iv. Slides.
 - v. Any proprioceptive input that heightens postural extensors (e.g., quick stretch, tapping, resistance, vibration, joint compression). Remember to use the most natural first, such as quick stretch versus vibration.
- b. Rapid anterior-posterior motion in prone position, weight-bearing patterns such as on elbows or extended elbows while rocking and crawling.
- c. Weight-shifting in kneeling, half-kneel, or standing positions (first in vertical and then off vertical within limits of stability by an activity itself [reaching]).
- d. Do activities with eyes closed.
- e. Create dual-task activities such as walking and talking, stepping over obstacles while on unstable surfaces, reading while maintaining balance in a confusing environment.
- f. Challenge balance in distracting environments (e.g., moving surround, multisensory stimuli in visual surround).
3. Facilitatory techniques to influence whole-body responses^{33,105,265}
 - a. Movement patterns in specific sequences.
 - i. Rolling patterns.
 - ii. Prop on elbows (prone and side-lying positions) and extend and flex elbows as well as crawling (e.g., side by side, or linear and angular motion).
 - iii. Coming to sit (side-lying to sit [using upper trunk and head rotation], prone to four-point position to sit [four-point position to lower trunk rotation to side sit to sit], adult sit [full flexion leading with head]).
 - iv. Coming to stand (squat to stand, half-kneel to stand, standing from a chair or stool).
 - b. Spinning.
 - i. Mesh net.
 - ii. Sit and spin toy.
 - iii. Office chair on universal joint.

Continued

BOX 8.6 Summary of Intervention Strategies to Facilitate Neuroplasticity—cont'd

- c. Any activity that uses acceleration and deceleration of head.
 - i. Sitting and reaching.
 - ii. Walking.
 - iii. Running.
 - iv. Moving from sit to stand.
 - v. Doing activities with eyes closed, head still, and then eyes closed, head turning.
- d. Performing activities that require attention, memory, and cognitive processing at the same time.
- 4. Combined facilitatory and inhibitory technique: inverted tonic labyrinthine activities
 - a. Inverted tonic labyrinthine activities.
 - i. Semiinverted in-sitting (head between the legs).
 - ii. Squatting to stand (head below heart).
 - iii. Thirty degrees to total inverted vertical position beginning in supine.
 - b. Somatosensory and sensorimotor stimulation (refer to earlier in this chapter).
 - i. Proprioceptive stimulation.
 - (a) Vibration over joints.
 - (b) Vibration in opposite direction of movement.
 - (c) Wear weights around ankles or on belt.
 - (d) Position the limbs and the trunk to match a position visually presented.
 - (e) Move slowly to the count of a metronome and then change speeds.
 - (f) Look at pictures and position the body to match the pictures.
- c. Auditory discrimination (localization).
- 5. Techniques to facilitate specific task performance
 - a. Forced use.
 - i. Create training activities in which patients must use the affected extremity.
 - ii. Minimize the need to use the unaffected side.
 - iii. Use bilateral activities in which both hands and upper extremities are required.
 - b. Constraint-induced movement therapy (CIMT) (forced use)^{423–425,468,490,491}
 - c. Mass task practice
 - d. Mental imagery.
 - e. Mental practice.
 - f. Body weight–supported treadmill training (BWSTT).^{394–397,492}
 - g. Integration of robotics and technology (see Chapter 38).
 - h. Use of gaming (Wii Fit, Brain Fit).^{479,482–485}

CONCLUSION

The CNS is in a constant state of change throughout life. The brain is unique to each individual. Each brain has idiosyncrasies but also has an enormous number of predictable responses. These factors affect the success or failure of the patient/client-therapist interaction. In **Box 8.7** the reader will find guidelines that may assist in determining the type of interventions (functional, impairment, augmented, or somatosensory training) that will best match the patient's functional movement capability. In answering the questions presented, the therapist will gain a better idea of which examination tools will best help to objectively measure the progress of the patient toward that patient's specific goals. From that thorough examination process, the therapist must decide which treatment is appropriate and the most efficient course of intervention on the basis of the goals of the patient and family, the movement system deficit, the prognosis, the resources available, and the skills of the therapist. Once a decision is made regarding whether the interventions should be based on compensation, substitution, habituation, neural adaptation, or a combination of the four, the team must select the best options available given all the resources. The options include functional retraining, impairment training, augmented and contrived interventions, and somatosensory reintegration. No matter

the specifics of the intervention selection, the therapist must cognitively organize intervention options in a sequential process, be willing to change direction or options as the patient changes, and develop greater clinical repertoire of intervention strategies.

When specific augmented interventions are needed, the therapist must select specific interventions according to the needs of the patient, the time available for therapy, the level and extent of the functional involvement, the motivation of the patient and family, the creativity of the therapist, and, of course, the existing pathology, whether it be stable or an active disease process. A therapist must choose whether somatosensory retraining, functional training, impairment training, augmented treatment interventions, or any combination of these four will provide the patient with the most environmentally effective, cost-efficient, and quickest map to functional independence or maximal quality of life. How each therapist combines the interventions with the patient's specific needs will vary according to education, belief, skill, and openness to learning from the total environment itself. Learning should lead to further learning. Answers to unknowns will be found, with new unknowns coming to consciousness. The brain is still more mystery than not, so for most OTs and PTs beginning or ending their practice, the adventure has just begun. *Enjoy the experience.*

BOX 8.7 Conceptual Guidelines for Clinical Decision Making: How to Select Treatment Options for Patients With Neurological Impairments

After performing examination procedures in which you identify problems with activities and participation, you will then be able to classify these into clusters or syndromes (i.e., the physical therapy diagnosis). You then need to formulate a prognosis and determine the intervention options.

To determine the *best* treatment options for a patient with a neurological condition with movement problems, you must simultaneously consider non-physical therapy–based as well as non-neurological system–based limitations along with the specific neurological impairments.

Assume the *best-case scenario* (which never exists) in which there are no limitations in health benefits, from cultural beliefs or family, caused by conflict with other care providers, or in systems other than motor such as cognitive, emotional, vascular, integumentary, pulmonary, cardiac, and so on.

First, what does the patient want to do compared with what his or her motor system can do? Can you work on improvement of impairments and function within activities the patient is motivated to do? *If so, do it!*

BOX 8.7 Conceptual Guidelines for Clinical Decision Making: How to Select Treatment Options for Patients With Neurological Impairments—cont'd

Second, without altering the patient's normal feedback (intrinsic) mechanisms, can he or she perform the functional activity without causing program adaptations that are so stereotypical that those programs may limit future movement functions and carryover?

For example: can you create an activity that will do the following without contriving the environment and while still running flexible, malleable motor programs?

1. Improve range of motion (ROM) or
2. Improve power or
3. Improve coordination or
4. Improve balance or
5. Improve endurance or
6. Any or all of the above
7. Have any similar effect

If so, do it!

If not, you will need to contrive the environment to create functional change through treatment intervention.

Ask Yourself

1. Where in the activity can you optimize biomechanics, and where are biomechanics deoptimized? If the body was placed at a better biomechanical advantage:
 - a. Would the patient be able to run and power the program?
 - b. Would the motor program run more fluidly and procedurally?
 - c. Would there be greater endurance?

If your answer is *yes*, then proceed with the activity initially and then increase the range and challenge all components of the program.
2. Throughout the activity, where would the least and greatest power be needed? Does the program run differently at different points throughout the activity depending on power production? Optimize what power you have, while maintaining fluid, relaxed program generators. Hypertonicity will often be observed if you ask for more power than the generators can create in a normal fashion.
3. Look at the program itself.
 - a. What CNS components are missing (impairments or functional problems)? These are usually your neurological diagnoses (physical therapy diagnoses).
 - b. Can you elicit through treatment intervention corrections of the impairments in any aspect of the program? *If so, how?*
 - Caused by biomechanical advantage
 - Caused by musculoskeletal advantage
 - Caused by the program advantage itself

Optimize:

- Synergistic advantage
- Balance synergies
- Sensory processing
- And so on

These treatment answers will lay the foundations for your specific intervention strategies.

- c. Can you elicit those components in any other movement programs? If so, these are treatment alternatives, although they will not be task specific and have less immediate carryover.
4. Select movement activities that use existing components procedurally and facilitate or elicit function from impairment component of subsystems.
5. Prioritize functional activities by identifying daily living needs of the patient, goals of the patient, and functional skill of the patient. Determine which impairments affect the greatest number of functional activities. Similarly determine which impairments can be quickly changed to gain functional skill. Decide within the limits of the environment which activities to focus on first.

For example: assume the patient has poor balance in sitting and standing. He plans to sit in the lounge chair most of the day but walk to the toilet when necessary. Although range, power, and postural control would need to be considered, you might decide to work on standing balance and balance during walking before sitting balance owing to task specificity and functional need. This is not stating that sitting balance is not important; it is prioritizing the activities according to need. Power, range, posture, and so on may determine the specific intervention strategies used to work on standing and walking balance.

6. If normal programming cannot be elicited, look at adaptations and determine alternative interventions such as the following:
 - a. Adaptive equipment: biofeedback, orthotics, canes, and so on
 - b. Adaptive environments: ramps, rails, lights, changing walkways, changing surfaces (e.g., removing shag carpets)
 - c. Encouraging stereotypical and inflexible programs
 - d. Combination of a, b, or c

Make sure that when selection of alternative approaches or adaptations is made, consideration is given to what will be given up by adapting the environment and central nervous system. Consider whether that decision is truly cost efficient and the best alternative to meet the needs and goals of the patient, his or her family, and the physical and cultural environment within which he or she will function.

Case Examples:

CASE STUDY 8.2 Patient With Lack of Head Control

Impaired head control is a common clinical problem in developmentally delayed children or in individuals who have sustained a severe injury to the central nervous system (CNS). Virtually all functional activities are affected by this impairment.

The patient is Timothy, a 16-year-old adolescent male with a closed-head injury sustained 3 months ago. He currently demonstrates the following attributes regarding head control:

- Mild extensor hypertonicity is present in the supine position, and Timothy is unable to rotate his neck or lift his head off the mat.
- In prone position, extensor hypertonicity is absent and hypotonicity prevails. The patient is able to briefly bob his head off the mat in a cervical hyperextension pattern. Mild tonal shifts occur in his trunk and lower extremities when his head is passively turned to either side or when his neck is flexed or extended.
- Timothy is unable to roll or perform any functional activity in the horizontal plane.

- When placed in a long sitting position, he is unable to hold the position and his head remains in total flexion with his chin on his chest. Extensor tone dominates the lower extremities.
- When placed in a short sitting position on a mat table, he is unable to hold the position. General hypotonicity prevails, and his neck remains flexed with chin nearly to chest and his trunk is slightly flexed. When asked to pick up his head, he initiates a partial movement with cervical hyperextension. A position of cervical extension increases his trunk extensor tone. Extensor tone of lower extremities is diminished compared with long sitting.
- When placed upright with the head vertical, he is unable to hold this head position.
- Timothy does not mind being touched and responds well to handling techniques.

Continued

CASE STUDY 8.2 Patient With Lack of Head Control—cont'd

From the analysis of these clinical signs, the following clinical interpretations are presented:

1. In the horizontal position, Timothy has persistence of a motor program that is enhanced by the spatial position and its influence on the vestibular system. The result might be considered persistence of a tonic labyrinthine reflex (TLR). In this patient the dominant synergic pattern is extension. While he is supine, extension prevails. While he is prone, extension is inhibited, although flexion tone is not dominant. Because of the persistence of hyperactivity among the extensor motor generators, the ability to initiate rolling using a neck-righting pattern is prevented. The presence of a mild, asymmetrical tonic neck reflex to both sides and a symmetrical tonic neck reflex has been noted. Because of his instability and low tone, Timothy seems to be using these stereotypical patterns volitionally to assist in gaining some control over his motor patterns. In prone position, Timothy has the ability to move into a neck extension or optic and labyrinthine righting (OLR) pattern but is unable to hold it. Movement and range are present but postural holding is missing.
2. As a result of ventriflexion of the head in sitting, the vestibular apparatus is placed in a position similar to that when prone. In a like manner, the total patterns remain fairly consistent. The decrease in extensor tone in trunk and extremities in short sitting may result from the positioning of hip and knee flexion and kyphosis of the back. The inability to flex the hips with knee extension suggests that total tonal patterns or synergies are dominant. The patient is unable to break out of those dominant patterns. Dominant OLR is not present.
3. When asked, Timothy carries out the command to the best of his motor ability. This suggests the presence of some intact verbal processing, which is translated into appropriate motor acts. Similarly, when asked to pick up his head, he does just that, suggesting some perceptual integrity of body image, body schema, and position in space. Knowing where his head is in space and where to reposition it also suggests that some proprioceptive-vestibular input and processing are occurring.
4. Timothy's enjoyment of being moved in space as related to handling techniques suggests proprioceptive-vestibular integrity. Similarly, his tactile systems seem to be functioning in a discriminatory manner and modifying negative responses of withdrawal and arousal. However, specific tactile perception would need a great deal of further testing. Thus he demonstrates functional strengths in cognition and perception, in limbic motivation, in some areas of sensory integrity, and in control over available but limited motor programming. Yet performance on any functional test would result in identification of an individual whose functional limitations prevent him from independence in any activity. Prognosis must be guarded until the therapist has had an opportunity to augment the environment to determine how quickly he will regain control and retain the learning. The initial plan of care is assumed to focus on development of head control as a preliminary and necessary motor program for all functional daily living activity. The estimated time it will take to regain this function will not be identified until after the first intervention session.

Evaluation of Movement Deficits

The patient is unable to functionally control his head in any position in space, which limits independence in all functional activities. Lack of postural coactivation and adequate control over the motor generators has led to imbalances in the tonal characteristics of flexor and extensor patterns with the compensatory development of stereotypical patterns of movement.

Goal of Intervention Program

The goal is development of independent head control, initially in a vertical midline posture with the intent of enlarging that biomechanical window to include all positions in space.

Now that the clinical problem has been analyzed and the goal of development of head control set, an intervention sequence or protocol must be established. Timothy lacks head control in all planes and in all patterns of movement. Thus flexors and extensors must be facilitated to develop a dynamic coactivation or postural holding pattern of the neck. The categorization scheme can now be of some assistance. The therapist can ask, "Are there any inherent mechanisms that enhance flexors or extensors in a holding pattern?" The OLR reaction should elicit the desired response. Similarly, the clinician can ask, "Are there any inherent motor programs that would prevent righting of the head to face vertical OLR?" The TLR would block or modify the facilitation of OLR. Knowing that the TLR is most dominant in horizontal and least dominant (if at all affected) in vertical is of clinical significance. It is also important to know that the OLR is most frequently tested in a vertical position and seems most active in that position. Awareness that the patient is sensitive to total patterns (e.g., flexion facilitates flexion or extension facilitates extension) gives additional treatment clues.

After all this information has been assimilated, the following treatment could be established.

For enhancement of neck flexors, the patient will be placed in a totally flexed position in vertical, with the head positioned in neutral. The patient will be rocked backward toward supine, allowing gravity to quick stretch the flexors (Fig. 8.2A). As soon as the neck flexors are stretched, the head should be tapped forward and then back to vertical but not beyond. This avoids hyperextension, extreme stretch to the proprioceptors, and the horizontal supine position of the labyrinths, all of which dampen the flexors and facilitate the extensors. The quick stretch and position should optimally facilitate OLR, which should activate the neck flexors. The total flexion of the body similarly facilitates the neck flexors. Once the neck flexors respond, Timothy can be rocked farther and farther backward while maintaining the head in vertical or ventriflexion (see Fig. 8.2B). Once Timothy can be rocked from vertical to horizontal and back to vertical while maintaining good flexor neck control, his CNS has demonstrated inherent control and modification over the stereotypical patterns, such as the TLR in supine with respect to its influence over the neck musculature. This rocking maneuver can be done on diagonals to practice flexion and rotation (see Fig. 8.2C), the key to eliciting a neck-righting, rolling pattern from supine to prone. The total flexed pattern can also be altered by adding more and more extension of the extremities. This decreases the external facilitation to the flexors and demands that Timothy's CNS takes more and more control (internal regulation). Additional treatment procedures can be extracted from a variety of sensory categories. To add additional proprioceptive input, any one of those listed techniques might be used. The rotation and speed of the rocking pattern affect the vestibular mechanism. Auditory and visual stimuli can be used effectively. If the therapist takes a position slightly below the patient's horizontal eye level, the patient (to look at the therapist) will need to look down and flex his head, thus encouraging the desired pattern. Any type of visual or auditory stimulus that directs the patient into the desired pattern would be appropriate. The therapist must remember that neck flexion is one of the identified goals. Rotation was added to incorporate and set the stage for inherent programming that will lead to rolling, coming to sit, and reaching while sitting. Because the postural extensor component still needs integration, total head control has not been attained. To facilitate neck extension, a procedure similar to the one for flexion can be established. A vertical position, thus eliminating the influence of the TLR, would again be the starting position of choice.

With extension facilitating extension, the patient should be placed in as much extension as possible without eliciting excessive extensor tone. An inverted labyrinthine position, a kneeling position, or a standing position would be viable spatial patterns to facilitate OLR of the head and coactivation of postural extensors. The vestibular system sensory category can be checked to identify the treatment procedure for use with an inverted labyrinthine position. The kneeling

CASE STUDY 8.2 Patient With Lack of Head Control—cont'd

or standing position places the patient in a vertical position with hip and trunk extension. Kneeling rather than standing is used first because of the influence of the positive supporting reaction in standing and the massive facilitation of total extension. Kneeling avoids total extension while maintaining a predominant extensor pattern. As a result of the gravitational pull of body weight through the joints, approximation to facilitate postural extension is constantly maintained. The upper extremities can be placed in shoulder abduction and external rotation, which tends to inhibit abnormal upper-extremity flexor tone and facilitate postural tone into the shoulder. This extensor tone has the potential through associated spinal reactions to facilitate neck and trunk extension. The arms can be placed in this position over a bolster or ball or by the therapist handling the patient from the rear (Fig. 8.3A). The head should begin again in a neutral position. The patient is rocked forward (see Fig. 8.3B) to facilitate OLR of the head and to elicit a quick stretch to the postural extensors. If the head begins to fall forward, the therapist can tap the patient's forehead immediately after the quick stretch. This tapping action is the reverse tap procedure described under the proprioceptive stretch receptors category. The tapping is done to passively move the head back to vertical.

A variety of additional procedures can easily be combined to summate facilitation to the postural extensors. Tapping, vibration, and approximation through the head to the shoulders are only a few of the proprioceptive modalities; all would be facilitatory. A variety of auditory and visual stimuli could be used to orient the patient to a position in space and thus righting of the head. Techniques listed under the exteroceptive and vestibular systems could also be part of the treatment protocol. The therapist would want to sequence the patient toward prone while the head remained in a vertical postural holding pattern. As the therapist rocks the patient toward prone again, a rotational component should be added (see Fig. 8.3C). The patient will extend and rotate to counterbalance the movement, thus incorporating the neck-righting pattern of extension and rotation necessary when rolling from prone to supine. Resistance to neck extension with or without rotation is an important element in regaining normal functional control. The patient is alert and has some functional use of the arms and legs. This rocking pattern in kneeling can be done as a functional activity. The therapist asks the patient to assist in reaching toward an object with one upper extremity. The therapist can guide the patient in the

reaching pattern in a forward, sideward, or cross-midline direction. While reaching, the patient can be rocked forward to elicit right and equilibrium reactions. In incorporating an activity into the treatment of head control, the patient not only is entertained but also attends to the task rather than cognitively trying to keep his head up. In this way, automatic head control is facilitated, and often postural patterns follow. In a partial kneeling pattern the patient can be sequenced to on-elbow over a bolster or ball or on a chair. These activities should be sequenced from vertical to prone to ensure both total postural programming in prone and optimal integration of OLR, as well as to let the patient experience control of various motor strategies in many different environmental contexts.

Once the patient can maintain good flexor, extensor, and rotational components of head control, the activity should, if possible, be practiced with the patient's eyes closed. If the patient can still maintain head control, labyrinthine righting would be adequate for any functional activity. If the patient loses head control, then additional labyrinthine facilitation would be indicated. If a patient uses only vision to right the head, then any time vision is needed to lead or direct another activity, head control might be lost. Because symmetrical vestibular stimulation plays a key role in activating the neck muscles to hold the head in vertical, it also is a key element leading to the perception of vertical and all the directional activities sequencing out of the concept of verticality. The postural extensor programming for head control needs to be practiced in a standing position and a sitting position. The patient needs to be able to stand quietly without excessive extension to run both postural and balance programs. Similarly, he needs to be able to sit with hip flexion while coactivating postural extension in the trunk and neck.

Head control is a complex motor response. A therapist can facilitate inherent mechanisms to assist a patient in regaining function. Simultaneously, multitiduous external input techniques classified under the various sensory modalities and combined modalities can be used to give the patient additional information. Awareness of one technique and the ability to categorize it appropriately allow easy identification and implementation of many additional approaches. The therapist always needs to remember that the patient must practice the behavior (head control) in a variety of spatial positions during various functional activities. This practice must be functional and no longer contrived.

Fig. 8.2 Development of Flexor Aspect of Head Control. **(A)** Vertical position: head at midline and midrange (total-body flexion) to optimally facilitate neck flexors. **(B)** Facilitating symmetrical neck flexion, using position, gravity, and flexor positions. **(C)** Facilitating flexion and rotation to develop pattern necessary for neck-righting pattern.

Fig. 8.3 Development of Extensor Aspect of Head Control. **(A)** Vertical position: head midline with long extensor in midrange and postural extensors in shortened range; body in postural weight-bearing pattern. **(B)** Facilitating symmetrical extension of head, trunk, and hips while inhibiting abnormal upper-extremity tone. **(C)** Facilitating head and trunk extension and rotation to encourage neck righting pattern; patient reaches for an object, which is then placed on the opposite side.

CASE STUDY 8.3 Initial Augmented Intervention Transitioning to Independence in Bed Mobility

Teaching the patient to roll in bed can be approached in a variety of ways to accomplish the goal. The entire rolling pattern may be practiced with enough assistance for the patient to be able to accomplish the goal but also limiting help so that the patient must use the maximum amount of power and range of motion (ROM) available within the key movement pattern.

Rolling

The patient is a 73-year-old man, status post–ischemic infarct in the frontoparietal cortex with resultant left hemiplegia, hemisensory deficit, and left homonymous hemianopia. The patient demonstrates visual-spatial inattention to the left environment. The patient must learn to roll independently in bed for comfort and function. An example of a treatment session aimed at reaching the goal of independent rolling to the right and left may include the following sequence of

activities: (1) begin in side-lying on one side; (2) ask patient to tip back a few degrees and then return to the side-lying position (impairment training within limited ROM); and (3) progressively increase the degree the patient must roll backward, assisting (augmenting) him as needed. By the end of several repetitions, the patient may be rolling from supine to side lying and the movement is functional because he is performing independently. The patient will need to practice many times to relearn the activity before that activity would be considered functional training within the environment practiced. Rolling on a therapeutic mat table is not the same as rolling on a soft mattress at home. There may or may not be carryover. That needs to be identified by the therapist and appropriate steps taken to ensure that independence in all environments is obtained.

Refer to the online video for a demonstration of handling while working on rolling for bed mobility.

ACKNOWLEDGMENT

All the present authors and editors would like to express their deepest gratitude to Dr. Darcy A. Umphred, Dr. Nancy N. Byl, and Dr. Margaret L. Roller who helped develop this chapter in the previous editions of the text.

Abstract: This chapter provides a comprehensive discussion of interventions used by therapists to improve activity and participation of patients and patients with movement limitations. This chapter presents current evidence, clinical implications, and considerations for utility of these interventions in neurorehabilitation.

Keywords: evidence-based practice, functional training, intervention for impairments, augmented intervention

Medical and Developmental Challenges of Infants in Neonatal Intensive Care: Management and Follow-Up Considerations

Jane K. Sweeney, Teresa Gutierrez, and Joanna C. Beachy

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Discuss current theoretical frameworks guiding neonatal therapy services in the neonatal intensive care unit.
2. Identify the physiological and structural vulnerabilities of preterm infants that predispose them to stress during neonatal therapy procedures.
3. Outline mentored clinical training components and acute pediatric care experiences to prepare for entry into neonatal intensive care unit practice.
4. Describe how the grief, fear, and emotional trauma may affect behavior and caregiving performance of parents of neonates in the intensive care unit.
5. Differentiate the developmental course and neuromotor risk signs in infants with emerging neuromotor impairment from the characteristics of infants with typical variations in motor behaviors.
6. Identify instruments for neuromotor examination of infants in neonatal intensive care units and in follow-up clinics and compare psychometric features of the tests.
7. Describe program plans and follow-up for neonates and infants in neonatal intensive care unit and home settings.

physiological and musculoskeletal risks
subspecialty training

Premature birth continues to be associated with an increased prevalence of major and minor neurodevelopmental disability despite ongoing advancement in newborn resuscitation and neonatal intensive care procedures.¹⁻³ The risk of neurodevelopmental disability in infants born preterm remains high, with increasing prevalence of mild neurological impairment reported in infants with a late preterm birth (34 to 36 weeks of gestation).^{4,5}

Neurodevelopmental and movement assessments combined with brain imaging provide moderate to high prediction of neurodevelopmental outcome.^{6,7} Serial clinical examinations and careful monitoring of neurodevelopmental status are critical during the neonatal period, at discharge from the neonatal intensive care unit (NICU), and

sequentially in the outpatient follow-up phase of care. Pediatric therapists with mentored, subspecialty training in neonatology, infant examination, and infant therapy approaches can serve these increasing numbers of surviving neonates at neurodevelopmental risk by

- collaborating with neonatal care teams in NICU rounds and family conferences,
- providing diagnostic data through neurological, developmental, and behavioral examinations
- participating in developmental, feeding, and environmental interventions adapted to each infant's physiological, motor, and behavioral needs

- facilitating parent teaching on developmental and feeding strategies
- reinforcing preventive aspects of health care through early intervention and long-term developmental monitoring

The focus of this chapter is clinical management during the NICU and outpatient follow-up phases for neonates at neurodevelopmental risk and their parents. A theoretical framework for neonatal practice is presented, and an overview of neonatal complications associated with adverse outcomes is provided. In-depth discussion in the neonatal section includes neurodevelopmental examination and pain assessment, intervention plans, and therapy strategies in the NICU. The section on outpatient follow-up addresses critical time periods for neuromotor and musculoskeletal reexamination, assessment tools, and clinical cases.

THEORETICAL FRAMEWORK

Concepts of dynamic systems, neuronal group selection theory (NGST), and parental hope-empowerment provide a theoretical framework for neonatal therapy practice. In this section, three models provide a theoretical structure for practitioners designing and implementing neuromotor and neurobehavioral programs for neonates and their parents.

Dynamic Systems

Dynamic systems theory applied to infants in the NICU refers to multiple interacting structural and physiological systems within the infant as well as to dynamic interactions between the infant and the environment. The synactive model of infant behavioral organization is an example of a neonatal dynamic systems model for establishing physiological stability as the foundation for organization of motor, behavioral state, and attention or interactive behaviors in infants. Als and colleagues^{7,8} described a “synactive” process of four subsystems interacting as the neonate responds to the stresses of the extrauterine environment. They theorized that the basic subsystem of physiological organization must first be stabilized for the other subsystems to emerge and allow the infant to maintain behavioral state control and then interact positively with the environment (Figs. 9.1 and 9.2).

To evaluate infant behavior within the subsystems of function addressed in the synactive model, Als and associates⁹ developed the Assessment of Preterm Infants' Behavior (APIB). With the development of this assessment instrument, self-regulation, a fifth subsystem of behavioral organization, was added to the synactive model. The self-regulation subsystem consists of physiological, motor, and behavioral state strategies used by the neonate to maintain balance within and between the subsystems (see Fig. 9.2). For example, many infants born preterm appear to regulate overstimulating environmental conditions with a behavioral state strategy of withdrawing into a drowsy or light sleep, thereby shutting out sensory input. The withdrawal strategy is used more frequently than crying because it requires less energy and causes less physiological drain on immature, inefficient organ systems. Neonatal therapists may find a dynamic systems framework useful in conceptualizing and assessing changes in infants' multiple subsystems during and after therapy procedures. In Fig. 9.1 neonatal movement and postural control are targeted as a core focus in neonatal therapy, with overlapping and interacting influences from the cardiopulmonary, behavioral, neuromuscular, musculoskeletal, and integumentary systems. A change or intervention affecting one system may diminish or enhance stability in the other dynamic systems within the infant. Similarly, a change in the infant's environment may impair or improve the infant's functional performance.

This theory guides the neonatal practitioner to consider the many potential physiological and anatomical influences (dynamic systems

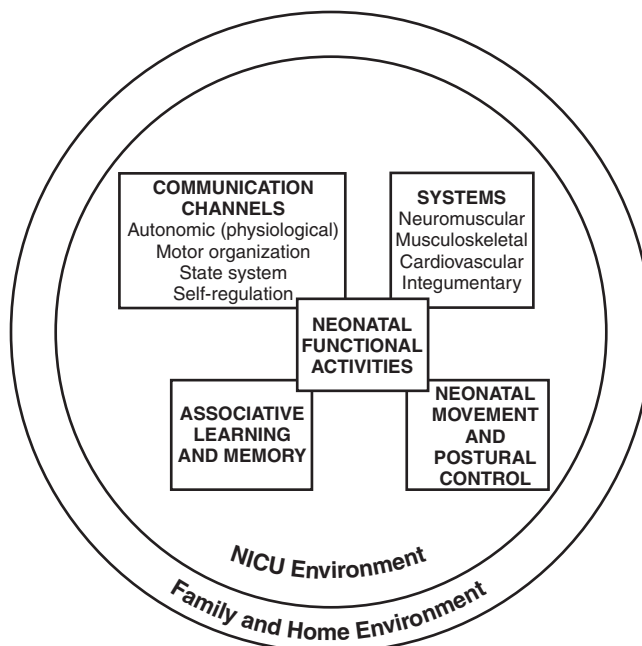

Fig. 9.1 Dynamic systems within neonates and interacting external influences on functional performance. *NICU*, Neonatal intensive care unit. (From Sweeney JK, Heriza CB, Blanchard Y, et al. Neonatal physical therapy. Part II: practice frameworks and evidence-based practice guidelines. *Pediatr Phys Ther.* 2010;22:3.)

Fig. 9.2 Pyramid of synactive theory of infant behavioral organization with physiological stability at the foundation.

within the infant) that make preterm infants vulnerable to stress during caregiving procedures, including neonatal therapy. In dynamic systems theory, emphasis is placed on the contributions of the interacting environments of the NICU, home, and community in constraining or facilitating the functional performance of the infant.¹⁰

Neuronal Group Selection Theory

This theoretical framework was developed by Edelman^{11,12} on the hypothesis that specific behaviors are the product of neuronal groups, which are dynamically organized to be selected by development. Edelman described three tenets:

- Tenet 1: Development of primary repertoires
Millions of neurons are interconnected to form functional units known as neuronal groups.

Neuronal groups come together to form primary neuronal repertoires capable of adaptation and accommodation. Formation of primary repertoires does not rely on experience and are endogenously generated.

- Tenet 2: Development of secondary repertoires

Preexisting primary repertoires are modified by environmental and individual experiences.

The experience of movement strengthens or weakens repertoires based on value, repetition, or availability of other repertoires. Secondary repertoires develop as a result of this selection.

- Tenet 3: Development of neural maps

The selection process gives way to neural maps. Neuronal groups are distributed throughout the nervous system. These maps are organized in such a way that distinct and distant areas of perception, cognition, emotion, movement, and posture can be activated simultaneously for one task.

The NGST has been further explored in recent literature as one of the leading theories explaining the dynamic nature of infant development, with variability as one of the main properties of normal movement.^{13,14} The continuity of neural functions from prenatal to postnatal life has been well documented over the years. Prechtl^{15,16} documented the timing of prenatal, endogenously generated behaviors such as swallowing, sucking, yawning, hand-to-mouth movements, and general body movements.

Preterm infants are born with an innate repertoire of spontaneous movement with specific qualitative characteristics. Variability and complexity of movement are key indicators of central nervous system integrity. Changes in the quality of spontaneous movement with decreased variability may indicate neuromotor dysfunction.^{17,18}

Hope-Empowerment Model

A major component of the intervention process in neonatal therapy is developing a therapeutic relationship with the family and supporting family-centered care practices in neonatal care units. A hope-empowerment framework (Fig. 9.3) may guide neonatal practitioners in building the therapeutic partnership with parents; facilitating adaptive coping; and empowering them to participate in caregiving, problem solving, and advocacy. The birth of an infant at risk for a disability, or the diagnosis of such a disability, may create both developmental and situational crises for the parents and the family system.

The developmental crisis involves adapting to changing roles in the transition to parenthood and in expanding the family system. Although not occurring unexpectedly, this developmental transition for the parents brings lifestyle changes that may be stressful and cause conflict.¹⁹ Because parents are experiencing (mourning) loss of the “wished for” baby they have been visualizing in the past 6 months, they may struggle with developing a bond with their “real” baby in the NICU.²⁰

A situational crisis occurs from unexpected external events presenting a sudden, overwhelming threat or loss for which previous coping strategies are not applicable or are immobilized.²¹ The unfamiliar, high-technology, often chaotic NICU environment creates many situational stresses that challenge parenting efforts and destabilize the family system.²² The language of the nursery is unfamiliar and intimidating. The sight of fragile, sick infants surrounded by medical equipment and the sound of monitor alarms are frightening. The high frequency of seemingly uncomfortable, but required, medical procedures for the infant are of financial and humanistic concern to parents. No previous experiences in everyday life have prepared parents for this unnatural, emergency-oriented environment. This emotional trauma of unexpected financial and ongoing psychological stresses during parenting and caregiving efforts in the NICU contributes to potential

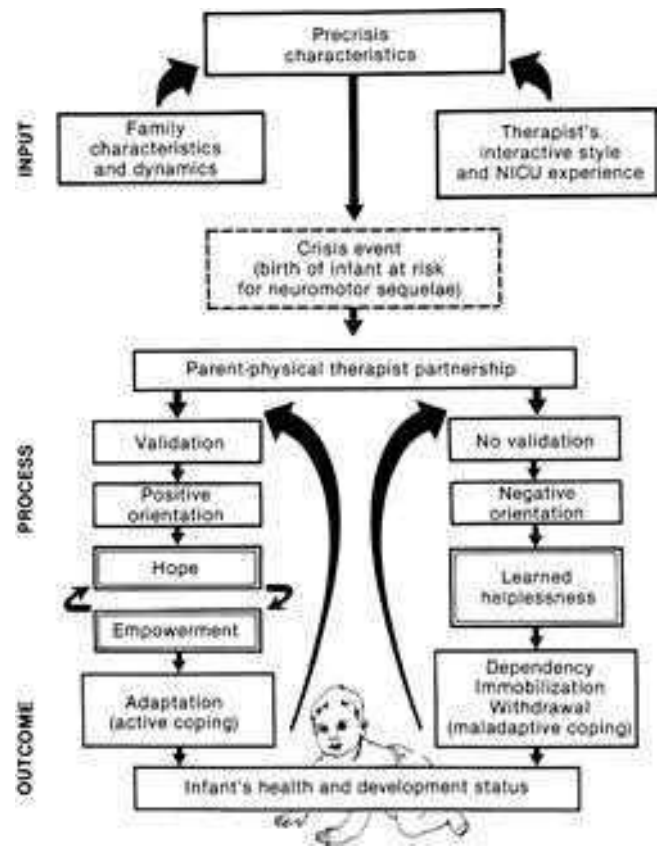

Fig. 9.3 Hope-empowerment (left) versus learned helplessness (right) processes of the therapeutic partnership between parents and the neonatal therapist. NICU, Neonatal intensive care unit.

posttraumatic stress disorder in parents of infants requiring intensive care.^{23–26}

The quality and orientation of the helping relationship in neonatal therapy affect the coping style of parents as they try to adapt to developmental and situational crises (see Fig. 9.3). Although parents and neonatal therapists enter the partnership with established interactive styles and varying life and professional experiences, the initial contacts during assessment and program planning set the stage for either a positive or negative orientation to the relationship.

Despite many uncertainties about the clinical course, prognosis, and quality of social support, a positive orientation can be developed by acknowledging and validating parents’ feelings and experiences. Validation then becomes a catalyst to a hope-empowerment process in which many crisis events, negative feelings, and insecurities are acknowledged in a positive, supportive, nonjudgmental context in which decision making power is shared.²⁷ In contrast, a negative orientation may be inadvertently facilitated by information overloading without exploring and validating parents’ feelings, experiences, and learning styles. Uncertainty, fear, and powerlessness may be experienced by parents attempting to participate in neonatal therapy activities.

In a hope-empowerment framework, parent participation in neuromotor and feeding intervention allows sharing of power and responsibility and can promote continuous, mutual setting and revision of goals with reality grounding. Adaptive power can be generated by helping parents stabilize and focus energy and plans and by encouraging active participation in intervention and advocacy

activities.²⁷ Exploring external power sources (e.g., online groups supporting parents of infants born preterm) early in the therapeutic relationship may help parents focus and mobilize.^{28–30}

Hope and empowerment are interactive processes. They are influenced by existential philosophy: the hope to adapt to what is and the hope to later find peace of mind and meaning for the situation, regardless of the infant's outcome. In describing the effect of an infant born prematurely on the parenting process, Mercer³¹ stated that "hope seems to be a motivational, emotional component that gives parents energy to cope, to continue to work, and to strive for the best outcome for a child." She viewed the destruction of hope as contributing to the physical and emotional withdrawal frequently observed in parents who attempt to protect themselves from additional pain and disappointment and then have difficulty reattaching to the infant.

Hope contributes to the resilience parents need to get through the arduous NICU hospitalization period and then begin to face the future in their home and community with an infant at neurodevelopmental risk. Groopman³² proposed that hope provides the courage to confront obstacles and the capacity to surmount them. He described the process of creating a *middle ground* where truth (of the circumstances) and hope reside together as one of the most important and complex aspects in the art of caregiving.

In a hope-empowerment context, parental teaching activities are carefully selected to contribute to pleasurable, reciprocal interaction between infant and parent. Gradual participation in infant care activities and therapeutic handling in the NICU provides experience and builds confidence for continuation in the home environment.³³

Conversely, if the parents' learning styles, goals, priorities, values, time constraints, energy levels, and emotional availability are not considered in the design of the developmental program, parents may experience failure, low self-esteem, powerlessness, immobilization, or dependency. The neonatal therapist may recognize signs of learned helplessness in parents when they show nonattendance, noncompliance, negative interactions with infant and staff, or a hopeless, overwhelmed outlook during bedside teaching sessions.

New events in the infant's health or developmental status may create new crises and destabilize the coping processes. In long-term neurodevelopmental follow-up, many opportunities occur within the partnership to validate new fears and chronic uncertainties within a hopeful, positively oriented, therapeutic relationship. This model provides a framework for understanding the processes of hope and empowerment for mediating emotional trauma of parents during the unexpected experience of parenting their baby in a NICU.

NEONATAL COMPLICATIONS ASSOCIATED WITH ADVERSE OUTCOMES

Improvements in neonatal intensive care over the last 30 years have led to increased survival of preterm and term infants. Specific obstetric advances include earlier identification of high-risk pregnancies, improvement in prenatal diagnosis using ultrasound and non-invasive prenatal screening, establishment of specialized tertiary care centers for high-risk pregnancies, and medications such as progesterone to assist in prolonging pregnancy and betamethasone to enhance fetal pulmonary development. Availability of commercial surfactant, advances in ventilator design, and improvement in the management of neonatal respiratory distress have resulted in significantly decreased pulmonary damage after preterm birth (refer to [Table 9.6](#) for a description of ventilators and other specialized equipment in the NICU).

For infants born at 23 weeks gestation, survival has increased from approximately 0% to more than 50%, and for infants born at 26 weeks gestation, survival has increased from 25% to 85% over the past 20 years.³⁴ Importantly, the incidence of severe neurological injury has decreased over time; however, an increased number of preterm infants will exhibit long-term neurological impairment owing to increased survival.

Preterm Birth

Preterm birth is defined as any infant born alive under 37 weeks gestation. Late preterm infants (born between 34 and 36/7 weeks gestation) comprise more than 70% of all preterm births. These infants are at risk for respiratory compromise, apnea, feeding problems, jaundice, and temperature instability.³⁵ In addition, they are at increased risk for neurodevelopmental delay because a significant amount of brain growth, development, and maturation occurs during the last 6 weeks of gestation.³⁶

For infants born less than 34 weeks gestation, mortality and neurodevelopmental impairment increase with decreasing gestational age. Very preterm infants are born between 28 and 32 weeks gestation, and extremely preterm infants are born less than 28 weeks gestation; however, the exact gestational age of the preterm infant is frequently unknown, and infants are frequently categorized by birth weight groups to predict survival and the risk of short and long-term outcomes. Low birth weight (LBW) infants weigh less than 2500 g at birth and are usually under 37 weeks gestation. Very low birth weight (VLBW) infants weigh less than 1500 g and extremely low birth weight (ELBW) infants weigh less than 1000 g at birth regardless of gestational age. The most frequent reasons for an infant to have a birth weight less than expected for their gestational age (i.e., small for gestational age or growth restricted infants) are twin and higher order multiple pregnancy, maternal disease such as pregnancy-induced hypertension, maternal smoking, placental dysfunction, and/or chromosomal abnormalities.

Survival of extremely preterm infants has dramatically increased over time, resulting in increasing numbers of infants with neurodevelopmental delay. The neurodevelopmental outcome of extremely preterm infants assessed at 18 to 30 months of age is reported widely.^{37–40} Developmental outcome of Swedish infants born at less than 27 weeks gestation between 2004 and 2007 indicated that 56% had no cognitive, language, or motor impairment, and 20% had moderate to severe impairment.³⁹ Moderate to severe language delay (16%) or motor impairment (15%) were more prevalent than cognitive disability (11%). Cerebral palsy (CP) was present in 7% of this extremely preterm cohort.

In France, in 2011, 49% of infants born at less than 27 weeks gestation survived to 2 years without detection of neurodevelopmental impairment. CP was present in 7% of this sample. Infants born between 27 and 31 weeks gestation had increased survival without impairment (90%) compared to very preterm infants born at less than 27 weeks gestation. Infants born at full term gestation rarely had neurodevelopmental impairment (2%).³⁸

In a study conducted from 2011 to 2015 in the United States, 19% of infants born at less than 27 weeks demonstrated neurodevelopmental delay. Ten percent had significant cognitive delay and 13% had motor impairment. Predictors of developing CP included decreasing gestational age, intraventricular hemorrhage (IVH), and chronic lung disease (CLD), with the incidence of CP decreasing over time.³⁷ More than 50% of ELBW infants in a US sample had receptive language delay at 30 months, and 23% were severely delayed. Forty eight percent of the infants had some expressive language delay, and 30% were severely delayed. Infants requiring assistance with feeding were at

higher risk of expressive language delay (2.3-fold increase). The need for feeding assistance and decreased cognition was significantly associated with receptive language delay.⁴¹

At 6 to 7 years of age, only 36% of infants born at less than 27 weeks gestation in Sweden had a normal IQ. One-third of these very preterm infants had moderate to severely decreased IQ compared to 2.2% of term infants. The average IQ of preterm infants was 17 points lower than the IQ of term infants. Thirty percent of preterm infants had moderate to severe cognitive delay, specifically in verbal comprehension, working memory, reasoning, and processing speed. Overall, 36.2% of these preterm infants demonstrated no neurodevelopmental delay and 33.6% had moderate to severe delay.⁴²

Does cognitive and motor ability at 2 years of age predict outcomes at school age? A cohort of very preterm infants born in Sweden at less than 27 weeks gestation were tested at 2 and 6 years of age. Sixty six percent of infants had no or only mild delays at 6 years. Overall, 21% of infants exhibited improved outcome, 32% had worse outcome, and the remainder were stable. The percentage of infants with moderate to severe disability increased over time from 27% to 34% showing that disability level was inversely related to gestational age. At 6 years of age, decrease in cognitive ability was likely due to decreased executive functioning, a cognitive area not tested at the younger age;^{39,42} thus neurodevelopmental testing at 2 years of age identifies most infants at risk for developmental delay and allows them access to needed therapy and educational assistance.

The fetal brain undergoes tremendous growth, development, and maturation during the second and third trimester. The preterm brain is especially vulnerable to injury from hypoxia, medications, stress, and pain. The long-term impact of adverse conditions depends on the gestational age of the infant as well as timing, frequency, nature, and duration of the insult. Expanded description of brain development can be accessed in Volpe's *Neurology of the Neonate*,⁴³ a comprehensive resource for health professionals.

Brain development and maturation are categorized into five primary phases (proliferation, migration, organization, synaptogenesis and apoptosis, and myelination). All neurons and glial (support) cells are generated in the germinal matrix, an area adjacent to the ventricle. Neuronal proliferation is nearly complete by 5 months of gestation, well before preterm delivery. Neuronal migration starts at 3 months of gestation and continues for 3 more months, with developing neurons guided by glial cells to form neuronal columns. The organization phase lasts from 5 months gestation through several years after birth. In this phase, neurons are oriented, neuronal projections (axons and dendrites) are elaborated, and interconnections between neurons are generated. Synaptic formation (neuronal interconnections) and elimination (programmed cell death—apoptosis) are present in the third trimester but are most active after birth. Synaptogenesis and apoptosis are experience-dependent and confer plasticity to the preterm brain, ensuring individuality. The final phase of brain maturation involves glial maturation of astrocytes and oligodendrocytes. Astrocytes help maintain the blood-brain barrier, provide nutrient support, regulate neurotransmitter and potassium concentration, and assist in neuronal repair after injury. Oligodendrocytes produce the myelin sheath that covers neurons and facilitates nerve transmission. Myelination starts in the second trimester and continues through adulthood. The oligodendrocytes are especially sensitive to hypoxia and other insults. Disruption of normal myelination results in white matter hypoplasia and periventricular leukomalacia (PVL) (see later discussion) leading to impaired motor function.⁴³

Specific insults to the fetal and neonatal brain are associated with impaired neurological functioning and long-term developmental

TABLE 9.1 Conditions Associated With Impaired Neurodevelopment

delay. The next section focuses on specific diseases and conditions: IVH, PVL, hypoxic-ischemic (H/I) encephalopathy (HIE), CLD, sepsis, necrotizing enterocolitis (NEC), and in utero drug exposure (Table 9.1)

Intraventricular Hemorrhage

IVH is the most common brain injury in preterm infants born at less than 32 weeks gestation and is a significant risk factor for neurodevelopmental impairment. The incidence of IVH varies inversely with gestational age. The incidence of severe IVH has decreased over time and is currently less than 15% for infants born at under 27 weeks gestation.⁴⁴

The origin of IVH is in the microcirculation/capillary network of the germinal matrix. The germinal matrix is a highly vascularized area due to the high metabolic demand from rapidly proliferating neuronal stem cells. The vessels in the germinal matrix have thin walls and are fragile, predisposing them to rupture and hemorrhage. Preterm infants have impaired cerebral vascular autoregulation. During labor, delivery, and the immediate postpartum transition period, decrease in blood pressure can lead to cerebral hypoperfusion and ischemia and, conversely, increased blood pressure can lead to hyperperfusion and blood vessel rupture. Risk factors for IVH include asphyxia, alterations in serum carbon dioxide, rapid infusion of fluids (especially hypertonic solutions), platelet and coagulation disturbances, anemia, and pain.⁴⁵ In infants with gestational age greater than 28 weeks, IVH is rarely seen owing to the developmental involution of vessels in the germinal matrix.

IVH is diagnosed by cranial ultrasound and graded in severity from 1 to 4. The IVH Grade 1 is considered mild, with the hemorrhage confined to the germinal matrix. In IVH Grade 2, the hemorrhage extends into the ventricle (Fig. 9.4). Grade 3 hemorrhage occurs when more than 50% of the ventricle is filled and causes ventricular distention. The evolution of IVH Grade 3 over 10 days is shown in Fig. 9.5. Grade 4 IVH, or periventricular hemorrhagic infarct (PVHI) illustrated in Fig. 9.6, is not caused by germinal blood vessel rupture but, instead, is derived from venous congestion of the terminal veins that border the lateral ventricles, resulting in white matter necrosis and the development of a porencephalic cyst.⁴⁶ The usual distribution of PVHI as seen on cranial

Fig. 9.4 Grade 2 intraventricular hemorrhage, sagittal view on cranial ultrasound. Arrow points to area of germinal matrix bleed in the cardio-thalamic notch. Arrowhead points to blood layering out in the posterior aspect of the lateral ventricle.

ultrasound is initially fan-shaped in the periventricular location. The PVHI lesion is usually unilateral (~70%) and approximately ¾ are associated with severe IVH.⁴⁴

IVH may not be apparent on ultrasound in the first few days after birth, but 90% of IVH can be detected by 4 days of age. Grades 1 and 2 IVH are not associated with a significant increase in neurodevelopmental impairment. Infants with severe IVH (Grade 3 and/or 4) have increased mortality and are at markedly increased risk for developmental disabilities, specifically spastic hemiplegia and diplegia because the motor tracts innervating the lower extremities are in close proximity to the germinal matrix⁴⁷ (refer to Fig. 9.7 for schematic diagram of corticospinal [motor] tracts). Infants with small unilateral PVHI have no increased risk of developmental delay compared to infants with Grade 3 IVH. If the PVHI is bilateral or if large or multiple porencephalic cysts are present, the risk for severe motor impairment is significantly increased. The full extent of the hemorrhage may not be appreciated for several days after the initial diagnosis of IVH is made. The extent and impact of cerebral damage from IVH may not be evident on cranial ultrasound at term gestation, and magnetic resonance imaging (MRI) may give more information on the extent of injury. Owing to plasticity of the preterm brain, undamaged portions may assume tasks lost to damage, potentially leading to less impact on neurodevelopmental outcome than anticipated.

Fig. 9.6 (A) Left Grade 4 intraventricular hemorrhage on day of life 3 and (B) day of life 9 with initial hyperechoic area and subsequent dissolution of brain matter (arrow) as imaged with cranial ultrasound, coronal view.

Fig. 9.7 Schematic diagram of corticospinal tract fibers that extend from the motor cortex through the periventricular region into the pyramid of the medulla. The lower motor neurons affected by intraventricular hemorrhage and periventricular hemorrhagic infarct are located in close proximity to the ventricle. Bulbar and upper motor neuron tracts are affected in term infants with hypoxic-ischemic encephalopathy and are parasylvian in location. (From Volpe JJ. Hypoxic ischemic encephalopathy: neuropathology and pathogenesis. In: Volpe JJ, ed. *Neurology of the Neonate*. Philadelphia: WB Saunders; 1995.)

POSTHEMORRHAGIC VENTRICULAR DILATATION

Approximately 50% of infants with severe IVH (Grade 3 or 4) will develop posthemorrhagic ventricular dilatation (PHVD) caused by either blockage of the normal flow of cerebrospinal fluid (CSF) or decreased absorption of CSF. Approximately 50% to 75% of these infants will develop progressive PHVD resulting in the need for treatment. The severity of ventricular dilatation can be measured on serial cranial ultrasounds.^{48,49} Severe ventricular dilatation is usually evident by 2 to 3 weeks after birth while pathological increase in head circumference does not occur until 1 to 2 weeks later. PHVD is treated with serial removal of CSF by spinal tap, subgaleal shunt, or placement of Ommaya reservoir. Removal of CSF has been shown to decrease intracranial pressure and improve cerebral perfusion⁵⁰ and increase cortical gray and white matter.⁵¹ In addition, there is indirect evidence that ventricular distention itself may cause secondary brain injury through axonal stretching and disruption, gliosis, and loss of oligodendrocytes (cells that make the myelin sheath).

No consensus has been reached on the optimal management of PHVD.^{52,53} Infants with PHVD that does not resolve with serial removal of CSF require ventriculoperitoneal (VP) shunt placement. Significant complications of VP shunt include sepsis, specifically ventriculitis, or shunt malfunction, such as blockage or leaking, necessitating a shunt revision. These complications further impact the neurodevelopmental outcome of infants with VP shunts. The National Institute of Child Health and Development, a consortium of 17 tertiary NICUs, reported results on the neurodevelopmental outcome at 2 years in ELBW infants with Grade 3 and 4 IVH, born between 1993 and 2002.⁵⁴ Infants who required shunt placement had significantly worse outcome when compared to infants with Grade 3 or 4 as

TABLE 9.2 Outcome of Extremely Low Birth Weight Infants With Grade 3 or 4 Intraventricular Hemorrhage With or Without Ventriculoperitoneal Shunt

	No VP Shunt	VP Shunt	
MDI < 70	326/719 (45.3%)	146/214 (68.2%)	<0.001

From Modified from Adams-Chapman I, Hansen NI, Stoll BJ, et al. Neurodevelopmental outcome of extremely low birth weight infants with posthemorrhagic hydrocephalus requiring shunt insertion. *Pediatrics*. 2008;121:1167–1177.

assessed by the Bayley Scale of Infant Development (Table 9.2). A score of less than 70 denotes an infant who is severely delayed. Moreover, the number of infants who were untestable (score = 49) owing to severe neurodevelopmental handicap and the incidence of CP were significantly increased in infants who received a VP shunt compared to infants with only Grade 3 or 4 IVH.⁵⁴

Retrospective studies from the Netherlands indicated that earlier intervention when the ventricles were only moderately dilated significantly decreased the need for VP shunt from 62% to 16% and tended to improve long-term developmental outcome with a decreased incidence of moderate to severe handicap.^{48,55} Halting the progression of PHVD and decreasing the need for VP shunt are likely to improve long-term outcome in these infants. With the possibility of spontaneous resolution of PVHD without intervention, identification of factors for accurate prediction is needed to determine which infants will develop persistent PHVD and subsequently require VP shunt placement.

PERIVENTRICULAR LEUKOMALACIA

PVL is the most common ischemic injury to the preterm infant's brain. This injury involves nonhemorrhagic (ischemic) cellular necrosis of periventricular white matter in the arterial watershed area caused by the lack of cerebral autoregulation. Like IVH, PVL is inversely related to gestational age and is present in less than 10% of preterm infants. The PVL lesion can either be cystic or global and may be difficult to identify on radiological images. Cystic PVL (Fig. 9.8) results from the focal dissolution of cellular tissue approximately 3 to 4 weeks after the asphyxial insult and can be identified on ultrasound if greater than 0.5 cm in diameter;⁴⁴ however, cysts visualized by cranial ultrasound may disappear over time owing to fibrosis and gliosis; thus the incidence of cystic PVL is considered to be underestimated by cranial ultrasounds. Global PVL results from diffuse white matter injury and myelin loss. This finding can be subtle with moderate ventricular dilatation and/or a mild increase in extraaxial fluid on cranial imaging. Infants with severe PVL have marked ventricular dilatation, increased extraaxial fluid, and decreased head growth.

Brain imaging by MRI obtained at term may be more sensitive in identifying white matter injury from PVL and can be predictive of subsequent neurosensory impairment and cognitive delay present in up to 50% of extremely preterm infants.⁵⁶ Newer techniques, such as diffusion tensor imaging (DTI), functional connectivity MRI (fcMRI),

Fig. 9.8 Cystic periventricular leukomalacia is present on cranial ultrasound in sagittal view on the right (A) and left (B) side of the brain as marked by arrows. (C) Coronal view. Cysts are evident using magnetic resonance imaging (D and E).

and morphometry for analysis of cortical folding, are being investigated as early markers of impaired neurodevelopmental outcome. With DTI, the restriction of water diffusion in the myelin sheath surrounding axons is measured and yields information at the microstructure level about axon caliber change and aberrations in myelination. In addition, DTI allows for visualization of brain fiber tracks and neuronal connectivity. The interaction between areas of the brain at rest and during tasks using changes in blood flow is examined with fMRI, currently a research tool. Morphometric analysis of sequential MRI scans has been used to create maps of cortical folding with quantification of surface area and degree of gyral formation. White matter injury results in delayed myelination and altered cortical folding.⁵⁶

CEREBELLAR INJURY

The cerebellum is essential for gross and fine motor control, coordination, motor sequencing, and also plays an important role in attention and language.⁵⁴ Although the hallmark of damage to the cerebellum is ataxia, recent advances in fMRI have demonstrated interactions between the cerebellum and nonmotor brain areas involved in language, attention, and mental imagery. Cerebellar injury can also be noted by cranial ultrasound on specific mastoid views. The incidence of cerebellar injury may be as high as 20% in ELBW infants.⁵⁷ While the mechanism for damage is unknown, IVH is present in more than 75% of infants with cerebellar injury, implicating similar risk factors. The majority of cerebellar lesions (70%) are unilateral.

Cerebellar lesions are usually clinically silent at birth, and the full impact of the damage is noted over time. As a result of the intricate interconnections between the cerebellum and cerebrum, damage in one area can greatly impact development in other areas of the brain,

thereby amplifying the damage. Preterm infants with isolated cerebellar hemorrhage had significant neurological impairments: hypotonia (100%), abnormal gait (40%), ophthalmological abnormalities (~40%), and microcephaly (17%).⁵⁸ Overall, preterm infants with cerebellar hemorrhage had visual deficits and performed significantly lower on tests of gross and fine motor and expressive and receptive language. Infants with both cerebellar injury and IVH had greater motor impairment than infants with isolated cerebellar hemorrhage. Socially, infants with isolated cerebellar hemorrhage exhibited lower communication skills, more withdrawn behavior, and decreased attention skills. Cerebellar injury therefore increases the risk for poor neurodevelopmental outcome in cognition, learning, and behavior in preterm infants.⁵⁹

BRONCHOPULMONARY DYSPLASIA

Bronchopulmonary dysplasia (BPD) or CLD is the result of mechanical ventilation and supplemental oxygen delivered to preterm infants to treat their immature lungs that lack surfactant. It was originally defined as an oxygen requirement at 28 days of life in conjunction with classic x-ray findings of atelectasis (areas of collapsed lung) and multiple cysts. The presence of BPD leads to the need for continued respiratory support owing to insufficient air exchange and, frequently, the placement of a tracheostomy tube. With recent treatment advancements such as maternal betamethasone to promote fetal lung maturity, exogenous surfactant, gentler, refined ventilation strategies, and careful supplemental oxygen administration, BPD is now defined as oxygen requirement at 36 weeks corrected gestational age. The level of BPD can be either moderate (requires supplemental oxygen) or severe (requires tracheostomy and ventilator support). The incidence of BPD

in infants born at less than 27 weeks gestation or birth weight 500 to 750 g is 60%.⁶⁰ The incidence of BPD for infants with birth weight 751 to 1000 g, 1001 to 1250 g, and 1251 to 1500 g is 33%, 14%, and 6%, respectively.⁶¹

Infants with BPD can have altered pulmonary function, reactive airway disease, asthma, and delayed neurodevelopment. They may have decreased pulmonary reserve and frequent hospitalizations related to bacterial or viral pneumonia.⁶⁰ Owing to the need for prolonged ventilation, infants with BPD may develop oral aversion resulting in difficulty with oral feeding and delayed expressive language.⁴¹ Dexamethasone has been used to decrease the dependence on mechanical ventilation but alters brain development, thereby negatively affecting neurodevelopmental outcome.^{62,63} Hydrocortisone used instead of dexamethasone may result in lowering the incidence of BPD and appears to have decreased impact on neurodevelopmental outcome at 2 years of age.⁶¹

SEPSIS

Preterm infants are at high risk of developing sepsis owing to immature immune responses and decreased concentration of acquired maternal antibodies through the placenta. Approximately 2% of infants will be born septic, and 21% will develop sepsis during their NICU stay, with a mortality of 10% to 30% depending on infant age and other confounding factors. Cytokines are released from cells of the immune system in response to bacterial infection and can damage organs (e.g., lungs, kidneys, and brain). Infants with sepsis require increased time on mechanical ventilation and supplemental oxygen and have an increased incidence of BPD with its associated morbidities. Hypotension often accompanies sepsis leading to malperfusion of the brain and impaired development of oligodendrocytes. A two- to three-fold increase in the risk for CP and neurodevelopmental impairment is reported in infants with sepsis.⁶⁴ For infants with acquired sepsis, an increase in white matter injury is seen on MRI, especially if repeated episodes of sepsis occur.⁶⁵

Central line-associated blood stream infections (CLABSI) are hospital-acquired infections in conjunction with the presence of a central line. Much effort has been focused on decreasing CLABSI such as requiring stringent hand hygiene practices, minimizing central line use, decreasing number of central line interruptions, improving skin care, and enforcing strict infection control monitoring.

NECROTIZING ENTEROCOLITIS

NEC is the most common neonatal intestinal disease with an incidence of 10% in extremely preterm infants. An early presentation occurs within the first month of life, and NEC is frequently associated with intestinal perforation. Surgery is necessary for 50% of infants with NEC when medical management is insufficient or persistent intestinal perforation is present. Surgery is associated with an increased risk of mortality (20% to 40%) compared to infants treated medically. The etiology of NEC is not established, but risk factors include prematurity, umbilical artery catheterization, asphyxia, congenital heart disease, blood transfusion, and enteral feedings. Several viruses (adenovirus, enterovirus, and rotavirus) and bacteria have been implicated as causative agents for NEC. Infants with NEC are usually bacteremic either at the time of presentation of NEC or secondary to intestinal perforation.⁶⁶

Complications of NEC include sepsis, wound infection, and stricture formation that occurs in 10% to 35% of infants and requires additional surgeries to remove the stricture. If removal of intestines is required, wound infection and short gut condition are further

complications. Growth of infants with NEC can be impaired owing to feeding intolerance, prolonged parenteral nutrition, removal of a significant amount of intestine, and repeated surgeries and infections. Persistence of weight at under 10% for age is correlated with decreased neuromotor and neurodevelopmental outcome. Failure to achieve normalization of head growth is associated with abnormal performance at 1 year and probably reflects significant white matter injury. Infants with surgically managed NEC have significantly increased incidence of CP (24% vs 15%), deafness (4.1% vs 1.5%), and blindness (4.1% vs 1%), compared to infants with medically treated NEC.^{66,67} A meta-analysis of 7 studies investigating the impact of NEC on neurodevelopmental outcome showed that infants with surgically treated NEC have a statistically significant increase in cognitive, psychomotor, and neurodevelopmental impairment compared to preterm infants without NEC.⁶⁷ Impaired neurodevelopmental outcome in infants with NEC is further exacerbated by sepsis with the release of inflammatory cytokines and mediators leading to white matter injury as noted above.³⁴

HYPOXIC-ISCHEMIC ENCEPHALOPATHY IN TERM AND NEAR TERM NEONATES

Perinatal asphyxia affects approximately 3 to 5 per 1000 infants annually and can lead to HIE in 0.5 to 1/1000 live births. Approximately 15% to 20% of infants with HIE will die, and 25% of the surviving infants will exhibit permanent neurological sequelae. Clinical findings will vary depending on the timing and duration of the H/I insult, preconditioning, fetal adaptive mechanisms, comorbidities, and resuscitative efforts. Impaired oxygen delivery to the fetus leading to asphyxia can result from maternal hypotension, abruption placenta, placental insufficiency, cord prolapse, prolonged labor, and fetal-maternal transfusion. Frequently, infants who develop HIE have associated factors such as abnormal maternal thyroid status, chorioamnionitis, and intrauterine growth retardation.⁶⁸

It is important to note that the injury from a H/I insult is an evolving and progressive process that begins at the time of the insult and continues through the recovery period, allowing the opportunity to decrease the damage from the asphyxial event. The H/I insult leads to decreased oxygen and glucose delivery to the brain causing a shift from aerobic to anaerobic metabolism. This shift causes a decrease in high-energy compounds such as adenosine triphosphate (ATP) production leading to failure of the energy-dependent membrane sodium potassium pump. Sodium enters the neuronal cell causing depolarization and release of excitatory neurotransmitters. This initial phase can last several hours and is marked by significant acidosis, depletion of high-energy compounds, cellular swelling caused by entry of sodium and water, and cellular necrosis causing spillage of intracellular contents into the extracellular space and activation of microglia. The degree of neuronal necrosis is directly related to the duration and severity of the H/I insult. During the reperfusion phase, an increase in free radical production and activation of microglia occur with release of inflammatory mediators caused by improved oxygen delivery. The second phase of energy failure ensues with calcium entering the mitochondria to activate the apoptotic pathway (programmed cell death). During this second phase of energy failure, seizures are often present. Activation of the apoptotic pathway accounts for the majority of cellular death and inactivation of this apoptotic pathway is the target for treatment.⁴⁷

The damage from HIE in term infants is located in the deep structures of the brain (basal ganglia, thalamus, and posterior limb of the internal capsule) as well as in the subcortical and parasagittal white

Fig. 9.9 Magnetic Resonance Imaging (MRI) Diffusion Weighted Imaging. **(A)** MRI of normal infants with no areas of increased signal. **(B)** An infant with severe hypoxic-ischemic encephalopathy with arrows pointing to increased signal in the subcortical areas.

matter. Diffusion-weighted imaging MRI (DWI) is an early and sensitive technique to identify damage after the H/I insult. As shown in Fig. 9.9, a marked increase in signal is found in the subcortical and parasagittal white matter as well as in the deep nuclear structures. MRI spectroscopy, usually in the area of the basal ganglia, yields information about the degree of secondary energy failure by analyzing the depletion of the high-energy compound N-acetylaspartate and the presence of lactate. The degree of secondary energy failure is predictive of death and poor neurodevelopmental outcome at 1 and 4 years of age.⁶⁹

The Sarnat score (Table 9.3) classifies the severity of HIE based on clinical signs.⁷⁰ Approximately 20% of infants with stage 1 HIE will have long-term sequelae.⁷¹ Infants with Grade 2 or moderate HIE have abnormal tone and reflexes and decreased spontaneous activity. Seizures are a common finding in infants with moderate HIE, and approximately 10% of these infants will die and up to 30% will have neurodevelopmental delay. Infants with severe HIE (Grade 3) have minimal or no spontaneous activity or reflexes, and approximately 50% of these infants will die and, of the survivors, more than 60% to

80% are profoundly impaired. Seizures are present in up to 40% of infants with HIE and are identified either clinically or by EEG or amplitude integrated EEG. Long-term consequences of HIE include bulbar palsies with difficulties in sucking, swallowing, and facial movement.⁷² Upper extremity involvement is more prominent than lower extremity deficits. The development of epilepsy occurs in approximately 30% of infants with HIE. Owing to the fact that approximately 50% of infants with moderate or severe HIE treated with hypothermia will exhibit normal neurodevelopmental outcomes, other modalities such as Xenon gas, topiramate, melatonin, tetrahydrocannabinol, and erythropoietin are being investigated to enhance the efficacy of hypothermia.

Mild hypothermia (33.5°C) is becoming the standard of care for infants under 36 weeks gestation who present with moderate or severe HIE. Hypothermia has been shown to decrease metabolic demand and therefore help preserve high-energy compounds, delay membrane depolarization, and decrease neuronal excitotoxicity. Free radical production and microglial activation are also decreased. Most

TABLE 9.3 Sarnat Scoring Scale for Encephalopathy

Stage Encephalopathy	Normal	Stage 1 (Mild)	Stage 2 (Moderate)	Stage 3 (Severe)
1. Level of consciousness	Alert, responsive	Hyper-alert, responds to minimal stimulation	Lethargic	Stupor/coma
2. Spontaneous activity	Changes position	Normal or ↓	Decreased	None
3. Posture	Flexed when quiet	Mild flexion distal	Distal flexion, full extension	Decerebrate
4. Tone	Strong flexor tone	Normal or slightly ↑	Hypo- or hyper-	Flaccid or rigid
5. Reflex:				
Suck	Strong	Weak or incomplete	Weak	Absent
Moro	Complete	Intact	Incomplete	Absent
6. Autonomic:				
Pupils	Normal	Mydriasis	Myosis	Variable
HR	100-160	Tachycardia	Bradycardia	Variable
Respirations	Regular	Hyperventilation	Periodic breathing	Apnea, assisted

TABLE 9.4 Effect of Moderate Hypothermia on Neurological Outcomes at 18 Months Compared With Controls

	Risk Ratio (95% Confidence Interval [CI])	Risk Difference (95% CI)	Number Needed to Treat (95% CI)	P Value
Death or severe disability ^a	0.81 (0.71–0.93)	–0.11 (–0.18––0.04)	9 (5–25)	.002
Survival with normal outcome ^b	1.53 (1.22–1.93)	0.12 (0.06–0.18)	8 (5–17)	<.001
Mortality	0.78 (0.66–0.93)	–0.07 (–0.12––0.02)	14 (8–47)	.005
Severe disability in survivors ^a	0.71 (0.56–0.91)	–0.11 (–0.20––0.03)	9 (5–30)	.006
Cerebral palsy in survivors	0.69 (0.54–0.89)	–0.12 (–0.20––0.04)	8 (5–24)	.004
Severe neuromotor delay in survivors ^c	0.73 (0.56–0.95)	–0.10 (–0.18––0.02)	10 (6–71)	.02
Severe neurodevelopmental delay in survivors ^d	0.71 (0.54–0.92)	–0.11 (–0.19––0.03)	9 (5–39)	.01
Blindness in survivors	0.57 (0.33–0.96)	–0.06 (–0.11–0.00)	17 (9–232)	.03
Deafness in survivors	0.76 (0.36–1.62)	–0.01 (–0.05–0.03)	NA	.47

^aSevere disability was defined in the CoolCap and TOBY trials as the presence of at least one of the following impairments: Mental Developmental Index score of less than 70 (2 standard deviations below the standardized mean of 100) on the Bayley Scales of Infant Development; gross motor function classification system level 3 to 5 (where the scale is from 1 to 5, with 1 being the mildest impairment); or bilateral cortical visual impairment with no useful vision. The NICHD trial defined disability as a Mental Developmental Index score of 70 to 84 plus one or more of the following impairments: gross motor function classification system level 2; hearing impairment with no amplification; or a persistent seizure disorder.

^bSurvival with normal outcome was defined as survival without cerebral palsy and with a Mental Developmental Index score of more than 84, a Psychomotor Developmental Index score of more than 84, and normal vision and hearing.

^cSevere neuromotor delay was determined on the basis of a Psychomotor Developmental Index score of less than 70 in survivors.

^dSevere neurodevelopmental delay was determined on the basis of a Mental Developmental Index score of less than 70 in survivors.

From Edwards AD, Brocklehurst P, Gunn AJ, et al. Neurological outcomes at 18 months of age after moderate hypothermia for perinatal hypoxic ischaemic encephalopathy: synthesis and meta-analysis of trial data. *BMJ*. 2010;340:c363.

importantly, the activation of the apoptotic pathway is diminished. Transient side effects of hypothermia, such as bradycardia, mild hypotension, thrombocytopenia, and persistent pulmonary hypertension, can be treated medically and are usually not significant. A meta-analysis of published randomized studies comparing infants with moderate and severe HIE treated with either hypothermia or normothermia showed that hypothermic treatment significantly decreased mortality and morbidity (Table 9.4).⁷³ It is known that hypothermia is most effective when administered prior to the onset of the second phase of energy failure. As the timing of the H/I insult can occur prior to delivery, hypothermia should be initiated as quickly as possible after delivery to increase the likelihood that it will diminish the neuronal damage and improve neurodevelopmental outcome.⁴⁷

MATERNAL MEDICATION

The impact of maternal medications on the developing fetal brain depends on the specific drug or combinations of drugs, as well as on the timing and duration of the drug exposure. Whereas the insults discussed previously cause predominantly cellular necrosis and apoptosis, medications given to the fetus and preterm infant can also cause alterations in the structure and function of genetic material. The hypothesis that factors acting early in life have a long-lasting impact on development is called the Barker hypothesis or the fetal origins of adult disease.^{74,75} It is proposed that the biological value of this reprogramming is to prepare the fetus for maximal adaptation through methylation and deacetylation of histones, thereby determining the quantity of specific proteins that are produced. This section will focus on maternal use of opioids, cocaine, cannabis, and selective serotonin reuptake inhibitors (SSRIs) during pregnancy.

Opioids

In the past decade, increasing concern has emerged over the marked use of opioids, both by prescription for pain relief and illicit use, leading to an increase in deaths owing to overdose. Most commonly used are naturally occurring opioids (morphine and codeine) and synthetic opioids (heroin, methadone, buprenorphine, and, recently, fentanyl). Opioids act on receptors present in both the central nervous system and gastrointestinal tract leading to euphoria and constipation, respectively. Continued use of opioids leads to tolerance resulting in a need to increase the drug's dose for the same effect. Physical dependence is manifested by withdrawal symptoms when the drug is discontinued. Addiction is a complex issue including tolerance, dependence, and psychological compulsion to use the drug.

Use of pain relievers, specifically opioids, during pregnancy has increased fivefold during the past decade.⁷⁶ These drugs are highly addictive to the mother and can readily cross the placenta and affect the fetus. Methadone and buprenorphine are commonly used in pregnant females to decrease the need for illicit drug use and stabilize maternal narcotic dependence. Opioid use during pregnancy has been associated with premature rupture of membranes, uterine irritability, preterm labor, preeclampsia, and growth-retarded infants.

Neonatal abstinence syndrome (NAS) is a constellation of symptoms in infants exposed prenatally to opioids and, after delivery, are subject to cessation of opioids leading to withdrawal symptomatology. Infants will demonstrate neurological hyperexcitability with high-pitched crying, increased muscle tone, irritability, decreased sleep, hyperalert state, and tremors at rest. Gastrointestinal symptoms can also be present such as vomiting and diarrhea. Impaired oral feeding and an increased need to suck on a pacifier are common. Autonomic

signs include sweating, mottling of the skin, increased temperature, and nasal stuffiness. Occasionally, seizures are present. In Ohio, hospital admissions for infants with NAS increased from 1.4 to 5.6 per 1000 live births.⁷⁶

Withdrawal from narcotics occurs 2 to 5 days after delivery depending on the opioid. Withdrawal from heroin and morphine usually starts by 24 hours after delivery. Neonatal withdrawal from maternal methadone or buprenorphine use is delayed up to 5 days after delivery owing to the long half-life on these medications. Severity of neonatal withdrawal symptoms is not exclusively related to the dose of maternal medications, but is influenced by polysubstance drug exposure, cigarette use, and genetics differences. Two commonly used scoring methods for determining the severity of NAS and the need for treatment are scales by Lipsitz⁷⁷ and Finnegan and colleagues.⁷⁸ The Lipsitz scale has 11 components scored from 0 to 3, with any score over 4 necessitating treatment. The Finnegan scale is a comprehensive assessment with more than 30 elements. A modified Finnegan assessment tool has been validated and is most frequently used.⁷⁹

Nonpharmacological supportive care consists of minimizing environmental stimuli by decreasing light and noise and decreasing irritability with swaddling, holding, pacifier use, and on-demand feeding. Maternal rooming-in and breastfeeding have beneficial effects on decreasing symptoms of withdrawal. This supportive care should be implemented even if the infant is on medications because they continue to demonstrate hyperexcitable behavior and have decreased tolerance to stimulation. Approximately 30% to 80% of in utero opioid-exposed infants will require medical treatment for NAS with either morphine or methadone. Phenobarbital and/or clonidine have been used as adjunctive treatment if symptoms continue. The goal of treatment is to decrease irritability, improve nipping efforts and weight gain, and decrease vomiting and diarrhea. The incidence of apnea and sudden infant death syndrome (SIDS) is increased in opioid-exposed infants. Long-term effects of in utero exposure to opioids include tremulousness, hypertonicity, irritability, and increased crying episodes. In addition, they are less able to interact with people, demonstrate decreased age-appropriate free play, and have delayed fine motor coordination. An appropriate and nurturing home environment is essential after discharge from the hospital to maximize neurodevelopmental outcome.

Cocaine

It is difficult to ascertain the exact frequency of cocaine use during pregnancy because its use is frequently associated with other illicit drugs. Cocaine is extracted from the leaves of the coca plant and induces an intense and immediate euphoric state through inhibiting uptake of neurotransmitters, specially serotonin and dopamine. Dependence can occur, and cocaine is highly addictive with severe and intense cravings lasting for several months with potential recurrence years after cessation of cocaine use.

Cocaine can cause vasoconstriction leading to placental abruption, preterm labor, uterine irritability, and premature rupture of membranes. In the fetus, there is an increased risk for H/I injury and middle cerebral artery stroke. Cocaine also negatively affects fetal neuronal proliferation, migration, growth, and connectivity, which distort neuronal cortical architecture; however, the effects of intrauterine exposure to cocaine are difficult to determine because cocaine use is frequently associated with the abuse of other illicit drugs, cigarettes, and alcohol. Other confounding variables increasing the risk for negative fetal outcomes include inadequate maternal nutrition and limited prenatal care. In a large prospective blinded study, more infants exposed to cocaine *in utero* were delivered prematurely and exhibited decreased weight, length, and head circumference compared

with matched controls.⁸⁰ Neonates with prenatal cocaine exposure demonstrate tremors, hypertonia, irritability, poor feeding ability, and abnormal sleep patterns and are at a threefold to sevenfold increased risk of SIDS.⁸¹ In addition, *in utero* cocaine exposure has been linked to increased incidence of behavioral problems and special education referrals in school-aged children with abnormalities in executive functioning.

Cannabis

As a result of the legalization of marijuana (cannabis) in many states, an increasing number of pregnant females are using cannabis during pregnancy to treat nausea and vomiting in addition to recreational use. Marijuana use is increased in mothers who are younger (18 to 25 years), habitually smoke, use illicit drugs, have completed high school, are unemployed, and are enrolled in federal subsidy programs (e.g., women, infants, and children nutrition program).⁸² Mixed reports about the impact of marijuana on the brain of the developing fetus are a result, in part, of concomitant exposure to cigarette smoking and other confounding drugs (cocaine, opioids, etc). Marijuana readily crosses the blood-brain barrier and modulates the release of specific neurotransmitters from glial and neuronal cells that are important for the normal maturation of the brain in utero. Marijuana use has been implicated in an increased incidence of stillbirths and preterm labor, increased risk of infection, and increased neurological morbidity (specifically IVH and PVL). Infants tend to have decreased birth weight and an increased risk of admission to the NICU. Long-term *in utero* exposure to maternal marijuana appears to impact attention span and short-term memory, with increased risk of impulsivity and hyperactivity in school-aged children.⁸³ The American Academy of Pediatrics (AAP) discourages the use of marijuana during pregnancy owing to concerns for the long-term impact on the developing brain. The AAP also discourages the use of marijuana during breastfeeding because the active compound is present in breast milk.⁸⁴

Selective Serotonin Reuptake Inhibitors

Depression during pregnancy can cause serious side effects in both the mother and the developing fetus. At least 600,000 infants are born yearly to mothers who have a major depressive disorder during their pregnancy. It is reported that at least 6% of pregnant woman use SSRIs during pregnancy, and almost 40% of depressed women have been reported to use antidepressants at some time during pregnancy.⁸⁵ The most common SSRI medications used to treat anxiety and depression during pregnancy are fluoxetine (Prozac, Fontex, Seromex, and Seronil), sertraline (Zoloft, Lustral, Serlain, and Asenta), paroxetine (Paxil, Seroxat, Sereupin, and Paroxat), fluvoxamine (Luvox and Favoxil), escitalopram (Lexapro, Ciprale, and Esertia), and citalopram (Celexa, Seropram, Citox, and Cital).⁸⁶ A meta-analysis found that maternal depression was significantly associated with an increased incidence of preterm labor and neonatal birth weight less than 2500 g but not intrauterine growth retardation of the fetus.⁸⁷ Unfortunately, this study was unable to evaluate the effect of only SSRI therapy on these outcomes.

The SSRI drugs readily cross the placenta and inhibit serotonin reuptake in neuronal cells. The serotonergic system is present early in gestation and is important in fetal brain development. Perturbations in this system are associated with alterations in somatosensory processing and emotional responses. Infants exposed to SSRIs in the third trimester have symptoms similar to withdrawal from opioid exposure (irritability, tremors, jitteriness, agitation, and difficulty sleeping). These symptoms are transient, appearing 2 to 4 days after birth and disappearing by the second week of life.⁸⁸ Neonatal feeding difficulties are quite common in infants exposed to SSRIs. Seizures and abnormal

posturing are occasionally noted. In addition, infants exposed to SSRIs *in utero* have a twofold increased risk of developing pulmonary hypertension.⁸⁹ It is difficult to identify any specific adverse neurodevelopmental outcomes in infants exposed prenatally to SSRIs from published studies because of the variability in the specific SSRI taken, the duration and timing of SSRI use, and the confounding factors of maternal depression and the use of multiple medications.

CLINICAL MANAGEMENT: NEONATAL PERIOD

Pediatric therapists with mentored subspecialty training in neonatology and infant therapy approaches can expand neonatal services by creating clinical protocols and pathways designed to optimize the development and interaction of neonates and parents. The therapeutic partnership between parents and neonatal therapists during developmental intervention in the NICU sets the stage for parental support and competency in caregiving and compliance with follow-up in the outpatient period. General aims of NICU clinical management of infants at risk for neurological dysfunction, developmental delay, or musculoskeletal complications are to

- promote posture and movement appropriate to gestational age and medical stability
- support symmetry and biomechanical alignment of extremities, neck, and trunk while multiple infusion lines and respiratory equipment are required
- decrease potential skull and extremity musculoskeletal deformities and acquired joint-muscle contractures
- foster infant-parent attachment and interaction
- modulate sensory stimulation in the infant's NICU environment to promote behavioral organization and physiological stability
- provide consultation or direct intervention for neonatal feeding dysfunction and oral-motor deficits
- enhance parents' caregiving skills (feeding, dressing, bathing, positioning of infant for sleep, interaction and play, and transportation)
- prepare for hospital discharge and integration into home and community environments

Educational Requirements for Therapists

Examination and intervention for neonates are advanced-level, not entry-level, clinical competencies. Neonatology is a recognized subspecialty within the specialty areas of pediatric physical therapy^{10,90,91} and pediatric occupational therapy.⁹² No amount of literature review, self-study, or experience with other pediatric populations can substitute for competency-based clinical training with a mentor in a NICU. The potential for causing harm to medically fragile infants during well-intentioned intervention is enormous.^{93,94} The ongoing clinical decisions made by neonatal therapists in evaluating and managing physiological and musculoskeletal risks while handling small (2 or 3 lb), potentially unstable infants in the NICU should not be a trial-and-error experience at the infant's expense. Therapists with adult-oriented training and even those with general pediatric clinical training (excluding neonatal) are not qualified for neonatal practice without a supervised clinical practicum (2 to 6 months). The NICU is not an appropriate practice area for physical therapy assistants, occupational therapy assistants, or student therapists on affiliations for reasons outlined by Sweeney and colleagues¹⁰: "handling of vulnerable infants in the NICU requires ongoing examination, interpretation, and multiple adjustments of procedures, interventions, and sequences to minimize risk for infants who are physiologically, behaviorally, and motorically unstable or potentially unstable." The physical or occupational therapy assistant and student therapist are not prepared, even with supervision, to "provide moment-to-moment examination and evaluation of

BOX 9.1 Neonatal Intensive Care Unit Observational Experiences for Entry-Level Students

- Reviewing neonatal literature and neonatal therapy clinical practice guidelines before site visit to neonatal intensive care unit (NICU)
- "Shadowing" neonatal nurses to observe:
 - Neonatal equipment (refer to Table 9.6)
 - Caregiving routines
 - Teaching styles with parents and grandparents
 - Feeding procedures and equipment
 - Unique culture of the NICU compared with adult intensive care units
 - Skin-to-skin holding by parent
 - Environmental adaptations (light, sound, and clustered handling)
- "Shadowing" neonatal therapist to observe:
 - Chart reviews
 - Interdisciplinary rounds
 - Discharge planning conferences
 - Behavioral and physiological baseline examinations
 - Examination and intervention procedures adapted for medically stable infants at varying gestational ages, acuity levels, and behavioral organization
 - Parental teaching
 - Collaboration with neonatal nurses for positioning, feeding, and parent instruction
- Observing and participating with neonatal therapist in NICU follow-up clinic

From Rapport MJ, Sweeney JK, Dannemiller L, et al. Student experiences in the neonatal intensive care unit: addendum to neonatal physical therapy competencies and clinical training models. *Pediatr Phys Ther.* 2010;22:439–440.

the infant and have the ability to modify or stop preplanned interventions when the infant's behavior, motor, or physiological organization begins to move outside the limits of stability with handling or feeding."¹⁰ Appropriate nonhandling, observational experiences for physical therapist or occupational therapist students in the NICU are delineated by Rapport and colleagues,⁹⁵ with a wide range of observational learning experiences with a preceptor recommended in this specialized practice environment (refer to Box 9.1 for appropriate nonhandling, observational experiences for entry-level students during hospital clinical affiliations).

Delineation of advanced-level roles, competencies, and knowledge for the physical therapist,^{10,91} occupational therapist,⁹⁹ and speech pathologist^{96–98} in the NICU setting have been described separately by national task forces from the respective national professional organizations. These practice guidelines provide a structure for assessing competence of individual therapists working in NICU settings and offer an ethicolegal practice framework for designing clinical paths and an evidence base for specific neonatal therapy services.

A gradual, sequential entry to neonatal practice is advised by building clinical experience with infants born at term gestation as well as with physiologically fragile older infants and children and their parents. The experience may include managing caseloads of hospitalized children on physiological monitoring equipment, external feeding lines, and supplemental oxygen or ventilators. Participating in discharge planning and in outpatient follow-up of high-risk neonates are other options for providing exposure to examination, intervention, and family issues when the infants and parents are more stable. This clinical experience and a competency-based, precepted practicum in the NICU offer the best preparation for appropriate, accountable, and ethical practice in neonatal therapy.^{10,99} In-depth study of perinatal

and neonatal medicine and related obstetrical, neonatal nursing, high-risk parenting, and neonatal therapy literature is recommended before pediatric therapy clinicians begin to participate on the intensive care nursery team.

Neonatal Pain and Neurological Assessment

Multiple neonatal neurological and neurobehavioral examinations have been developed to assess the integrity and maturation of the nervous system and to describe newborn behavior. Most of these tests offer information on the quality of motor performance, attention, and interaction and because these assessments are based on gestational age, an accurate calculation of gestational age is necessary at the time of the testing.

Pain Assessment

Despite immature myelination, premature infants *definitely* perceive pain and retain the memory of painful experiences. Skin receptors are developed by 14 to 16 weeks of gestation. In addition, the density of pain receptors in the skin of neonates at 28 weeks of gestation is considered similar to, and even exceeds, adult density during maturation from birth to 2 years of age.^{100,101} Blackburn¹⁰² explained that although pain transmission in neonates occurs mainly through the slower, unmyelinated C fibers, the shorter distance in neonates that impulses travel to reach the brain compensates for the slower rate of transmission and creates substantial pain reception. Early pain experiences may create later increased sensitivity to pain and vulnerability to stress disorders.^{103–105} If neonatal therapy assessment or intervention procedures immediately follow a noxious procedure in the NICU, handling techniques may need to be modified or therapy session rescheduled to avoid contributing to a cascade of aversive experiences for the infant. Parents showing distress and concern about infant pain may benefit from training in comfort care techniques of swaddling, pacifier use, touch, soft conversation, and holding.

Psychometric data and clinical use of the pain tools are described for infants as early as 28 weeks of gestation.¹⁰⁶ Many elements in the pain assessments have been identified by Als⁹ as signs of excessive stimulation and stress in the preterm infant. Specific extremity movements, such as hand-to-face, elevated leg extension, salute, lateral extension of arms, finger splay, and fisting, have been proposed by Holsti and Grunau¹⁰⁷ as indicators of stress and/or pain.

In addition to practice guidelines on pain assessment developed primarily by neonatal nurses, numerous instruments are available to assess pain in infants. Pain scale data are integrated into NICU nursing assessments and can be a valuable adjunct to the neonatal therapist's baseline and post-therapy observations. Indicators of pain are detailed in the instruments outlined below. These pain assessments provide documentation for pain or distress signs in the following three categories: (1) physiological (heart rate, oxygen saturation, and breathing pattern), (2) behavioral (eye squeeze, brow bulge, facial grimace, and behavioral state, including crying and sleeplessness), and (3) motor (tone and movement in extremities).

- The Premature Infant Pain Profile (PIPP¹⁰⁸) assigns points for changes in three facial expressions (brow bulge, eye squeeze, and nasolabial fold), heart rate, and oxygen saturation. Gestational age and preprocedural behavioral state are included in the assessment. The maximal PIPP score is 21; the higher the score, the greater the pain. A score of 0 to 6 points indicates minimal or no pain, whereas a score of 12 or more indicates moderate to severe pain.
- The Face, Legs, Activity, Cry, and Consolability Behavioral tool (FLACC) uses grades of 0 to 2 for facial expression, leg activity, general activity, cry nature, and ability to be consoled and has been used in pediatric and adult settings. This test is capable of assessing

pain in normal as well as cognitively impaired children, thereby giving it a high degree of versatility and usefulness.¹⁰⁹ Change in FLACC score has been used to demonstrate that the use of sucrose and a pacifier during venipuncture is more effective in consoling infants younger than 3 months of age compared to infants older than 3 months of age.¹¹⁰

- The Neonatal Pain, Agitation, and Sedation Scale (N-PASS) uses five indicators: (1) crying and irritability, (2) behavioral state, (3) facial expression, (4) extremity movement and tone, and (5) vital signs. As with the PIPP scale, additional points are added for decreasing gestational age.¹¹¹ Good correlation was established between the N-PASS and the PIPP assessments during routine heelstick in infants younger than 1 month old born at 23 to 42 weeks' gestation.¹¹²
- The Neonatal Infant Pain Scale (NIPS) has six indicators for pain or distress and can be used with both preterm and full term infants. On a 7-point scale, pain behavior is assessed by facial expression, cry nature, breathing pattern, arm and leg posture, and arousal state.¹¹³

Neonatal Behavioral Assessment Scale

To document individual behavioral and motor differences in infants at term gestation to 2 months of age, Brazelton and Nugent¹¹⁴ developed a neonatal behavior scale to assess neuromotor responses within a behavioral state context. The 30- to 45-minute examination consists of observing, eliciting, and scoring 28 biobehavioral items on a 9-point scale and 18 reflex items on a 4-point scale. This interactive test assesses the infant's ability to respond to stimuli and return to an alert state. The reflex items are derived from the neurological examination protocol of Prechtl and Beintema.¹¹⁵

The scale was designed to assess newborn behavior in healthy 3-day-old term (40 weeks of gestation) Caucasian infants whose mothers had minimal sedative medication during an uncomplicated labor and delivery. Use of this examination with infants born preterm requires modification of the examination procedure to the environmental constraints of an intensive care nursery and interpretation of findings relative to the gestational age and medical condition of the infant. For preterm infants approaching term gestation (minimum of 36 weeks of gestation), nine supplementary behavioral items are offered. Many of these items were developed by Als⁹ for use with preterm and physiologically stressed infants (see discussion of the APiB, later). In the manual,¹¹⁴ methods of adapting the Neonatal Behavioral Assessment Scale (NBAS) for preterm neonates with accompanying case scenarios are described to illustrate use of the findings to enhance parent-infant interaction and guide developmental interventions.

Six behavioral state categories are outlined in the NBAS: deep sleep, light sleep, drowsiness or semi-dozing, quiet alert, active alert, and crying. Behavioral state prerequisites are provided for each biobehavioral and reflex item to reduce the state-related variables in testing. During the assessment the examiner systematically maneuvers the infant from the sleep states to crying and back to the alert states to evaluate physiological, organizational, motor, and interactive capabilities during stimulation and physical handling. The scoring is based on the infant's best performance, with flexibility allowed in the order of testing, repetition of items encouraged, and scheduling of the assessment midway between feedings to give the infant every advantage to demonstrate the best possible responses.

Four dimensions of newborn behavior are analyzed in the NBAS: interactive ability, motor behavior, behavioral state organization, and physiological organization. *Interactive ability* describes the infant's response to visual and auditory stimuli, consolability from the crying

state with intervention by the examiner, and ability to maintain alertness and respond to social or environmental stimuli.

Motor behavior refers to the ability to modulate muscle tone and motor control for the performance of integrated motor skills, such as the hand-to-mouth maneuver, pull-to-sit maneuver, and defensive reaction (e.g., removal of cloth from face). In the assessment of *behavioral state organization*, the infant's ability to organize behavioral states when stimulated and to shut out irritating environmental stimuli when sleeping are analyzed. *Physiological organization* is evaluated by observing the infant's ability to manage physiological stress (changes of skin color, frequency of tremulous movement in the chin and extremities, number of startle reactions during the assessment). For analysis, the information is divided into seven clusters: habituation, orientation, motor, range of state, regulation of state, autonomic stability, and reflexes. The cluster systems are highly useful for clinical interpretation and for data analysis in clinical research. Performance profiles of worrisome or deficient interactive-motor and organizational behavior are identified by clusters of behavior associated with potential developmental risk.¹¹⁴

Definite strengths of the NBAS are the well-defined indicators of autonomic stress, analysis of coping abilities of high-risk infants experiencing external stimuli and handling, and quality of infant-examiner interaction. These features generate specific findings to assist therapists in grading the intensity of assessment and treatment within each infant's physiological and behavioral tolerance and in guiding the development of parental teaching strategies to address the individual behavioral styles of infants. The NBAS has proved to be more sensitive to the detection of mild neurological dysfunction in the newborn period compared to classic neurological examinations that omit the behavioral dimensions. This assessment is not predictive but gives a good analysis of the infant's strengths and weaknesses. Improved performance from repeat examinations over time is a better predictor of the infant's ability and potential.

Participation of the parent in the newborn assessment may yield long-term positive effects on infant-parent interaction and later on cognitive and fine motor development. Widmayer and Field¹¹⁶ reported significantly better face-to-face interaction and fine motor-adaptive skills at 4 months of age and higher mental development scores at 12 months of age when teenage mothers of preterm infants (mean gestational age at birth, 35.1 weeks) were given demonstrations of the NBAS. These demonstrations were scheduled when the premature infants had reached an age equivalence of 37 weeks of gestation.

A four-step examiner training involving self-study, skill test, practice, and certification phases is coordinated through the Brazelton Institute/Touch Points Center, Children's Hospital, Boston, Massachusetts.¹¹⁷ For clinicians beginning to develop competence in examining at-risk infants, the NBAS provides a system for developing basic handling skills with healthy, term infants without concerns of stressing medically fragile preterm infants during the training period. Learning the NBAS in term infants before entering NICU practice provides familiarity with similar testing and scoring procedures for preterm infants.

Newborn Behavioral Observations System

The Newborn Behavioral Observations (NBO) system, developed from the pioneering work and philosophy of Brazelton, is an interactive, observational tool for use with infants and parents in hospital, clinic, and home settings.¹¹⁸ The focus is on prematurely born infants and at-risk infants, with emphasis on cultural competence, family-centered care, and infant development. The NBO system helps determine the behavioral profile of the infant and allows the practitioner to

provide parents with individualized and unique information about their infant. This behavioral information promotes positive parent-infant interaction and also a positive partnership between parents and practitioners.

Certification in administering, interpreting, and scoring the 18-item NBO assessment is arranged through the Brazelton Institute/Touch Points Center, Boston, MA, in a 2-consecutive-day format. The training encompasses the following observation categories: (1) habituation to external light and sound; (2) muscle tone and motor activity level; (3) behavioral self-regulation (crying and consolability); and (4) visual, auditory, and social-interactive abilities.¹¹⁹

Neurological Assessment of the Preterm and Full-Term Newborn Infant

The Neurological Assessment of the Preterm and Full-Term Newborn Infant is a streamlined neurological and neurobehavioral assessment designed by Dubowitz and colleagues¹²⁰ to provide both a systematic, quickly administered newborn examination applicable to infants born preterm or at term gestation and a longer infant examination for children to 24 months of age. A distinct advantage of this tool is the minimal training or experience required by the examiner and the ease of adapting it to the infant and the environment. The adaptability of the test and use of the scoring form with stick figure diagrams have made it useful for implementation in developing countries where English is not widely spoken.

The test includes the six behavioral state categories of the NBAS and seven orientation and behavior items scored on a 5-point grading scale and sequenced according to the intensity of response. The orientation and behavior items consist of the following categories: (1) auditory and visual orientation responses; (2) quality and duration of alertness; (3) irritability (the frequency of crying to aversive stimuli during reflex testing and handling throughout the examination); (4) consolability (the ability after crying to reach a calm state independently or with intervention by the examiner); (5) cry (quality and pitch variations); and (6) eye appearance (absent, transient, or persistent appearance of sunset sign, strabismus, nystagmus, or roving eye movements).

The 15 items that assess movement and tone and the six reflex items evolved from clinical trials on 50 term infants using the clinical assessment of gestational age by Dubowitz and colleagues,¹²¹ the neurological examination of the newborn by Parmelee and Michaelis,¹²² and the neurological examination of the full-term newborn infant by Prechtl.¹²³ The examination format was then used during a 2-year period on more than 500 infants of varying gestational ages. After 15 years the authors revised the assessment in the second edition by eliminating seven items, expanding the tone pattern section, and developing an optimality score. Reliability data are not reported, but modification of examination procedures occurred during the pilot phase that promoted objectivity in scoring and a high interrater reliability among examiners, regardless of experience level.

The examination protocol is available in two formats: (1) Hammersmith Short Neonatal Neurological Examination and (2) Hammersmith Infant Neurological Examination (HINE; age range, 2 to 24 months) (see later in this chapter). The examination forms are illustrated with stick figures and can accommodate both baseline and repeat assessments. For neonatal therapy examinations the forms can be effectively combined with a narrative impression, treatment goals, and plan of care. A numerical score for each item and a summary score are provided in the revised edition of the test. The authors advised that the scoring system was primarily intended for the purpose of research and for numerical charting of progress with sequential examinations. Because of the continued clinical emphasis on patterns of responses,

selected parts of the protocol (without summary scoring) are appropriate for examining premature or acutely ill infants on ventilators, in incubators, or attached to monitoring or infusion equipment. Scheduling of examinations is recommended two-thirds of the way between infant feeding sessions.

Evolution of neurological patterns in infants with IVH, PVL, and HIE is described in the test manual and correlated with brain imaging. Abnormal neonatal clinical signs associated with long-term neurological sequelae were persistent asymmetry, decreased lower-extremity movement, and increased tone. Infants with IVH had significantly higher incidence of abnormally tight popliteal angles, reduced mobility, decreased visual fixing and following, and roving eye movements. The authors cautioned that early signs of motor asymmetry in neonates with cerebral infarction may be associated with normal outcome, but normal neonatal neurological examinations after cerebral infarction do not exclude the possibility of later hemiplegia.¹²⁴

Long-term follow-up data beyond 1 year have not been reported with this examination. Dubowitz and colleagues¹²⁵ reassessed 116 infants (27 to 34 weeks of gestation) at 1 year of age. Of 62 infants assessed as neurologically normal in the newborn period, 91% were also normal at 1 year of age. Of 39 infants assessed as neurologically abnormal in the newborn period, 35% were found to be normal at 1 year of age. The predictive value of a negative test result with this instrument was 92%, and the predictive value of a positive test result was 64%.

Assessment of Preterm Infant Behavior

Als⁹ designed the APIB to structure a comprehensive observation of a preterm infant's autonomic, adaptive, and interactive responses to graded handling and environmental stimuli. It involves six maneuvers with increasing challenging and complex interactions with a highly structured format. As previously described in the theoretical framework section of this chapter, this assessment is derived from synactive theory and is focused on assessing the organization and balance of the infant's physiological, motor, behavioral state, attention and interaction, and self-regulation subsystems. The APIB has testing sequences and a scoring format similar to those used in Brazelton's NBAS, with increased complexity and expansion for premature infants.

Administration and scoring of the APIB may require 2 to 3 hours per infant and often two or more sessions with the infant depending on examiner experience and infant stability. Although the APIB may be an instrument of choice for the clinical researcher, it is not usually practical (time efficient) for many neonatal clinicians with heavy case-loads in managed-care environments. Extensive training and reliability certification are required to safely administer and accurately score and interpret the test for clinical practice or research.

Neonatal Individualized Developmental Care and Assessment Program

Als and colleagues¹²⁶ developed Neonatal Individualized Developmental Care and Assessment Program (NIDCAP) to document the effects of the caregiving environment on the neurobehavioral stability of neonates. This naturalistic observation protocol includes continuous observation and documentation at 2-minute intervals of an infant's behavioral state and autonomic, motor, and attention signals, with simultaneous recording of vital signs and oxygen saturation. Documentation occurs before, during, and after routine caregiving procedures. The infant's strengths, weaknesses, and coping skills are identified. A narrative description of the infant's responses to the stress of handling by the primary nurse and to auditory and visual stimuli in the NICU environment is provided to assist caregivers and parents in identifying the infant's behavioral cues and providing appropriate in-

teraction. Options are described in the care plans for reducing aversive environmental stimuli and modifying physical handling procedures. This clinical tool allows neonatal therapists to determine the infant's readiness for assessment and intervention by observing the baseline tolerance of the infant to routine nursing care before superimposing neonatal therapy procedures.¹²⁷ Sequential documented observations occur weekly or biweekly. Parental involvement is strongly encouraged and instrumental in facilitating a smooth transition from hospital to home. Examiner training in the NIDCAP may be coordinated through the NIDCAP Federation International¹²⁸ where priority is given to NICU teams, rather than to individuals.

NICU Network Neurobehavioral Scale

Lester and Tronick¹²⁹ designed a tool for preterm and drug-exposed infants from 30 weeks of gestation to 6 weeks postterm. The test includes items from the NBAS, APIB, Finnegan abstinence scale, and other neurological assessments and consists of 115 items in general categories of neurological and neuromotor integrity (tone, reflexes, and posture), behavioral state and interaction (self-regulatory competence), and physiological stress abstinence signs (drug-exposed infants). This test is state dependent and gives a comprehensive and integrated picture of the infant. More than half of the test items are infant observations, and 45 items require physical handling of the infant. Test-retest reliability of preterm infants indicated correlations of 0.30 to 0.44 at 34, 40, and 44 weeks of gestation. This test is useful for the management of drug-exposed infants but may have limited predictive value. Training and certification in administration and scoring of the test are coordinated through Brookes Publishing Company and available in the United States and internationally with use of videoconferencing for lectures and demonstrations.

Test of Infant Motor Performance

Developed by Campbell and colleagues,^{130,131} the 42-item Test of Infant Motor Performance (TIMP) is focused on evaluating postural control, spontaneous movement, and head control for neonates at 34 to 35 weeks of gestation to 16 weeks postterm. Functional motor performance is assessed through observation of infant movement and through responses to various body positions and to visual or auditory stimuli. Because the elicited reflex and tone items on the TIMP may contribute to physiological and behavioral stress for infants born preterm, a shorter form of the test is available, the Test of Infant Motor Performance Screening Items (TIMPSI).¹³² The elicited tone and reflex items in the screening test still require judicious use with the tone and reflex items and careful monitoring with hospitalized late preterm infants.

Psychometric components of the TIMP have been developed. These components include (1) construct validity¹³¹ and ecological validity,¹³³ (2) concurrent validity at 3 months of age with the Alberta Infant Motor Scale (AIMS),¹³⁴ and (3) predictive validity at 5 to 6 years of age with the Bruininks-Oseretsky Test of Motor Proficiency¹³⁵ and at 4 to 5 years of age with the Peabody Developmental Motor Scales and Home Observation for Measurement of the Environment: Early Childhood.¹³⁶ Training on test procedures is available through 2-day workshops or through a self-guided training method with a CD-ROM from the test developer.¹³⁷

Neurobehavioral Assessment of the Preterm Infant

The Neurobehavioral Assessment of the Preterm Infant (NAPI) was developed by Korner as a developmental test to assess medically stable infants from 32 weeks to term gestation using a sequence of specific movements. This test focuses on tone, reflexes, movement, response to visual and auditory stimulation, and observation of cry and state. This tool does not require a specific preassessment state as is required by the

previously mentioned tests, but starts with the infant asleep. It does not take as long to administer (<½ hour) than the previously described tests and is easy to analyze. The data are categorized into seven clusters and compared with standardized scores. With repeated examinations over time, persistent deviations from the normative scores indicate that the infant is at risk for developmental delays and is in need of close follow-up. In addition, the NAPI has been shown to be predictive of short-term and long-term neurodevelopmental outcomes.¹³⁸

General Movement Assessment

The assessment tools reviewed so far in this chapter require direct handling of the infant. Infants born preterm are particularly vulnerable to developing physiological stress during the maneuvers required by most tools available for infant assessment. Instead, noninvasive, repeated observation and assessment are needed to accommodate the concurrent motor variability, immature nervous system, and physiological vulnerability of the preterm infant.¹³⁹ Based on the pioneering work of Prechtl examining the continuity of prenatal to postnatal fetal movement,¹⁴⁰ this criterion-referenced test focuses on evaluating the quality of spontaneously generated movements in preterm, term, and young infants until 16 weeks postterm. A wide repertoire of spontaneous motility in the fetus including isolated limb movements, stretches, hiccups, yawning, and breathing movements can be identified as early as 9 weeks.^{139–142}

General movements (GMs) are spontaneously generated, complex movements involving the trunk, limbs, and neck in varied speed and intensity. These movements are among the number of movement patterns emerging during fetal life and continuing until approximately 16 weeks postterm, when goal-oriented movements appear. The quality of movement is assessed through observation and scoring of videotaped spontaneous movement of an infant in supine position without stimulation or handling.¹⁴³ A distinct difference occurs between the GMs in the preterm infant and those in the term and postterm infant. GMs in the term infant, and for the first 8 weeks, change in amplitude and speed, taking on a writhing quality. The writhing movements gradually give way to the fidgety movements, which are present in awake infants between 9 and 16 to 20 weeks postterm. Fidgety movements are small, circular movements of small amplitude and varying speed involving the neck, trunk, and extremities.¹³⁹

This neonatal and young infant assessment instrument has gained substantial attention in the past 20 years for its high reliability, sensitivity, and predictive validity. In a comprehensive review of the psychometric qualities of neuromotor assessments for infants, the GM assessment was rated among the tools with the highest reliability, averaging interrater and intrarater correlation coefficient, or *k*, greater than 0.85.¹⁴⁴ Multiple studies have corroborated the predictive validity and sensitivity of this method. The sensitivity for identifying abnormal movement is lower during the preterm period and writhing movement stage, but improved during the fidgety movement period of the older infant. Sensitivity as high as 95% has been reported.¹⁴⁵

Hadders-Algra¹⁴⁶ created a scoring system for infant general movements based on the original work of Prechtl. Many similarities are described between the two approaches in the observation of complexity and variation in general movements of neonates.¹⁴⁷ Hadders-Algra has expanded the general movement assessment by profiling preterm infants with mild neurological impairment¹⁴⁸ and by extending the observational movement assessment from 3 to 18 months of age in a new assessment, The Infant Motor Profile.^{149,150}

Testing Variables

Neuromuscular and behavioral findings in the newborn period may be influenced by several variables. Increased reliability in examination

results and in clinical impressions may occur when these variables are recognized. Medication may produce side effects of low muscle tone, drowsiness, and lethargy. Such medications include anticonvulsants, sedatives for diagnostic procedures (computed tomography [CT] scan, electroencephalography, and electromyography), and medication for postsurgical pain management. Intermittent subtle seizures may produce changes in muscle tension and in the level of responsiveness. Mild, ongoing seizures may occur in the neonate as lip smacking or sucking, staring or horizontal gaze, apnea, and bradycardia. Stiffening of the extremities occurs in neonatal seizures more frequently than clonic movement. Fatigue from medical and nursing procedures can result in decreased tolerance to handling, decreased interaction, and magnified muscle tone abnormalities. Fatigue may also result when neurodevelopmental assessment is scheduled immediately after laboratory (hematologic) procedures, suctioning, ultrasonography, or respiratory therapy. Tremulous movement in the extremities may be linked to conditions of metabolic imbalance (hypomagnesemia, hypocalcemia, and hypoglycemia), and low muscle tone may be associated with hyperbilirubinemia, hypoglycemia, hypoxemia, and hypothermia.¹⁵¹

Summary

Practitioners must be aware of the normative and validation data and of the predictive characteristics of the test(s) administered to allow appropriate interpretation of the results. Specific clinical training with a preceptor is essential to administer, score, and interpret neonatal assessment instruments accurately; to establish interrater reliability; and to plan treatment based on the evaluative findings. Even low-risk, healthy preterm infants are vulnerable to becoming physiologically and behaviorally destabilized during neurological assessment procedures.⁹⁴ This risk is reduced with precepted, competency-based clinical training in the NICU.

Intervention Planning

Level of Stimulation

The issue of safe and therapeutic levels of sensory and neuromotor intervention is a high priority in the design of developmental intervention programs for infants who have been medically unstable. The concept of “infant stimulation,” introduced by early childhood educators in the 1980s to describe general developmental stimulation programs for healthy infants, is highly inappropriate in an approach based on concepts of dynamic systems, infant behavioral organization, and individualized developmental care.

For intervention to be therapeutic in a NICU setting, the amount and type of touch and kinesthetic stimulation must be customized to each infant’s physiological tolerance, movement patterns, unique temperament, and level of responsiveness. Rather than needing more stimulation, many preterm or acutely ill term infants have difficulty adapting to the routine levels of noise, light, position changes, and handling in the nursery environment. General, nonindividualized stimulation can quickly magnify abnormal postural tone and movement, increase behavioral state lability and irritability, and stress fragile physiological homeostasis in preterm or chronically ill infants. Implementation of careful physiological monitoring and graded handling techniques are essential to prevent compromise in patient safety and to facilitate development. Infant modulation, rather than stimulation, is the aim of intervention. Techniques of sensory and neuromotor facilitation and inhibition developed for healthy infants and children are inappropriate for the developmental needs and expectations of an infant with physiological fragility or premature birth history (<37 weeks of gestation).

Timing

The timing of neurodevelopmental examination and intervention for infants in the NICU is based on the medical stability of the infant and, in some centers, gestational age. All therapy activities must be synchronized with the schedules of the neonatal nurses and intensive care unit routines.

Neonatal therapists should not interrupt infants in a quiet, deep sleep state but instead wait approximately 15 minutes until the infant cycles into a light, active sleep or semi-awake state. Higher peripheral oxygen saturation has been correlated with quiet rather than with active sleep in neonates. Preterm infants reportedly have a higher percentage of active sleep periods in contrast to the higher percentage of quiet sleep observed in term infants.¹⁶⁹ Allowing the preterm infant to maintain a deep, quiet sleep by not interrupting is a therapeutic strategy for enhancing physiological stability.

Timing of parental teaching sessions is most effective when they express readiness to participate in the care of the infant. Some parents need time and support to work through the acute grief process related to the birth of a fragile, potentially impaired child before they can begin to participate in developmental activities. Other parents find the neonatal therapy program to be a way of contributing to the care of their infant that also helps them cope with often overwhelming fears, stresses, and grief.

Physiological and Musculoskeletal Risk Management

Many maturation-related anatomical and physiological factors predispose preterm infants to respiratory dysfunction (Table 9.5). For this reason many preterm neonates require the use of a wide range of respiratory equipment and physiological monitors (Table 9.6). Pediatric therapists preparing to work in the NICU and those involved with designing risk management plans are referred to the neonatal nursing literature for evidence and perspectives on assessing and managing neonatal stressors during interventions in the NICU.^{152–154} Owing to the fact that infants born prematurely or experiencing critical illness

communicate through subtle behavioral cues, their understated language is “not easily interpreted unless caregivers understand how infants’ ability to respond to stress reflects their maturation and neurodevelopment.”¹⁵⁵ Their behavioral cues are considered more subtle and more likely to be disregarded than those of infants born at term gestation.

In this subspecialty area of pediatric therapy practice, neonatal therapists are responsible for preventing physiological jeopardy in LBW infants while providing developmental services in the NICU. Before examination, discussions with the supervising neonatologist and clinical nurse are advised regarding specific precautions and the safe range of vital signs for each infant. Medical update and identification of new precautions before each intervention session are recommended because new events in the last few hours may not have been recorded or fully analyzed at the time therapy is scheduled. The nurse should be invited to maintain ongoing surveillance of the infant’s medical stability and provide assistance in interpreting physiological and behavioral cues during neonatal therapy activities in case physiological complications occur. Physiological and behavioral baseline before intervention and physiological and behavioral recovery documentation are fundamental expectations. If medical complications develop during or after therapy, immediate, comprehensive co-documentation of the incident with the clinical nurse and discussion with the neonatology staff are essential to analyze the events, outline related clinical teaching issues, and minimize legal jeopardy.

Numerous potential musculoskeletal and physiological risk concerns are prevalent during neonatal therapy activities. These risk areas include

- fracture, dislocation, or joint effusion during the management of limited joint motion
- skin breakdown or vascular compromise during splinting or taping to reduce deformity
- apnea or bradycardia during therapeutic neuromotor handling with potential deterioration to respiratory arrest

TABLE 9.5 Factors Contributing to Decreased Tolerance to Evaluative and Therapeutic Handling in Preterm Infants

System

Pulmonary

- Surfactant deficiency prior to 35 weeks
- Initial noncompliant lungs owing to retained fetal fluid and surfactant deficiency
- Rib cage more compliant than lungs leading to retractions and pectus, stabilized by prone position
- Diaphragm fatigue leading to decreased respiratory stability
- Central (prematurity) and obstructive apnea
- Decreased gag reflex with concern for aspiration

Neurological

- Increased risk of intraventricular hemorrhage (IVH) owing to persistence of vascular germinal matrix through 32 weeks
- Decreased tolerance of stimulation

Cardiac

- Patent Ductus Arteriosus (PDA) causes either:
 - Persistence of increased pulmonary vascular resistance leading to right-to-left shunting
 - Decreased pulmonary vascular resistance leading to excess blood flow to the lungs

Hypothermia

- Caused by decreased brown fat stores
- Head-to-body ratio increased leading to heat loss if not covered
- Immaturity of skin leading to fluid loss and heat loss
- Causes increased oxygen consumption

TABLE 9.6 Equipment Commonly Encountered in the Neonatal Intensive Care Unit

Equipment	Description
Thermoregulation Radiant Warmer	Unit composed of mattress, adjustable side panels, and radiant heat source controlled either manually or by servo-control. Advantage: ready access to infant Disadvantage: increases convective heat loss, insensible heat loss, and encourages excessive stimulation
Double Walled Incubator	Enclosed unit providing heat and humidity controlled either by environmental or servo control. Access to infant is through port holes or opening up incubator Advantage: barrier to tactile stimulation, decrease heat loss Disadvantage: difficult to gain access to infant and no decreased ambient noise
Respiratory Assistance Oxyhood Nasal Cannula (NC) Humidified High Flow NC	Clear hood that fits over infant's head to provide heated and humidified supplemental oxygen Delivers specific concentration of oxygen via soft nasal cannula, usually <2 L/min Delivers specific concentration of heated and humidified oxygen via slightly larger soft nasal cannula, usually <6 L/min with some distending pressure to assist in lung inflation.
Continuous Positive Airway Pressure	Nasal prongs or mask provides constant pressure and heated and controlled oxygen delivery provided by bubble or ventilator.
Conventional Ventilator	Delivers positive pressure ventilation with positive end expiratory pressure and either a specific delivered pressure or volume.
High Frequency Ventilator Oscillator Jet	Delivers shorts bursts of supplemental oxygen at high rate (240–720 breaths/min) with active inhalation and exhalation. Delivers shorts bursts of supplemental oxygen at high rate (240–480 breaths/min) with active inhalation and passive exhalation, is noisy, and requires conventional ventilator.
Monitors Cardiorespiratory Oxygen (O ₂) Saturation Transcutaneous carbon dioxide (CO ₂) Near Infrared Spectroscopy (NIRS) Amplitude Integrated Electroencephalogram (aEEG)	Displays heart rate, respiratory rate, and blood pressure with high and low limits. Measures arterial oxygen saturation and uses a light sensor. Measures partial pressure of O ₂ and CO ₂ noninvasively using a heated sensor. Noninvasive method to measure tissue (brain, renal, intestinal) oxygen saturation to ensure adequate oxygen delivery. Continuous recording of cerebral electrical activity to evaluate presence of seizures and maturation of the brain.

- oxygen desaturation or regurgitation with aspiration during feeding assessment or oral-motor therapy
- hypothermia from prolonged handling of the infant away from the neutral thermal environment of the incubator or overhead radiant warmer
- propagation of infection from inadequate compliance with infection control procedures in the nursery

Signs of overstimulation may include labored breathing with chest retractions, grunting, nostril flaring, color changes (skin mottling, paleness, and gray-blue cyanotic appearance), frequent startles, irritability or drowsiness, sneezing, gaze aversion, bowel movement, and hiccups. Signals of overstimulation expressed through infants' motor systems are finger splay (extension and abduction posturing), arm salute (shoulder flexion with elbow extension), and trunk arching away from stimulation.⁹ Harrison and colleagues¹⁵³ found that motor activity cues of preterm infants were correlated with low oxygen saturation and should be carefully monitored during caregiving procedures to minimize physiological instability.

Even a baseline neurological examination, usually presumed to be a benign clinical procedure, may be destabilizing to the newborn infant's cardiovascular and behavioral organization systems. The physiological and behavioral tolerance of low-risk preterm and term neonates to evaluative handling by an experienced neonatal physical therapist was studied in 72 newborn subjects.⁹⁴ During and after administration of the Neurological Assessment of the Preterm and

Full-Term Newborn Infant, preterm subjects (30 to 35 weeks of gestation) had significantly higher heart rates; greater increases in blood pressure; decreased peripheral oxygenation inferred from mottled skin color; and higher frequencies of finger splay, arm salute, hiccups, and yawns than term subjects. Neonatal practitioners must examine the safety of even a routine neurological examination and weigh the risks and anticipated benefit of the procedure given the expected physiological and behavioral changes in low-risk, medically stable neonates.⁹⁴

High-Risk Profiles

Four high-risk profiles are observed from a dynamic systems perspective. In these profiles movement abnormalities, related temperament or behavioral characteristics, and interactional styles associated with motor status are identified.

Irritable, hypertonic infant. The first high-risk profile involves the *irritable, hypertonic infant*. These infants classically have a low tolerance level to handling and may frequently reach a state of overstimulation from routine nursing care, laboratory procedures, and the presence of respiratory and infusion equipment. They may express discomfort when given quick changes in body position by caregivers and when placed in any position for a prolonged time. Predominant extension patterns of posture and movement are associated with this category of infants. Quality of movement may appear tremulous or disorganized, with poor midline orientation and limited antigravity movement into flexion as a result of the imbalance of increased proximal

extensor tone. Visual tracking and feeding may be difficult because of extension posturing or the presence of distracting, disorganized upper-extremity movement. In addition, increased tone with related decreased mobility in oral musculature may complicate feeding behavior. Hypertonic infants frequently demonstrate poor self-quieting abilities and may require consistent intervention by caregivers to tolerate movement and position changes. These temperament characteristics and the signs of neurological impairment previously discussed may place infants at considerable risk for child abuse or neglect as the stress and fatigue levels of parents rise and as coping strategies wear thin during the demanding care required by irritable, hypertonic infants.¹⁵⁶ Hypertonic, irritable infants constituted large percentages of neonatal therapy caseloads in the 1970s through the 1990s, but advances in neonatal pulmonary management have now decreased the numbers of infants with pulmonary conditions matching this neurobehavioral profile. Instead, infants with intermittent hypertonic postures and behavioral agitation now consistently present in NICUs have NAS and are experiencing a withdrawal process from prenatal drug exposure.

Lethargic, hypotonic infant. Conversely, the *lethargic, hypotonic infant* excessively accommodates to the stimulation of the nursery environment and can be difficult to arouse to the awake states, even for feeding. The crying state is reached infrequently, even with vigorous stimulation. The cry is characteristically weak, with low volume and short duration, and related to hypotonic trunk, intercostal, and neck accessory musculature and decreased respiratory capacity. These infants are exceedingly comfortable in any position, and when held they easily mold themselves to the arms of the caregiver. Depression of normal neonatal movement patterns is common. To compensate for low muscle tone when in the supine position, some preterm infants appear to push into extension against the surface of the mattress in search of stability. Although potentially successful in generating a temporary increase in neck and trunk tone, the extension posturing from stabilizing against a surface in supine lying interferes with midline and antigravity movement of the extremities. Such infants dramatically respond to containment positioning in side-lying and prone positions. Drowsy behavior limits these infants' spontaneous approach to the environment and decreases their accessibility to selected interaction by caregivers. Feeding behavior is marked by fatigue, difficulty remaining awake, weak sucking, and incoordination or inadequate rhythm in the suck-swallow process, with the need for supplementation of caloric intake by gavage (oral or nasogastric tube) feeding. The risk for sensory deprivation and failure to thrive is high for hypotonic infants because they infrequently seek interaction, place few if any demands on caregivers, and remain somnolent. Representing this profile in the NICU are infants of diabetic mothers who are large for gestational age and difficult to arouse for feeding in the NICU. A similar behavioral profile of drowsy behavior and slow progression with oral feeding proficiency is common in infants with intrauterine growth restriction.

Disorganized infant with fluctuating tone and movement. The third high-risk profile is the *disorganized infant with fluctuating tone and movement* who is easily overstimulated with routine handling but remains relatively passive when left alone. Disorganized infants usually respond well to swaddling or containment when handled. When calm, these infants frequently demonstrate high-quality social interaction and efficient feeding with coordinated suck-swallow sequence. When distracted and overstimulated, however, these infants appear hypertonic and irritable. Caregiving for intermittently hypertonic, disorganized, and irritable infants can be frustrating for parents unskilled in reading the infant's cues, in implementing consolation and containment strategies, and in using pacing techniques during

feeding. This profile of infant motor and behavioral disorganization represents a large proportion of infants in a typical neonatal therapy caseload.

Neonatal brachial plexus injury (NNBPI). A fourth high-risk profile is the term infant with *neonatal brachial plexus palsy*.

Neonatal brachial plexus injury (NNBPI), also known as obstetric brachial plexus palsy (OBPP), occurs in 1 out of 1000 live births. An uncommon, unpreventable, and unpredictable complication of child birth, NNBPI is the result of a stretch to the brachial plexus when pulling the infant's head away from the shoulder at the time of delivery.¹⁵⁷⁻¹⁵⁹ Recent reports have questioned early assumptions on the cause of the injury, citing multiple factors including prenatal causes such as increased intrauterine mechanical forces and maladaptation.¹⁶⁰ Regardless of the cause, the end result is varied injury to the nerve with resulting muscle weakness or paralysis. The extent of the resulting paralysis depends on the extent of the nerve injury, ranging from a neuropraxic injury (mildest) to complete avulsion (most severe). The initial presentation depends on the level of the injury. For example, an infant with NNBPI at the level of C-5-C-6+/-C7, also known as Erb's palsy, presents with shoulder adduction, internal rotation, elbow extension, forearm pronation, and wrist flexion.¹⁶¹ The prognosis depends on the severity of the injury.

Two classification systems guide early management and ongoing follow-up of infants with NNBPI.¹⁶² The first system identifies four groups with differing clinical presentations depending on the injury location. Infants in Group I with injury to the nerve roots C5 to C6 are characterized by weakness of the deltoid and biceps with active elbow flexion and wrist/hand function. The rate of full, spontaneous recovery for these infants is reported to be 90%. In group II, infants with injury to C5, C6, and C7 nerve roots present with absent or weak wrist extension in addition to deltoid and biceps paresis and have a recovery rate of approximately 65%. In group III, the rate of recovery drops to 50% for an infant with injury to nerve roots from C5 to T1, which is manifested by paralysis or paresis of the entire arm. Finally, infants in group IV with proximal injury to nerve roots from C5 to T1 and Horner syndrome present with a flail upper extremity and ptosis of the ipsilateral eye. The rate of recovery for infants in group IV drops to 0%.

The second classification system is based on the type and extent of injury to the nerve roots. A transient nerve injury resulting from compression, ischemia, or stretching of the axonal structure is known as neurapraxia. A transient or permanent nerve injury known as axonotmesis results from rupture of the axonal fibers with preservation of all other structures (endoneurium, perineurium, and epineurium). A likely permanent injury may occur from damage to the axon and supporting structures, the endoneurium and perineurium. Finally, a complete transection of the entire nerve will result in a permanent injury.¹⁶²

Regardless of the etiology or the classification scheme, the clinical presentation of NNBPI will guide early management and follow-up from a pediatric therapist's perspective. General agreement exists that early multidisciplinary management optimizes recovery for infants who fail to regain function within the first few weeks of life.¹⁶³⁻¹⁶⁶

Individualized early handling and NNBPI positioning while hospitalized. Early physical therapy evaluation while the infant is still in the hospital can play an important role in establishing a baseline. This examination includes pain assessment and overall neurodevelopmental evaluation to rule out other asymmetries or atypical patterns of posture, movement, and tone. Musculoskeletal examination of passive and active range of motion for neck rotation are also recommended to rule out congenital muscular torticollis, a common comorbidity.^{162,166,167}

After the severity of weakness or paralysis is established, a management plan with emphasis on overall comfort, pain management, and protection of the injured arm are implemented as follows:

- Providing support to affected upper extremity to prevent injury to the shoulder joint is recommended for infants when the affected arm is flaccid. Not allowing the upper extremity to dangle during feeding, holding, and carrying the infant will minimize the risk for shoulder subluxation during the acute phase.¹⁶⁶ Using a sling or pinning the clothing can be useful for short-term management of Erb's palsy where the shoulder is the most involved joint. Additional care must be taken when more global paralysis is present, and the infant has a flail wrist. In that case, a soft splint may be used in addition to sling or pinning to prevent wrist deformity. Infants may experience pain and discomfort during the first 2 weeks of life; this possibility must be taken into consideration to guide decisions regarding the use of short-term immobilization of the upper extremity. The presence of clavicular or humeral fractures will make it necessary to immobilize the upper extremity for at least 2 weeks.
- Positioning in supine or side lying on the nonaffected side is recommended to prevent twisting or additional compression of the affected arm. Frequent changes in head position are recommended to prevent development of plagiocephaly and/or torticollis. Infants with NNBPI are at higher risk of developing asymmetrical head position caused by sensory loss and neglect of the affected upper extremity.
- Gentle passive range of motion can be initiated particularly in the elbow, wrist, and hand. The presence of physiological flexion and normal joint mobility in the neonate are considered when implementing PROM, especially in the shoulder. Many infants born at term gestation do not have passive range of shoulder flexion beyond 90 to 100 degrees in the first 1 to 2 weeks, and care must be taken not to exceed what would be considered normal compared to the uninvolved upper extremity. It is recommended that passive movement of the shoulder be performed within the normal range for a newborn and within the limits of pain.^{162,166,167}
- Early somatosensory awareness of the involved hand is important to minimize neglect especially if sensory loss is suspected. Promoting hand-to-mouth movement on the affected side and providing sensory input can be effective and recommended unless the infant's response to touch suggests possible hypersensitivity and nerve pain, which can be present early after the birth injury.^{162,163,166} Pain assessment and documentation are an integral part of early management.^{162,166,167}

NNBPI discharge planning and parent teaching. Strong consensus exists on the importance of parent education as an essential component for the early and ongoing management of infants with NNBPI. Most infants with NNBPI are term infants who are otherwise healthy. Unless a medical complication keeps them in the hospital, the infants are likely discharged within the first 2 days of life. It therefore may fall on the parents to implement the early management strategies at home without immediate support. Parental anxiety and comfort with management of the infant's arm need to be assessed and considered when deciding how early and how frequently to arrange follow-up in the outpatient clinic or in the home. Parents are often afraid of harming the affected upper extremity or inflicting pain on their infant and must be reassured, empowered, and educated early on. Activities and positioning practices that can be implemented within the routine of daily care are the most effective to build confidence and ensure compliance.^{162,163,166}

- If indicated and initiated in the hospital, parent teaching occurs on how to support the infant's upper extremity to maintain comfort,

prevent twisting or possible subluxation of a flaccid shoulder caused by lack of joint stability and support. Parents are taught to support the arm when feeding the infant, carrying or holding him or her to prevent the upper extremity from dangling or getting caught under infant's body.^{162,166}

- Positioning in supine or side lying over the nonaffected side to keep the affected arm free from compression and prevent possible twisting of the shoulder. Parent education must include monitoring head position and frequent repositioning to prevent plagiocephaly and/or torticollis.
- Promoting somatosensory awareness by encouraging the infant to bring the affected hand to the mouth, gentle massage to the upper extremity if tolerated by infant, and early visual orientation to the affected hand.^{162,163,166}
- Teaching dressing and undressing of the affected arm is imperative to prevent twisting or undue pulling on the affected arm. Parents are taught how to dress with upper body garments by gently sliding the sleeve over the affected arm first for dressing and removing the sleeve from the affected arm last for undressing.^{162,163}
- Gentle passive range of motion of the elbow, wrist, and hand while protecting the affected shoulder from movement. If shoulder pain is not an issue, parents can be taught how to gently move the shoulder within the infant's normal range of movement and within the level of comfort.^{162,163,167,168}
- Follow-up appointment within 1 week to 10 days from discharge is recommended.

NNBPI ongoing follow-up. Consistent and frequent follow-up with a pediatric physical therapist with specialization in infant therapy procedures is essential. The infant therapy goals are created to (1) prevent muscle contractures and maintain full range of motion in all joints, (2) individualize and progress parent education, (3) continuously monitor functional recovery, (4) address all developmental needs of the infant, and (5) ensure access to multidisciplinary team when paralysis persists.^{162,163,167,168} It is generally accepted that infants with NNBPI benefit from a multidisciplinary approach (including physical and occupational therapy) to address the full range of developmental needs. A persistent paralysis of the upper extremity will have an impact on trunk control, transitions, symmetry, and play. The management of these infants requires a holistic, developmental approach considering the impact that the lack of upper extremity functional use has on development as a whole.^{162,163,165,167}

While physical and occupational therapy are essential for the ongoing management of infants with NNBPI, when paralysis persists it will be necessary for the infant to have access to subspecialized neurosurgical consultation. The consensus, according to current literature, is that if by 3 months of age the infant has not gained function of the biceps muscle, referral for a multidisciplinary brachial plexus clinic should be considered for evaluation for early exploratory surgery option and potential nerve graft procedure.^{159,161,162,168}

These four high-risk profiles identify infants with varied motor and behavioral challenges and suggest a need for identifying different tolerance levels of handling and interaction even though long-term developmental goals may be similar. Outpatient surveillance of neonates is advised to monitor the course of even mildly abnormal motor and interactive behaviors and also to support the caregiving stresses of parents. Infants with brachial plexus injuries require specialized, continuous follow-up and particular surveillance of the bicep muscle to determine early need for neurosurgical consultation.

Intervention Strategies

This section addresses components of intervention for enhancing movement, minimizing contractures and deformity, promoting

TABLE 9.7 Evidence-Based Recommendations for Neonatal Physical Therapy

Type	Recommendations	Level of Evidence	References
Prevention	Collaborate with caregivers to reduce risk of skull deformity, torticollis, and extremity malalignment through diligent positioning for symmetry and neutral alignment	Level II	Van Vlimmeren et al., 2007 ¹⁷⁰
		Level II	Vaivre-Douret et al., 2004 ¹⁷¹
		Level II	Monterosso et al., 2003 ¹⁷²
Examination	Conduct baseline observation to determine physiological and behavioral stability (readiness) for evaluative handling	Level II	Sweeney and Blackburn, 2013 ⁹⁴
	Provide continuous physiological and behavioral monitoring during and after evaluative handling to determine adaptation to evaluative handling and to signal the need for modification of pace and sequence, given expected physiological changes, particularly during neuromotor test procedures	Level II	Sweeney and Blackburn, 2013 ⁹⁴
Intervention	Collaborate with caregivers to create a developmentally supportive environment with modulated stimulation from light, noise, and handling	Level I	Symington and Pinelli, 2006 ¹⁷⁵
	Support body position and extremity movement—(1) supine: semiflexed, midline alignment using blanket for swaddling containment or “nest” of positioning rolls; (2) prone: vertical roll under thorax; horizontal roll under hips	Level II	Westrup et al., 2004 ¹⁷⁶
		Level I	Peters et al., 2009 ¹⁷⁷
		Level II	Vaivre-Douret et al., 2004 ¹⁷¹
	In selected neonates with movement impairment or disorganization consider therapeutic handling carefully graded in intensity and paced to facilitate head and trunk control, antigravity movement, and midline orientation	Level II	Monterosso et al., 2003 ¹⁷²
		Level II	Short et al., 1996 ¹⁷⁸
	Consider gradual exposure to multimodal stimuli for stable neonates approaching hospital discharge	Level II	Ferrari et al., 2007 ¹⁷⁹
		Level II	Girolami and Campbell, 1994 ¹⁸⁰
	Provide opportunities for independent oral exploration through positioning with hands to face, and for nonnutritive sucking to improve state organization and readiness to feed	Level I	Symington and Pinelli, 2006 ¹⁷⁵
	Determine readiness for and advancement of oral feeding trials using infant behavioral cues	Level I	Pinelli and Symington, 2005 ¹⁸¹
Level II		Kirk, Alder, and King, 2007 ¹⁸²	
Encourage parental involvement with feeding while providing interventions for physiological stability (pacing and slowed flow rate)	Level II	McGrath and Medoff-Cooper, 2002 ¹⁸³	
	Level III	Law-Morstatt et al., 2003 ¹⁸⁴	
Consider hydrotherapy before feeding for stable infants with movement impairment	Level II	Chang et al., 2007 ¹⁸⁵	
	Level IV	Sweeney, 2003 ¹⁸⁶	
Education	Educate parents on behavioral cues and developmental status to mitigate parental stress and improve parental mental health outcomes	Level II	Kaarsen et al., 2006 ¹⁸⁷
		Level I	Melnyk et al., 2006 ¹⁸⁸
		Level II	Byrne et al., 2019 ¹⁸⁹
	Implement multiple methods of instruction for parents and caregivers (demonstration, discussion, video, and written materials)	Level IV	Dusing, Murray, and Stern, 2008 ¹⁹⁰

feeding behaviors appropriate to corrected age, developing social interaction behaviors, and fostering attachment to primary caregivers. Management approaches are presented for body positioning, extremity taping, sensory and neuromotor intervention, neonatal hydrotherapy, and oral motor therapy. Parent support and education processes are described. Evidence-based practice recommendations for neonatal therapy are outlined in [Table 9.7](#) and [Box 9.2](#).

Many complexities exist in the management of a neonatal therapy caseload in an intensive care unit. A high degree of adaptability and creativity is demanded from the neonatal therapist in response to many ongoing, simultaneous challenges: (1) constant physiological and behavioral monitoring; (2) frequent modification of techniques to adapt to the constraints of medical equipment, tubes, and lines; (3) flexible scheduling of interventions to coincide with visits of the parents and peak responsiveness of the infants; and (4) ongoing coordination and reevaluation of goals, plans, and follow-up recommendations with NICU team members. Willingness to change an established assessment plan, treatment strategy, or therapy schedule to meet the

immediate needs of the infant, parents, or NICU staff is paramount. For infants with prolonged periods of only borderline stability during minimal handling by nurses, neonatal therapy services may be limited to consultation on body positioning and assistance to parents in creating and maintaining a calm, developmentally supportive bedside environment. Despite an active referral in place, best practice involves deferring evaluative handling by the neonatal therapist until infant stability and responsiveness are evident. Productivity standards of billable hours used for other caseloads of stable pediatric or adult patients in the hospital are not appropriate for the NICU setting and necessitate negotiation and reinterpretation with rehabilitation or therapy department managers to protect both the infant and the neonatal therapist. Tolley¹⁹¹ reported an expected mean productivity of 5.0 billable hours (range 4 to 6.5 hours) for hospital-based pediatric physical therapists among hospitals surveyed across 32 states and the District of Columbia. Productivity expectations for neonatal therapy services have not been reported.

Positioning

A diligently administered positioning program can greatly assist infants in incubators, on mechanical ventilators, or on respiratory support through mask or nasal prongs, to simulate the flexed, midline postures of term gestation newborns swaddled in an open crib. Preterm infants characteristically demonstrate low postural tone, with the amount of maturation-related hypotonia varying with gestational age. Infants born prematurely do not have the neurological maturity or the prolonged positional advantage of the intrauterine environment supporting the development of flexion. They are instead placed unexpectedly against gravity and presented with a dual challenge of compensating for maturation-related hypotonia and adapting to ventilatory and infusion equipment that frequently reinforces extension of the neck, trunk, and extremities.

Imbalance of excessive extension may occur in preterm infants with prolonged mechanical ventilation who appear to gain postural stability in the nonfluid extrauterine environment by leaning into or stabilizing against a firm mattress while in the supine position. De Groot¹⁹² explained the postural behavior of preterm infants as an imbalance between low passive muscle tone and active muscle power. She theorized that because preterm neonates may have prolonged periods of immobility, exaggerated active muscle power can be observed in the

BOX 9.3 Potential Components of Hypertonic Postural Profile

- Hyperextended neck
- Elevated shoulders with adducted scapulae
- Decreased midline arm movement (hand to mouth)
- Excessively extended trunk
- Immobile pelvis (anterior tilt)
- Infrequent antigravity movement of legs
- Weight bearing on toes in supported standing

extensor musculature, particularly in the trunk and hips. This imbalance of extension is viewed as nonoptimal muscle power regulation that may negatively influence postural stability, coordinated movement, and, later, hand and perceptual skills.¹⁹²

Some neonates, especially those born at less than 30 weeks of gestation, may attempt to posturally stabilize by hyperextending the neck in supine or side-lying positions to compensate for maturation-related hypotonia.¹⁹³ Neck hyperextension posturing, without a balance of movement into flexion, may trigger later development of a host of related abnormal postural and mobility patterns to compensate for inadequate proximal stability.¹⁹² In some infants, excessive postural stabilizing into neck hyperextension may contribute to sequential “blocking” or limiting mobility in the shoulder, pelvis, and hip regions. The potential components of this high-risk, hypertonic postural profile appear in [Box 9.3](#).

Shaping of the musculoskeletal system occurs during each body position experienced by neonates in the NICU. A variety of positional deformities in the extremities and skull can result from inattention to alignment. In [Table 9.8](#), common neonatal positional deformities, musculoskeletal consequences, and functional limitations are outlined. Supporting the skeletal integrity of infants born prematurely is challenging in the midst of numerous equipment obstacles, restricted physical handling because of physiological instability, and limited spontaneous movement. Infants with gastroesophageal reflux are frequently positioned on elevated surfaces or wedges that make symmetrical, midline postures difficult to maintain. Skull flattening may continue to evolve after NICU discharge from overuse

TABLE 9.8 Musculoskeletal Malalignment and Functional Limitations in Neonates

Positional Deformity	Consequences	Functional Limitations
Plagiocephaly	Unilateral, flat occipital region; head turn preference; high risk for torticollis	Limited visual orientation from asymmetrical head position; delayed midline head control
Scaphocephaly	Bilateral, flat parietal and temporal regions	Difficulty developing active midline head control in supine position from narrowing of occipital region
Hyperextended neck and retracted shoulders	Shortened neck extensor muscles; overstretched neck flexor muscles; excessive cervical lordosis; shortened scapular adductor muscles	Interferes with head centering and midline arm movement in supine position; interferes with head control in prone and sitting positions; limits downward visual gaze
“Frog” legs	Shortened hip abductor muscles and iliotibial bands; increased external tibial torsion	Interferes with movement transitions into and out of sitting and prone positions; interferes with hip stability in four-point crawling; prolonged wide-based gait with excessive out-toeing
Everted feet	Overstretched ankle invertor muscles; altered foot alignment from muscle imbalance	Pronated foot position on standing; retained, immature foot-flat gait with potential delay in development of heel-to-toe gait pattern from excessive pronation

From Sweeney JK, Gutierrez T. The dynamic continuum of motor and musculoskeletal development: implications for neonatal care and discharge teaching. In: Kenner C, McGrath JM, eds. *Developmental Care of Newborns and Infants*. 2nd ed. Glenview, IL: National Association of Neonatal Nurses; 2010.

of infant seats, reflux wedges, and limited prone play experiences. Plagiocephaly (asymmetrical occipital flattening) and a secondary torticollis may emerge when a strong head turn preference remains, and parents do not vary the direction of head turn for sleeping and infant seat use.

Thirty years ago an abnormal postural profile in preterm infants was linked to body positioning in the NICU and identified when the infants returned for High Risk Infant Follow-up. Retracted shoulder posture (scapular adduction with shoulder elevation and external rotation) was often present. These postures were found to interfere with later reaching, shoulder stability in the prone position, and rolling during the first 18 months of life.^{194,195} Excessive tibial torsion and out-toeing gait were reported in preterm infants at 3 to 8 years of age and traced to prolonged “frog leg” (excessive abduction and external rotation with foot eversion) in the NICU.^{196,197}

Diligent NICU positioning programs have greatly reduced these postural malalignment outcomes due to collaborative efforts by nurses, parents, and neonatal therapists. Goals of neonatal positioning procedures guiding musculoskeletal and developmental positioning practices include the following:

- Optimize alignment toward neutral neck-trunk position, semi-flexed, midline extremity posture, and neutral foot position
- Support posture and alignment within “containment boundaries” of rolls, swaddling blanket, or other positioning aids; avoid creating a barrier to spontaneous movement, and allow space for partial movement of extremities
- Create positions that promote alert states for enhanced short-duration interaction and sleep states to promote comfort and physiological stability
- Offer positions that allow controlled, individualized exposure to proprioceptive, tactile, visual, or auditory stimuli while monitoring signs of behavioral and physiological stress from potential overstimulation

The use of blanket or cloth diaper rolls or varied commercial neonatal positioning aids may modify increasing imbalance of extension in selected preterm or chronically ill infants and promote movement and postural stability from positions of flexion. After the infant is facilitated into a flexed posture in the side-lying position, posterior rolls behind the head, trunk, and thighs provide a surface against which the infant can posturally stabilize while a flexed midline posture is maintained. An additional anterior roll between the extremities and the use of a pacifier may promote further midline stabilization in flexion (Fig. 9.10). Small neonates can be maintained in a flexed,

Fig. 9.10 Infant positioned on side with diaper rolls to reduce extension postures.

symmetrical posture in a circular nest with cloth body straps and foot support against the walls of the nest (see Fig. 9.11). Increased frequency of extremity movements across midline and reduced spine hyperextension were reported in neonates positioned in a circular nest compared to the supine position without a nest.^{179,198} Postural asymmetry was reduced when infants were positioned in the nest with an elastic swaddling blanket.¹⁹⁹

Individualized application of a swaddling blanket can strategically support body alignment while allowing extremity movement in prone, supine, and side positions. Creating space inside swaddling containment for spontaneous kicking is critical for reducing risk of hip dysplasia from excessive hip adduction and extension position.²⁰⁰ Improved neuromuscular development and motor organization, less physiological distress, longer sleep duration, and improved behavioral self-regulation were documented in swaddled infants.²⁰¹ During routine nursing care procedures of bathing,^{202,203} heel sticks,²⁰⁴ and weighing,²⁰⁵ swaddling was found to modulate physiological and behavioral stress in neonates.

Endotracheal tube placement may contribute to the neck hyperextension posture in infants requiring mechanical ventilation. This iatrogenic component can be avoided by repositioning ventilator hoses to allow enough mobility for slightly tucked chin and partially flexed trunk posture. For neurologically impaired infants with severe pulmonary disease necessitating prolonged ventilatory support, inattention to the alignment of the neck and shoulders may lead to the development of a contracture in the neck extensor muscles (Fig. 9.12).

During the hospital stay, infants on ventilators (Fig. 9.12) are routinely positioned to enhance extremity and trunk flexion in the prone position, improve oxygenation, and decrease irritability.^{206–209} Monterosso and colleagues¹⁷² reported that using a small vertical roll along the torso (sternum to pubis) improved hip flexion and scapular alignment (decreased scapular adduction) in the prone position. Vaivre-Douret and associates¹⁷¹ found that repositioning neonates at 3 to 4 hour intervals in alternating positions (prone, supine, side) in a semicon-toured nest contributed to semiflexed body position at hospital discharge compared to extensor postures of infants placed only in prone with a roll under hips (Fig. 9.13). They observed spontaneous head and extremity movements in supine and side positions more than in prone.

A wide range of detailed positioning techniques are reported for application in NICU settings.^{210,211} A positioning competency assessment

Fig. 9.11 Preterm infant positioned prone in nest with rolls to promote extremity flexion and hand toward mouth.

Fig. 9.12 Clinical presentation of contracture in neck extensor muscles related to hyperextension posture during prolonged mechanical ventilation.

tool to support positioning consistency with positioning interventions by NICU care givers was developed by Coughlin and associates.²¹² The Infant Positioning Assessment Tool (IPAT) has been used as an education tool with a 2-point scoring system for body posture at six areas: head, neck, shoulders, hands, hips, and lower leg (knees, ankles, and feet). Repositioning is indicated with an IPAT score of 8 or lower to adjust alignment and provide improved positioning support materials.

After infants are moved from an incubator to an open crib in the NICU, a transition to a standard mattress without positioning aids is recommended to allow time for adaptation to the type of mattress and bed environment to be used at home. Infants are also transitioned to the supine sleeping position at least a week before hospital discharge to model sleep safety for the home environment to reduce the risk of sudden infant death associated with the prone sleeping position and other factors.²¹³

The neonatal therapist provides consultation on body alignment of infants in car seats when the LBW infant has not passed the peripheral oxygen saturation test for 90 minutes in the car seat conducted by the neonatal nurse before discharge. Some infants require the use of a car bed with body harness when they are unable to tolerate the upright position of a car seat without oxygen desaturation. Other infants may require a smaller car seat designed for infants at weights of 4 pounds.

Extremity Taping

The presence of perinatal elasticity encourages early management of congenital musculoskeletal deformities in the neonatal period (birth to 28 days of age). A temporary ligamentous laxity is presumed to be present in the neonate related to transplacental transfer of relaxin and estrogen from the mother. In addition to the influence of maternal hormones, the rapid growth of the neonate can foster correction of malalignment if the deforming forces are expeditiously managed. This peak period of hyperelasticity offers pediatric physical therapists with advanced orthopedic expertise many opportunities to manage congenital joint deformities.²¹⁴

Intermittent taping of foot deformities (Fig. 9.14) is highly adaptable to the nursery setting than either casts or splints and is more effective in achieving mobility than range-of-motion exercises. Access to the heel for drawing blood, inspection of skin, determination of vascular status, and placement of intravenous lines can be accomplished with the tape in place or by temporary removal of the tape as needed. Therapists without a sound knowledge of arthrokinematic principles and techniques should not attempt the taping procedure, which involves articulation of the joint(s) into a corrected position before taping. Other components of the taping process include application of an external skin protection solution under the tape, application of an adhesive removal solution when removing the tape, observation of skin condition and vascular tolerance, development of a taping schedule beginning with 1 hour and increasing by 1-hour intervals as tolerated, and clinical teaching with selected neonatal nurses for continuation of the taping if needed on night shifts and weekends. The goal of inpatient taping for infants with congenital foot deformities is preparation for outpatient orthopedist management and likely shorter periods of casting in the outpatient period with parents informed and skilled with foot and ankle mobility techniques. Taping is not appropriate for medically fragile infants on minimal handling protocols or for infants younger than approximately 33 weeks of gestation because of potential epidermal stripping from tape removal or vascular compromise from inadvertent, excessive compression by either the tape or the underwrap layer.

The availability of thin, self-adherent foam material now allows taping on an underwrap (bandage) layer rather than on the infant's skin (Fig. 9.16, A and B). Although this method creates a definite advantage in skin protection, it may cover the calcaneal region for blood drawing. Compromise in alignment may occur if the underwrap layer is applied loosely; conversely, restriction in circulation may be observed by edema or purple-blue color changes in the toes if the underwrap is excessively tight around the foot or ankle. An alternative approach for infants with mild equinovarus deformity is using a neonatal intravenous infusion board on the lateral surface of the foot secured

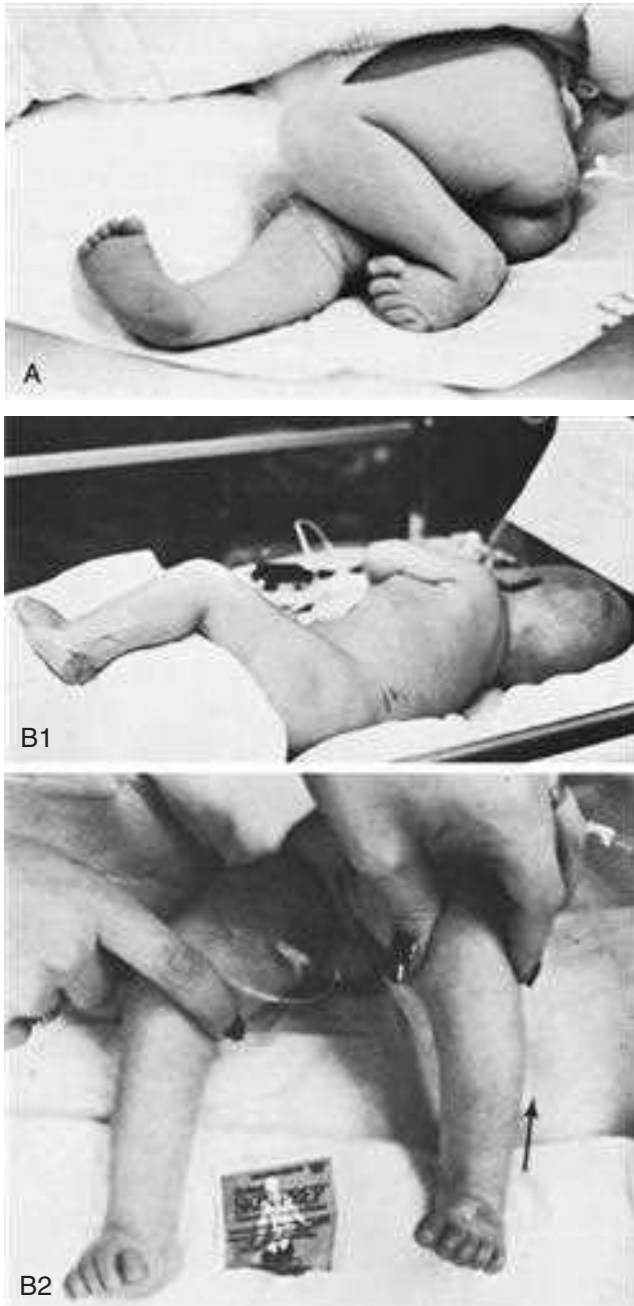

Fig. 9.14 (A) Infant with lumbar meningomyelocele demonstrating marked varus foot deformities before taping. (B1 and B2) Significant correction in alignment of varus foot deformities in neonate with a lumbar meningomyelocele. **B1**, Lateral stirrup with open heel taping procedure. **B2**, Moderate correction.

with elastic bandage (Fig. 9.15). Regardless of the taping or soft splinting technique used, specific bedside guidelines for wearing time and removal are needed. Tape or splint removal by the bedside nurse should occur with observation of color changes in toes, capillary refill greater than 2 seconds, skin rash, edema, or prolonged fussy behavior.

Infants with wrist drop from radial nerve compression related to intravenous line infiltration also benefit from the use of taping (Fig. 9.17). The wrist is supported in a functional position of slight extension. As muscle function returns, the taping is used intermittently to reduce fatigue and overstretching of the emerging, but still weak, wrist extensor musculature.

Fig. 9.15 Mild equinovarus foot deformity is held in corrected position with padded, flexible intravenous (IV) board and elastic wrap.

Instead of using rigid, thermoplastic materials or taping, soft foam straps with Velcro closures provide an alternative method of support for wrist drop or hand-wrist malalignment (Fig. 9.18). The splinting material is illustrated in Fig. 9.19 with a small notch for the thumb on the longer strap placed across the palm and the shorter strap for the wrist band (longer strap attaches to posterior wrist band by Velcro). The wearing time is increased by 1-hour intervals to a 3-hour total wearing time and is often synchronized with nurse caregiving schedules (approximately 3-hour intervals) for alternate on-off application. Collaboration with neonatal nurses on wearing schedule, skin and vascular tolerance, alignment, and parental teaching is critical for successful integration of soft splints into the care plan.

Therapeutic Handling

Use of tactile, vestibular, proprioceptive, visual, and auditory stimuli to facilitate infant development has been reported and reviewed by many authors.^{215–219} Selection and application of the sensory or neuromotor treatment options in neonatal therapy must occur with judicious attention to the prevention of sensory overload and related physiological consequences. Decision making on the type, intensity, duration, frequency, and sequencing of intervention within the context of infant physiological and behavioral stability can be learned only in a mentored clinical practicum in the NICU setting. The current general guidance on intervention is more observation, less handling, protection from bright lights and loud conversation, and readiness for handling determined on the basis of behavioral and physiological cues of the infant.

Primary aims of therapeutic handling include assisting the newborn to achieve maximal interaction with parents and caregivers and facilitating the experience of postural and movement patterns appropriate to the infant's adjusted gestational age. Helping infants reach and maintain the quiet, alert behavioral state and age-appropriate postural tone appears to enhance opportunities for visual and auditory interaction and for antigravity movement experiences. The typical early movement experiences include hand-to-mouth movement, scapular abduction and adduction, anterior and posterior pelvic tilt, free movement of the extremities against gravity, and momentary holding of the head in midline.²²⁰

Behavioral state and some movement abnormalities can be modified by creative swaddling and gentle weight shifts and nesting in the

caregiver's lap. Swaddling the infant in a blanket with flexed, midline extremity position appears to promote flexor tone, increase hand-to-mouth awareness, inhibit jittery or disorganized movement, and elicit quiet, alert behavior. These effects can also be accomplished in skin-to-skin holding of infants against the parent's chest, implemented routinely with stable infants.^{221,222} Application of neonatal therapy techniques must be contingent on both the infant's readiness for interaction and the need for a recovery break in interaction related to sensory overload. Teaching parents and caregivers to read and respond to the infant's motor cues for interaction, feeding, change of body position, and rest breaks is a critical quality-of-life component of the infant's NICU therapy program.

A semiinverted supine flexion position (Fig. 9.20) with preterm neonates should be used with caution, even for diaper changes. This position may be used in therapy procedures with older infants (6 months old) to facilitate elongation of neck extensor muscles and decrease the neck hyperextension posture, but with neonates the position may compromise breathing from positional compression of the chest and from potential airway occlusion associated with maximal flexion of the neck. The use of cardiorespiratory and oxygen saturation monitors during therapeutic handling activities is recommended for objective measurement of physiological tolerance. Although the peripheral oxygen saturation values from monitors may be intermit-

Fig. 9.20 Potential respiratory compromise to the infant from neck extensor muscle elongation in excessively flexed position while supine.

tently unreliable because of motion artifacts from either the infant's spontaneous movement or the therapist's handling of the infant, reliable readings of oxygen saturation may be taken approximately 1 minute after the infant's body is not moved.

Easily overstimulated preterm infants may not tolerate multimodal sensory stimulation but may instead respond to a single sensory stimulus.²¹⁶ Implementation of any components of a neonatal therapy or developmental procedure can be instituted only in collaboration with the shifts of bedside nurses in charge of the infant's 24-hour day in the NICU. Collaboration with nurses is a major component of precepted neonatal therapy training and requires integration into and valuing of the unique culture of the NICU. Part of the NICU culture is the unique ecology of environmental light and sound modifications, medical procedures, equipment, and caregiving patterns. Observing and analyzing the effects of the environment on an infant's behavior, physiological stability, postural control, and feeding function are critical elements for establishing a prehandling baseline status before each neonatal therapy contact as well as guiding parent teaching on infant strengths and vulnerabilities. Research on the risks and benefits of neonatal therapy and developmental procedures is critically needed to guide future directions of neonatal developmental practice.

Neonatal Hydrotherapy

Modified for use in an intensive care nursery setting, the traditional physical therapy modality of hydrotherapy has been adapted and implemented into neonatal therapy programs in some NICUs. Neonatal hydrotherapy was conceptualized in 1980 at Madigan Army Medical Center in Tacoma, Washington, and results of a pilot study of physiological effects were first reported in 1983.²²³

Indications for referral of medically stable infants to the hydrotherapy component of the neonatal therapy program include (1) muscle tone abnormalities (hypertonus or hypotonus) affecting the quality and quantity of spontaneous movement and contributing to the imbalance of extension in posture and movement; (2) limitation of motion in the extremities related to muscular or connective tissue factors; and (3) behavioral state abnormalities of marked irritability during graded neuromotor handling or, conversely, excessive drowsiness during handling that limits social interaction with caregivers and lethargy that contributes to feeding dysfunction.

Infants are considered medically stable for aquatic intervention when ventilatory equipment and intravenous lines are discontinued and when temperature instability and apnea or bradycardia are resolved. A standard plastic bassinet serves as the hydrotherapy tub, and the water temperature is prepared at 37.8°C to 38.3°C (100°F to 101°F). An overhead radiant heater is used to reduce temperature loss

and enhance thermoregulation in the undressed infant. Agitation of the water is not included in the hydrotherapy protocol in the NICU.

After medical clearance and individualized criteria for the maximum acceptable limits of heart rate, blood pressure, and color changes during hydrotherapy have been received from the neonatal staff, the baseline heart rate and blood pressure values are recorded and pre-treatment posture and behavioral states are observed. The undressed infant is swaddled and moved into a semiflexed, supine position. The blood pressure cuff is placed around the distal tibial region to continuously measure heart rate and blood pressure at 2-minute intervals during the 10-minute water immersion period. After being lifted into the water, the swaddled infant is given a short period of quiet holding in the water without body movement or auditory stimulation to allow behavioral adaptation to the fluid environment (Fig. 9.21). A second caregiver (e.g., nurse or parent) is recruited to stabilize the infant's head and shoulder girdle region while the neonatal therapist provides support at the pelvis (Fig. 9.22).

Fig. 9.21 Adjustment to water immersion before introduction of guided movement during neonatal hydrotherapy.

Fig. 9.22 Swaddled infant is supported in neonatal hydrotherapy tub by neonatal physical therapist and neonatal nurse. The blanket is gradually loosened to encourage spontaneous, midrange movement of the extremities.

Within the loosened boundaries of the swaddling blanket, the movement techniques involve midline positioning of the head and slow, graded movement incorporating slight flexion and rotation of the trunk, followed (if tolerated) by progression distally to the pelvic girdle region and finally to the shoulder girdle region. After guided trunk extensor flexion with partially dissociated movement at the shoulder or pelvic girdle, most infants will demonstrate active extremity movement in the water and the swaddling blanket is adjusted (or removed) to allow more movement or more stability depending on the response of the infant. The improved range and smoothness of spontaneous extremity movement is facilitated by the buoyancy and surface tension of the water. Movement experiences in the supine, side-lying, and prone positions are offered as tolerated. If the movement therapy becomes stressful, with agitation or crying by the infant, body movement is stopped immediately, and the infant is either consoled or removed from the water and held with warmed towels. Compromise in hemodynamic stability (increased heart rate, increased blood pressure, decreased respiratory rate) and decrease in arterial oxygen tension during crying have been well documented in neonates.²²⁴ Careful monitoring of behavioral tolerance to hydrotherapy (with avoidance of crying) is considered critical for reducing physiological risk with hydrotherapy.

Multiple therapeutic benefits have been observed from the selective use of 10-minute aquatic intervention sessions. Improved postural tone with semiflexed posture is obtained with less time and effort by the therapist and with higher behavioral tolerance by the infant than when a similar therapeutic handling approach is used without the medium of water. Postural tone changes are frequently maintained for 2 to 3 hours when aquatic intervention is followed by flexed, midline body positioning in the side-lying or prone position supported by positioning rolls, swaddling blanket, and containment nest. Mild flexion contractures of knees and elbows and dynamic hip adduction contractures can be safely and quickly reduced by gentle muscle elongation techniques in warm water. Enhancement of visual and auditory orientation responses (e.g., visual fixing and tracking, auditory alerting, and localization to human voices), prolonged high-quality alertness, and longer periods of social interaction with caregivers are clinically observed during and after hydrotherapy sessions.

Improved sleep quality and behavioral organization were documented in 12 preterm infants (less than 36 weeks of gestation) after a 10-minute hydrotherapy session in a NICU in Brazil.²²⁵ In this study the infants were used as their own controls, and responses were measured by a Neonatal Facial Coding System scale and by sleep-wake cycles from an adapted NBAS.

A later study of neonatal hydrotherapy effects on stress reduction was conducted in Brazil with 15 neonates at a mean adjusted age of 34.2 weeks at the time of testing. Salivary cortisol levels and cardiopulmonary measures indicated short-term, significant decreases in stress after a 10-minute hydrotherapy session with gentle, facilitated movements in a plastic bucket in the NICU. No changes were found in pain responses before and after hydrotherapy using the Neonatal Infant Pain Scale.²²⁶

Feeding performance may improve when hydrotherapy is scheduled 30 minutes before feeding to prepare the infant for arousal to the quiet, alert state and for flexed, midline postural changes for optimal feeding. A sample of 31 preterm infants received both a 10-minute hydrotherapy session and a 10-minute rest period control condition (crossover design) before bottle feeding by a nurse blinded to the order of the treatment phase. Mean duration of feeding was significantly decreased ($P < .004$) after hydrotherapy compared with the rest condition. Mean daily weight gain after hydrotherapy was significantly higher ($P < .026$) than after the rest condition. All infants consumed

100% of the required feeding volume after the 10-minute hydrotherapy session, indicating that potential overstimulation or fatigue did not occur. On a short-term basis, weight gain was enhanced.¹⁸⁶

Therapeutic bathing techniques are incorporated into the parental teaching program to foster early parental participation in child care and in specific neonatal therapy activities during the inpatient period to prepare for carryover into the home environment. This early pleasurable involvement of parent and child in hydrotherapy and therapeutic bathing may provide a strong base for future participation in aquatics as a family leisure sports activity and, if needed, as an adjunct to an outpatient therapy program.

When oriented to treatment goals and trained in specific hydrotherapy techniques for individual infants, the nursing staff can effectively carry on the hydrotherapy program established by the neonatal therapist. This release of the neonatal therapist's role to nurses allows additional use of hydrotherapy on evening and night shifts and continued teaching and supervision of parents during evening and weekend visits (Fig. 9.23).

An additional advantage of neonatal hydrotherapy is cost-effectiveness, with the use of equipment readily available in the newborn nursery and the short time (10 minutes) required for therapeutic swaddled bathing. Hydrotherapy becomes labor efficient for the neonatal therapist when it is incorporated into nursing care plans and conducted by nurses and parents, with the therapist assuming a supervisory role.

Although many clinical benefits may be obtained by judicious use of hydrotherapy in the newborn nursery, pilot study data obtained on physiological changes in high-risk infants during hydrotherapy clearly indicate a physiological risk.²²³ This risk (7% increase in blood pressure and heart rate in the pilot sample) must be carefully evaluated relative to each infant's general medical stability and baseline heart rate and blood pressure status before hydrotherapy can be included safely in a neonatal therapy program. In collaboration with the neonatology and nursing staff, the therapist must use established criteria for general medical stability and the maximal limits during hydrotherapy for blood pressure, heart rate, and acceptable color changes; this step is essential for risk management. Physiological monitoring of mean blood pressure and heart rate with a neonatal vital signs monitor during aquatic intervention is recommended. The blood pressure cuff is a pneumatically driven device that is not electronically connected to the infant and can be safely immersed in water. Hypothermia is a

Fig. 9.23 Parents being trained in hydrotherapy techniques for later therapeutic bathing at home.

recognized risk with both infant bathing and neonatal hydrotherapy. Body temperature should be measured routinely before and after the hydrotherapy session with a thermometer with a digital display. A risk-benefit analysis of the potential physiological risk to each infant and the expected therapeutic benefits is strongly advised before hydrotherapy techniques are incorporated into a neonatal therapy program.

Oral-Motor and Feeding Therapy

Feeding difficulties in preterm neonates may be related to neurological immaturity, depressed oral reflexes, prolonged use of an endotracheal tube for mechanical ventilation with subsequent oral tactile hypersensitivity, insufficient postural tone, or drowsy behavior. Because behavioral state affects the quality of feeding behavior, feeding performance may be significantly improved by specific arousal or calming procedures before feeding and synchronizing feeding according to behavioral readiness cues.²²⁷ Other variables influencing feeding may include decreased tongue mobility, decreased latch and lip seal on nipple, tactile hypersensitivity in the mouth, inefficient and uncoordinated respiratory patterns, reflux or regurgitation insufficient proximal stability from hypotonic neck and trunk musculature, or posturing of the neck and trunk in extension.²²⁸

Three instruments for assessing oral-motor and feeding behaviors in the nursery are the Neonatal Oral-Motor Assessment Scale (NOMAS),²²⁹ the Early Feeding Skills (EFS) Assessment for preterm infants, and the Supporting Oral Feeding in Fragile Infants, (SOFFI) method.^{230–232} The NOMAS is used to evaluate the following oral-motor components during sucking: rate, rhythmicity, jaw excursion, tongue configuration, and tongue movement (timing, direction, and range). Tongue and jaw components are analyzed during nutritive and nonnutritive sucking activity. Cutoff scores were derived from a pilot study with the instrument: a combined score of 43 to 47 indicated “some oral-motor disorganization”; a score of 42 or less indicated oral-motor dysfunction.²²⁹ The absence of a category to evaluate breathing pattern, work of breathing or respiratory exertion, and physiological variables during feeding limits the use of this instrument to low-risk, healthy neonates.

The EFS Assessment is a 36-item observational measure of oral feeding readiness, feeding skill, and feeding recovery.²³⁰ The assessment tool includes examination of physiological and behavioral stability, behavioral feeding readiness cues, oral-motor coordination and endurance, coordination of breathing and swallowing, and post-feeding alertness, energy level, and physiological state. Preliminary content validity and intrarater and interrater reliability procedures were described as “stable and acceptable” (correlation data not reported) with predictive, concurrent, and construct validity testing recently reported.²³¹ This tool is specifically designed for feeding examinations in the NICU environment and with emerging psychometric testing will be a relevant instrument in managing neonates with feeding impairment.

The SOFFI method provides a decision making algorithm for bottle feeding to guide neonatal practitioners and parents in observing infant behavior to guide pacing (pausing, restarting, and stopping) of the feeding rather than focusing on volume consumed. The individualized starting and stopping of feedings is determined by the infant's physiological and behavioral responses.²³² Feeding outcomes of the SOFFI Method, compared to typical NICU feeding methods, showed significantly less trunk arching, gagging and discomfort, spitting and vomiting with meals, as well as fewer feeding therapy referrals in preterm and term infants at 3 to 5 months corrected age.²³³

General strategies during feeding may include semiflexed, swaddled alignment in an elevated sidelying position.²³⁴ Techniques such as use of a pacifier during gavage feedings,¹⁸¹ light manual support to the

Fig. 9.24 Swaddled preterm infant fed in semiupright position with light support under chin.

Fig. 9.25 Preterm infant fed in elevated, side-lying position to control milk flow rate and enhance swallow—respiratory coordination.

jaw, and use of specialized feeding equipment are frequent components of oral-motor therapy programs (Fig. 9.24). Scheduling of feeding based on the infant's readiness (behavioral cues of physiological stability, hunger, and alertness) is shown to be effective in helping infants advance the frequency of oral feedings.^{235,236}

For some infants, oral intake by bottle may be improved by individualizing nipple selection according to contour, length, hole size, texture, and compression resistance. Wolf and Glass²²⁸ advised evaluation of the flow rate of liquid from various types of nipples and analysis of the effects of nipple size, shape, and consistency on an infant's sucking proficiency. Feeding infants in the side-lying position may decrease flow rate and improve tongue position, particularly if tongue retraction is present (Fig. 9.25). The timing of movement therapy or neonatal hydrotherapy 30 minutes before feeding may improve performance by preparing postural tone, facilitating oral musculature, and enhancing alertness.

Infants with orofacial anomalies (e.g., cleft palate and hypoplastic mandible) often respond to bottle feeding with a Haberman feeding system (Medela, McHenry, Illinois), which allows control of the flow rate through a valve in the bottle and manual compression of the nipple. The Haberman feeder is an ideal option for infants with large bilateral cleft lip and palate because of the long, flexible nipple, which allows formula to be released from manual compression of the nipple by caregivers instead of requiring negative pressure for suction by the

Fig. 9.26 Term infant with cleft palate fed with specialized nipple (Haberman Feeding System) in upright sitting to minimize regurgitation and milk backflow into middle ear.

baby (Fig. 9.26). Placement of the nipple on the middle of the tongue is advised regardless of the location of the palate or lip defect. Another bottle system for infants with cleft palate also uses a valve to prevent backflow of milk from the nipple, but the infant is able to functionally compress the nipple to express milk without manual assist from caregivers. This feature allows self-pacing of sucking rhythm by the infant (Infant Specialty Feeder, Dr. Brown's Medical, St. Louis, MO).

Specialized feeding support and teaching for breast feeding is optimally managed by lactation consultants (nurses; educators) in the NICU. Breast feeding aids allow supplementation of oral intake during breastfeeding through a small tube that goes to the mouth from a sterilized bag containing infant formula or breast milk (e.g., Lact-Aid, JJ Avery, Denver, Colorado). A plastic covering to assist infants in securing a latch on the nipple is used frequently (nipple shield, Medela, McHenry, IL).

Monitoring the infant's physiological tolerance, breathing pattern, and work of breathing is critical during oral-motor examination, intervention, and feeding trials. Heart rate values may be monitored from either the cardiorespirograph or with peripheral oxygen saturation from a pulse oximeter. Color changes, diminished tone in facial muscles, and behavioral stress cues (e.g., restlessness and trunk arching) must be carefully monitored to allow appropriate response to early signs of fatigue, overexertion, and potential airway difficulty. Regurgitation with aspiration of milk or formula into the lungs may occur during feeding trials, with complications of pneumonia, cardiopulmonary arrest, and associated asphyxia. Because of these risks, feeding trials should not be attempted by neonatal therapists untrained in current preterm infant feeding approaches and in managing the respiratory and general physiological monitoring components of neonatal feeding.

Success during feeding activities enhances parent-infant interaction and perceived competency in parenting. Building parent confidence in infant breast or bottle feeding can start early by learning body positioning, pacing, interpreting the infant's behavioral cues, and selecting feeding equipment.

Parental Support

Grief Process

Strong, continuous support is essential to help parents through perhaps the most frightening crisis in their adult lives—the potential

death or disability of their infant.²³⁷ Although touching and holding infants contribute to infant-parent attachment,²³⁸ parents may initially establish emotional and physical distance from the infant as they cope with the knowledge that the baby may die. During this time of anticipatory grief, peer group support from other parents of prematurely born children can be of immeasurable value. Actively listening to the parents' feelings and concerns and providing support without judgment through their episodes of detachment and anger are critical. Although long-range plans include participation of parents in all aspects of the developmental program, the timing and amount of initial teaching must be individualized to the levels of stress and acute grief present.

When an infant dies, the neonatal therapist begins the important work of closure. This work includes attending memorial or funeral services to support the family, writing a note expressing sympathy to the family, and initiating a personal closure process. Neonatal therapists are advised to find a senior nurse mentor to guide them through the closure process of identifying and dealing with feelings of loss regarding the infant and family. Finding meaning and value in the process of caregiving rather than solely in functional outcomes is an important task in the work of closure and in preventing professional burnout.

Parent/Caregiver Teaching

Collaboration with family members is a keystone in neonatal therapy. Components of the parental/caregiver teaching process may include (1) discussion of the program goals and services in the NICU; (2) orientation to the interdisciplinary follow-up plan after discharge; (3) guidelines for recognizing and understanding the infant's temperament, stress, and stability cues; (4) methods of creating a calm environment with protection from aversive light and sound; and (5) specific instructions on body positioning, oral feeding techniques and equipment, corrected age-appropriate developmental activities, or therapeutic handling techniques. When used in conjunction with verbal instructions and demonstrations, a packet of written guidelines and pictures individualized to the infant's needs may improve parents' overall skills and understanding of the program. Parents benefit from multiple methods of neonatal therapy instruction. While direct demonstration and video instruction were equally effective, the written-pictorial instruction alone was not as effective for parent teaching of motor tasks in the NICU.^{189,190}

Teaching strategies are most effective when they are adapted to the learning style of the parents. This adaptation may involve more demonstrations and an increased opportunity for supervised practice for some parents, particularly those with reading or language difficulties that limit use of a written instructional packet. Cultural caregiving practices of the family may necessitate elimination of common procedures such as the use of pacifiers for nonnutritive sucking or hand-to-mouth engagement.

With consultation and collaboration with neonatal therapists, neonatal nurses can incorporate recommendations to support skeletal and motor development into their routine discharge teaching activities. General considerations for discharge teaching may include the following²³⁹:

- Varying the direction of head turn for sleeping in the supine position to prevent plagiocephaly
- Placing the head in midline with lateral rolls extending along the side of the head and trunk for car seats and swings
- Limiting the use of infant seats and encouraging the use of prone play on the floor with a roll under the arms and upper chest to assist in head lifting and weight bearing on the arms

- Highlighting the importance of the prone play position for strengthening the neck, trunk, and arm musculature to prepare for sitting and rolling
- Reinforcing the value of interdisciplinary follow-up for musculoskeletal and neurodevelopmental monitoring
- Recommending expedient follow-up if parents notice signs of head flattening, persistent lateral head tilt, strong asymmetrical head turn preference, or asymmetrical arm use

In the neonatal period, the quality of infant-parent attachment and comfort level and proficiency in routine caregiving and therapeutic handling set the stage for later-parenting styles. Helping parents find and appreciate a positive aspect of the neonate's motor or other developmental behaviors gives them a spark of hope from which emotional energy can be generated to help them through the marathon of the NICU experience. Empowering parents early in their parenting experience with the infant is crucial. In the life of the child, the effects of parent empowerment will last far longer than neonatal movement therapy and positioning strategies.

CLINICAL MANAGEMENT: OUTPATIENT FOLLOW-UP PERIOD

Purpose of Outpatient Follow-up for the at-Risk Infant

Systematic follow-up of the at-risk infant after discharge from the NICU is an essential component of the clinical management of high-risk infants. The purpose of this follow-up is threefold: (1) monitor and manage ongoing medical issues, such as respiratory problems and feeding difficulties; (2) provide support and guidance to parents and caregivers in care and nurturing of at-risk infants; and (3) assess the developmental progress of infants to ensure that neuromotor impairments and delays in motor development can be identified and intervention initiated as early as possible. Issues of assessment, intervention, and developmental profiles of the high-risk infant after discharge from the NICU are discussed in this section.

Medical Management

The routine medical care of preterm infants after discharge may be provided by a pediatrician or primary care provider. Infants at neurodevelopmental risk are frequently followed by a number of additional professionals, including neurologists, ophthalmologists, cardiac or pulmonary specialists, nutritionists, orthopedists, pediatric social workers, physical and occupational therapists, and infant educators. Communication among these specialists is often minimal, especially when they are located at different facilities, and access to providers may be restricted by policies of varied hospital or managed-care systems. The parent is often confronted with conflicting opinions, demands, and expectations. The follow-up clinic can play a valuable role in this situation by providing case management to assist caregivers in coordinating services, verifying that all needs of the infant are being met, and helping parents set realistic goals and priorities for themselves and their child.

Family Support

The stress that a vulnerable, premature, or at-risk infant brings to a family is well documented. Grief, anger, and depression are common reactions to the trauma and anxiety of an unanticipated premature birth.^{240–242} The caregivers of high-risk infants are required to become knowledgeable about complex medical terminology and equipment. At discharge, they often become responsible for the administration of multiple medications of varying dosages, cardiopulmonary resuscitation procedures and equipment, and complicated feeding schedules

requiring daily measurement and recording of nutritional intake and output. In addition, families are often faced with an unexpected, large financial obligation to the hospital and the confusion of dealing with different billing agencies and funding sources.

These stresses and demands are even more overwhelming for parents who are young, are single, or do not speak English. In contrast to the 1980s, a greater proportion of at-risk infants now seen in follow-up clinics are living with caregivers other than their biological mothers. These caregivers may include other relatives, such as single fathers, grandparents, aunts and uncles, foster care providers, or preadoptive parents. At the same time the changing demographics of American society are reflected in the increasing ethnic diversity of preterm infants. Whether they are recent immigrants to the United States, seasonal workers, or residents of an ethnic neighborhood, parents from minority ethnic groups are frequently overwhelmed by the complexities and procedures of a large medical institution. To serve this population adequately, a follow-up clinic team should have access to interpreters and include social workers who are knowledgeable about community resources outside the predominant culture. Cultural competence, defined as performing “one’s professional work in a way that is congruent with the behavior and expectations that members of a distinctive culture recognize as appropriate among themselves,” is an essential prerequisite for professionals working in a high-risk infant follow-up clinic.²⁴³ For the pediatric therapist conducting an evaluation, cultural competence includes familiarity with differing cultural norms regarding personal interaction, child-rearing practices, and family dynamics.

Preterm or at-risk infants may be irritable, hypersensitive to stimulation, less responsive to the social engagement efforts of adults, and more irregular in sleeping and feeding schedules compared with the term infant.²⁴⁴ The demands such an infant place on caregivers can be extremely stressful, especially when combined with financial concerns and sleep deprivation. Although these stresses may resolve as the infant’s schedule and temperament become more stable, some studies raise concerns about their long-term impact on the parent-infant relationship and the infant’s social and affective development.^{245,246}

The pediatric therapist in the follow-up clinic must be sensitive to these parent or caregiver stresses and concerns, and because social work and nursing services may not be routinely available, the therapist, within the context of the examination, needs to be alert to cues in the behavior of the infant or caregiver that may indicate problems in the home. Thoughtful questions regarding daily routines, feeding patterns, the sleep schedule of the caregiver as well as the infant, the caregiver’s impression of the infant’s temperament, and the availability of supportive resources can prompt a discussion of concerns that may not be readily communicated to a pediatrician or other professionals involved in the child’s care.

Follow-up Clinic Examination and Evaluation Processes

It is widely recognized that preterm infants are at risk for neurodevelopmental and musculoskeletal impairments that may lead to functional limitations.^{247,248} Early assessment plays an important role for discharge teaching, follow-up planning, and identifying infants at the highest risk for developmental impairments so they can be appropriately referred for early intervention. As consultants to the multidisciplinary team, pediatric therapists are in a unique position to become involved in the process of identification of infants at risk, care coordination, and follow-up planning. Critical examination periods and signs of neuromotor or musculoskeletal abnormality indicating a need for comprehensive examination by a pediatric physical therapist are described in the next sections.

Fig. 9.27 Goal-directed reaching and symmetrical lower-extremity alignment in 4-month-old born at term gestation.

Months 2 to 4

Important changes in postural control, movement, and behavioral organization occur at 2 to 4 months. Head control and balance reactions are emerging, and functional skills are present with orientation around the midline.²⁴⁹ This is also the time when the transition from GMs to goal-directed movement begins to take place (Fig. 9.27).¹⁸ The pediatric therapist can perform an early developmental follow-up evaluation to provide parent education and monitor changes in infant posture and movement, head control, midline orientation, and visual skills. A marked increase in the prevalence of positional plagiocephaly^{170,250} has occurred after positioning practices for sleeping were changed to supine only. In 2016, The American Academy of Pediatrics released a position paper with updated recommendations including supine positioning for sleeping to minimize risk of SIDS.²¹³ Two to 4 months postterm is a critical window of time for identifying positional preferences in infants and providing parental education to prevent plagiocephaly.

Months 6 to 8

For most LBW infants, medical concerns have resolved at this age and caregivers are raising questions about developmental expectations. This period has great variability in the development of goal-directed behaviors and attainment of motor milestones that are dependent on postural control. General agreement exists that most typically developing infants achieve independent sitting in this time frame.²⁴⁹ Definitive predictions on long-term prognosis are difficult for a preterm infant at this age. Tools measuring specific milestones have low clinical value owing to variability in the acquisition of motor skills and postural control.¹⁸ A developmental assessment with emphasis on postural control at 6 to 8 months’ adjusted age (e.g., Alberta Infant Motor Scale) can document an infant’s current level of performance and provide a baseline for subsequent evaluations.

Months 10 to 14

During the first year of life, infants gain increasing levels of postural control and express neurological integrity and capabilities through movement and exploration. Lack of variability and variety in movement strategies may be an early indicator of atypical development. Learning to transition out of supine position and crawling are typically

achieved at 10 to 12 months, and by 12 to 14 months most infants have achieved the ability to walk independently.^{18,249} By 12 months corrected or chronological age, infants demonstrate a wide repertoire of behaviors in other domains including cognitive and language intertwined with motor development. Multidisciplinary evaluation at 12 months is recommended for infants at risk to create a more comprehensive developmental profile.²⁵¹

Months 18 to 24

With the foundation for gross motor skills well established by 18 months, identifying deficits in the fine motor, cognitive, social adaptive, and language domains that might interfere with school performance becomes the main focus of assessment during this period. High prevalence of positive screening for autism in infants born preterm has been described in the recent literature.²⁵² These data suggest that while the focus of most follow-up programs for high-risk infants is on motor and cognitive abilities, evidence now supports the inclusion of screening tools to identify early signs of social and behavioral dysfunction. Recent evidence also points to a high prevalence of cerebellar damage or dysgenesis in preterm infants. Cerebellar hemorrhage represents a high risk for cognitive and motor delays in these infants.²⁵² D'Amore and colleagues reported findings that assessment at 2 years of age can reliably identify developmental impairments.²⁵³

Comprehensive assessment at 24 months is recommended, including language, fine motor, adaptive, and cognitive skills. Most multidisciplinary follow-up programs stop at this time owing to cost and high rate of attrition.²⁵¹ Growing evidence is reported of higher rates of educational and behavioral challenges becoming apparent at school age among children with ELBW; thus ongoing follow-up beyond 24 months is desirable.²⁵³

Age Correction

Premature infants are scheduled for evaluations in the follow-up clinic according to their corrected age (age adjusted for weeks of prematurity). The issue of whether to adjust for prematurity when assessing cognitive or motor development is an ongoing question. Several researchers have demonstrated that if chronological or unadjusted age is used for standardized testing, the premature infant who is developing appropriately will have a low developmental quotient and test scores indicative of motor delay.^{254–257} If age is adjusted for prematurity, the performance of the premature infants is comparable to that of term infants at 1 year. Although some investigators caution that adjustment for prematurity tends to result in overcorrection, particularly for infants born at less than 33 weeks' gestation,²⁵⁸ the general consensus is that infants born prematurely should be evaluated according to their corrected age.²⁵⁹

Neuromotor Assessment Tools for At-Risk Infants

A range of instruments has been designed specifically for examination and evaluation of infants after discharge from the NICU. The choice of instrument for a particular clinical setting depends on the emphasis and purpose of the clinic as well as on the professional disciplines represented in the follow-up team. Evaluation of the at-risk infant with a quantitative, standard assessment tool serves two major purposes in a follow-up clinic:

1. Documentation of the infant's motor status relative to developmental norms or relative to the infant's performance on previous examinations. The information is used to determine the child's developmental progress, rate of change, or extent of motor delay. Achievement of this objective is determined by the scope and focus of the assessment tools used in the evaluation.

2. Identification of a neuromotor impairment to initiate appropriate intervention services. Early identification is not simply a task of detecting signs of neuromotor deviation. The challenge is to identify those infants who are most likely to have an abnormal neurodevelopmental outcome.

A brief review of the infant assessment tools commonly used in follow-up clinics is presented in the following sections.

Bayley Scales of Infant Development

The Bayley Scales of Infant Development (BSID) were first published in 1969 in a format used extensively in clinical and research settings throughout the United States. The BSID-II,²⁶⁰ a revised version of the BSID, was published in 1993. The goals of the revision process included updating the normative data, extending the upper age level of the test from 30 to 42 months, and adding more relevant test items and materials. The revised test was standardized on 1700 young children representing a distribution of race, gender, geographical region, and level of parental education as an indicator of socioeconomic status. In addition, approximately 370 children with various clinical diagnoses, including autism, Down syndrome, developmental delay, preterm birth, and prenatal exposure to drugs, were tested with the BSID-II. Test scores from these children were not included in the normative data and are intended to provide a baseline of performance for children with these diagnostic conditions.²⁶⁰

The expanded age range and updated normative data offered by the BSID-II enhanced its overall use as an assessment tool; however, several areas of weakness were identified in using the BSID-II, particularly with preterm infants.²⁶¹ Unlike the protocol of the original test, the administration of items and the scoring procedures for the BSID-II are based on item sets. The appropriate item set for an individual child is usually determined according to the child's chronological age, but the examiner is told to "select the item set that you feel is closest to the child's current level of functioning based on other information you might have."²⁶⁰ The option to begin testing at different item sets, which can yield different raw scores for the same infant, introduces a level of variability in administration procedures and test results that is inconsistent with the purpose of a standardized test.²⁶¹ This problem is magnified for preterm infants because it places even greater importance on the decision of whether to test the infant according to chronological or corrected age.²⁶⁰

The third edition of the BSID (BSID-III), published in 2006, is the most recent update.²⁶² The goals for developing the current edition included updating the normative data, fulfilling the requirements set by the Individuals with Disabilities Education Improvement Act of 2004, strengthening psychometric measures, updating testing materials, simplifying test administration, and improving the test's clinical utility. The BSID-III is a comprehensive assessment for children aged 1 to 42 months to be administered by experienced and trained professionals. This edition comprises five different subscales—cognitive, expressive, and receptive communication; gross and fine motor development; and parental report scales to assess social-emotional development and adaptive behaviors.

The cognitive scale of the BSID-III assesses sensorimotor development, object manipulation and relatedness, concept formation, memory, and simple problem solving. The expressive and receptive language subscales examine verbal comprehension, vocabulary, babbling, utterances, and gesturing. The fine motor subscale examines grasping, motor planning, speed, and visual motor activities, and the gross motor subscale includes sitting, locomotion, standing, and balance. Social-emotional and adaptive behaviors are tested using the parental report scales. Administration times vary depending on the age of the child but can range from approximately 50 minutes for children

aged 12 months or younger to 90 minutes for children aged 13 months and older. The child's chronological age (adjusted for prematurity as needed) gives the examiner a starting point. The rules for establishing basal and ceiling levels are the same for the cognitive, language, and motor scales. The child must pass three consecutive items to establish a ceiling, and the test is discontinued after the child fails five consecutive items. The BSID-III has expanded basal and ceiling levels with standardized scores ranging from 40 to 160. The mean for the standardized composite score for the cognitive, language, and motor skills is 100 with standard deviation of 15. The language and motor skills also yield scaled scores with a mean of 10 and standard deviation of 3. In addition, percentile rank, age equivalents, and growth scores can be derived.^{262,263}

The BSID-III was standardized on a normative sample of 1700 children from the ages of 16 days to 43 months 15 days living in the United States in 2004. Stratification was based on age, gender, parental education level, ethnic background, and geographical area. Norms for the social-emotional and adaptive behavior scales were derived from smaller groups (456 and 1350 children, respectively), but the same stratification pattern was followed.²⁶² There are a total of 91 items in the new cognitive scale, including 72 items from the BSID-II. Many items from the former cognitive scale were removed, modified, or moved to other subscales such as language and fine motor scales. The fine and gross motor scales contain a total of 66 items, including 18 new items. The parental report scales are a new addition to assess social-emotional and adaptive behaviors.^{262,264}

The psychometric attributes of the BSID-III are as strong as those of the earlier editions and are thoroughly described in the technical manual.^{262,263} Reliability coefficients for the subscales and composite scores range from 0.86 to 0.93, with similar or higher coefficients obtained when the reliability was examined testing special groups. Test-retest reliability was examined in a sample of 197 children tested on two separate occasions with an average interval of 6 days. Reliability coefficients ranged from .67 to .94, with an average correlation score of .80. The technical manual describes in great detail the convergent and divergent validity, illustrating the correlation between the BSID-III and other relevant testing tools.^{262,264}

Many questions remain on the potential limitations and clinical application of the BSID-III. Administration of the full test is a lengthy procedure, and the composite scores are reported to be higher than those of the BSID-II.²⁶⁵ Anderson and colleagues²⁶⁶ examined the ability of the BSID-III to detect developmental delay in 2-year-old extremely preterm children and those born at term with normal birth weights. The study participants were former preterm infants born at less than 28 weeks or weighing less than 1000 g ($n = 221$). Two hundred and twenty healthy full-term infants with normal birth weight were randomly selected as a control group. Developmental assessment was conducted at 2 years (age corrected for prematurity) using the cognitive, language, and motor scales of the BSID-III. The social-emotional and adaptive behavior scales were not used. The authors observed a serious overestimation in the developmental progress of this sample. Questions were raised regarding the sensitivity of this test to detect developmental delay in children. More research is needed to examine this test's sensitivity and the interpretation of test results, especially for high-risk or premature infants. Continued use of the BSID-III should be conducted with caution in the absence of more data to establish the sensitivity of this tool.²⁶⁴

Alberta Infant Motor Scale

The AIMS²⁶⁷ was designed to evaluate gross motor function in infants from birth to independent walking, or birth through 18 months. The stated purposes of the AIMS are (1) to identify infants who are delayed

or deviant in motor development and (2) to evaluate motor maturation over time. The AIMS is described as an "observational assessment" that requires minimal handling of the infant by the examiner. The test includes 58 items, organized by the infant's position, designed to evaluate three aspects of motor performance: weight bearing, posture, and antigravity movements. The normative sample consisted of 2200 infants born in Alberta, Canada.

Raw scores obtained on the AIMS can be converted to percentile ranks for comparison with motor performance of the normative sample. Test-retest and interrater reliabilities, established on normally developing infants, ranged from 0.95 to 0.98 depending on the age of the child. The AIMS reportedly had high agreement with the Motor Scale of the BSID and the Gross Motor Scale of the Peabody Developmental Motor Scales (PDGMS) ($r = 0.93$ and $r = 0.98$, respectively). An evaluation of concurrent validity between the AIMS and the Movement Assessment of Infants (MAI) at 4 and 8 months demonstrated acceptable agreement ($r = 0.70$ and $r = 0.84$, respectively).²⁶⁸

Hammersmith Infant Neurological Examination

The HINE is a brief, infant assessment reported to be easily accessible to clinicians in the area of high-risk infant follow-up. The format for the assessment was adapted from the work of Dubowitz and Dubowitz,¹²⁰ and the intended age range is 2 to 24 months. The authors divided the examination into two sections with a combination of age-dependent and non age-dependent items. Selected behavioral assessment items were adapted from the Bayley Scales.^{262,263} It is considered to be a reliable tool, easily learned, and feasible to administer in high-risk infant follow-up clinics.²⁶⁹

Movement Assessment of Children

The Movement Assessment of Children (MAC) assesses functional gross motor and fine motor skills of children from age 2 months to 24 months.²⁷⁰ The motor assessment is composed of three sections including head control, upper extremities and hands, and pelvis and lower extremities. In addition, four assessment sections (general observations, special senses, primitive reactions, and muscle tone) contribute to the interpretation of MAC findings for any one child. These four sections assist therapists in making a therapy diagnosis, thereby focusing on the therapist's selection of treatment modalities. The MAC, on average, has five functional test items per month over 23 months of development. It is anticipated that this number of items will allow for accuracy in evaluative and discriminative measures, leading to effective clinical judgments. The MAC can be completed in less than 30 minutes (20 minutes for some children), and it takes 5 minutes to update during reevaluation.

Four hundred and seven assessments were completed on typically developing children aged 2 to 24 months in the greater Denver, Colorado, area. The gestational ages of the children at birth were 37 to 42 weeks, and the majority were Caucasian (77%).

Construct validity of the MAC was established using Rasch analysis with the 407 assessments. In brief, 34 of the 37 super items fit the model based on fit statistics (infit and outfit mean square error values of 0.5 to 1.7). Unidimensionality of the MAC was also achieved: Rasch principal component analysis showed that the model explained 90.4% of the variance. The Rasch analysis also indicated that the MAC has excellent person and item reliabilities. The person reliability index was .98, indicating that the person ability ordering would be stable if these children were assessed on another evaluation tool with the same construct as "the motor super items" of the MAC. Cronbach's α was .97, implying that the MAC super items were internally consistent with little redundancy. The item reliability index was 1.00, indicating that the difficulty hierarchy of these motor super

items would be stable if another group of children with the same traits and sample size were tested. (Min-Mei Shih. Personal communication).²⁷¹

The validity, reliability, and sensitivity of the MAC were recently studied in a group of typically developing infants and toddlers from 2 months to 2 years of age. In this study, the construct validity was established and the inter-rater reliability ranged from 0.83 to 0.99. Percent agreement for explanatory items ranged from 0.72 to 0.96. Finally, the stability within age grouping was reported to be consistent.²⁷²

High-Risk Clinical Signs

Longitudinal studies of LBW infants have been used to identify specific clinical signs or conditions that are most predictive of abnormal neurodevelopmental outcome, such as CP. The conclusions among studies are inconsistent because of the lack of standard criteria for the risk variables, demographic and clinical variation in the study samples, and use of different outcome measures. High-risk motor signs for surveillance by practitioners during high-risk infant follow-up are summarized in Table 9.9.

TABLE 9.9 Motor Impairment “Red Flags” During Neonatal Intensive Care Unit Follow-Up

2 months ^a	Persistent asymmetrical head position; risk for plagiocephaly and torticollis Absent midline orientation even when visual stimulation is present Jerky or stiff movements of extremities Excessive neck or trunk hyperextension in supine position
4 months ^a	Poor midline head control in supine position Difficulty engaging hands at midline and in reaching for dangling toy Persistent fisting of hands Difficulty lifting head and supporting weight on arms in prone position Trunk hypertonicity or hypotonicity Resistance to passive movement in extremities Persistent, dominant asymmetrical tonic neck reflex (“fencing” position of arms) Stiffly extended or “scissored” legs with weight bearing on toes in supported standing
8 months ^a	Inability to sit and roll independently Inability to transfer objects between hands Persistent asymmetry of extremities with differences in muscle tone and motor skill Hypertonicity of trunk or extremities
12 months ^a	Inability to pull to stand, four-point crawl, walk around furniture Movement between basic positions Persistent asymmetry of control in extremities

^aAges corrected for prematurity.

In: Kenner C, McGrath JM, eds. *Developmental Care of Newborns and Infants*. 2nd ed. Glenview, IL: National Association of Neonatal Nurses; 2010.

Neonatal Period

During the neonatal period through 1 to 2 months after term (40 weeks of gestation), clinical signs suggestive of neuromotor abnormality include stiff, jerky movements or a paucity of movement. Abnormal general movements have reduced complexity and variation. They lack fluency and frequently have an abrupt onset with all parts of the body moving synchronously.¹¹⁵ Persistence of these movements is considered to be predictive of CP or cognitive impairment.²⁷³

Infancy

At 4 months of age, hypertonicity of the trunk or extremities is recognized as a high-risk clinical sign.²⁷⁴ This finding correlates with neck hyperextension and shoulder retraction associated with the tonic labyrinthine reflex in the supine position, which has been identified in other studies as a high-risk sign.²⁷⁵

The predictive value of primitive reflexes has been extensively debated. Reflexes and neurological signs, such as the asymmetrical tonic neck reflex (ATNR) and tremulousness, have been correlated with CP in some studies²⁷⁶ but not in others.²⁷⁵ The positive support reflex, characterized by stiff extension of the lower extremities when the infant is held in supported standing, is frequently cited as a high-risk sign, but this posture is seen in both term and LBW infants and has not been consistently associated with adverse sequelae.²⁷⁵ Persistent primitive reflex activity and asymmetry have been identified as early signs of athetoid CP, more common in infants born at term.²⁷⁷ In Fig. 9.28 a dominant ATNR posture is demonstrated by a 4-month-old infant with athetoid CP. Immature automatic reactions of balance and equilibrium at 4 months, including head righting and the Landau reaction, have been found to be a significant predictor of abnormal neurological outcome.²⁷⁵

Comparing an infant’s spontaneous, active movements with reflex or passive responses is important in determining risk for neurodevelopmental disability. Systematic observation of kicking activity in LBW infants indicated that infants with neurological impairment demonstrated less alternate kicking movement compared with typically developing LBW infants.²⁷⁸ Abnormal patterns of kicking, including simultaneous flexion and extension of the hips and knees, were associated with subsequent CP.²⁷⁹ Abnormalities of kicking described by Prechtel as “cramped-synchronized,” that is, limited in variety and characterized by “rigid movement with all limbs and the trunk contracting and relaxing almost simultaneously,” were observed in 3-month-old infants who were subsequently diagnosed with CP.²⁸⁰

In addition to qualitative differences in motor function, delayed acquisition of motor milestones is an important indicator of neuromotor impairment. In particular, delay in achieving upright, gross motor milestones, such as sitting without support, creeping on hands

Fig. 9.28 Dominant asymmetrical tonic neck reflex in 4-month-old infant with athetoid cerebral palsy.

to knees, and pulling to stand, was found to be useful in identifying infants with neuromotor impairment.²⁸¹

Challenges to Prediction of Neurodevelopmental Outcome

Accurate prediction of neurodevelopmental outcome of LBW infants on the basis of standard neuromotor tests is particularly challenging because of several complicating factors.

Impact of Medical Status on Test Performance

Infants with LBW often exhibit motor delay or neuromotor deviations because of health or medical status, not because of neurological impairment. Two primary examples are residual influences from habitual positioning in the NICU and chronic medical conditions.

Variations in posture and movement caused by residual influences from time in the neonatal intensive care unit. Although current NICU positioning and handling procedures are increasingly sensitive to the developmental needs of the neonate, the application of life-sustaining interventions (e.g., mechanical ventilation) assumes priority in clinical management. On follow-up evaluation, these infants may show delays in reaching skills and in achieving antigravity postures.

Infants born preterm may exhibit asymmetry related to intrauterine position or prolonged positioning in the NICU necessitated by surgical or medical intervention. On outpatient follow-up examinations, this asymmetry may appear as visual orientation to one side of the body, more mature upper-extremity skill on the same side, and asymmetry of primitive reflex activity. Physical deviations, such as tightness of neck musculature on the preferred side and relative weakness of the opposing muscles, or skull deformities (plagiocephaly) may also be present. Asymmetrical motor function resulting from intrauterine or NICU positioning can usually be distinguished from early spastic hemiplegia or other hemisyndromes by clinical examination and by review of the infant's medical history.²⁵⁵ Positional asymmetry is generally not associated with differences in muscle tone between the two sides of the body or with neuromotor abnormalities, such as fisting of the hand on the less-active side. Caregivers are advised to promote symmetrical posture through movement and positioning of the infant including strategic placement of the infant in relation to toys, social activity in the room, and use of cushions or rolls to maintain midline positioning for the infant's head and proximal musculature.

Prolonged motor delay from chronic medical conditions. Infants with CLD typically exhibit low muscle tone, delayed gross motor function, and immature balance reactions. Motor skills are often delayed as long as the infant's pulmonary capacity is compromised, but the rate of developmental progress typically accelerates when the respiratory condition resolves.²⁸² Intervention for infants with persistent respiratory disease includes providing reassurance and support to the caregivers who are dealing with the demands and stresses of parenting a medically fragile child. Caregivers are advised to avoid aggressive physical activity and excessive sensory stimulation that could cause fatigue or tax the infant's limited respiratory capacity. At the same time, the child should be given opportunities to develop skills in nonmotor tasks. Adaptive positioning techniques reduce energy expenditure and fatigue while enabling the infant to be supported in age-appropriate postures (e.g., prone or upright sitting) for developing hand function, vestibular responses, and social skills.

Differences Between Preterm and Term Infant Neuromotor Function

Even when not compromised by chronic illness or neurological impairment, the motor development of preterm LBW infants differs

Fig. 9.29 (A) Typically developing term infant at 4 months of age demonstrating ability to bring hands to midline and elevate legs with flexion and abduction of hips and dorsiflexion of ankles. (B) Infant diagnosed with cerebral palsy at 5 months of age; note inability to bring hands to midline because of shoulder retraction, extension and adduction of hips with limited movement into flexion, and plantarflexion of ankles.

from that of typical term infants. Compared with term infants, healthy preterm infants demonstrate variations in passive and active muscle tone and initially have greater joint mobility, such as increased popliteal angles and low muscle tone in the trunk.^{192,193} In the older infant, increased extremity tone is often present, particularly in the hips and ankles. Preterm infants tend to exhibit more neck hyperextension and scapular adduction and fewer antigravity movements in the supine position (Fig. 9.29).

Primitive reflexes such as the ATNR, Moro reflex, and positive support reflex persist longer in preterm infants, even when assessed at corrected age.¹⁹² Gross and fine motor skills are frequently delayed in preterm infants, especially activities requiring active flexion, such as (1) bringing hands to midline and feet to hands; (2) trunk stability required for head control and upright sitting; and (3) trunk rotation for rolling and transitional movements.

Preterm infants exhibit more asymmetry in active movement compared with infants born at term gestation, but asymmetry is usually not observed in passive tone or reflex activity. The asymmetry may be a typical feature of postterm development of relatively healthy preterm infants.²⁵⁵ For most premature infants, these early variations in movement and posture eventually resolve; however, in the first months of life neuromotor deviations may influence the infant's performance on a standard assessment of motor function or neurological status.

NEUROMOTOR INTERVENTION

Levels of Intervention

Therapeutic intervention for the high-risk infant in the outpatient phase after discharge from the NICU occurs at multiple levels. Type and intensity of intervention depend on (1) the needs of the infant and family; (2) the structure and organization of the follow-up clinic; and (3) the availability of resources in a particular clinical and geographical setting.

Assessment as Intervention

The clinical assessment of an infant is a unique opportunity for intervention on behalf of the infant and family. For the full potential of this interaction to be realized, parents or caregivers must be informed and involved participants in the assessment process, not passive observers. The focus of intervention in this context is on parent or caregiver support with two primary components: education and positive reinforcement for parenting skills.

Education

The educational component of intervention includes enabling the parents of an at-risk infant to recognize their child's unique capabilities and strengths and ability to respond to and influence the surrounding environment. Caregivers learn about their infant's individual responses to stimuli—for example, what causes their child to focus on a stimulus and what elicits stress reactions. Education of parents includes describing typical characteristics and common developmental patterns of the LBW or medically fragile infant that may differ from expectations based on observations of healthy, full-term infants. Parents of at-risk infants are informed about the appropriate sequence and pace of development for their child so they will be realistic in their expectations and interpretation of the child's progress. This anticipatory guidance enables parents to prepare for and maximize learning opportunities.

Reinforcement for Parenting Skills

During the follow-up examination, opportunities to provide positive reinforcement to caregivers need to be emphasized. They should be reassured that they are providing appropriate and beneficial parenting and reminded that the infant's behavioral responses reflect neurobehavioral immaturity or instability rather than an unpleasant personality or negative affective feelings toward the caregiver.

Instruction in Home Management

A critical component of intervention is instruction in specific activities and handling techniques for home management. The recommendations are made on the basis of the therapist's knowledge of the infant's medical and neurological history, current health status, and findings from the neurodevelopmental assessment. The overall purpose may be to maximize a healthy child's growth potential or to promote developmental progress in an infant who demonstrates delay or neuromotor abnormality. In either case, the parent or caregiver must have a clear understanding of the purpose of the activity, what motor behavior will be facilitated or counteracted, the underlying neurodevelopmental process that the activity will support, and the desired response from the infant. Parents can be encouraged to participate creatively in the process of therapy by adapting and modifying the recommendations according to the infant's responses and progress at home.

Although neuromotor handling recommendations are specific to the individual child, some intervention activities are applicable to many preterm infants.

Activities to Counteract Shoulder Retraction

Preterm infants may demonstrate scapular adduction or shoulder retraction postures. This posture may inhibit the infant's ability to bring hands to midline and often results in delayed achievement of upper-extremity skills and rolling. To overcome shoulder retraction, play activities and carrying techniques that bring shoulders forward and hands to midline are encouraged.

Fig. 9.30 Healthy preterm infant at 4 months of corrected age demonstrating neck hyperextension, scapular adduction and shoulder retraction, and limited antigravity movement into flexion.

Reaching

Most premature infants are immature in reaching skills, reducing their ability to interact with the environment (Fig. 9.30). Activities to counteract shoulder retraction will promote reaching, but the infants should also be provided with other opportunities to practice this skill. Infants who are ready to initiate reaching at 3 to 4 months of age often have only a visually stimulating mobile suspended beyond their reach in the crib. Caregivers are advised to hang toys *within the child's reach* in the crib, playpen, infant seat, or other suitable places. Objects that are suspended, rather than handed to or placed in front of the infant, are preferred to promote the development of directed reach and grasp as well as shoulder stability (Fig. 9.31). Commercially available, relatively inexpensive activity gyms that stand upright on the floor are highly recommended for infants at neurodevelopmental risk.

Head Centering and Symmetrical Orientation

Midline positioning of the head with symmetrical alignment of the trunk and extremities is encouraged to counteract the residual effects of asymmetrical positioning in utero or during hospitalization. Midline orientation will reduce the influence of the ATNR and

Fig. 9.31 Toys suspended directly in front of infant to encourage symmetrical reaching and midline orientation of head.

promote symmetrical function of the right and left sides of the body. Asymmetry that is not caused by neurological dysfunction tends to resolve when positioning and environmental influences are modified.

Prone Positioning

Active playtime in the prone position with weight bearing on the arms is beneficial for the development of neck and trunk postural and shoulder girdle stability. The prone position also counteracts extension posturing tendencies because the influence of the tonic labyrinthine reflex in the prone position contributes to extremity flexion; however, parents of vulnerable premature infants are often hesitant to place their infants in the prone position for play. Many preterm infants demonstrate a low tolerance for prone positioning, particularly if they have relatively large heads and are visually attentive. Duration of the prone play position can be gradually increased. Visually stimulating objects, including mirrors, musical toys, and the faces of siblings or caregivers, can be arranged in front of the infant to encourage acceptance of the prone position. A roll or wedge positioned under the infant's axillae and upper chest will facilitate the ability to push up in prone, particularly for the infant with low muscle tone. An infant who is apprehensive or stressed when placed on the stomach may tolerate prone lying on the caregiver's chest, where reassuring eye contact can be maintained.

Head Balance

Balance activities to develop active head control are frequently recommended for preterm infants. Tilting responses are usually achieved

most effectively with the infant in the parent's lap. Instruction to the caregivers often includes demonstration and practice using a doll before attempts with the infant. Emphasis is placed on the importance of (1) adequate trunk support; (2) movement through small ranges; (3) slow, graded motion; (4) desired head-righting response; and (5) sensitivity to indications of stress or fatigue.

Limited Use of Infant Jumper or Baby Walker

For infants with increased lower-extremity tone or a tendency for toe-standing, the use of baby walkers and jumpers is discouraged because of potential increased stiffness and extension posturing of the legs.²⁸³ Mobile baby walkers are associated with a high risk of injury, including serious trauma such as burns, drowning, and severe head injuries resulting from falls down stairs^{284–286}; however, baby walkers are usually enjoyable for infants and may provide caregivers with some needed moments of respite in stressed households. When recommending that time in a baby walker or jumper be restricted, the therapist should help the caregivers find alternative methods of positioning and amusement for the infant. Parents are often reluctant to discard a baby walker, believing that it promotes early ambulation and is beneficial for infants. Informing caregivers of the hazards of infant walkers and research findings indicating walker use may delay the acquisition of gross and fine motor skills enhances the likelihood of their cooperation to eliminate walkers and jumpers.^{287,288} The lower-extremity tone and movement effects of semisitting activity centers that allow supported standing and some lateral steps have not been documented.

SUMMARY

This chapter on the NICU management and follow-up of at-risk neonates and infants has presented three theoretical models for NICU practice, reviewed neonatal neuropathological conditions related to movement disorders, and described expanded professional services for at-risk neonates and infants in the subspecialty of neonatal therapy. Pediatric therapists participating in intensive care nursery and follow-up teams in the care of high-risk neonates and their parents are involved in an advanced-level practice area that requires heightened responsibility for accountability and for precepted clinical training (beyond general pediatric specialization) in neonatology and infant therapy techniques. Practice guidelines for the NICU from national task forces representing the American Physical Therapy Association, American Occupational Therapy Association, and American Speech-Language, Hearing Association delineated subspecialist roles, proficiencies, and knowledge for neonatal therapy. All three professional organizations concur that the NICU is a restricted and inappropriate practice area for therapy assistants, aides, entry-level students on affiliation, and new graduates.

Inherent to this subspecialty practice is the challenge to design comprehensive neonatal therapy protocols and clinical paths that include standardized examination instruments, comprehensive risk-management plans, long-term follow-up strategies, and systematic documentation of outcome. Ongoing analyses of the physiological risk–therapeutic benefit relationship of neuromotor and neurobehavioral treatment for chronically ill and preterm infants must guide the NICU intervention process. The quality of collaboration between therapists and neonatal nurses largely determines the success of neonatal therapy implementation in the 24-hour care environment of the nursery.

Pediatric therapists working in neonatal units are encouraged to participate in follow-up clinics for NICU graduates to identify and analyze the development of movement dysfunction and behavioral sequelae that may, in the future, be minimized or prevented with creative neonatal treatment approaches. The important preventive aspect of neonatal treatment must be guided by careful analyses of neurodevelopmental and functional outcomes in the first year of life and by the priorities and values of the family.

CASE STUDY 9.1 High-Risk Infant A

Infant A was born prematurely at 29 weeks of gestation with a birth weight of 940 grams. Her neonatal course was complicated by idiopathic respiratory distress syndrome, which was treated with surfactant.

She was first evaluated in the high-risk infant follow-up clinic at 4 months' corrected age (6 months' chronological age). Her mother stated that the infant had several respiratory illnesses after discharge from the NICU. She reported that her infant felt "tense" compared with her older child born at term and seemed to be "a little behind" in overall development. Performance on the Bayley Scales of Infant Development II (BSID-II) generated a Mental Development Index (MDI) of 94 and a Psychomotor Development Index (PDI) of 82. On the Movement Assessment of Infants (MAI) she demonstrated mildly increased lower-extremity muscle tone evident in mild resistance to passive range of motion of her hips and ankles. Persistent primitive reflexes, including the Asymmetric Tonic Neck Reflex (ATNR), Moro reflex, and tonic labyrinthine reflex influence, were present in the supine position. Head balance was immature, but emerging righting reactions were noted. When the infant was observed in the supine position, her posture was extended, but she was beginning to bring her hands to midline. In prone, she had started to push up on elbows, but posture was immature and unstable. Her parents were given recommendations for handling to include holding and carrying positions with shoulders forward to inhibit retraction, frequent play in the prone position, and increased opportunities for reaching in the supine position.

When the infant returned at 8 months' corrected age, her mother reported that progress had been made in the areas of rolling, talking, and sitting. She indicated that the body "stiffness" was less evident, but the infant still did not like to play on her "tummy" and instead preferred to use the baby walker. BSID-II scores at this time were MDI of 101 and PDI of 81. Increased muscle tone observed previously was less evident, and she had full hip mobility but some resistance to passive ankle movement. Muscle tone of the trunk was mildly hypotonic, but age-appropriate antigravity movements were demonstrated in all positions. Primitive reflexes were no longer evident except for the positive

support reflex, characterized by toe-standing tendency during weight bearing. Balance reactions were present but immature in some areas, including head righting into flexion and protective extension reactions. In volitional skills, the infant was now sitting independently for up to 30 seconds, could roll from supine to prone, and could pivot sideways in the prone position. She could pick up a block with either hand and transfer objects. Immaturity was observed in sitting balance, inability to move out of sitting, and failure to move forward on the floor (i.e., low two-point crawl). She attempted to pick up a pellet but was unable to do so. Her parents were advised to discontinue using the baby walker and to maximize playtime on the floor. The infant reportedly enjoyed watching her 4-year-old sibling, so the therapist recommended that he play on the floor beside her. Her mother was also advised to provide the infant with tiny bits of food (e.g., Cheerios) to practice fine motor dexterity.

When seen at 12 months' corrected age, the infant had an MDI of 108 and a PDI of 88. Although not yet walking independently, she was cruising with good weight shift and balance. She was able to creep reciprocally on hands and knees and pulled to stand. She picked up a pellet with an inferior pincer grasp. No deviations of muscle tone or reflex development were observed during examination by the developmental pediatrician. The infant was developing normally and will return for follow-up at 2 years of age. Her parents were advised to call if she was not walking within 2 months or if they had any concerns regarding her pattern of independent walking.

In the management of this child who demonstrated abnormal signs, the primary responsibilities of the pediatric therapist were ongoing assessment and parental guidance and teaching. Although initial concerns about this infant's muscle tone and reflex deviations were present, diagnosing her with a particular condition would have been inappropriate. When followed up over time, the abnormalities resolved and proved to be transient. This child should continue to be followed up in the high-risk infant clinic because she remains at risk for other neurodevelopmental problems that may not become evident until school age.

CASE STUDY 9.2 High-Risk Infant B

Infant B was born prematurely at 29 weeks of gestation with a birth weight of 1200 grams. The neonatal course was complicated by idiopathic respiratory distress syndrome and persistent apnea and bradycardia. Cranial ultrasonography revealed a left subependymal hemorrhage with ventriculomegaly and left-sided periventricular leukomalacia.

She was first seen in the high-risk infant follow-up clinic at 4 months' corrected age (6 months and 17 days' chronological age). The parents stated they had no specific concerns regarding their daughter's development. On the BSID-II the infant received an MDI of 96 and a PDI of 87. On the MAI, muscle tone was normal at rest but increased when she was active or agitated. Tone in the lower extremities was mildly increased with restricted passive movement in the hip adductor and gastrosoleus muscles bilaterally. In the supine position she was frequently in an extended posture and brought her hands to midline only once during the examination. In the prone position she was able to push up and elevate her head while kicking actively. In the prone suspended position, she showed good postural elevation, but movements were stiff. Persistent primitive reflexes included the tonic labyrinthine reflex in supine, ATNR, neonatal positive support reflex, and bilateral ankle clonus. Plantar grasp with toe curling was observed on the right. Righting and equilibrium reactions were emerging. She showed a mature Landau reflex with full extension in prone suspension, which is atypical for her age. In volitional movement, mild asymmetry was evident because she had difficulty bringing her right arm forward when prone and brought her left arm to midline more frequently. Her kicking pattern when supine was low (close to the surface), and she did not elevate her hips. On the right side, hip extension was

accompanied by knee extension and plantarflexion of the ankle. She was not yet reaching for objects, and her hands were frequently fistled, particularly on the right. Her parents were assisted with handling skills to reduce shoulder retraction and extension posturing and to facilitate symmetry in movements and posture.

When the family returned for a follow-up visit at 6 months, they reported that their daughter was making good progress, but she continued to prefer use of her left hand in spite of their efforts to encourage using the right hand. At this evaluation, Bayley Scale scores were an MDI of 94 and a PDI of 83. The infant had made the following developmental progress: (1) rolling from supine to prone (over the right side only); (2) beginning sitting balance; and (3) reaching and grasping objects. She showed a preference for, and greater skill and dexterity with, the left hand. Occasional fistling was still observed on the right hand. She transferred objects only from right to left. Muscle tone continued to be increased in the lower extremities, with restricted passive mobility of the gastrosoleus muscles bilaterally. Toe clawing was observed on the right with minimal spontaneous dorsiflexion observed on this side. Primitive reflexes were integrated except for persistent neonatal positive support and ATNR to the right. Automatic reactions were improved, but balance responses were asymmetrical, with equilibrium reactions and protective extension reactions delayed on the right. Although the developmental progress was encouraging, the persistent asymmetry remained a major concern. The infant was referred to a developmental intervention program with the recommendation that she receive consistent pediatric therapy in her home at least once a week.

The infant was seen in the follow-up clinic at 12 months' corrected age (14 months' chronological age). On the BSID the MDI was 95 and the PDI

CASE STUDY 9.2 High-Risk Infant B—cont'd

was 82. She now was creeping reciprocally on hands and knees. When she pulled to stand, she consistently brought the left foot up first. She cruised holding onto furniture with a tendency to stand on her toes on the right. She picked up cubes with either hand but showed partial palmar grasp on the right. She picked up a pellet with an inferior pincer grasp on the left but scooped it into the palm of the right hand. Muscle tone continued to be mildly increased in the lower extremities with Achilles tendon tightness, particularly on the right. She sat independently with a mildly flexed thoracic spine. When moving into and out of sitting, she lacked full trunk rotation, and weight was predominately over the left hip. Language development was considered appropriate for her age. The infant was diagnosed with mild right hemiplegic cerebral palsy. It was recommended that she continue in

the intervention therapy program and return for reevaluation at 2 years of age.

In the management of this child, the role of the pediatric therapist was assessment of neurodevelopmental status and referral to therapy when it became evident that the abnormalities of muscle tone were persisting and interfering with developmental progress. Of note, this child's MDI scores were in the normal range at both the 4- and 8-month examinations. Because the BSID-II does not require infants to perform tasks with both hands, a normal score can be obtained by using just one side of the body. This child should continue to be followed in the high-risk infant clinic after 2 years of age to provide periodic reassessment and guidance to the family as they confront questions of school placement and program planning for their child.

ACKNOWLEDGMENT

We appreciate significant contributions to the case studies by Marcia Williams, PT, MPH, PhD.

REFERENCES

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this

textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 288 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Abstract: The focus of this chapter is clinical management during the neonatal intensive care unit (NICU) and outpatient follow-up phases for neonates at neurodevelopmental risk and their parents. A theoretical framework for neonatal practice is presented, and an overview of neonatal complications associated with adverse outcomes is provided. In-depth discussion in the neonatal section includes neurodevelopmental examination and pain assessment, intervention plans, and

therapy strategies in the NICU. The section on outpatient follow-up addresses critical time periods for neuromotor and musculoskeletal reexamination, assessment tools, and clinical cases.

Keywords: high-risk clinical signs, medical complications of prematurity, neonatal intensive care unit environment, neuromotor assessment, neuromotor intervention, parent instruction, physiological and musculoskeletal risks, subspecialty training

Management of Clinical Problems of Children With Cerebral Palsy*

Claudia R. Senesac and Rachel McAhren

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify the parameters of the diagnosis of cerebral palsy including motor, family, and psychosocial components.
2. Analyze the multifaceted aspects of the clinical problem and appreciate a multifaceted approach to evaluation and treatment.
3. Analyze treatment strategies and their application to clinical problems.
4. Identify and critique current research for the pediatric patient with cerebral palsy.
5. Identify the therapist's role in the treatment of the child with cerebral palsy, with family involvement, in different settings, and with other health professionals.

KEY TERMS

cerebral palsy
direct intervention
family
indirect intervention

postural and movement compensation
research
spasticity
treatment strategies

OVERVIEW

Perspective

Cerebral palsy (CP) is a misnomer at best. Little¹ suggested the name in the mid-1800s, but there is still no established direct relationship between the identifiable state of the brain and the distortions in posture and movement control that we are able to observe in the individual.^{2,3} The condition is not always evident at birth, although the work of Precht⁴ statistically supports the possibility of a link between the quality of spontaneous movements in the first months of life and later difficulties in coordinated movement expression. Recently in a systematic review of spontaneous infant movement as a predictor of later CP, 47 studies were scrutinized. The authors found that Precht's General Movement Assessment had the strongest sensitivity for predictive validity for a later diagnosis of CP.⁵ They caution practitioners in the use of this tool in isolation due to a high level of false positive results. In only a small number of children has a specific lesion been identified that corresponds to the observed motor responses of the child, and this elite group includes children with porencephaly and other early developmental malformations of the brain. Whether there is a biochemical element in the brain of a child that distorts the actual motor learning process has not been established. There is a shocking variability in the age at which intervention is initiated for individual children with CP. The continuation of a "wait and see" philosophy in many cases postpones the delivery of services and resultant early intervention. Programs that provide early screening for infants under the Individuals with Disabilities Educational Act (IDEA) utilize a team

of professionals trained in early childhood and typical development to identify children at risk.^{6,7} These programs vary from state to state but through Federal and State funding provide services for children 0 to 3 years of age for early intervention. Understanding the process of movement and postural distortion that characterizes children who carry the label of "cerebral palsy" is a critical piece in the delivery of services to this population.

Historically, the evolution of diagnosis and treatment intervention or management is clear and relates to the recognition of the special needs of this minority of society. The British physician, Little, identified the condition on the basis of observable characteristics of movement and posture, or—in other words—the external features of the condition, so the initial efforts at remediation fell to physiatrists and orthopedists such as Deaver and Phelps.^{1-3, 8,9} In an article by Kottke and Knapp in 1988 physiatrist Dr. George Deaver was considered the "Grandfather" of physical medicine and rehabilitation, treating individuals with cerebral palsy when others would not consider it. Deaver placed importance on external bracing that was periodically reduced in the hope that the child would take over control of increasing parts of his or her own body.⁸ Phelps, an orthopedist, used bracing and surgery and was a significant force in obtaining schooling for these children in the United States.^{10,11} He pointed out that these children did not belong in academic classes with children diagnosed as retarded or mentally handicapped, and that children with CP should be exposed to a traditional academic curriculum. In his Children's Rehabilitation Institute in Reisterstown, Maryland, he also advocated restriction of a more functional limb to encourage the use of the one less used, particularly in work with the upper extremities, which was an early introduction of constraint-induced movement therapy (CIMT) known to us today.

*Videos for this chapter are available at studentconsult.com.

In the 1950s and 1960s new theories simultaneously emerged of neuromotor behavior that redefined the clinical characteristics of CP and permitted clinicians to orient their intervention strategies to the principles of motor development and motor learning. Kabat, in conjunction with Knott, introduced proprioceptive neuromuscular facilitation (PNF), which was applied to children with movement disorders and to adults with a history of trauma. In 1952 Dorthoy Voss joined Kabat and Knott and expanded on the techniques.¹² The use of diagonal patterns of movement in this approach changed the customary postures of the child and introduced more functional movement patterns in logical learning sequences. Physical and occupational therapist Margaret Rood added the more specific sensory components of ice and light, quick brushing of the skin surface to guide the desired motor response.¹³ She spoke of the need to focus attention on both “heavy work” and “light work” during the early development of movement skills. These terms referred to the central body moving over a limb that has been fixed or bearing weight and extremity movement with central stability. Bobath was working in London at this same time and observed the need to have a dynamic distribution between stability and mobility, after finding that inhibition of the reflexive movements was not sufficient to change the functional outcome of the child with CP.¹⁴ Both Rood and Bobath pointed out that the areas of the child’s body that appeared to be spastic changed when the body was placed in a different relationship to gravity. This observation held up for reexamination of the prevailing view of the time, namely, that spasticity existed in a tendon or muscle, a specific structure. CP was identified in the mid-1900s as an incident that occurred shortly before, during, or shortly after the birth of the infant. Early intervention was recommended. This timeline was extended to cover the first 2 years of life, which included early cases of meningitis, encephalitis, drowning accidents, and so forth. These factors are true today; however, multiple causes of CP have been documented.^{15–17} A systematic review and meta-analysis on the prevalence of CP in 2013 revealed that infants with a gestational age less than 28 weeks and birth weights of 1000 g to 1499 g were at highest risk for CP.¹⁸

Interestingly, the overall prevalence of CP was found to be 2.11 per 1000 live births, which has remained consistent despite an increased survival rate and improved neonatal care. The Centers for Disease Control and Prevention report a slightly higher incidence of 1.5 to 4 per 1000 births.¹⁹

Although early clinicians defined CP as a “disorder of posture and movement control,” many of the children also had learning problems and inadequate general brain development affecting cognitive skills, reasoning, and judgment. There was a general agreement on categories according to movement characteristics that included spasticity, athetosis, flaccidity, ataxia, and rigidity. Categorization according to the part of the body affected was added to identify hemiplegia, quadriplegia, diplegia, and even monoplegia (affecting one limb), and triplegia (affecting three limbs). It was noted that some children “appeared” to move from one category to another as their body changed with growth and hormonal expression. Therapists began to be aware that a child with high tone could have varying degrees of low tone and muscle weakness underneath when spasticity was inhibited. Fluctuating tone could be confused with ataxia, and the precise intervention strategy might be elusive.

The birth process is complex at many different levels. Sequential hormonal changes alert both the fetus and the mother that it is time for a separation. The infant moves into position for exiting the uterus through the birth canal while the mother’s body prepares to participate in the work (labor) of the expulsion. When all goes smoothly, the head of the infant is molded by the passage through the birth canal, and the fibrous sutures of the cranial plates return to their balanced alignment and functional motion. When the birth process is prolonged for any of

many reasons, the physiological timing of these changes is interrupted. In the majority of healthy infants born at term, spontaneous movements seem to assist in the activation of the central body (trunk) and the limbs to permit a typical expression of developmental movement responses after birth. Body movement and respiration are coordinated with the infant’s physiological rhythms in this initial adaptation to the world of gravity. With complications of the pregnancy or the birth process, these spontaneous movements that are so easily made by the healthy infant become laborious and sometimes impossible, affecting motor actions, postural mechanisms, and the basic physiological rhythms. CP is a heterogeneous collection of clinical syndromes, not a disease, or pathological, or etiological entity.^{15–17,19,20} Little described CP as “a persistent disorder of movement and posture appearing early in life and due to a developmental nonprogressive disorder of the brain.”^{1–3} Current definitions have reiterated that atypical execution of movement and interference with postural mechanisms are the key characteristics of this nonprogressive disorder affecting the developing brain, with wide-ranging presentations.^{15,17,19–21}

CP affects the total development of the child. The primary disorder is of motor execution, but common associated dysfunctions include sensory deficits (hearing or vision); epilepsy; learning disabilities; cognitive deficits; emotional, social, and behavioral problems; and speech and language disorders. The degree of severity varies greatly from mild to moderate to severe, and may be combined with multiple comorbidities.^{20–23}

Diagnostic Categorization of the Characteristics of Cerebral Palsy

In general, a diagnosis of CP suggests that the individual has a lesion within in the brain affecting the motor control system with a residual disorder of posture and movement control. Varying degrees of associated components are seen with this disorder that further defines the category that a child may fall into: severity of motor abnormalities, anatomical and magnetic resonance imaging (MRI) findings, extent of associated impairments, and the timing of the neurological injury. Further, the severity and type of CP depend on the extent and damage to associated area(s) in the brain affecting the motor cortex. The labeling process helps to identify the parts of the body that are primarily involved. Diplegia, hemiplegia, and quadriplegia indicate that the lower extremities, one side of the body, or all four extremities, respectively, are affected. This can be misleading to the therapist who is working with infants because these children often change their clinical presentation and their respective disabilities. The disorder is not progressive, but the presentation of involvement of body segments may manifest itself differently with hormonal influences as the child grows and his or her structure and tonal distribution changes against gravity. Structure and function are closely related as the child grows and the body matures.

The clinician must be aware that the categorization of CP is based on descriptions of observable characteristics; thus it is a symptomatic description. The *hypertonus* of spasticity prevents a smooth exchange between mobility and stability of the body and interferes with reciprocal innervation. Constriction of respiratory adaptability occurs with poor trunk control. Incrimination of postural tone occurs with an increase in the speed of even passive movement, and clonus may occur in response to sudden passive movement. Although diagnostic terms reflect the distribution of excessive postural tone, the entire body must be considered to be involved. Spasticity, by nature, involves reduced quantity and quality of movement, which makes its distribution easier to identify. Recruitment of the corticomotor neuron pool is affected in the presence of spasticity, and therefore timing issues result in the poor grading of agonists and antagonists.²⁴ There is also a risk of reduction

in the range of limb movements over time when therapy does not include active adaptation in end ranges and organization of postural transitions.²⁵ Category (spasticity) has the highest occurrence of cases of CP.^{17,19} There are several spastic types of CP that require clarification. Fig. 10.1 Spastic diplegia implies that the lower extremities are more involved than the upper extremities but could manifest with varying degrees of arm and hand function, and often the involvement is asymmetrical.^{22,23} Hemiplegia displays involvement of one side of the body and can manifest itself with the arm involved more than the leg or the leg involved as much as or more than the arm.^{20,22,23} This group of individuals is at risk of developing seizures as they go through puberty; however, a seizure disorder can occur in any of the types of CP as a comorbidity. Quadriplegia, as the term implies, involves the entire body.^{20,22,23}

Dyskinetic syndromes, which include athetosis and dystonic types of CP, are characterized by involuntary movements. This type of CP is a result of damage to the basal ganglia, which is responsible for regulating voluntary movements. This area of the brain also is important in regulating emotions, mood, and behavior in general.²⁶ The term *dyskinetic* is commonly used with children who lack posture, axial, and trunk coactivation. The excessive peripheral movement of the limbs occurs without central coactivation to stabilize the trunk. Dystonic types of CP are dominated by tension and can result in repetitive, sustained movements, or awkward postures.²⁶ Movement behavior is slow or fast with little control over the movements and may be associated with pain. Athetosis usually has a hypotonic base or underlying tone with slow writhing movements seen at rest, which get more pronounced with increased movement attempts. The child with athetosis can become floppy or be quite spastic within a moment's notice. Muscle tone can fluctuate in both types of dyskinetic CP from hypotonia to hypertonia, making their movements unpredictable. These changes in tone are spontaneous and often related to varied stimuli, which are often specific to each child including—but not limited to—mood, hormones, and environmental influences. Dyskinetic

syndromes may occur with greater involvement in particular extremities, although the condition most often interferes with postural stability as a whole. When pathological or primitive reflexes are used to accomplish movement, there is difficulty with midline orientation and symmetry.

Tonic neck reflexes are observed in this population with the asymmetrical tonic neck reflex (ATNR) the most common although others may also be present. Dyskinetic distribution of postural tone is changeable in force and velocity, particularly during attempted movement by the individual. Midrange control is limited—if present at all—and frequently end ranges of motion are used to accomplish a motor task.^{20,22,23} For these reasons, these children have a reduced risk for contractures over time. However, as with any habitual pattern of movement, muscular and joint tightness may occur. Fine motor skills, discrete movements, and skills that require slow control are difficult for these children. Expressive language also may be affected due to changes in muscle tone distribution influencing every muscle in the body, including those that support respiration and speech.

Hypotonicity is another category of CP, but it may also mask undiagnosed degenerative conditions (see Chapter 10). Recent reports suggest that “pure hypotonia” is not an attribute of CP, and further testing to rule out other causation may be indicated.^{19,25} Hypotonia in a young infant also may be a precursor of a dyskinetic syndrome. Often, athetoid movements or spasticity are not noticed until the infant is attempting antigravity postures, although there may be some disorganization of movement patterns apparent to the careful observer. Generalized hypotonia may disguise some specific areas of deep muscle tightness with accompanying local immobility in an effort to gain stability for function. Careful examination will assist the therapist in the interpretation of the child's movement strategies.

True *ataxia* is a cerebellar disorder that is seen more frequently as a sequela of tumor removal (see Chapters 20 and 22) than as a problem occurring from birth. Ataxic syndromes are more commonly found in term infants. This type of CP is a diagnosis of exclusion. In a small

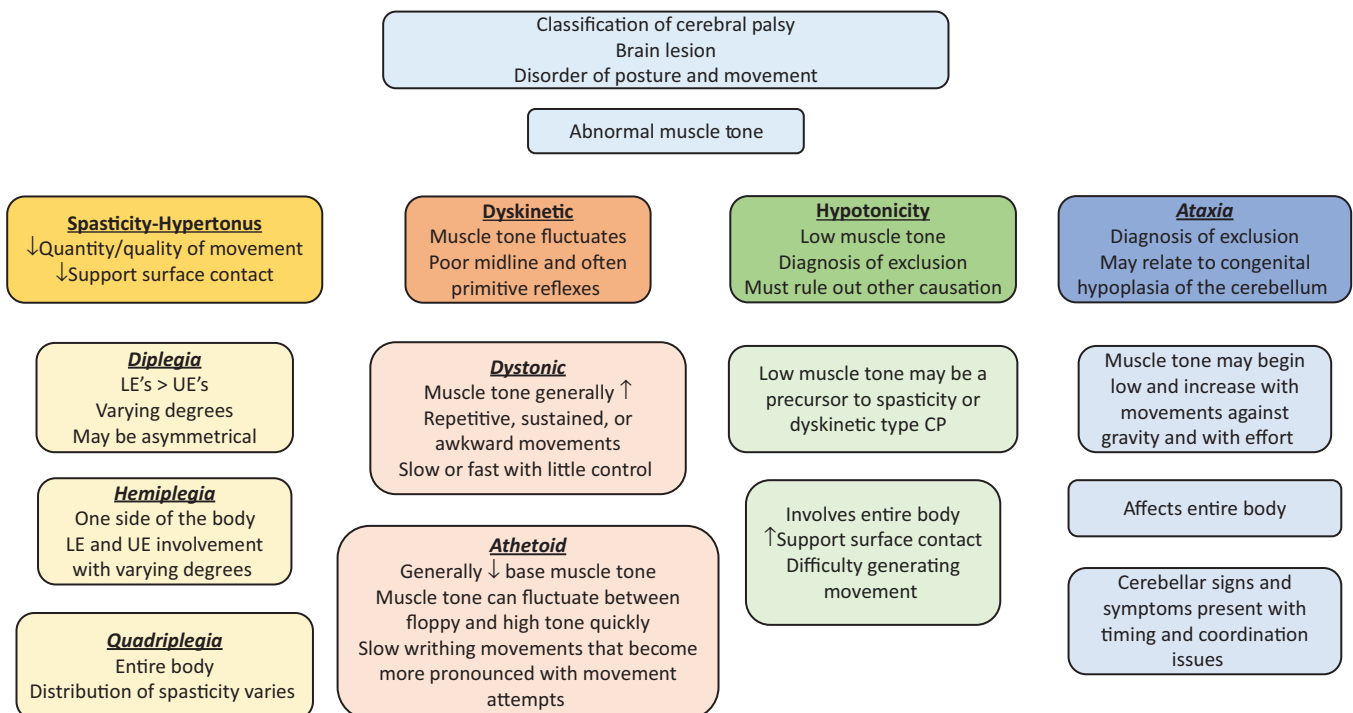

Fig. 10.1 Classification of Cerebral Palsy. CP, Cerebral palsy. LE's, Lower extremities; UE's, upper extremities. (Developed by Claudia Senesac © 2018.)

number of patients there is congenital hypoplasia of the cerebellum. Most of these children are hypotonic at birth and display delays in motor acquisition and language skills.²⁰ Recruitment and timing issues remain problems in this population. Trajectory of the limbs, speed, distance, power, and precision are frequently documented as problems in this category. Midline is often achieved, but control of midrange movements of the extremities and control of trunk postural reactions are affected. These classifications, even when accurately applied, give the therapist only a *general idea* of the treatment problem and must be supplemented by a specific analysis of posture and movement control during task performance, an interview for home care information, and assessment of treatment responses (see Chapters 6 and 7). The therapist is then ready to establish treatment priorities for the individual child. Refer to Fig. 10.1 for an overview of the classification for types of CP.

Many of the characteristics described in the preceding paragraphs also apply to children who have had closed head traumas or brain infections. Further information can be obtained in Chapters 22 and 26. Some of the treatment suggestions that follow may also be applied in such cases. As with CP, early positioning and handling after trauma may deter later problems.

EVALUATIVE ANALYSIS OF THE INDIVIDUAL CHILD

Initial Observations and Assessment

Examination of the individual child begins with careful observation of the interaction between parents and the child, including parental handling of the child that occurs spontaneously. Some additional insight can be gained about the relationship between parent and child by observing how the child is handled both physically and emotionally. Does the child receive and respond to verbal reassurance from the parent in the therapy situation? Are immediate bribes offered to the child? Does parent eye contact increase the child's confidence in responding? Does family communication convey the idea of negativity in the therapy situation or a difficult experience that will soon come to an end? The family orientation will affect the response of the child while working with the therapist. Making connections with the child and family is a critical component to a successful relationship that forms with ongoing treatment.

The therapist working as part of a team may have the advantage of a social worker or psychologist who will relate to the problems and motivations of the parents. Parental responses toward the disabled child arise from the parents' uncertainty, fear, concern for the future, disappointment, distress, and other typical reactions to this unforeseeable life experience. A period of grief is to be expected as their child is often unable to accomplish the milestones and dreams the parents had envisioned for them. Providing clear information for the family in the form of education and interpretation of medical information will assist parents discover how to help their child move forward in all domains. They may be further assisted by opportunities to interact with well-adjusted parents of older children with a diagnosis of CP. Assisting families to make connections with other families and children in the community provides them a supportive network of people who share similar experiences.

A problem-based approach to the assessment and management of the child with CP includes the family as key members of the team.²⁷ While observing the child, the experienced therapist will want to periodically elicit from the parents their view of the problem and their goals for their child. By listening carefully, the therapist also will be able to discern the emotional impressions that have surrounded previous experiences with professionals. Sometimes what is not said is more

Fig. 10.2 Typical infants accumulate a multitude of experiences as they move smoothly and spontaneously in their environments.

important than what is verbally offered immediately. Listening carefully and clarifying facts are more important than overwhelming the parents with excessive information and suppositions during early contacts. Observation of the family response to information will keep the therapist on track in developing a positive relationship with parents that deepens over time. The therapist's role is often as interpreter of medical information as parents attempt to make some sense of their child's diagnosis.

The next general step is to observe, in as much detail as possible, the spontaneous movement of the child when separated from the parent (Fig. 10.2). Is the child very passive? How does he or she react to the supporting surface (Fig. 10.3)? Are there atypical patterns of movement to reach a toy? Are there clearly typical responses occurring with specific interference by pathological synergies or total patterns of movement? Does the child rely heavily on visual communication? Do the eyes focus on a presented object, or does the postural abnormality increase with an effort to focus the eyes? Does the child lead or follow hand activity? Does an effort to move result only in an increase of postural tone with abnormal distribution? Does respiration adapt to new postural adaptations (Fig. 10.4)? Is the child able to speak as well while standing as while sitting? Fig. 10.5 provides key questions to keep in mind during the assessment.

This type of observation is valuable because movement patterns directly reflect the state of the central nervous system (CNS) and can generally be seen while the parent is still handling the child.²⁸ Once the child is on the mat or treatment table, outer clothing can be removed to observe interactions of limbs and trunk. Observation of the musculoskeletal system without the restriction of clothing allows the therapist to collect information about the initiation of movement, asymmetries, dynamic joint movement, reflexive behavior, support surface contact, and changes that occur with transitions that are difficult to visualize with clothing left on. Movement responses of the child can gradually be influenced directly by the therapist. Many children associate immediate undressing in a new environment with a doctor's office, and the chance to establish rapport is lost. In some instances, it is preferable to have the parent gently remove some of the child's clothing or even to leave the child dressed during the first

Fig. 10.3 Lack of support surface contact demonstrates difficulty conforming to and activating off of the supporting surface.

Fig. 10.4 Emotional reactions are also translated into stronger spastic reactions influencing respiratory adaptation.

therapy session. Gaining the trust of the child and parent is crucial during the first few sessions.

The International Classification of Functioning, Disability and Health (ICF)^{29,30} is well known in the field of health care and allows one to see the overall interaction of the person with his or her environment, activities, and participation in the presence of the health condition.²⁹ Fig. 10.6 depicts this health care model with examples of behaviors and information of which the therapist should be cognizant while collecting data for later integration into a treatment plan.

Examination of the child's status is more likely to be adequate if the therapist follows the child's lead when possible. Photos or video recording are beneficial in capturing the interactions and movement patterns of the child; however, parents must be consented prior to using these forms of documentation. Sánchez and colleagues reinforces this idea of video recording as a way to further assess segmental posture of the head and trunk.³¹ In addition, the Segmental Assessment of Trunk Control (SATCo) has been found to have excellent reliability and good absolute agreement in children with CP, and offers another objective estimate of sitting trunk control.³²

Often notes can be organized later to conform to a specific format. It is possible to jot down essential information while observing the child moving spontaneously or while the parent is holding the child. Reactions to the supporting surface will differ in these circumstances. After the session, the therapist will need to record the salient information either electronically, or by hand as part of the evaluation, sending a copy to the primary care physician. Attention should be given to the

typical movements of the child and to those postures that the child spontaneously attempts to control. Building a treatment plan will be based on the strengths of the child noted in these first encounters and will serve as a foundation to build the plan of care (POC). Eye alignment is important; the correspondence between visual and postural activity relates directly to quality of movement control. It is important to note the interaction between the two sides of the body. In noting atypical reactions and compensatory movement patterns, the therapist must also indicate the position of the body with respect to the supporting surface. There is a tendency to compile more pertinent data by learning to cluster observations and relating one to the other. Figs. 10.7 and 10.8 provide examples of how to group data collected during observation and handling of the child. Children are vibrant beings. Their choices of position tell us something about their movement behaviors and how comfortable they are in particular situations. Although it is important to see the child in every position, making smooth transitions from one to another will ensure that the child is secure and give the therapist a more accurate assessment of the child's abilities. Noting the "preferred" position or movement strategy can provide information about the ability to conform to a support surface, the initiation of movement from the surface they are weight bearing on, muscle tightness, muscle tone distribution, and movement variety in the child's repertoire.

Standardized assessments are often used by facilities to document the developmental level of the functioning of a child with disability and to justify treatment. The Gross Motor Function Measure (GMFM) was developed to assess children with CP and has good reliability and validity for children aged 5 months to 16 years.^{33–35} This assessment is well studied in the literature and often used to document a baseline and progress, but can also serve to help develop a POC. The Gross Motor Function Classification System (GMFCS), developed in 1997, is often used in conjunction with the GMFM.^{36,37} The GMFCS has five levels of classification for gross motor function, emphasizing movement initiation related to sitting, walking, and mode of mobility. Descriptors of motor function span an age range of 2 to 18 years, reflecting environmental and personal factors. Both of these tools have also been used in research studies as a measure to meet inclusion criteria and as outcome measures. The GMFM continues to be investigated for use in different populations and those with visual impairment.³⁸

The Pediatric Evaluation and Disability Inventory (PEDI) assesses children aged 6 months to 7.5 years in three domains: social, self-care, and mobility.³⁹ A computer based version of this instrument, Pediatric Evaluation of Disability Inventory-Computer Adaptive Test (PEDI-CAT), has demonstrated strong construct validity and reliability in children with CP.⁴⁰ Both versions of this tool have been used to track outcomes over time. The Functional Independence Measure for Children was developed as a test of disability in children aged 6 months to 12 years. This assessment covers self-care, sphincter control, mobility, locomotion, communication, and social cognition.^{36–43} Often the decision to use an instrument to assess development will be left up to the clinician or facility. To date, there is no single tool that will cover all the categories necessary to document change in a child with CP, so the clinician will need to rely on observational skills to describe quality of movement and response to changes in position in space and handling. Each child will differ in the ability to separate from her or his parents. Spontaneity of movement, interest in toys, general activity level, and communication skills will also vary from child to child. Responding to the specific needs of the child enables the therapist to set priorities more effectively. If fatigue is likely to be a factor, it is important first to evaluate those reactions that present themselves spontaneously, followed by direct handling to determine the child's response and

Questions to Guide Therapist-Reminders

Child's name: _____ Caregiver/Parent _____
 Date of Birth: _____ Date of Visit _____ Dx _____

1. Does the child make eye contact and interact with caregivers and environment?
2. Does the child adapt to the supporting surface and use the supporting surface contact for movement initiation?
3. Are there "<u>atypical</u>" patterns of movement to reach a toy or during movement of any kind?
4. Are "<u>typical</u>" responses occurring with specific interference by pathological synergies/reflexive behavior or total patterns of movement?
5. Does the child rely heavily on visual communication? Note the child's ability to communicate.
6. Do the eyes focus on a presented object, or does atypical postural response(s) increase with an effort to focus the eyes?
7. Is the child able to dissociate the eyes from the head and the head from the eyes?
8. Does the child lead or follow hand activity?
9. Does an effort to move result only in an increase of postural tone with abnormal distribution?
10. Does respiration adapt to new postural adaptations?
11. Is the child able to speak while standing as well as sitting?
12. What is the child's response to changes in position?
13. Does the child tolerate transitions of movement when made by the therapist?
14. Does the movement of a limb demonstrate smooth controlled movement without unwanted associated reactions in other parts of the body?

potential for more typical movements. Movements or abilities for which there is a major interference from spasticity, primitive reflexive responses, or poor balance reactions (righting, equilibrium, and protective reactions) may be better checked at the termination of the assessment so that the child remains in a cooperative mood as long as possible. Information regarding favorite sleeping positions, self-care independence, and any equipment used at home can be requested as the session comes to a close.

Clinical reasoning involves taking information from the assessment, including observations, results from standardized tools, family

input, and the therapist's handling of the child to formulate a treatment plan. Placing this information into a framework that makes sense to the therapist, the physician, other health professionals, and the family will assist in goal writing. Refer to Figs. 10.9 and 10.10 as examples of evaluation formats that are easily incorporated.

Reactions to Placement in a Position

If the child totally avoids certain postures during spontaneous activity, these are likely to be the more important positions for the therapist to evaluate. Observing how the child conforms to the support surface and

how much contact there is with the surface will provide information about the ability to initiate movement from the surface. Support surface contact is essential for weight bearing and weight shifting to occur; both are critical for movement. Placement of the child in the previously avoided position will permit the therapist to feel the resistance that prevents successful control by the child.⁴⁴ As mentioned previously, this may be held for the end of the assessment. The parent should play an active role in the assessment whenever possible. Continued dialog with the parents reveals factors such as the frequency of a poor sitting alignment at home or a habitual aversion to the prone position. Gathering general information about the child's habits in her or his environment can further enhance the therapists' understanding of how well the child is integrating the visual-motor system, perception, and motor systems; that is, tilting the head when looking at books or watching TV may indicate neck tightness and/or difficulty with functional vision skills.⁴⁵ These contributions by the parents establish the importance of good observation and the need for parents and the therapist to work cooperatively as a team. Therapists of different specialties need to initiate continued communication to coordinate therapy objectives. According to the guide for typical development, infants should be able to maintain the posture in which they are placed before they acquire the ability to move into that position alone.⁴⁶⁻⁴⁷

The problems presented by CP occur to some extent as a reaction to the field of gravity in which the child moves.⁴⁶ Visual perceptions of spatial relationships motivate and determine movement patterns while the child must react at a somatic level to the support surface. It is helpful therefore to attempt placement of the infant or child into developmentally or functionally appropriate postures that are not assumed spontaneously (Fig. 10.11). Resistance to placement indicates an increase in tone, a structural problem, or an inability to adapt to the constellation of sensory inputs for that alignment. A movement that resists control by the therapist will be even less possible for the child. What appears to be a passive posture may hide rapid increases in hypertonicity when movement is initiated or instability of a proximal joint when weight bearing is initiated. A child may have learned to avoid excitation of the unwanted reactions and may fix the body position to avoid the alignment that cannot be controlled. Another child may enjoy the sensory experience of accelerated changes in postural tone and deliberately set them off as a means of receiving the resulting stimulation to his or her system. These movement behaviors provide the therapist with valuable information for treatment planning.

Fig. 10.11 Baby treatment must be dynamic and precisely oriented to individual needs.

VISUAL-MOTOR ASSESSMENT

The visual-motor aspect of performance function is the primary driver of movement in children 0 to 3 years of age. Vision provides motivation, spatial judgment, and orientation to self-body awareness with the external environment needed to control movement of the body in an upright alignment. The child with CP most often demonstrates significant neuromotor delay in the developmental process, which often results in an inadequate establishment of matching of inputs from the postural and visual systems. Visual-motor learning experiences are filled with compensatory responses from both systems. Vision plays an important role in early motor development for learning about, manipulating, and exploring the environment. Therefore vision requires attention during the assessment of motor abilities. (Refer to Chapter 28.)

The visual system in its development has many parallels with the postural system.^{48,49} Binocular control and freedom of movement is necessary for the system to function properly. Ambient visual processing must be integrated with central visual processing to take in information that relates to position in space and to focus on a particular target. A simple screening examination may check acuity at 20 feet on the E chart and declare vision to be normal. An ophthalmological examination is needed to determine the health of the eye structures, particularly in the case of infants born preterm. Equally important is a functional vision examination given by a behavioral or developmental optometrist to reveal the level of efficiency that the two eyes have achieved in working together and whether the ability to focus in far and near ranges is well established. Strabismus dysfunctions commonly coexist with CP and may cause the child to receive a double image of environmental objects. Judgments about space are related to a three-dimensional perception of the surrounding environment, which requires coordinated use of the two eyes. Conservative management of eye alignment problems is done with the use of lenses and prisms by the experienced optometrist, which permits the therapist to work for basic head control by the child before compensatory changes are made to the eye muscles. Eye movement differentiates from head movement in much the same way that the hand differentiates from general arm movement, corresponding to general maturation of the central system.

Because the visual system is first a motor system, children with CP most often have difficulty separating eye movement from head movement (referred to as dissociation) and controlled convergence for focal changes. When their posture is supported, eye movement can proceed to evolve in accuracy and complexity. With inadequate alignment of the head in relation to the base of support, the visual system accumulates distortions and inconsistent input, which leads to the formation of an inadequate perceptual base for later motor learning (see Chapters 3 and 28). Even after improvement in the control of posture and movement, the visual system may continue to adapt to the previous faulty visual-motor learning, resulting in perceptual confusion and inefficient organization of body movement in space. The therapist who is working for improved motor control may notice that such a child reacts with adequate postural adaptations when facing the therapist or a support (closed environment—more predictable) and that the movement quality seems to disintegrate when the child faces an open environment or space that is unpredictable.

This immediately jeopardizes the ability of the child to use her or his new responses after leaving the therapy environment. Visual orientation to the environment will dictate alignment against gravity, and the reverse is also true; poor alignment against gravity will affect visual orientation to the environment. An example of this would be the child that is unable to attain and maintain a midline orientation with the

head spontaneously. Over time the visual system will adapt to this faulty position and demonstrate great difficulty adjusting to the horizon while the head is in midline. There may be a drive to resort back to a head tilt that is perceived to be the “normal” alignment of the head and neck for visual orientation. Movement, postural stability, and muscle activation are all closely related to vision.^{50,51}

By incorporating an understanding of visual observations into intervention strategies, physical and occupational therapists are able to note compensatory adaptations by the complementary systems and to use them to their advantage in effective treatment intervention. Simple interventions may include visual tracking, dissociation of eye movement from the head maintained in midline, dissociation of the head with eyes focused on a fixed target, and visual location of targets in the environment as examples of exercises that could be integrated into a therapy session. The therapist should consider starting these exercises in a gravity eliminated position first to ensure success and then increase the difficulty by providing support against gravity. Progressing in difficulty as the child gains success. Understanding the nature of the continuing dynamic interaction between vision, perception, and motor systems and how to incorporate strategies in intervention to address those deficits improves the successful evolution of patients with CP.

POSTURE AND MOVEMENT COMPENSATIONS

Compensatory patterns of movement arise from the motivation of the child to move in spite of various restrictions on the expression of that movement. Components in the developmental process that drive a person to right the head with the horizon and the body upright against gravity are met with interference from the CNS. Visual impressions of the environment motivate movement, and the infant attempts to influence nearby objects or confirm visual impressions by reaching into the environment and touching. As visual awareness enlarges to include more distant targets, the infant is motivated to move toward the object or person seen. With poor balance between flexion and extension and poor grading of agonist with antagonist, the resultant movements are influenced. When the child’s body does not respond in a smooth way, the child begins to learn and perfect these uncoordinated attempts. Repetition of inadequate ranges of movement and limited variability of movement patterns begin to establish the atypical appearance of posture in the child with CP.

The characteristics of a body posture or position in space determines the quality of the movement that is expressed. Lack of head control, poor midline organization, and deficient trunk strength begin the process of compensation. From a distorted starting position, the movement initiated is one that is restricted (Fig. 10.12). The lack of “core” stability (trunk control) and the presence of abnormal muscle tone in the body restricts the full available joint range of a limb in attempts to move. This limitation over time is further restricted with developing fascial and muscular stiffness affecting smooth coordinated muscle action. The child continues to learn the atypical responses because the movement patterns tend to be reinforced by repetition as the child accomplishes some movement success during exploration. Compensatory movement patterns evolve out of necessity rather than any feedback as to efficiency or functional smoothness. A child that is motivated to move will do so in any way possible to reach their goal; therefore the development of atypical patterns of movement emerge.

Habitual movement patterns are established on the basis of frequency of use, so the child with CP tends to repeat the atypical responses that have been learned with few variations. In the therapy situation the child has the opportunity to learn new combinations of input to create the basis for more stable postural control. Careful

Fig. 10.12 Compensatory postures restrict movement initiation.

analysis of the postural adjustments and movement patterns of the child with CP is crucial to initiate effective intervention strategies.⁵² Keep in mind that patterns of movement are additionally influenced by positioning against gravity, head, neck, and trunk position, and the presence of primitive reflexes. Considering the classification of CP and other factors a therapist might be prioritizing when delivering intervention will influence the treatment options that will be most effective. Ultimately, providing more variability and increasing the number of choices a child has for movement also requires repetition for motor learning to occur. The availability of these new movements retrieved from long-term memory to working memory opens up “other” possibilities for the child when enough practice has been provided. There are many factors to be considered in the context of the continuing developmental changes in the child, which makes a simple solution impossible in the treatment of the child with CP. No two children with CP are alike, and each require an individual treatment plan and strategies that are tailored to that child.

Active therapy intervention allows the sensorimotor learning of the child to be modified so that some parts of the compensatory response may become unnecessary and the movement becomes more efficient (Fig. 10.13). This relative approximation of what is expected in a typical response may occur in the area of initiation, timing, strength, or ability to sustain an antigravity alignment. As movement expression and postural stability are better established, the compensatory patterns are used less often, and new movement strategies may begin to be an option for functional tasks. Compensatory processes have their positive aspects.⁵² The independence finally achieved by the older child reflects her or his intelligence and motivation, and the family’s attitude toward the child and the disability. Developing a positive self-image is a critical part to moving forward and is dependent in part on those that surround and support the child. Compensatory movement patterns may permit greater independence, if and when they do not limit or block the active learning of new motor strategies. Movement is influenced by multiple factors, which include motivation, family, environment, opportunities to practice, comorbidities, muscle stiffness, joint range of motion, medications, and emotional support to mention a few. The therapist will need to keep an open mind and a

keen awareness of the elements that can affect a child's response to treatment intervention.

OTHER ASSESSMENT CONSIDERATIONS

Nutritional Aspects of Neuromotor Function

Nutrition is viewed as providing an important biochemical base and foundation for enhanced human performance. It is not uncommon for children with CP to have feeding difficulties resulting in poor nutrition. Children with neurodevelopmental problems may present with difficulty managing food and liquids in their mouth, swallowing, and digestive issues. The more severely involved the child the higher the prevalence of feeding issues.^{53–55}

Poor nutrition effects energy levels, behavior, and physical and cognitive functioning. In the first 2 years of life patterns for sucking, managing food in the mouth, and control of the related structures (including head control) are developing.^{53,56} As the child grows and matures it is critical that they receive the essential nutrients. This can be problematic in someone that has difficulty isolating motor control over large and small muscles throughout their body. Gastroesophageal reflux is also common in infants and older children with developmental problems.⁵⁷

In some infants, reflux decreases or subsides as the muscular stress is reduced in the tissues of the neck, upper thoracic, and cervical region. Furthermore, allergies may also play a role in inadequate caloric intake. To supplement nutritional intake in the child with CP, the individual child must be considered with regard to age, size, activity level, and growth factors.^{58,59} The rehabilitative process places increased demands on the entire system and requires fuel to set the stage for improved muscle function.

Protein, carbohydrates, and adequate hydration are sources that build muscle and provide fuel, which provides a foundation for strengthening and the advancement of motor skills in populations without disability.^{55,58,60,61} A well-balanced diet will provide the requisite energy for exercise. Little research has been done specifically on children with CP; therefore appropriate levels of protein needed during exercise in this population of children are yet to be determined.

Studies investigating feeding issues in neurodevelopmental disabilities are beginning to emerge in the literature. These studies are exploring assessment tools to better evaluate the problems and potential interventions providing a better understanding for clinicians and families.⁵⁸ Therefore it is crucial to discuss these issues with the family using caution in treatment unless specifically trained to do so. A nutritional consultation is warranted when concerns arise in this area.

Consideration of Supplemental Oxygen

Oxygenation of the blood is responsible for the delivery of oxygen to muscle tissue. It is generally accepted that respiratory support increases incrementally to permit faster or stronger movement patterns in a typical individual. Therapists often note that children with CP resist moving into new ranges of movement and that respiratory adaptation does not occur automatically. Supporting the child in the novel posture until a respiratory adaptation is noted results in acceptance of the new experience. Oxygen needs increase in children during growth spurts or when mastering more vertical postural alignments. Increased oxygen is also required for sustained activity such as continuous walking. Incorporating breathing exercises into therapy interventions can help support the child's movement strategies. Children with developmental disabilities have few opportunities to exercise at an intensity level high enough to raise their heart rate. Monitoring oxygen saturation, heart rate, and blood pressure are easily done in a therapy session and can be tracked over time to document progress and to help guide the therapy intervention.

In 2016, Garcia and colleagues performed a careful study of 215 children with CP who were identified by chart review with signs and symptoms of obstructive sleep apnea (OSA) and surveyed with the Pediatric Sleep Questionnaire, for inclusion in the study. They found that children with CP were at a higher risk of OSA with increased severity of their condition, and the risk increased in the presence of seizure activity.⁶²

Decreased oxygen levels have been associated with impaired cognitive and physical performance in the literature.⁶³ In the presence of inadequate peripheral oxygen saturation, low levels of oxygen can be administered during the night. This practice has been used with selected low tone and athetoid children for improved energy during the day during growth changes, but formal study is needed on a larger group of children with CP. Better oxygenation of the tissues can also result in increased nutritional intake and consequently improved energy levels. The therapist should work closely with the primary care physician or pulmonary specialist if there are concerns in this area. It may be suggested that a child have a sleep study to determine oxygen saturation at night while sleeping.

ROLES OF THE THERAPIST

Role of the Therapist in Direct Intervention

The primary role of the therapist is in direct treatment or physical handling of the child in situations that offer opportunities for new motor learning. This should precede and accompany the making of recommendations to parents, teachers, and others handling the child. Positioning for home, general handling, and exercise recommendations should always be tried first by the therapist during a treatment session to ensure that the chosen techniques are successful. As noted for the initial assessment, many interventions will cause a reaction unique to the particular youngster.^{23,64} It is the role of the therapist to analyze the nature of the response that is accompanied by adaptation inadequacies, to analyze the movement problems, and to choose the most effective intervention (Fig. 10.14). It will then be possible for other
