Shuttle Walk Test. The shuttle walk test is a standardized incremental test during which walking is initiated at an audio-guided set pace for a prescribed length of time.²⁸⁰ Walking speed is increased at each stage until the subject can no longer maintain the required pace. Peak systemic responses have been reported to be consistent with those achieved during a progressive cycle test.²⁷⁵ A variation of this test, the endurance shuttle walk test, involves walking as far as possible at a constant speed determined in a previously performed progressive walk test.²⁸¹

Adherence to Program

The benefits of training are lost unless some form of training stimulus is maintained; therefore, sustained behavioral change must be an important goal in any exercise program. A decrease in mobility or inactivity can lead to rapid loss of cardiovascular and pulmonary fitness. For example, a 25% reduction in maximum oxygen uptake has been observed in nondisabled young adults after 3 weeks of bed rest.⁹⁴ In secondary prevention of stroke, behavioral modifications may be as beneficial as antihypertensive and cholesterol-lowering agents.⁷⁸ Yet establishing and maintaining a regular fitness regimen in patients with neurological impairments pose challenges. In one study, 39% of 691 patients did not engage in the exercise program created by their physical therapist.²⁸² In addition, 75% of people poststroke reported that they were not ready to incorporate exercise into their lifestyle.^{203,283}

Some individuals are reluctant to engage in exercise owing to the fear of increasing their symptoms. Indeed, people with Parkinson disease avoid exercise out of fear they will increase their already high levels of fatigue.²⁸⁴ Similarly, people with MS avoid exercising to avert increases in their level of fatigue and body temperature.⁹⁰ Furthermore, the frequency of MS-related symptoms has been found to be significantly and inversely related to physical activity.²⁸⁵ It has been shown that less than 30% of 2995 people with MS reported engaging in any form of exercise,²²⁸ with one study revealing an overall adherence rate of 65%.²⁸⁶ Morris and Williams²⁸⁷ reported that many individual factors (e.g., sex, level of disability), social factors, and environmental factors (e.g., access to facilities, travel) influence the level of engagement in exercise and physical activity in people with mixed disabilities. In addition, numerous psychological, cognitive, and emotional factors have been identified as potential mediators of engagement in physical activity (e.g., self-efficacy, attitude, competence, intention, knowledge of health and exercise

benefits, motivation, readiness to change, and the value of exercise benefits).²⁸⁸ One study involving people poststroke reported self-efficacy as an important psychological factor predicting engagement in exercise.²⁸⁹ Snook and colleagues²⁸⁵ reported that self-efficacy was significantly and moderately correlated with physical activity in people with MS.

A better understanding of theoretical frameworks of behavior change [see recent overview²⁹⁰] would be helpful for neurorehabilitation clinicians to increase participant engagement. Garner and Page²⁸³ exposed community-based, chronic stroke survivors to a theoretically based intervention using the transtheoretical model with five stages of change (i.e., precontemplation, contemplation, preparation, action, and maintenance). Change is mediated at each stage by self-efficacy, decisional balance, and processes of change.²⁹¹ In a study by Gillham and Endacott,²⁹² a stroke-specific score based on the transtheoretical model was used to assess readiness to change behavior in patients undergoing enhanced secondary stroke prevention. The authors found that the prevention program, which consisted of conventional rehabilitation plus additional advice, motivational interviewing, and telephone support, improved exercise frequency and increased consumption of fruits and vegetables when compared with the control group receiving conventional rehabilitation.²⁹² They also reported a nonsignificant trend of more patients in the enhanced group progressing from contemplation to action stages of change.²⁹² Several other behavioral theories (i.e., social cognitive theory, theory of reasoned action, theory of planned behavior, health belief model, protection motivation theory, and self-determination theory) may also be useful in facilitating long-term engagement.²⁹³ The American College of Sports Medicine (ACSM)²⁷ acknowledged that assessing the participants' self-motivation and readiness for change can provide important information toward adapting the exercise program to meet the specific needs of the participants.

In the cardiac rehabilitation literature, Piepoli and colleagues²⁹⁴ recommended that in order for an individual to pursue and engage in an exercise program, both physiological and psychosocial changes are needed. Progression from promotion of physical activity within the patient's current domestic, occupational, and leisure settings to participating in vigorous and structured exercise programs is recommended.²⁹⁴ In a systematic review also involving people with cardiac conditions, evidence supported the use of educational sessions, spousal and family involvement, flexible and convenient scheduling of sessions, ongoing positive reinforcement and enjoyment (e.g., motivational letters, pamphlets, conversations), and self-management aids (e.g., self-report diaries, activity logs, individualized goal setting).²⁹⁵ Other strategies to enhance long-term exercise adherence include gradually progressing the exercise intensity, establishing regularity of training sessions, minimizing the risk of muscular soreness, and exercising in groups. Training sessions should be scheduled at a convenient time and in an accessible location, and if feasible, assistance with transportation and childcare should be offered. With the established emphasis on patient-centered care, it is consistent to have

the patient identify individual goals and time frames to achieve these goals. Incorporating physical activity within everyday life will help to promote cardiovascular and pulmonary fitness as a life activity and not solely an exercise program conducted within a medical environment or rehabilitation setting.

Lifestyle Modifications

Aerobic training alone is not sufficient to optimize the health and fitness of people with neurological disabilities. Education and counseling regarding daily physical activity, nutrition, energy conservation techniques, smoking cessation, and coping strategies are essential.

CONCLUSION

Several conclusions can be made based on available evidence. Neuromuscular, cardiovascular, and pulmonary impairments associated with most neurological conditions interact with contextual factors and the health condition itself to adversely affect exercise capacity and cardiovascular fitness. Aerobic training is now unequivocally regarded as an effective intervention to reduce the functional decline associated with the deconditioned state. Research, albeit limited, suggests that although patients with neurological impairments generally manifest poor cardiopulmonary fitness, they have the capacity to respond to exercise training in essentially the same manner as individuals without impairments. Trainability is evidenced by their ability to increase exercise capacity or VO_2 peak in response to the metabolic stress imposed by aerobic exercise. Although not abundant, research findings also suggest that involvement in aerobic exercise can also improve walking capacity and reduce risk factors for secondary complications. On the basis of the positive results of training studies, more aggressive training programs are now being introduced into neurorehabilitation, with the goals of interrupting the cycle of debilitation and enhancing neurological recovery. There is an obvious need for further, properly controlled research to examine the impact of aerobic training on all domains of function and quality of life, especially in a population in which chronic impairments might be diminished and quality of future life improved. Patients with neurological insults clearly have compounding system variables that interact when they are trying to perform any movement. A clinician who is assisting individuals to regain functional control over movement to improve their quality of life cannot afford to ignore the cardiovascular and pulmonary system regardless of the medical diagnosis.

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 329 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

APPENDIX 30-A ■ Abbreviations Commonly Used When Discussing Cardiovascular and Pulmonary Problems and Their Effect on Function

6MWT: 6-Minute walk test

ADL: Activities of daily living

a-vO₂diff: Arteriovenous oxygen difference

a-vO₂diffmax: Maximal arteriovenous oxygen difference

BP: Blood pressure

CAD: Coronary artery disease

CO₂: Carbon dioxide

DBP: Diastolic blood pressure

ECG: Electrocardiogram

H⁺: Hydrogen ion

HR: Heart rate

HRmax: Maximal heart rate

HRpeak: Peak heart rate

HRR: Heart rate reserve

HRrest: Resting heart rate

ICF: International Classification of Functioning, Disability and Health

MET: Metabolic equivalent

O₂: Oxygen

Q: Cardiac output

Qmax: Maximal cardiac output

RER: Respiratory exchange ratio

RERpeak: Peak respiratory exchange ratio

RPE: Rate of perceived exertion

SPB: Systolic blood pressure

SV: Stroke volume

SVmax: Maximal stroke volume

VCO₂: Carbon dioxide production per minute

VO₂: Oxygen consumption per minute

VO₂max: Maximal oxygen consumption per minute

VO₂peak: Peak oxygen consumption per minute

Human Immunodeficiency Virus Infection: Living with a Chronic Illness

KERRI SOWERS, PT, DPT, MARY LOU GALANTINO, PT, PhD, MSCE, and
DAVID M. KIETRYS, PT, PhD, OCS

KEY TERMS

AIDS
human immunodeficiency virus (HIV)
psychoneuroimmunology

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Appreciate the role of the immune system in chronic HIV disease.
2. Discuss the neuropathological features of HIV infection and understand potential neurocognitive and neuropsychological alterations that may occur.
3. Understand the various systems (integumentary, musculoskeletal, cardiopulmonary, and neurological) that affect function in HIV-infected adult and pediatric patients.
4. Appreciate the role of psychoneuroimmunology in HIV rehabilitation management.
5. Establish safe exercise parameters in the HIV-positive population.

IDENTIFICATION OF THE CLINICAL PROBLEM

Initially recognized in 1982, acquired immunodeficiency syndrome (AIDS) has been one of the leading causes of death among young adults in the United States since that time. Even with significant advancements in the medical management of the disease, there continues to be a devastating impact in the developing world.^{1,2} The course of human immunodeficiency virus (HIV) disease in industrialized nations, including the United States, has changed dramatically as a result of advancements in medications used to treat the disease, as well as increased public awareness and the expansion of programs in poverty-stricken areas. Although the disease was once considered a death sentence, the long-term prognosis for those diagnosed with HIV/AIDS has drastically changed in most industrialized countries. In the United States, HIV is no longer found in the top 10 causes of death for the entire adult population. Yet, HIV is the seventh leading cause of death in young adults (age 20 to 24 years); for both older teens (ages 15 to 19 years) and young teens (ages 10 to 14 years), HIV is ranked fourteenth; for children (ages 5 to 9 years), HIV drops to nineteenth on the list.³ Although still alarming, this is actually an improvement compared with the 1990s. Most epidemiologists and clinicians attribute improved life expectancy to the impact of new, highly active antiretroviral therapies (HAART). Implementation of these medications has resulted in a decline in AIDS deaths nationally.^{4,5} However, the incidence of HIV disease, which demonstrated some decrease in the 1990s, demonstrated an increase from 1999 to 2006. HAART regimens have fostered longevity for many, resulting in the evolution of HIV infection into a chronic disease. Individuals previously disabled by the disease now have the potential to return to work and functional activities and often can expect to live a normal life expectancy. Despite these gains, HIV disease, related comorbidities, and the side effects of medications

used to treat the disease have a great impact on rehabilitative medicine because of the multisystem involvement, which often progresses slowly throughout the life span. The advancements in medications that have led to increased life expectancies and improved functional capabilities have also led to a greater demand for rehabilitative services.

HAART has slowed and prevented the progression from HIV infection to AIDS and from AIDS to death.⁶ In communities with access to antiretroviral medications, the incidence of perinatally acquired AIDS has declined significantly as a result of administration of HAART during pregnancy.⁷ Unfortunately, perinatal transmission of the virus in developing nations continues to be a crisis.

The clinical and pathological information about this disease is constantly increasing. Certainly, our understanding of the disease process and advances in drug regimens will change between the writing and the publication of this book. Changes in terminology reflect this evolution of clinical knowledge. The definitions used throughout this chapter reflect current usage.

The virus thought to be responsible for the transmission of AIDS was first identified in 1984; it was named *human immunodeficiency virus* in 1986 at the International Conference on AIDS in Paris. A second virus, HIV-2, was soon after identified in western Africa, and the original strain was renamed HIV-1. Infection caused by HIV-2, less widely distributed, has since been established in Europe and in South, Central, and North America. Both HIV-1 and HIV-2 have resulted in AIDS, but evidence suggests that HIV-2 may be less virulent than HIV-1. In addition to these subtypes, several strains or mutated forms of HIV-1 have been identified. Different strains reflect variations in cellular affinities and resistance to medications. The context of discussion for the purpose of this chapter will be HIV-1, herein discussed as *HIV*. HIV infection is identified via a positive HIV antibody screening test (enzyme immunoassay [EIA]) and confirmation with a

supplemental HIV antibody test (Western Blot) or a positive result from an HIV virological test (nucleic acid detection test, p24 antigen test, or viral culture).

In 2008 the Centers for Disease Control and Prevention (CDC) revised its definition of AIDS and its classification system of HIV disease. To reflect current scientific knowledge, the new system elucidates the importance of CD4⁺ T-lymphocyte cell counts as indicators for pharmacological disease management. Based on laboratory criteria and clinical presentation, the disease is classified into four stages. Stage 1 has no AIDS-defining condition and either a CD4⁺ T-lymphocyte count greater than or equal to 500 cells/mL or a ratio of CD4⁺ T-lymphocytes to total lymphocytes greater than or equal to 29%. Stage 2 also has no AIDS-defining condition and either a CD4⁺ T-lymphocyte count of 200 to 499 cells/mL or a ratio of CD4⁺ T-lymphocytes to total lymphocytes of 14% to 28%. Stage 3 is classified by the CDC as AIDS; it is defined as a CD4⁺ T-lymphocyte count less than 200 cells/mL or a ratio of CD4⁺ T-lymphocytes to total lymphocytes less than 14% or documentation of an AIDS-defining condition (Box 31-1). A fourth stage was also identified as HIV Infection, Stage Unknown (for cases in which no information is obtained regarding the CD4⁺ T-lymphocyte counts or ratios or regarding any AIDS-defining conditions); the primary use of this stage is for surveillance purposes.⁸ The entire spectrum of illness from initial diagnosis to AIDS can be covered by the term *HIV disease*. In addition, the terms *acute HIV infection*, *asymptomatic HIV disease*, *symptomatic HIV disease*, and *advanced HIV disease (AIDS)* are used throughout this chapter. In general, asymptomatic HIV disease corresponds with Stage 1, symptomatic HIV disease with Stage 2, and advanced HIV disease (AIDS) with Stage 3. Table 31-1 presents the various

modifiers of quality of life throughout the various stages of HIV disease.

Epidemiology

It is currently estimated that over 30 million people are infected with HIV globally. In the United States, the CDC estimated that 1.1 million adults and adolescents were HIV positive at the end of 2006. Because of complex social and economic factors, African Americans are disproportionately affected, with approximately half of the cases in the United States involving this minority group. Alarming, it is estimated that approximately 25% of individuals in the United States infected with HIV are unaware of the infection.⁹

In the most recent publication of the World Health Report from the World Health Organization (WHO), HIV/AIDS is the sixth leading cause of death worldwide, with an estimated 2.04 million deaths per year.¹⁰ Worldwide, of the 33 million people (all ages) living with HIV, 30.8 million are adults, 15.5 million are women, and 2.0 million are children (under the age of 15 years). New HIV infections in 2007 totaled 2.7 million, with 2.3 million in adults and 370,000 in children under 15 years old. Global AIDS deaths totaled nearly 2.0 million; adult deaths were 1.8 million, whereas children under age 15 years totaled 270,000.¹¹ It was estimated that in 2006 the United States had approximately 14,561 deaths from AIDS-related illnesses.⁹

Tuberculosis (TB) is a former leading microbial killer; it is caused by infectious bacteria that spread through the air in microscopic droplets. WHO estimates that there were 9.27 million new TB cases in 2007; of those, 1.37 million cases (14.8%) were in HIV-positive individuals. Approximately 456,000 deaths caused by TB occurred in HIV-infected individuals (23% of the estimated 2 million HIV deaths were caused by TB).¹²

BOX 31-1 ■ AIDS-DEFINING CONDITIONS

Bacterial infections, multiple or recurrent*
 Candidiasis of bronchi, trachea, or lungs
 Candidiasis of esophagus[†]
 Cervical cancer, invasive[‡]
 Coccidioidomycosis, disseminated or extrapulmonary
 Cryptococcosis, extrapulmonary
 Cryptosporidiosis, chronic intestinal (>1 month's duration)
 Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 month
 Cytomegalovirus retinitis (with loss of vision)[†]
 Encephalopathy, HIV related
 Herpes simplex: chronic ulcers (>1 month's duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 month)
 Histoplasmosis, disseminated or extrapulmonary
 Isosporiasis, chronic intestinal (>1 month's duration)
 Kaposi sarcoma[†]

Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex*[†]
 Lymphoma, Burkitt (or equivalent term)
 Lymphoma, immunoblastic (or equivalent term)
 Lymphoma, primary, of brain
Mycobacterium avium complex or *Mycobacterium kansasii*, disseminated or extrapulmonary[†]
Mycobacterium tuberculosis of any site, pulmonary,^{†‡} disseminated,[†] or extrapulmonary[†]
Mycobacterium, other species or unidentified species, disseminated[†] or extrapulmonary[†]
Pneumocystis jiroveci pneumonia[†]
 Pneumonia, recurrent[†]
 Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
 Toxoplasmosis of brain, onset at age >1 month[†]
 Wasting syndrome attributed to HIV

*Only in children aged younger than 13 years.

[†]Condition that might be diagnosed presumptively.

[‡]Only in adults and adolescents aged 13 years or older.

Normal Immunity

The immune system is complex and dynamic, comprising a multitude of components and subsystems, all of which interact continuously. The normal immune system has two main components, or lines of defense, against illness (Figure 31-1). The first is the innate, or inborn, component, which includes the skin, the cilia and mucosal linings of the respiratory and digestive systems, the gastric fluids and enzymes of the

stomach, and the phagocyte cells. This innate component of the immune system keeps pathogens out of the body by creating barriers against them, by ejecting them, or by enveloping them and eliminating them. The second, the acquired component of the immune system develops defenses against specific pathogens, starts in utero, and continues throughout life. It is acquired (or antibody) immunity that is most pertinent to understanding HIV infection and its progression.

TABLE 31-1 ■ QUALITY-OF-LIFE ISSUES FOR HIV DISEASE STAGES

STAGE	CD4 ⁺ COUNT	PHYSICAL INDICATORS	MODERATORS OF QUALITY OF LIFE	GENERAL QUALITY-OF-LIFE ISSUES
<i>Stage 1:</i> <i>Asymptomatic</i> Disease, HIV infection	>500 cells/mcL	May have persistent generalized lymphadenopathy	Appraisals: Anticipatory grieving, catastrophizing, and other cognitive distortions; changed expectations of future; identity and self-esteem issues Coping: Dealing with present and future uncertainties; at risk for denial, disengagement, substance abuse, risky sex, suicide; issues of eliciting social support	Emotional functioning: Anxiety, anger, often increasing at diagnosis and diminishing and recycling as individual confronts realities of living with HIV disease Role functioning: Often able to work; possible decrements in job mobility and career opportunities; job loss Social functioning: Fear, isolation, issues of trust in relationships; stigmatization; changes in social support networks because of deaths; relationship and sexual changes; isolation, withdrawal Physical functioning: Normal but may be altered because of depression or anxiety; may have hypervigilance regarding all physical symptoms Spiritual functioning: Opportunity to direct attention inward, thus yielding to contemplation of life’s meaning, reassessment of spiritual and existential issues
<i>Stage 2:</i> <i>Symptomatic</i> Disease, HIV infection	201-499 cells/mcL	Emergence of symptoms such as thrush, night sweats, low-grade fevers, oral hairy leukoplakia, peripheral neuropathy; commonly taking antiretroviral drugs and/or <i>Pneumo-</i> <i>cystis jiroveci</i> prophylaxis	Appraisals: Anticipatory grieving, catastrophizing, and other cognitive dis- tortions; changed expec- tations of future; identity and self-esteem issues related to threats to occupational and functional abilities Coping: Dealing with present and future uncer- tainties; at risk for denial, disengagement, substance abuse, and risky sex	Emotional functioning: Anxiety, anger, often increasing on emergence of symptoms and then fluctuating with challenges and threats to present and future functioning Role functioning: Often able to work; may take on new roles as part of HIV support-related network Social functioning: Changes in social support networks resulting from deaths, isolation, withdrawal, relationship and sexual changes, and stigmatization Physical functioning: May have reduced energy levels; moderate symptomatology; possible cognitive deficits; pain; wasting Spiritual functioning: Anticipatory grieving, sense of relatedness to something greater than the self, unavoidable confrontation with one’s own mortality

TABLE 31-1 ■ QUALITY-OF-LIFE ISSUES FOR HIV DISEASE STAGES—cont'd

STAGE	CD4 ⁺ COUNT	PHYSICAL INDICATORS	MODERATORS OF QUALITY OF LIFE	GENERAL QUALITY-OF-LIFE ISSUES
Stage 3: AIDS Disease	<200 cells/mcL	Opportunistic infections such as extensive candidiasis, cryptococcal meningitis; Kaposi sarcoma; tuberculosis; <i>P. jiroveci</i> pneumonia; lymphomas; commonly taking antiretroviral drugs, chemotherapy, antibiotics, and so on	Appraisals: Facing chronic illness and death; grieving about current and anticipated losses; catastrophizing and other cognitive distortions; reassessment of spiritual and existential issues Coping: Coping strategies may be overwhelmed in dealing with current difficulties such as financial losses, medical costs, treatment and side effects, housing; may lose some traditional coping strategies such as recreational outlets	Emotional functioning: Anxiety, anger may cycle according to fluctuations in disease status and appraisals; relief from uncertainty Role functioning: Diminished capacity for work; role changes—often need care instead of being a caretaker Social functioning: May have diminished social networks because of lack of mobility, illness, and deaths among friends Physical functioning: Self-care difficulties; fatigue; wasting; much time spent in medical care; debilitation from infection and treatments; possible cognitive deficits Spiritual functioning: Essential worth is to provide a framework from which to pose and seek responses to metaphysical questions generated by presence of life-threatening disease; integration and transcending of biological and psychosocial nature, which gives access to nonphysical realms as prophecy, love, artistic inspiration, completion, and healing actions

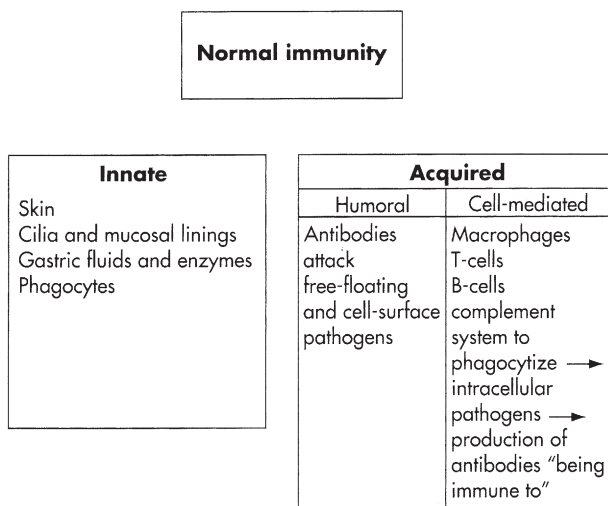

Figure 31-1 ■ Main components of immunity.

Acquired Immunity

Acquired immunity is divided into humoral and cell-mediated responses. Humoral immunity depends on the production of antibodies. This response is effective for disposing of free-floating or cell-surface pathogens. The cell-mediated response is required to destroy infected cells, those with intracellular

pathogens. Cell-mediated immunity is essential for destroying pathogens responsible for the opportunistic infections and neoplasms that are associated with AIDS.^{13,14}

For the study of HIV pathology, it is important to consider three types of immune system cells: macrophages, T lymphocytes (T cells), and B lymphocytes (B cells). Macrophages originate in the bone marrow and then migrate to the organs in the lymphatic system. Macrophages recognize and then phagocytize antigens—substances deemed foreign to the body. All but a fragment of the antigen is digested by the macrophage. This remaining fragment protrudes from the cellular surface, where it is then recognized by T and B cells, allowing those cells to develop an appropriate immune response.¹⁵

Both of the lymphocytes (T and B cells) originate in the bone marrow. Their differentiation into T and B cells depends on where they develop immunocompetence. Immunocompetence is the ability of the immune system to mobilize in response to an antigen; it can be weakened secondary to age-related changes, radiation therapy, chemotherapy, or viral infections. T cells migrate to the thymus to develop this ability. B cells develop it before leaving the bone marrow. T cells travel to lymph nodes, the spleen, and connective tissues, where they wait to phagocytize the antigens in the manner previously described. B cells function in the same way against free-floating blood-borne pathogens.¹⁵

There are at least eight types of T cells with various functions. Two relevant types are helper T cells (CD4) and suppressor T cells (CD8). The helper T cells enhance the immune response, whereas suppressor T cells regulate the immune response. HIV primarily attacks these two types of T cells, impairing the body's immune response. On recognition of an antigen, CD4 cells chemically stimulate production and activation of other lymphocytes to destroy the foreign material. When the action of the T and B cells is a sufficient immune response, the CD8 cells will halt the action, thus preventing the destruction of normal (uninfected) cells. The HIV virus causes the destruction of the CD4 cells. Declining CD4 cell counts occur in untreated disease; in healthy (uninfected) individuals, CD4 counts should be 500 to 1600 cells/mL. However, because T-cell counts fluctuate somewhat under normal circumstances, the ratio of CD4 to CD8 cells is considered a valuable laboratory value in tracking the progression of the disease.

In the process of identifying and destroying antigens, the acquired immune system retains a memory of the antigen. This allows the immune system to respond more rapidly and effectively to the pathogen if it is reintroduced into the body. Herein lies the pertinence of vaccination and the phenomenon of being immune to an illness.¹⁵

PATHOGENESIS OF HIV DISEASE

HIV belongs to a class of viruses known as *retroviruses*, which carry their genetic material in the form of ribonucleic acid (RNA) rather than deoxyribonucleic acid (DNA). HIV primarily infects the mononuclear cells, especially CD4 and macrophages, but B cells are also infected.¹⁶ HIV binds to the receptor sites on the surface of the CD4 lymphocytes, eventually fusing with and then entering the cells. Reverse transcriptase released from the HIV allows a DNA copy of the virus to be made within the host cell, which then becomes integrated into the host cell genome. Other enzymes, such as integrase and protease, turn the lymphocyte into a “virus factory,” and replicated virions bud out of the cell to infect others.

Within days of acute HIV infection, lymph nodes become sites of rampant viral replication, and viral loads in the blood are high. During the stage of acute HIV infection, the individual may remain asymptomatic or may experience nonspecific and self-limited flulike symptoms—fever, diarrhea, myalgias, and fatigue—for a period of 2 to 12 weeks. In the weeks after an acute infection, the body gradually produces an antibody response. The point at which antibodies can be detected with a blood test is known as *seroconversion*. Typically, seroconversion occurs within 3 months of the time of infection, but it can take as long as 12 months. Thus there is a period of time after HIV infection when the result of an HIV antibody test (the most commonly used test to determine HIV status) will be negative.

In asymptomatic HIV disease or Stage 1, individuals will have a positive antibody test result. This stage may last from 1 to 20 years. Although generally asymptomatic, individuals in this stage may express periods of generalized lymphadenopathy. Laboratory tests may reveal slowly declining immune dysfunction, as evidenced by an abnormally low CD4 cell count and an abnormal CD4/CD8 ratio. The viral load is typically at a “set point” during most of the asymptomatic stage of HIV disease. This set point is typically much lower

than the viral load occurring during the period of acute infection. The viral load will inevitably escalate as the disease progresses.

As CD4 cell counts decline and viral load escalates, the individual will eventually enter Stage 2, or symptomatic HIV disease. With the continuing advancements in medications, this stage may last several years. Improved effectiveness of medications, increasing access to health care services, and medical comorbidities all have a large influence on the length of time a patient is considered to be in Stage 2. CD4 cell counts are declining and viral loads are increasing. Concurrently with these laboratory value abnormalities, the individual begins to have one or more of an array of symptoms such as weight loss, fatigue, night sweats, fever, thrush, yeast infections, prolonged recovery from other illnesses, or neurological complications.

When the CD4 cell count drops below 200 cells/mL, the individual is diagnosed with an opportunistic infection or other AIDS-defining illness, or the individual demonstrates wasting syndrome or HIV-related dementia, he or she is reclassified as being in Stage 3—advanced HIV disease or AIDS. It is possible for patients in this stage to demonstrate remarkable recovery in terms of both laboratory values and function with HAART. Individuals who do not have access to HAART, or individuals in whom HAART has failed, will eventually die as a result of the effects of opportunistic infections that inevitably occur. Quality-of-life issues throughout the stages of HIV disease are described in [Table 31-1](#).

Medical Management

Cell Counts and Prophylaxis

Pharmacological interventions to combat the opportunistic infections associated with HIV infection are beyond the scope of this chapter, but a simplified summary of clinical information is pertinent. Medical management of HIV infection is most often guided by the CD4 cell count and viral load.

For the healthy HIV-negative adult, the average CD4 cell count is approximately 1000 cells/mL. However, counts fluctuate over time and may range from 500 to 1600 cells/mL.¹⁷ A CD4 cell count of 200 cells/mL marks a critical point in the course of HIV infection, often indicating that the stage of advanced HIV infection or AIDS has been reached. Serious opportunistic infections are likely to occur once this level of immune depletion has been attained.¹⁸⁻²⁰

Exercise, stress, seasons of the year, serum cortisol level, and the presence of acute or chronic illness and infection have all been reported to affect CD4 cell counts. Thus the initial CD4 lymphocyte numbers should be confirmed by repeat testing. Caution should be exercised to avoid overinterpreting small changes in CD4 lymphocyte test results. The overall trend of CD4 counts is more important than any single value. Testing is typically done at a frequency of four times annually. In addition to CD4 cell counts, CD4/CD8 ratios are used to evaluate the status of the immune system. CD4 counts above 500 cells/mL indicate no need for antiretroviral therapy because individuals are generally asymptomatic. It is currently recommended that HAART be initiated when CD4 levels are below 350 cells/mL, with individual parameters influencing the decision.²¹ CD4 cell counts below 200 cells/mL are an indication for prophylactic

Pneumocystis jirovecii (previously referred to in the literature as *Pneumocystis carinii*; this text will refer to the current terminology) pneumonia (PCP) and toxoplasmosis measures. Persons with counts below 100 cells/mcL may also receive prophylactic agents against cytomegalovirus (CMV) infection, infection with *Mycobacterium avium* complex (MAC), and fungal infections such as cryptococcosis and

candidiasis.¹³ In addition, it is recommended that HIV-positive pregnant women, those with HIV-associated nephropathy, and those co-infected with the hepatitis B virus be started on a HAART regimen immediately.²² Table 31-2 is a summary of common pharmacological agents prescribed to combat opportunistic infections and, most pertinent to rehabilitation, their potential side effects.

TABLE 31-2 ■ HIV DRUGS BY CLASS

BRAND NAME	GENERIC NAME	DOSE	SIDE EFFECTS	FDA APPROVAL	COMMENTS
NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NRTIs)					
Combivir	Zidovudine and lamivudine	One tablet twice a day Contains two NRTIs in one tablet	Similar side effects to Retrovir (zidovudine) and Epivir (lamivudine). Please note Retrovir's and Epivir's Black Box warnings.	September 27, 2007	Take with or without food.
Emtriva	Emtricitabine	One 200-mg capsule once a day	Black Box warning: Buildup of acid in the blood; fatty liver; should be used carefully by people with hepatitis B. Otherwise, minimal side effects.	July 2, 2003	Take with or without food.
Epivir	Lamivudine	One 300-mg tablet once a day or one 150-mg tablet twice a day	Black Box warning: Buildup of acid in the blood; fatty liver; should be used carefully by people with hepatitis B. Otherwise, minimal side effects.	November 17, 1995	Take with or without food. Approved for treatment of hepatitis B virus infection at a lower dose. Individuals with both viruses should use the higher dose.
Epzicom (Kivexa in some countries)	Abacavir and lamivudine	One tablet once a day Contains two NRTIs in one tablet	Similar side effects to Epivir (lamivudine) and Ziagen (abacavir). Please note Epivir's and Ziagen's Black Box warnings.	August 2, 2004	Take with or without food. Need to be tested for the HLA-B*5701 gene to reduce the risk of a severe allergic reaction.
Retrovir	Zidovudine	One 300-mg tablet twice a day	Black Box warning: Anemia and decrease in white blood cells; damage to muscle; buildup of acid in the blood; fatty liver. Nausea, stomach discomfort, headache, insomnia, and weakness.	March 19, 1987	Take with food to minimize stomach discomfort. Do not take with Zerit.
Trizivir	Abacavir, zidovudine, and lamivudine	One tablet twice a day Contains three NRTIs in one tablet	Similar side effects to Retrovir (zidovudine), Epivir (lamivudine), and Ziagen (abacavir). Please note Retrovir's, Epivir's, and Ziagen's Black Box warnings.	November 14, 2000	Take with or without food. Need to be tested for the HLA-B*5701 gene to reduce the risk of a severe allergic reaction.

TABLE 31-2 ■ HIV DRUGS BY CLASS—cont'd

BRAND NAME	GENERIC NAME	DOSE	SIDE EFFECTS	FDA APPROVAL	COMMENTS
Truvada	Tenofovir and emtricitabine	One tablet twice a day Contains two NRTIs in one tablet	Similar side effects to Viread (tenofovir) and Emtriva (emtricitabine). Please note Viread's and Emtriva's Black Box warnings.	August 2, 2004	Take with or without food.
Videx EC (generic is now available in the United States)	Didanosine	One 400-mg capsule once a day or one 250-mg capsule once a day if <132 lb	Black Box warning: Damage to the pancreas (pancreatitis); buildup of acid in the blood; fatty liver. Numbness, tingling, or pain in the hands or feet (peripheral neuropathy); nausea; diarrhea.	October 31, 2000	Take on an empty stomach. Can be taken at the same time as other HIV medications except for the protease inhibitors (PIs) Aptivus, Prezista, and Reyataz. Avoid alcohol.
Viread	Tenofovir	One 300-mg tablet once a day	Black Box warning: Buildup of acid in the blood; fatty liver; should be used carefully by people with hepatitis B. Weakness, headache, nausea, vomiting, diarrhea, flatulence (intestinal gas), and kidney problems.	October 26, 2001	Take with or without food. Approved for treatment of the hepatitis B virus. Can raise Videx EC level in the blood and increase side effects.
Zerit	Stavudine	One 40-mg capsule twice a day or one 30-mg capsule if <132 lb	Black Box warning: Buildup of acid in the blood (has been fatal in pregnant women when combined with Videx/Videx EC); fatty liver; damage to the pancreas (when combined with Videx/Videx EC). Numbness, tingling, or pain in the hands or feet (peripheral neuropathy); lipodystrophy; muscular weakness (rare); increased cholesterol and increased triglycerides.	June 24, 1994	Take with or without food. Do not take with Retrovir or Combivir.
Ziagen	Abacavir	One or two 300-mg tablets once a day	Black Box warning: Severe allergic reactions (symptoms include fever; rash; severe nausea, diarrhea, abdominal pain; sore throat; cough; and shortness of breath); buildup of acid in the blood; fatty liver.	December 17, 1998	Take with or without food. Need to be tested for the HLA-B*5701 gene to reduce the risk of a severe allergic reaction.

TABLE 31-2 ■ HIV DRUGS BY CLASS—cont'd

BRAND NAME	GENERIC NAME	DOSE	SIDE EFFECTS	FDA APPROVAL	COMMENTS
NONNUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NNRTIs)					
Rescriptor	Delavirdine	Two 200-mg tablets twice a day	Rash, increased liver enzymes, and headaches.	April 4, 1997	Take with or without food. May need to reduce the dose of any PIs being taken at the same time.
Sustiva (also known as Stocrin)	Efavirenz	One 600-mg tablet once a day.	Rash; central nervous system symptoms, such as drowsiness, insomnia, confusion, inability to concentrate, dizziness, and vivid dreams; increased liver enzymes; false-positive drug testing (marijuana); and birth defects if taken during pregnancy.	September 17, 1998	Take on an empty stomach at bedtime to reduce side effects. The dosage of some PIs may need to be increased or boosted with Norvir.
Intelence	Etravirine	Two 100-mg tablets twice a day.	Rash, nausea.	June 18, 2008	Take with food. May not be combined with certain Norvir boosted PIs, but other PIs must be boosted with Norvir; Do not use with other NNRTIs.
Viramune	Nevirapine	One 200-mg tablet once a day for 14 days, then one 200-mg tablet twice a day.	Black Box warning: Severe, life-threatening liver problems, notably among women with T-cell counts >250; severe skin reactions; careful dosing and monitoring needed at start of treatment.	June 21, 1996	Take with or without food. Dosage of certain PIs may need to be increased or boosted with Norvir. Do not use with Reyataz.
Atripla	Efavirenz, tenofovir, and emtricitabine	One tablet once a day. Contains two nucleoside reverse transcriptase inhibitors (NRTIs) and one NNRTI in one tablet.	Similar side effects to Sustiva (efavirenz), Viread (tenofovir), and Emtriva (emtricitabine). Please note Viread's and Emtriva's Black Box warnings.	August 2, 2004	Can be used with or without other HIV medications. Take on an empty stomach at bedtime to reduce side effects.
PROTEASE INHIBITORS (PIs)					
Aptivus	Tipranavir	Two 250-mg capsules plus two 100-mg Norvir capsules twice a day.	Black Box warning: Bleeding in the brain; hepatitis (extra care needed for HIV-positive people with hepatitis B or C). Rash, increased cholesterol, increased triglycerides, lipodystrophy, increased bleeding in patients with hemophilia.	June 22, 2005	Take with food. Approved only for treatment-experienced patients. Do not take with other PIs except for Norvir.

TABLE 31-2 ■ HIV DRUGS BY CLASS—cont'd

BRAND NAME	GENERIC NAME	DOSE	SIDE EFFECTS	FDA APPROVAL	COMMENTS
Crixivan	Indinavir	Two 400-mg capsules twice a day; preferred regimen is two 400-mg capsules twice a day plus one or two 100-mg Norvir capsules twice a day.	Kidney stones, nausea, vomiting, diarrhea, increased cholesterol, increased triglycerides, increased glucose (sugar), lipodystrophy, increased bilirubin (not harmful), increased bleeding in patients with hemophilia. Others: headache, weakness, blurred vision, dizziness, rash, metallic taste, low platelets, hair loss, anemia.	March 13, 1996	Take on an empty stomach or with a light, low-fat snack. If taking the preferred dose, take with or without food. Drink six glasses of water each day to prevent kidney stones.
Invirase	Saquinavir	Two 500-mg capsules plus one 100-mg Norvir capsule twice a day.	Nausea, diarrhea, stomach discomfort, headache, increased cholesterol, increased triglycerides, lipodystrophy, increased glucose (sugar), increased liver enzyme levels, and increased bleeding in patients with hemophilia.	December 6, 1995	Must be used with Norvir. Take with food.
Kaletra (also known as Aluvia)	Lopinavir and ritonavir	Two tablets twice a day or four tablets once a day. Contains two PIs in one tablet.	Nausea, diarrhea, stomach discomfort, headache, increased cholesterol, increased triglycerides, lipodystrophy, increased glucose (sugar), increased liver enzyme levels, and increased bleeding in patients with hemophilia.	September 15, 2000	Take with or without food. Must be taken twice a day and dose may need to be increased if taken with certain other medications.
Lexiva (also known as Telzir)	Fosamprenavir	Two 700-mg tablets twice a day or two 700-mg tablets plus one 100-mg Norvir capsule once or twice a day.	Skin rash, nausea, diarrhea, stomach discomfort, headache, increased cholesterol, increased triglycerides, lipodystrophy, increased glucose (sugar), increased liver enzyme levels, and increased bleeding in patients with hemophilia.	October 20, 2003	Take with or without food. If other PIs have been taken in the past, only take the twice-a-day, Norvir boosted combination.

Continued

TABLE 31-2 ■ HIV DRUGS BY CLASS—cont'd

BRAND NAME	GENERIC NAME	DOSE	SIDE EFFECTS	FDA APPROVAL	COMMENTS
Norvir	Ritonavir	Six 100-mg capsules twice a day.	Nausea, vomiting, diarrhea, appetite loss, numbness or tingling around the mouth, increased cholesterol, increased triglycerides, lipodystrophy, and diabetes.	March 1, 1996	The full dose is rarely used. It is most often used to boost the levels of other PIs in the blood. Needs refrigeration in hot weather.
Prezista	Darunavir	Two 400-mg tablets plus one 100-mg Norvir capsule once a day (for those starting HIV medication) or one 600-mg tablet plus one 100-mg Norvir capsule twice a day.	Nausea, diarrhea, stomach discomfort, headache, increased cholesterol levels, increased triglycerides, lipodystrophy, increased glucose (sugar), increased liver enzyme levels, inflammation of the nose and throat, and increased bleeding in patients with hemophilia.	June 23, 2006	Take with food. Must be used with Norvir.
Reyataz	Atazanavir	Two 200-mg capsules once a day or one 300-mg capsule plus one 100-mg Norvir capsule once a day.	Increased bilirubin (not harmful), abnormal electrocardiogram results, increased glucose (sugar), lipodystrophy, and increased bleeding in patients with hemophilia.	June 20, 2003	Take with food. Do not combine with Viramune. Regimen may vary depending on other medications being taken.
Viracept	Nelfinavir	Two 625-mg tablets twice a day or five 250-mg tablets twice a day or three 250-mg tablets three times a day.	Diarrhea, increased cholesterol, increased triglycerides, lipodystrophy, increased glucose (sugar), increased liver enzyme levels, increased bleeding in patients with hemophilia, increased liver enzymes.	March 14, 1997	Take with food. Can be dissolved in water (if trouble swallowing pill form).
Agenerase	Amprenavir	Twenty-four 50-mg capsules twice a day (to be combined with other HIV medications).	Nausea, vomiting, diarrhea or loose stools, taste disorders, tingling feeling (especially around the mouth), depression and mood problems, changes in body fat, high blood sugar or diabetes, diabetes complications, increased cholesterol, or increased triglycerides, severe or life-threatening rash.	April 15, 1999	Take with or without food. High fat meals will decrease the absorption of the medication. Do not take additional vitamin E. May need to adjust the dosage when taken with other HIV medications.

TABLE 31-2 ■ HIV DRUGS BY CLASS—cont'd

BRAND NAME	GENERIC NAME	DOSE	SIDE EFFECTS	FDA APPROVAL	COMMENTS
INTEGRASE INHIBITORS (INIs)					
Isentress	Raltegravir	One 400-mg tablet twice a day.	Diarrhea, nausea, and headache. In clinical trials, blood tests showed abnormally elevated levels of a muscle enzyme—creatine kinase—in some patients receiving Isentress. Isentress should be used with caution by patients who are at increased risk for muscle problems such as myopathy and rhabdomyolysis, which includes patients using other medications known to cause these conditions.	October 12, 2007	Take with or without food.
FUSION					
Fuzeon	Enfuvirtide	One 90-mg injection twice a day.	Skin reactions where Fuzeon is injected can include itching, swelling, redness, pain or tenderness, hardened skin, or bumps; increased risk of bacterial pneumonia; serious allergic reaction (rare).	March 13, 2003	Comes as a powder that must be mixed with sterile water in a vial before use.
RECEPTOR SITE/ENTRY INHIBITOR					
Selzentry (also known as Celsentri)	Maraviroc	One 150-mg tablet or one 300-mg tablet or two 300-mg tablets twice a day. Reacts with many other HIV medications, which will affect the regimen.	Cough, fever, colds, rash, muscle and joint pain, stomach pain, and dizziness. Less common side effects include cardiovascular problems and liver toxicity. Because Selzentry blocks the CCR5 co-receptor located on some immune system cells, there is a theoretical risk of developing infections and cancers.	August 6, 2007	Take with or without food. Effective only against CCR5-tropic HIV.

FDA, U.S. Food and Drug Administration.

Viral Load Measurement

Testing for the amount of HIV in plasma by measuring viral RNA has become a standard component of the management of HIV-infected patients.²³ There are important prognostic implications for the amount of viral load in persons with HIV disease.²⁴ In patients with higher viral loads, disease progression is more rapid, both immunologically, in terms of the rate of CD4 cell count decline, and clinically, in terms

of development of AIDS-defining illness. In addition, the plasma levels in HIV-positive pregnant women directly correlate with the risk of perinatal transmission.²⁵ Viral load is an important useful marker for judging the effectiveness of various antiretroviral drug interventions.^{26,27}

There are several assays available for testing HIV for resistance to antiretroviral agents. Genotype or phenotype testing is used to determine whether the virus has mutated.

The results of genotype or phenotype testing provide important information about resistance to specific antiretroviral drugs. If a mutant form is resistant to a particular antiretroviral drug, the HAART regimen may be altered so that the potential for viral suppression is maximized. Changes in the drug combinations used for HAART to respond to viral resistance are referred to as *salvage therapy*. Like genotypic testing, phenotypic testing may not detect small subpopulations of resistant HIV.²⁸

Researchers continue to work on developing effective HAART components and vaccines. The primary goal of antiretroviral therapy is to achieve prolonged suppression of HIV replication.^{23,29} At this time, there are six classes of HIV medications. Two classes of drugs, receptor site inhibitors and fusion inhibitors (FIs), work to prevent HIV from successfully entering the cell. CCR5 inhibitors (CIs) include maraviroc (Selzentry), a CCR5 co-receptor antagonist (receptor site inhibitor). Receptor site inhibitors are the most recently approved class of drugs. FIs such as enfuvirtide (Fuzeon) or T-20 act outside the T cells by blocking the entry of HIV into the cell. T-20 is often used as part of salvage therapy; it is a twice-daily injectable drug with a cost of more than \$25,000 per year.

The four other classes of drugs work within the cell by interfering with one of three enzymes that are involved with the replication process: reverse transcriptase, integrase, and protease. These classes include nucleoside reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), integrase inhibitors (INIs), and protease inhibitors (PIs). In 1987, zidovudine (AZT), an NRTI, was first approved by the U.S. Food and Drug Administration. Since that time, several more NRTI drugs have been approved.³⁰ Other drugs, such as nevirapine and efavirenz, also inhibit the reverse transcriptase enzyme, but they are not nucleoside analogs. These NNRTIs bind to the enzymatic binding pocket of the reverse transcriptase gene and block binding by the nucleosides.³¹ Like reverse transcriptase, integrase is an enzyme that is active in the early stages of the replication process, and INIs can be used to interrupt its function by preventing the integration of the virus in the host cell's DNA.³² INIs, such as elvitegravir or raltegravir (Isentress), are one of the most recently approved classes of drugs. Another drug target for anti-HIV agents is the protease enzyme. The PI drugs are structurally different from other drugs and include agents such as ritonavir, indinavir, nelfinavir, and saquinavir.³³

HAART may be NNRTI or PI based (i.e., NNRTI and PI drugs are used in combination with an NRTI such as AZT). There has been a gradual evolution of pharmacology that has allowed for multiple drugs to be combined into one pill. Thus the number of pills required per day as well as the administration schedule have become increasingly more manageable over recent years. However, drugs from different classes (NRTI, NNRTI, and PI) are typically included in HAART. The current recommendation from the Department of Health and Human Services for a treatment-naïve patient is either one NNRTI and two NRTIs or a PI (boosted with ritonavir) and two NRTIs.²² Because of the rapidly evolving nature of HAART, the reader is advised to consult with the CDC for the most current clinical practice guidelines.

Side effects and toxicities are common with drugs used to treat HIV disease. Purported side effects of NRTIs

include peripheral neuropathy, myopathy, anemia, gastrointestinal (GI) disturbances, hepatomegaly, and pancreatitis. NNRTIs may cause rash, liver dysfunction, cognitive problems, and lactic acidosis. PIs may cause lipodystrophy, peripheral neuropathy, GI intolerance, hyperlipidemia, hyperglycemia, and liver toxicity. Injection site reactions are common with T-20. This list of side effects is cursory, and the full impact of these and other HIV drugs on the various systems of the body is a continually emerging area. Occasionally an individual's HAART regimen is modified to mitigate the side effects that may occur with specific drugs.

Current medication regimens can significantly reduce the HIV level not only in the peripheral blood but also in the lymphoid tissue and the central nervous system (CNS).³⁴ The goal of HAART is to reduce HIV viral load to undetectable levels in serum. The greatest challenge with HAART is resistance to one drug in a class of agents, which may induce partial or complete resistance with other agents, depending on the specific mutations involved.^{28,35} In a field that is rapidly changing, specific recommendations for antiretroviral therapy are best made by an infectious disease specialist with experience in the management of patients with HIV disease. The major therapeutic decisions include (1) when to initiate therapy, (2) what drugs to prescribe, (3) when to change therapy, and (4) which drugs to change to. When PIs were introduced as a complement to already existing NRTI and NNRTI drugs, the mortality rate of HIV-infected patients and the incidence of opportunistic infections decreased, most likely as a result of the increased use of combination HAART.³⁶ The role of drugs with immunomodulating activity in combination with HAART is also undergoing extensive research.^{37,38} Drug regimens for HIV disease are dynamic, and clinical practice guidelines are consistently updated; many changes in the approach to drug interventions can be expected as HIV infection continues to be a chronic disease.³⁹

Vaccines

HIV-positive individuals respond less well than do uninfected persons to most vaccines. The degree of immunodeficiency present at the time of vaccination has an impact on the response to hepatitis A or B, pneumococcal, and influenza A and B vaccines.⁴⁰ Patients with a CD4 count of more than 200 cells/mcL have a more successful response to the vaccine. Patients should be informed that the extent and duration of the protective efficacy of these vaccines are still uncertain.

Vaccination for HIV has the potential to prevent or control disease progression. The development of an effective preventative vaccine for HIV is an area of continuing research. The first human immunizations with the potential AIDS vaccine took place in 1986 in healthy seropositive volunteers in France and Zaire. Low levels of both humoral and cell-mediated immune responses resulted. One conclusion of this study is that booster vaccinations could be effective.⁴¹ Several vaccine candidates have been developed and tested in human phase 1 or 2 trials. To date, at least 13 vaccine candidates have been created with use of different forms of recombinant proteins that target the HIV envelope. Research has found that the vaccine candidates introduced antibodies that rarely neutralized HIV progression, as evidenced by

assessment of patient blood counts (i.e., CD4 counts). Furthermore, these recombinant proteins rarely produced a cellular response that would target and destroy cells already infected with HIV.⁴² Currently there is no evidence of a vaccine that produces extended, high-titer neutralization across a variety of HIV strains.⁴² The most recent clinic trial, the Thai Phase III HIV vaccine trial (also known as *RV 144*), was completed in September 2009. The study incorporated two vaccines, a prime vaccine (ALVAC-HIV) and a booster vaccine (AIDSVAX B/E), which were based on strains found in Thailand, where the clinical trial was conducted. The clinical trial involved over 16,000 volunteers who received either the vaccine combination or a placebo. The clinical trial found that the vaccine regimen was safe and modestly effective, demonstrating that the vaccine combination lowered the HIV infection rate by 31.2% compared with the placebo. The study also found that the vaccine had no effect on the viral load of those volunteers who became infected during the clinical trial.⁴³

Genetic mutation of the virus further complicates attempts to disable it. Genetically similar but distinguishable strains of HIV can exist in one individual. Furthermore, drug-resistant strains of HIV have been identified.⁴⁴ Yet another difficulty with vaccination development is a lack of animal models. Chimpanzees replicate simian immunodeficiency virus, a similar but not identical disease. In addition, an average of 12 years and \$231 million is required for a new drug to gain Food and Drug Administration approval. Many major pharmaceutical companies seem wary of the immense research expenses and potential liability risks linked to vaccine development. The result is that smaller biotechnology companies with fewer resources are assailing the complicated problems of HIV infection.¹³ Recent advancements and plans for future clinical trials are largely supported by military or government programs. Researchers are optimistic that the vaccine will induce both humoral and cellular immune responses and have no toxic effects. It will protect against initial infection and retard disease onset in infected individuals.

In summary, as of July 2011 no HIV vaccines have been approved for use; there are clinical trials in process and research in this area is ongoing.

Nutrition

Involuntary loss of more than 10% of baseline body weight in a 12-month period or a 5% loss in baseline body weight in a 6-month period with chronic diarrhea or unexplained weakness and fever constitute HIV wasting syndrome.⁴⁵ Retrospective demographic research in the United States found that 17.8% of individuals with AIDS had wasting syndrome.^{46,47} The ensuing malnutrition contributes to further immunosuppression.⁴⁸ Nutritional consultation is critical for those patients experiencing wasting syndrome and as a preventative measure for those who are HIV positive. Studies have been done investigating the effects of nutritional counseling and other measures such as medications, hormone supplementation, and exercise on lean body mass in patients with HIV wasting syndrome. It has been shown that nutritional counseling, medications to inhibit tumor necrosis factor, androgen supplementation, growth hormone administration, and resistance strength training have all been effective in improving lean body

mass. Increased caloric intake alone increases lean body mass, but primarily through fat stores. Resistance strength training may prove to be the most beneficial in increasing lean body mass with minimal side effects and minimal cost.⁴⁹

Weight loss or reduction in lean body mass is also a problem for patients using HAART. Comprehensive nutritional intervention is advocated during the early stages of HIV infection to maintain nutritional status. HAART compromises nutrition in HIV patients because of complicated drug and nutrient interactions, adverse side effects including diarrhea and nausea, and in some cases excessive pill loads that must be consumed. Furthermore, HAART has been linked to a condition identified as *HIV-associated lipodystrophy*. This syndrome is marked by various combinations of insulin resistance, hyperlipidemia, visceral adiposity, loss of peripheral fat stores, and dorsocervical fat accrual.⁵⁰ Lipodystrophy is a syndrome that makes the nutritional management of HIV more difficult and may necessitate exercise, pharmacological intervention, and diet modifications.⁵¹

Systemic Manifestations

Integumentary System and Neoplasms

Cutaneous disorders develop in 64% to 90% of all individuals infected with HIV. Most HIV-induced skin findings develop only when the CD4 count falls below 500 cells/mL. As the CD4 cell count decreases further, multiple cutaneous disorders may develop.⁵² There are three AIDS-defining malignancies: Kaposi sarcoma (KS), non-Hodgkin lymphoma (NHL), and cervical cancer. KS was the first neoplastic condition to be related to HIV infection and it remains the most common. However, over the past decade the incidence of KS has diminished as a result of the use of more powerful antiretroviral therapy and maintenance of immune status.⁵² KS can involve almost every part of the body, but the most common site of initial KS presentations is the skin or mucous membranes.⁵³ The disorder manifests as cutaneous purple nodular lesions or as rife visceral lesions. AIDS-KS has been intimately associated with the lymphatic system, specifically, deficient lymphatic transport, nodal dysfunction, and tumors, which contribute to lymphedema.⁵⁴

In KS there is a broad therapeutic spectrum from cryotherapy to systemic chemotherapy.⁵⁵ In NHL, early therapeutic intervention is necessary because of the fast progression of the tumor.⁵⁶ The cervical cancer in HIV-positive women seems to be more aggressive than in HIV-negative women and requires early therapeutic intervention.⁵⁷ The cancer incidence in patients with HIV is reported to be higher among non-black patients.⁵⁸

Several other tumors occur in people with HIV infection: anorectal cancer, lung cancer, malignant testicular tumor, Hodgkin lymphoma, basal cell carcinoma, and malignant melanoma.^{56,59} It is beyond the scope of this chapter to detail all aspects of cancer and dermatological concerns; however, the therapist needs to be aware of the importance of differential diagnosis because the skin is the first line of defense of the immune system and further workup may be warranted. See [Table 31-3](#) for integumentary conditions associated with HIV.

TABLE 31-3 ■ HIV AND INTEGUMENTARY CONDITIONS*

VIRAL INFECTIONS	FUNGAL INFECTIONS	BACTERIAL INFECTIONS	ARTHROPOD INFECTIONS	INFLAMMATORY CONDITIONS	MALIGNANCIES	OTHER CONDITIONS
Acute morbilliform rash	Tinea	Cellulitis	Insect bites	Seborrheic dermatitis	Kaposi sarcoma	Lipodystrophy
Herpes simplex	Blastomycosis	Ecthyma	Scabies	Psoriasis	Cutaneous B-cell lymphoma	Ichthyosis
Varicella zoster	Candidiasis	Impetigo	Demodicosis	Eczema	Cutaneous T-cell lymphoma	Eosinophilic folliculitis
Molluscum contagiosum	Cryptococcosis	Folliculitis		Pruritic papular eruption of HIV	Skin cancer (melanoma, squamous cell carcinoma, basal cell carcinoma, and anal carcinoma)	HAART medication side effects
Human papillomavirus	Histoplasmosis	Bacillary angiomatosis				
Oral hairy leukoplakia	Pityrosporum folliculitis					
	Pityriasis versicolor					
	Systemic mycoses					
	Pneumocystosis					

HAART, Highly active antiretroviral therapies.

*Some skin conditions listed in this table are seen in the general population but may be more severe or more difficult to treat in HIV-infected patients.

Musculoskeletal System

Musculoskeletal manifestations of HIV infection are not as common as manifestations seen in other body systems, including the CNS, pulmonary system, and GI tract. Musculoskeletal disorders tend to occur in advanced HIV disease. Knowledge of the different abnormalities that may occur in the musculoskeletal system is crucial to patient management and affects morbidity and mortality. Primary abnormalities are seen as osseous and soft tissue infections, polymyositis, myopathy, and arthritis. Spinal infections such as pyogenic discitis, osteomyelitis, spinal TB, and epidural abscesses are more likely to occur in HIV-positive individuals than in those who are HIV negative. Discitis and osteomyelitis are more common in patients with CD4 counts >200 cells/mL, whereas spinal TB and epidural abscesses are more common in patients with CD4 counts <200 cells/mL.⁶⁰ Secondary musculoskeletal complications are often a result of the various compensatory patterns of gait as a result of HIV-related peripheral neuropathy syndrome or the change in biomechanics of the foot and ankle from KS and NHL.⁶¹ These lead to potential spinal changes and back pain.

HIV-positive patients with acute myopathy typically have proximal muscle weakness and elevated creatine phosphokinase levels.⁶² Patients may have initial symptoms of difficulty with basic activities of daily living (ADLs), such as rising from a chair or climbing stairs. If myopathy is in an acute inflammatory stage, resisted exercise is contraindicated.

Arthritis in HIV-positive individuals has a wide spectrum of presentations ranging from mild arthralgias to severe joint disability.⁶³ Arthritides seen in patients with AIDS have been classified into five groups on the basis of clinical presentation: (1) painful articular syndrome, (2) acute symmetrical polyarthritis, (3) spondyloarthropathic arthritis (Reiter syndrome, psoriatic arthritis), (4) HIV-associated arthritis, and (5) septic arthritis.⁶⁴ Standardized diagnostic tests and treatments are the same for HIV-positive individuals with

musculoskeletal impairments. A key difference to consider is the effect of HAART medications. Side effects of HAART may evoke symptoms that may complicate the differential diagnosis. The HAART drugs taken by HIV-positive patients may limit pharmaceutical treatment options for musculoskeletal conditions, namely immunosuppressant medications. See Table 31-4 for musculoskeletal conditions associated with HIV.

Cardiopulmonary System

Pulmonary diseases continue to be important causes of illness and death in patients with HIV infection, but changes in therapy and demographics of HIV-infected populations are changing their manifestations. The risk for development of specific disorders is related to the degree of immunosuppression, HIV risk group, area of residence, and use of prophylactic therapies.⁶⁵ Sinusitis and bronchitis occur frequently in the HIV-positive population, more so than in the general public. The increasing population of HIV-positive drug users is reflected in the increasing incidence of TB and bacterial pneumonia.

Anti-*Pneumocystis* prophylaxis has reduced the incidence of and mortality from PCP. The PCP-causing organism is usually acquired in childhood, and 65% to 85% of healthy adults possess PCP antibodies. Reactivation of latent infection is responsible for the recurrent fever, dyspnea, and hypoxia that characterize PCP.^{66,67} Adjunctive corticosteroid therapy has improved the outlook for respiratory failure.⁶⁵ Multiple studies have shown that the use of corticosteroids in HIV-positive patients in acute respiratory failure has not increased the risk for the development of opportunistic infections.⁶⁸

Mycobacterial infections in HIV-infected individuals usually manifest as either MAC infection or TB.⁵ Steadily increasing incidence of infection by *Mycobacterium tuberculosis* is likely the result of two factors: better medical management of HIV as a whole and the development of multidrug-resistant strains of mycobacteria. MAC infection

TABLE 31-4 ■ HIV AND MUSCULOSKELETAL CONDITIONS

CONDITION	SYMPTOMS AND COMMENTS	TREATMENTS
Reactive arthritis, septic arthritis, bursitis	Asymmetrical oligoarthritis or monoarticular arthritis, dactylitis, enthesopathy, joint effusion Most common in the foot and ankle May range from mild to severe Inflammation of synovial fluid, often gram negative	Surgical debridement Aspiration of fluid from the joint, antibiotics ROM activities
Idiopathic polymyositis	Bilateral proximal muscle weakness, elevated serum CK levels Often occurs early in infection Exact mechanism is still undetermined	Discontinue medication that causes inflammation or irritation of the muscle Antiinflammatory medications Corticosteroid medications
Zidovudine-associated myopathy	Causes mitochondrial toxicity Gradual myalgias, muscle tenderness, proximal muscle weakness, elevated CK levels	Discontinue AZT therapy CK levels return to normal within 4 weeks (of discontinuing AZT), weakness resolves in 8 weeks
Pyomyositis	Solitary or multiple muscle abscesses that are not formed by local extension from superficial subcutaneous tissue Acute, severe muscle pain with or without erythema, fever, edema Elevated ESR and CK levels Pathogen is most often <i>Staphylococcus aureus</i> Differential diagnosis includes muscle strain, contusion, hematoma, cellulitis, deep venous thrombosis, osteomyelitis, septic arthritis, and neoplasm	If not treated, septic shock and death can result in 3 weeks Open drainage or debridement of the site Antibiotic therapy
Psoriatic arthritis	Cutaneous manifestations (macropapules on the knees, elbows, scalp and trunk), nail changes, arthritic changes or deformities, soft tissue swelling, juxtaarticular erosions, osteopenia, osteolysis Five types: asymmetrical oligoarthritis, symmetrical polyarthritis, dominant desquamative interstitial pneumonia, arthritis mutilans, and sacroiliitis or spondylitis without peripheral involvement Synovial fluid usually contains 7000 to 15,000 white blood cells/mcL	NSAIDs Second-line agents (gold, methotrexate, and azathioprine) Intraarticular steroid injection (every 4 to 6 months) ROM activities
Reiter syndrome	Urethritis, conjunctivitis, and arthritis, nail involvement with subungual hyperkeratosis, circinate balanitis, keratoderma hemorrhagica, oral ulcers, uveitis, AIDS foot, weight loss, malaise, lymphadenopathy, and diarrhea Severe course of persistent and erosive polyarthritis, fevers, and enthesopathies, which responds poorly to treatment or has a mild and self-limited course Common enthesopathies include Achilles tendinitis, lateral or medial epicondylitis, rotator cuff tendinitis, and de Quervain tenosynovitis; axial skeleton involvement is rare Broad-based gait and stiff ankles with weight bearing through the lateral margins of the feet because of the painful heel; patients may become severely disabled and wheelchair bound	NSAIDs Second-line agents (gold, methotrexate, and azathioprine) Patients usually obtain relief after 5 to 7 days of therapy Intraarticular steroid injection (every 4 to 6 months) Methotrexate, other immunosuppressive agents, and phototherapy should be used only with extreme caution Early physical therapy and splinting of affected joints as needed to prevent atrophy and contractures
Diffuse infiltrative lymphocytosis syndrome (DLS)	Massive parotid enlargement, xerostomia, and lymphocytic hepatitis caused by CD8 lymphocytic infiltration of the liver Xerophthalmia (dry eyes), xerostomia (dry mouth), salivary gland enlargement, and arthralgias Extraglandular features may be pulmonary, neurological, gastrointestinal, renal, or musculoskeletal	Symptomatic treatment with artificial saliva and tears Antibiotics to address recurrent sinus, middle ear, and oral cavity infections Immunosuppressive therapy should be used only when patients are in life-threatening situations such as pulmonary insufficiency or renal disease Corticosteroids can be used for extraglandular features Radiotherapy to reduce the enlarged parotid gland

Continued

TABLE 31-4 ■ HIV AND MUSCULOSKELETAL CONDITIONS—cont'd

CONDITION	SYMPTOMS AND COMMENTS	TREATMENTS
Avascular necrosis or osteonecrosis	Results from direct or indirect damage to the vascular supply of the affected bone, leading to in situ death of subchondral bone Most common sites are the femoral head followed by the humeral head; may occur in other locations including the wrist (scaphoid [Preiser disease] or lunate [Kienböck disease]), knee, and ankle Deep, throbbing, intermittent pain that may be insidious or sudden in presentation and, in later stages, a loss of motion	Early osteonecrosis may be treated by minimizing the forces across the joint, either through avoiding weight-bearing activity (lower extremity) or through greatly limiting activity such as lifting and carrying (upper extremity) Advanced stages require surgical intervention in an attempt to restore vascularity, provide stabilization, or replace the joint ROM activities
Hypertrophic osteoarthropathy	Systemic disorder affecting bones, joints, and soft tissues, often develops in patients with PCP Severe pain in the lower extremity, digital clubbing, arthralgias, nonpitting edema, periarticular soft tissue involvement of the ankle, knees, and elbows; skin over the affected areas is glistening, edematous, and warm; chronic erythema, paresthesias, and hyperhidrosis may be noted in the hands and feet Radiography reveals extensive periosteal reaction and subperiosteal proliferative changes in the long bones of the lower extremity; bone scan demonstrates increased uptake along the cortical surfaces	Treatment of PCP usually alleviates this condition Surgical or chemical vagotomy or radiation therapy may be necessary in refractory cases
Acute symmetrical polyarthritis	Acute symmetrical polyarthritis exclusive to HIV-infected patients; resembles rheumatoid arthritis, develops in the small joints of the hand Characterized by ulnar deviation of the digits and swan neck deformities Acute onset and negative rheumatoid factor test result help differentiate it from rheumatoid arthritis Radiographic results also mimic those of rheumatoid arthritis, with periarticular osteopenia, joint-space narrowing, and marginal erosions	Gold therapy is effective treatment ROM activities
HIV-associated arthralgia	Asymmetrical, oligoarticular arthritis exclusive to HIV-infected persons; usually occurs in the late stages, but may occur in any stage Characterized by an acute onset of severe pain and disability, predominantly in the large joints such as the knees or ankles Self-limiting; may be mild to moderate severity; usually lasts a few weeks to 6 months Synovial fluid commonly contains only 50 to 2600 white blood cells/mcL Radiography may show diffuse osteopenia but without erosive changes; serum is negative for HLA-B27 and rheumatoid factor Synovial biopsy reveals a chronic mononuclear cell infiltrate	Symptomatic relief with NSAIDs Intraarticular corticosteroid injections ROM activities

AZT, Zidovudine; CK, creatine kinase; ESR, erythrocyte sedimentation rate; NSAIDs, nonsteroidal antiinflammatory drugs; PCP, *Pneumocystis jiroveci* pneumonia; ROM, range of motion.

tends to appear late in the course of HIV infection. Initial infection involves the GI and pulmonary tracts and eventually disseminates throughout the body. This disorder probably is caused not by latent reactivation of the organism but rather by primary infection by ingestion or inhalation.⁶⁹ Signs and symptoms of MAC infection include pneumonia,

fever, weight loss, malaise, sweats, anorexia, abdominal pain, and diarrhea.

As in many other infections, initial signs and symptoms of TB include fever, weight loss, malaise, cough, lymph node tenderness, and night sweats. Pulmonary involvement accounts for 75% to 100% of cases of TB infection in

HIV-positive patients, but extrapulmonary infection, especially in lymph nodes and bone marrow, occurs in up to 60% of these individuals as well.^{66,69-71} Less common areas of infection include the CNS, cardiac, and mucosal tissues. TB is communicable, preventable, and treatable. Tuberculin skin testing with follow-up chest radiographs when appropriate should be available and routinely offered to individuals at HIV testing sites. Individuals at highest risk for concomitant HIV and TB infections include the homeless, intravenous drug users, and prison inmates.^{66,71} The risk of infection in health care personnel and in the general public is a concern. Isolation rooms that provide negative-pressure, nonrecirculated ventilation, specific air filters, and higher air exchange rates offer the best protection to health care providers exposed to TB-infected individuals. Properly fitted face masks that filter droplet nuclei should be worn. Monitoring of personnel who work with these populations will identify the need for necessary preventive therapy.⁶⁶ The majority of health care facilities require personnel to have yearly screenings and have established guidelines to prevent the spread of TB in their patient population and within their workforce.

CMV can affect the GI and respiratory tracts but primarily targets optic structures and the CNS; 40% to 100% of healthy adults possess CMV antibodies.⁷² However, an individual who is immunosuppressed becomes more vulnerable to symptoms of infection with CMV. Predominant consequences of HIV-CMV co-infection are unilateral or bilateral deficits in visual acuity, visual field cuts, and blindness.

Although most other organ system involvement has been extensively described in studies and reviews, cardiac complications related to HIV infection have remained less characterized. Most studies have described cardiac problems as postmortem findings, although some clinical series have been reported. It is now clear that cardiac involvement in people living with HIV infection is quite common. Pericardial effusion and myocarditis are among the most commonly reported cardiac abnormalities. Cardiomyopathy, endocarditis, and coronary vasculopathy have also been reported. It is now apparent that HIV infection itself, the medical management of HIV disease, and secondary opportunistic infections can all affect the myocardium, pericardium, endocardium, and blood vessels.^{72,73} Cardiovascular risk in HIV-positive patients depends on several factors: direct and indirect vascular effects of chronic exposure to the virus, metabolic effects from prolonged HAART, the normal aging process (important to consider given the increased life expectancy of HIV-positive patients), and other cardiovascular risk factors (such as diet and genetics).⁷⁴

Body fat changes and lipid abnormalities have been reported in individuals with HIV disease.⁷⁵ Known as *lipodystrophy* or *fat redistribution syndrome*, these body fat and metabolic changes have been connected to PI use.⁷⁶ It is estimated that 50% of HIV-positive individuals taking HAART develop these metabolic conditions.⁷⁷ These body fat changes may have strong implications for patients undergoing rehabilitation interventions. Signs and symptoms of the syndrome vary, and not all need to be present in any particular patient. However, in both men and women, three main components of the syndrome have emerged. These include changes in body shape, hyperlipidemia, and insulin resistance. Clinically, distinct body

shape changes are apparent. The most prevalent include increased abdominal growth, dorsocervical fat pad, benign symmetrical lipomatosis, lipodystrophy, and breast hypertrophy in women.^{78,79} The increased abdominal growth is characterized by a redistribution and accumulation of fat in the central visceral areas of the body.^{79,80} Corresponding symptoms include GI discomfort, bloating, distention, and fullness.⁸⁰

In addition to visible signs and symptoms, adverse changes in lipid, glucose, and insulin levels have been reported.⁸¹ A number of studies have revealed hyperlipidemia to be present in HIV-positive patients, many of whom, but not all, were undergoing PI therapy.⁸²

To date, the exact cause of lipodystrophy has not been determined, but two main theories have been hypothesized. Each is still in the process of being studied.^{75,83} As individuals live longer with HIV disease, they are at greater risk for development of cardiac disease. Therapists need to be apprised of various changes in laboratory results and signs and symptoms of cardiac disease when designing an exercise program and facilitating the return to functional activities. Screening guidelines (from the Infectious Diseases Society of America HIV Medicine Association [IDSA HIVMA]) include the following:

- Monitor fasting lipid levels before beginning HAART and during the first 4 to 6 weeks of treatment
- Monitor fasting glucose levels before and during HAART
- Monitor body weight and body shape changes on a routine basis

See [Table 31-5](#) for effects of HIV treatment on cardiovascular factors and [Table 31-6](#) for cardiovascular risk factors associated with HIV.

Neurological System

The neurological manifestations of HIV disease are numerous and involve the autonomic nervous system (ANS), CNS, and peripheral nervous system (PNS).⁸⁴ Over the course of the disease, up to 70% of patients have some form of neurological symptom.⁸⁵ Significant progress in understanding and treating the neurologically involved HIV patient has been made over the past decade.⁸⁶ However, HIV continues to affect every division of the human nervous system ([Box 31-2](#)). HIV-positive infants show early, catastrophic encephalopathy, loss of brain growth, motor deficits, and cognitive dysfunction.⁸⁷ Unfortunately, neurobehavioral dysfunction in early pediatric AIDS remains unchanged after therapy. Dementia develops in some adult patients in spite of the multidrug therapies, and other patients have subtle neurobehavioral changes that diminish the quality of their prolonged lives. Thus HIV infection of the CNS remains an important clinical concern. A variety of host and viral factors are associated with an increased risk of developing HIV-associated neurocognitive disorders (HANDs). Studies are demonstrating similarities between factors that predispose HIV-positive patients to HANDs and the risk factors of Alzheimer dementia, suggesting the potential for a common pathological mechanism.⁸⁸ Evidence has shown that HIV-infected monocytes are carried across the blood-brain barrier and infect the macrophages and microglia in the CNS.^{89,90} HIV enters the CNS early, yet HANDs often do not occur until advanced stages when the patient is

TABLE 31-5 ■ EFFECTS OF HIV TREATMENT ON CARDIOVASCULAR FACTORS

CARDIOVASCULAR FACTOR	INCIDENCE WHEN TREATED AND UNTREATED	EFFECTS
Lipid metabolism (HDL-C)	Decreases in early infection. With viral suppression it will increase modestly, but not to premorbid levels.	Greater increases seen with NNRTI medications. Increased visceral adipose tissue and upper trunk fat associated with low HDL-C.
Lipid metabolism (LDL-C)	Decreases later in infection. With viral suppression it will increase modestly.	No evidence of direct medication effects on LDL-C.
Lipid metabolism (triglycerides)	Increases in late infection with viral suppression; decreased in early studies of AZT use.	No decrease or increase (primarily with PIs) with HAART medications. Increased visceral adipose tissue and upper trunk fat associated with elevated triglyceride levels.
Glucose metabolism (insulin sensitivity)	Current studies show a decrease if untreated. With viral suppression there is a trend toward decreased insulin sensitivity regardless of the medications; some insulin resistance shows a return to good health.	Some PIs and NRTIs may decrease insulin sensitivity. Increased visceral adipose tissue and upper trunk fat associated with insulin resistance.
Glucose metabolism (insulin secretion)	No evidence of effect if untreated. With viral suppression no evidence of effect.	Some PIs may decrease insulin secretion.
Glucose metabolism (fasting glucose)	No evidence of any effect if untreated. With viral suppression no evidence of effect.	Some PIs may increase glucose production.
Glucose metabolism (glucose tolerance)	No evidence of any effect if untreated. With viral suppression no evidence of effect.	With HAART there may be higher rates of impaired glucose tolerance.
Glucose metabolism (diabetes)	No evidence of differences in prevalence or incidence rates if untreated. With viral suppression there may be a higher prevalence of diabetes.	Higher prevalence of type 2 diabetes associated with certain PIs and NRTIs.
Body composition (lean body mass)	Decreases disproportionately with severe wasting if untreated. Increases modestly with the initiation of effective HAART.	No consistent evidence of direct medication effects.
Body composition (peripheral fat)	Decreases proportionately with wasting if untreated. Will initially increase with the start of effective HAART.	Subsequent depletion of subcutaneous fat in the face, arms, legs, and buttocks is associated with some NRTIs.
Body composition (visceral fat)	Decreased minimally when untreated; increases with effective HAART.	Preserved or increased visceral fat in some patients on HAART.
Renal function (renal disease)	HIV-associated nephropathy, proteinuria, microalbuminuria and elevated cystatin C if untreated. Decreased HIV-associated nephropathy but still have microalbuminuria and elevated cystatin C with viral suppression.	Some HAART may cause impaired renal function.

AZT, Zidovudine; HAART, highly active antiretroviral therapies; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; NNRTI, nonnucleoside reverse transcriptase inhibitor; NRTI, nucleoside reverse transcriptase inhibitor; PI, protease inhibitor.

categorized as having AIDS. Hypotheses for the development of HANDs in the advanced stages include the loss of immune control with disease progression, heightened immune activation, increased transfer of infected monocytes into the CNS, and variations or mutations in the virus. Because current HAART medications have poor CNS penetration, HANDs continues to pose significant challenges for advanced HIV/AIDS patients.⁹¹ See Table 31-7 for neurological conditions associated with HIV.

Autonomic Nervous System. Dysfunction of the ANS has been associated with HIV infection. This has implications for overall function and the design of a rehabilitation

program for people living with HIV disease. In one study, individuals with the greatest ANS involvement had dementia, myelopathy, and sensory peripheral neuropathy. Variations in heart rate, including resting tachycardia, were common. Abnormal blood pressure readings were identified in response to isometric exercise and positional changes (sit to stand and tilting).⁹²

Central Nervous System. HIV enters the CNS during the early stages of the disease and is hypothesized to traverse the blood-brain barrier during the initial acute primary infection stage. Although the initial CNS invasion by HIV is asymptomatic in most individuals, affective and cognitive

Text continues on page 965.

TABLE 31-6 ■ CARDIOVASCULAR RISK FACTORS AND HIV

RISK FACTOR	INTERVENTION	RESULT
Cigarette smoking HTN	Interpersonal counseling Dietary and physical activity counseling Calcium channel blockers, other antihypertensive agents	Increased quitting rates. Reduced blood pressure. Drug interactions between calcium channel blockers and protease inhibitors.
Dyslipidemia	Dietary and physical activity counseling Statins, fibrates, fish oil, niacin	Modest improvements in lipids. Statins improve endothelial function. Multiple drug interactions with HAART.
Disordered glucose metabolism	Dietary and physical activity counseling Metformin and thiazolidinediones	Improvement in glycemia. Metformin reduces insulin resistance and visceral adipose tissue. Thiazolidinediones may improve subcutaneous adipose tissue.
Use of HAART	Modification of initial HAART based on metabolic profile and CVD risk Switching HAART to reduce metabolic side effects	Modest effects on lipids and insulin resistance. Statins and fibrates may be more effective.

CVD, Cardiovascular disease; HAART, highly active antiretroviral therapies; HTN, hypertension.

BOX 31-2 ■ NEUROPATHOLOGY OF HIV INFECTION

CENTRAL NERVOUS SYSTEM (CNS)

Mechanism of CNS infection is unclear, but HIV seems unable to cross blood-brain barrier alone. It probably crosses in macrophages and T cells and most directly affects subcortical structures (basal ganglia, thalamus, brain stem).

AIDS dementia complex, a subcortical dementia, is different from cortical dementia such as Alzheimer disease.

Estimated 70% of infected individuals have cognitive, motor, and behavioral constellation that makes up the AIDS dementia complex.

PERIPHERAL NERVOUS SYSTEM (PNS)

Sensory—In early and middle stages, distal lower extremities are largely involved, with paresthesia and decreased

temperature sensitivity. In advanced stages, the patient has decreased ankle and knee reflexes; diminished temperature and vibration sensitivity and proprioception; and hyperesthesia.

Motor—Most closely resembles Guillain-Barré syndrome (progressive muscle weakness → paralysis, decreased deep tendon reflexes). Splints and ankle-foot orthoses may prevent deformities.

AUTONOMIC NERVOUS SYSTEM (ANS)

Arrhythmias, especially tachycardia.

Abnormal blood pressure, orthostasis (may be aggravated by isometric exercises).

ANS involvement has been associated with dementia, myelopathy, and peripheral sensory neuropathies.

TABLE 31-7 ■ HIV AND NEUROLOGICAL CONDITIONS

STAGE 1 HIV DISEASE (CD4 >500 CELLS/MCL)	STAGE 2 HIV DISEASE (CD4 200-499 CELLS/MCL)	STAGE 3 HIV DISEASE (CD4 <200 CELLS/MCL)
Aseptic meningitis	Cognitive impairment	HIV encephalopathy (dementia)
Acute encephalopathy with seizures and confusion	Distal sensory polyneuropathy	CNS toxoplasmosis
Inflammatory demyelinating polyneuropathy (Guillain-Barré syndrome)	Myelopathy	CMV infection
Cranial nerve palsies (e.g., Bell palsy)	Myopathy	Primary CNS lymphoma
Herpes zoster (shingles)		PML
Distal sensory polyneuropathy		

Continued

TABLE 31-7 ■ HIV AND NEUROLOGICAL CONDITIONS—cont'd

CONDITION	COMMENTS AND SYMPTOMS	PROGNOSIS AND TREATMENT
AIDS dementia complex (ADC; HIV-associated encephalopathy)	<p>Occurs primarily in persons with more advanced HIV infection (CD4 <200 cells/mcL); mild cognitive impairment may occur in earlier stages.</p> <p>Symptoms: encephalitis (inflammation of the brain), behavioral changes, and a gradual decline in cognitive function (decreased concentration, memory, and attention).</p> <p>May develop severe global dementia with memory loss and language impairment.</p> <p>Progressive slowing of motor function (decreased balance, weakness, decreased coordination) and loss of dexterity and coordination.</p>	<p>When left untreated it can be fatal.</p> <p>If ADC develops during treatment with HAART, additional or alternative agents should be tried. Neuroprotective therapies or global memory-enhancing agents such as memantine (Namenda) or donepezil (Aricept) may be useful in some individuals.</p> <p>Patients must often take multiple medications, many of which can affect thinking and memory and make the symptoms of ADC worse.</p>
CNS lymphomas	<p>Cancerous tumors that either begin in the brain or result from a cancer that has spread from another site in the body.</p> <p>Almost always associated with the Epstein-Barr virus.</p> <p>Symptoms: headache, seizures, vision problems, dizziness, speech disturbance, paralysis, and mental deterioration.</p> <p>May develop one or more CNS lymphomas.</p>	<p>Prognosis is poor owing to advanced and increasing immunodeficiency.</p>
Cryptococcal meningitis	<p>Manifests as meningitis, a space-occupying lesion, or meningoencephalitis; the fungus first invades the lungs and spreads to the covering of the brain and spinal cord, causing the inflammation.</p> <p>Symptoms: fatigue, fever, headache, nausea, memory loss, confusion, photophobia, stiff neck, altered vision, drowsiness, and vomiting.</p> <p>Develops when CD4 cell counts fall below 100 cells/mcL.</p>	<p>If untreated, patients with cryptococcal meningitis may lapse into a coma and die.</p> <p>Treatment relies on amphotericin B (Fungizone), which may be combined with flucytosine (Ancobon).</p> <p>An alternative for less severe cases is fluconazole (Diflucan), which is also the drug of choice for long-term prophylaxis (preventive therapy).</p> <p>Amphotericin B is an alternative maintenance therapy for people who relapse on fluconazole or do not tolerate it.</p> <p>Hydrocephalus can occur at times and requires a ventriculoperitoneal shunt (surgical drain of spinal fluid).</p> <p>Visual loss can be addressed by optic nerve surgery.</p>
Cytomegalovirus (CMV) infections	<p>Herpesvirus that causes infection of the brain, spinal cord, meninges, or nerve roots can lead to neurological problems such as encephalitis (inflammation of the brain), myelitis (inflammation of the spinal cord), retinitis (inflammation of the retina of the eye), polyradiculitis (inflammation of the spinal nerve roots), peripheral neuropathy, or mononeuritis multiplex.</p> <p>Infection of the spinal cord and nerves can result in weakness in the lower limbs and some paralysis, severe lower back pain, and loss of bladder function.</p> <p>Findings include low-to-normal glucose, normal-to-high protein, and increased numbers of white blood cells.</p>	<p>Untreated CMV encephalitis is almost always fatal and causes death within days to weeks.</p> <p>Anti-CMV drugs must be started immediately, often based on a suspected rather than proven diagnosis.</p> <p>Treatment relies on two drugs, ganciclovir (Cytovene) and foscarnet (Foscavir), used alone or in combination when monotherapy fails.</p> <p>Lifelong maintenance treatment is often necessary.</p>

TABLE 31-7 ■ HIV AND NEUROLOGICAL CONDITIONS—cont'd

CONDITION	COMMENTS AND SYMPTOMS	PROGNOSIS AND TREATMENT
Herpesvirus infections	<p>The herpes zoster virus (causes chickenpox and shingles) can infect the brain and produce encephalitis or myelitis.</p> <p>Signs of shingles include painful blisters (like those seen in chickenpox), itching, tingling, and nerve pain.</p>	<p>Antiherpes drugs: standard treatment for shingles is the drug acyclovir; new medications include famciclovir and valacyclovir.</p> <p>Nerve blocks: anesthetic drugs and/or steroids can be injected either into peripheral nerves or into the spinal column (central nervous system).</p> <p>Drugs normally used to treat depression, epilepsy, or severe pain are sometimes used for the pain of shingles; nortriptyline (antidepressant) is most frequently used for shingles pain; pregabalin is an epilepsy medicine used for pain after shingles.</p> <p>Skin treatments: several creams, gels, and sprays may provide temporary relief from pain; capsaicin has shown good preliminary results; the patch form of the anesthetic lidocaine provides pain relief for some people with shingles.</p>
Neurosyphilis	<p>Sexually transmitted infection caused by the spiral-shaped <i>Treponema pallidum</i> bacterium; <i>T. pallidum</i> gains access to the body through tiny abrasions of the skin or mucous membranes; this organism may invade the CNS a few months after initial infection.</p> <p>May proceed rapidly from the primary stage (skin chancres, or lesions, appearing about 21 days after infection) to secondary syphilis (skin rash) and tertiary syphilis (infection of different organs, including the brain) as early as 2 months after exposure.</p> <p>Tertiary syphilis may cause hearing loss, dizziness or vertigo, headache, failing vision, cognitive impairment, personality changes, peripheral polyneuropathy, gait imbalance, seizures, or stroke.</p>	<p>Choice of antibiotic depends on the stage of syphilis and follows general guidelines.</p> <p>Most common are different forms of penicillin.</p> <p>Although HIV-infected patients with neurosyphilis respond to antibiotics, they are less likely to have serological improvement than HIV-negative individuals; HIV-associated neurosyphilis may be more difficult to treat and more aggressive.</p>
Progressive multifocal leukoencephalopathy (PML)	<p>Characterized by widespread demyelinating lesions (loss of the insulating myelin sheath around nerves in the brain and spinal cord) and caused by the JC papovavirus.</p> <p>Symptoms include various types of mental deterioration, vision loss, speech disturbances, ataxia (inability to coordinate movements), paralysis, brain lesions, and coma; some may have compromised memory and cognition, and seizures may occur when CD4 cell counts fall below 200 cells/mcL.</p> <p>Onset is usually weeks to months.</p>	<p>Relentlessly progressive; death usually occurs within 6 months of initial symptoms.</p> <p>Typically progresses to severe dementia and death over several months.</p> <p>Whether HAART improves survival remains controversial.</p> <p>Survival correlates with suppression of plasma HIV viral load and higher CD4⁺ cell counts.</p> <p>Death may result not from PML, but from end-stage immunodeficiency.</p> <p>Some positive response has been reported with use of cidofovir (Vistide).</p>
Psychological and neuropsychiatric disorders	<p>Occur in different phases of the HIV infection and AIDS and may take various and complex forms.</p> <p>Some illnesses, such as ADC, are caused directly by HIV infection of the brain, whereas other conditions may be triggered by the drugs used to combat the infection.</p> <p>Patients may experience anxiety disorder, depressive disorders, increased thoughts of suicide, paranoia, dementia, delirium, cognitive impairment, confusion, hallucinations, behavioral abnormalities, malaise, and acute mania.</p>	<p>Treatment options include antidepressants and anticonvulsants.</p> <p>Psychostimulants may also improve depressive symptoms and combat lethargy.</p> <p>Antidementia drugs may relieve confusion and slow mental decline, and benzodiazepines may be prescribed to treat anxiety.</p> <p>Psychotherapy may also help some patients.</p>

TABLE 31-7 ■ HIV AND NEUROLOGICAL CONDITIONS—cont'd

CONDITION	COMMENTS AND SYMPTOMS	PROGNOSIS AND TREATMENT
Stroke and hemorrhage	<p>Causes include hypertension (high blood pressure), blood vessel abnormalities (aneurysms, vein or artery malformations), hypotension (low blood pressure), coagulopathies (defective blood clotting), thrombotic thrombocytopenic purpura (TTP; characterized by low platelet counts and blood clots), elevated lipids (contributing to coronary artery disease), viral infections of the heart muscle, herpes zoster (shingles), hepatitis C, and cocaine or heroin use.</p> <p>Characterized by the abrupt onset of weakness, language problems, or sensory loss; symptoms often occur on only one side of the body.</p> <p>Imaging studies help differentiate stroke, hemorrhage, infection, and tumors.</p>	<p>Treatment parallels that in the HIV-negative population.</p> <p>If a stroke is diagnosed within three hours after onset, the person may be a candidate for an infusion of tissue plasminogen activator (tPA), an agent that dissolves clots and opens blood vessels. tPA is contraindicated in cases of brain hemorrhage.</p> <p>Lipid-lowering drugs (statins), blood thinners such as warfarin (Coumadin), or antiplatelet agents such as aspirin or clopidogrel (Plavix) are indicated.</p> <p>Specific causes of stroke may require other forms of treatment.</p> <p>Brain hemorrhages occasionally may need to be treated with surgery to remove the mass of blood.</p> <p>Prognosis after a stroke or brain hemorrhage depends on the size and location of the damage; recovery is greatest during the initial few weeks, but improvement often continues for months; inpatient and outpatient rehabilitation is often helpful.</p> <p>Preventive treatment parallels that in the HIV-negative population and includes antiplatelet agents or blood-thinning drugs, removal of plaque from the walls of carotid arteries, and newer techniques of endovascular stenting.</p>
Toxoplasmosis	<p>Caused by the parasite <i>Toxoplasma gondii</i>.</p> <p>Signs and symptoms include encephalitis, fever, severe headache that does not respond to treatment, weakness on one side of the body, seizures, lethargy, increased confusion, vision problems, dizziness, problems with speaking and walking, vomiting, and personality changes.</p> <p>Onset is over days to weeks.</p>	<p>Condition is treatable, most improve by day 14 of therapy.</p> <p>Generally responsive to intravenous (IV) antibiotics, and response to therapy is often rapid; agents of choice are sulfadiazine combined with pyrimethamine and folinic acid; for people with sulfa intolerance, clindamycin is an alternative.</p> <p>Steroids may be used to reduce associated swelling in the brain.</p> <p>After the initial regimen is completed, oral maintenance treatment, usually TMP-SMX (Bactrim, Septra), is continued indefinitely to suppress reactivation of the parasite.</p> <p>Prognosis is linked to parallel treatment with HAART to raise the CD4 cell count.</p>
Vacuolar myelopathy	<p>Causes the protective myelin sheath to pull away from nerve cells of the spinal cord, forming small holes called <i>vacuoles</i> in nerve fibers.</p> <p>Symptoms include weak and stiff legs and unsteadiness when walking; walking becomes more difficult as the disease progresses, and many patients eventually require a wheelchair.</p>	<p>Prognosis is poor, options are limited, and care is primarily supportive.</p> <p>May improve after starting HAART to stabilize spinal cord damage; maximally potent HAART is required.</p> <p>L-Methionine (also known as <i>SAMe</i>, a common dietary supplement) is an experimental treatment.</p>

TABLE 31-7 ■ HIV AND NEUROLOGICAL CONDITIONS—cont'd

CONDITION	COMMENTS AND SYMPTOMS	PROGNOSIS AND TREATMENT
Primary central nervous system (PCNS) lymphoma	<p>Characterized by the growth of abnormal lymphocytes, or white blood cells (B cells and T cells). Occurs in the brain, rarely in the spinal cord, and causes brain lesions and changes in mental functioning.</p> <p>In almost all cases, Epstein-Barr virus (EBV) is found in the lymphoma-related lesions or the CSF.</p> <p>Often associated with CD4 cell counts below 100 cells/mL.</p> <p>Signs and symptoms are impaired cognition, aphasia (loss of ability to use or understand language), hemiparesis, and seizures.</p> <p>Onset is often more subtle, and progression slower.</p>	<p>Prognosis for PCNS lymphoma is generally poor. Whole brain radiation therapy (radiotherapy) has been the mainstay of treatment; it provides for a median survival of 2-5 months.</p> <p>Steroids are required for at least 48 hours before radiotherapy to minimize swelling; steroids should be continued throughout the course of treatment.</p> <p>High-dose methotrexate has been used with some success, given as frequently as every week for five cycles; combining methotrexate and radiotherapy can achieve survival of 1-2 years.</p> <p>Experimental chemotherapy agents include thiotepa (Thioplex) and procarbazine (Matulane). HAART should be continued.</p>
Meningitis	<p>Inflammation of the meninges, the membranes surrounding the brain and spinal cord.</p> <p>Signs and symptoms are malaise (vague body discomfort), fever, stiff neck, photophobia, and headache; less common are cranial neuropathies (one-sided facial weakness or double vision), confusion, drowsiness, and personality changes.</p> <p>HIV invades the brain early and may cause meningitis within days to weeks after infection.</p> <p>Chronic meningitis, or episodes of acute (rapid onset) meningitis for which no cause is found, can occur anytime during the course of HIV disease.</p>	<p>Treatment and prognosis vary by the specific cause of meningitis, severity at presentation, delay from symptom onset to treatment, and status of immunosuppression.</p>
Tuberculosis meningitis	<p>Bacterial disease caused by <i>Mycobacterium tuberculosis</i>, which can be suspended in tiny droplets in the air and transmitted person to person by inhalation.</p> <p>May cause persistent headache, fever, confusion, hemiparesis, seizures, stiff neck, double vision, or hearing loss.</p> <p>Hydrocephalus associated with tuberculosis may lead to drowsiness or stupor and, later, coma.</p> <p>Spinal cord damage can occur if the vertebrae (bones that encase the spinal cord) are infiltrated by TB (Pott disease) or as a result of abscesses inside or outside the spinal cord.</p>	<p>Triple antibiotic therapy—isoniazid, rifampin (Rifadin), and pyrazinamide—for 12-24 months is required; it is important that all doses be taken as directed. In cases of drug-resistant TB, a fourth drug, ethionamide (Trecator), should be added to this regimen.</p> <p>HAART should be continued.</p> <p>Significant interactions can occur between rifampin and protease inhibitors (PIs), so an alternative anti-TB drug may be necessary.</p>
Distal sensory polyneuropathy	<p>Damage to sensory nerves in the extremities (feet and hands), is the most common type of HIV-associated neuropathy.</p> <p>Nerves may be injured directly by HIV or by HIV-induced macrophages that secrete neurotoxic substances.</p> <p>May also be caused by nutritional and vitamin imbalances or drug toxicity, especially use of d4T (stavudine, Zerit), ddI (didanosine, Videx), or ddC (zalcitabine, Hivid).</p> <p>Occurs at any stage of HIV disease.</p>	<p>Treatment of symptoms may include local ointments (capsaicin, Aspercreme), antidepressant medications (amitriptyline [Elavil]), or antiepileptic medications (gabapentin [Neurontin], lamotrigine [Lamictal], carbamazepine [Tegretol]). Duloxetine (Cymbalta; an SSRI antidepressant) is FDA approved for painful diabetic polyneuropathy and is currently being used for HIV-associated painful polyneuropathy.</p> <p>Pregabalin (Lyrica; an antiepileptic drug) is under FDA review.</p> <p>Drugs should be chosen that are unlikely to interact with or influence the effectiveness of anti-HIV drugs.</p> <p>Lidoderm patches may provide partial pain relief without any systemic side effects and can be combined with oral drugs.</p>

Continued

TABLE 31-7 ■ HIV AND NEUROLOGICAL CONDITIONS—cont'd

CONDITION	COMMENTS AND SYMPTOMS	PROGNOSIS AND TREATMENT
Inflammatory demyelinating polyneuropathy (IDP)	<p>Inflammation of the myelin sheath that surrounds the spinal and peripheral nerves.</p> <p>Acute form of IDP (AIDP), also known as <i>Guillain-Barré syndrome</i> (GBS).</p> <p>Characterized by rapid onset and progression over hours to weeks.</p> <p>Chronic form (CIDP) has slower onset and progression over weeks to months, sometimes with a relapsing course.</p> <p>Both forms are autoimmune conditions in which the immune system attacks nerves.</p> <p>Causes varying degrees of weakness and sensory loss, which can develop in the limbs.</p> <p>Nerves around the head may also be affected and cause symptoms such as facial weakness and double vision.</p> <p>Other symptoms may include pain and diminished reflex responses; may have difficulty with urination and bowel movements, and occasionally respiratory paralysis, irregular heartbeat, and dangerously high or low blood pressure.</p>	<p>Treatment and response rates are similar to those seen in the HIV-negative population.</p> <p>Intravenous immunoglobulin (IVIG), a highly concentrated antibody infusion from many pooled blood donations, is the mainstay of therapy.</p> <p>Plasma exchange, or plasmapheresis, may be helpful; in this procedure antibodies are removed from the blood.</p> <p>Chronic IDP may also necessitate use of corticosteroids such as prednisone.</p>
Mononeuritis multiplex	<p>Painful condition that involves isolated nerves over the arms, legs, or trunk; nerves are affected asymmetrically.</p> <p>The involvement of more than two nerves is generally seen in people with advanced HIV.</p> <p>Patients complain of burning or shooting pain down an arm or leg, then, even as it is resolving, another burning pain will emerge over another nerve pathway down a different arm or leg.</p> <p>Weakness in the distribution of specific nerves is common.</p>	<p>Occurring early in HIV infection. May resolve with HAART.</p> <p>IVIG or plasma exchange should be considered in early or late HIV stages.</p> <p>Late-stage HIV disease may require anti-CMV medications (ganciclovir, foscarnet).</p>
Polyradiculopathy	<p>Nerves can be affected in the head and the body.</p> <p>Damage to the nerve roots where the nerves exit the spinal cord to form peripheral nerves.</p> <p>Polyradiculopathy may be caused by CMV, or less likely by lymphoma; may also be idiopathic (of unknown origin).</p> <p>Rapidly progressive ascending numbness, pain, and weakness affecting the legs, and later occasionally the arms, is characteristic of the CMV form.</p> <p>Early bowel and bladder control problems may suggest the syndrome.</p> <p>More benign, slower clinical progression characterizes the idiopathic form.</p>	<p>CMV polyradiculopathy is rapidly fatal without therapy.</p> <p>Treatment with foscarnet or ganciclovir may improve or stabilize the condition.</p> <p>HAART also may be useful.</p> <p>The idiopathic form may improve spontaneously without treatment.</p>

TABLE 31-7 ■ HIV AND NEUROLOGICAL CONDITIONS—cont'd

CONDITION	COMMENTS AND SYMPTOMS	PROGNOSIS AND TREATMENT
Myopathy	<p>HIV-associated myopathies fall into several categories: some are caused by drug toxicity, for instance, from cholesterol-lowering drugs (statins), ddI, or AZT (zidovudine [Retrovir]); others are caused by a variety of bacterial, viral, and other infections; still others, such as polymyositis (inflammatory disease of muscles), are caused by an abnormal immune response; HIV wasting syndrome may result from HIV infection itself.</p> <p>Progressive muscle weakness is the typical presentation, with the speed of progression depending on the cause.</p>	<p>If medications are the likely cause, they may need to be stopped or replaced.</p> <p>Muscle infections are treated with drugs specific to the responsible bacterium, virus, or other infectious agent.</p> <p>When inflammation results from an overactive immune system, corticosteroids may be a treatment option.</p>

CMV, Cytomegalovirus; CNS, central nervous system; CSF, cerebrospinal fluid; FDA, U.S. Food and Drug Administration; HAART, highly active antiretroviral therapies; PML, progressive multifocal leukoencephalopathy; SSRI, selective serotonin reuptake inhibitors; TB, tuberculosis; TMP-SMX, trimethoprim-sulfamethoxazole.

deficits may develop.⁹³ It is not possible in this context to discuss the neuropathological features of each of the many secondary infections and neoplasms of HIV illness. It is important to realize, however, that the clinical manifestations of these pathological processes overlap with one another and with the signs and symptoms of primary HIV infection of the CNS; lesions of the CNS can be the site of more than one opportunistic disease process simultaneously. In Table 31-8, a wide variety of organisms or conditions responsible for the neurological manifestations associated with HIV infection are listed. These include primary and secondary viral, protozoan, fungal, and *Mycobacterium* infections, as well as neoplasms and iatrogenic conditions. Infectious processes may cause large lesions in the brain, such as meningitis, encephalitis, or both. Such infections cause neurocognitive impairments that develop as dementia, amnesia, or delirium.⁹³ Thirty percent to 40% of healthy adults have contracted toxoplasmosis, caused by *Toxoplasma gondii*.^{34,94} Unchecked by the immune system, toxoplasmosis results in CNS dysfunction—namely, altered cognition, headache, focal neurological deficits, encephalitis, and seizures. Cerebellar disorders associated with HIV infection are typically the result of discrete cerebellar lesions resulting from opportunistic infections such as toxoplasmosis and progressive multifocal leukoencephalopathy or primary CNS lymphoma.⁹⁵ CNS lymphoma results in cognitive dysfunction and presentation of fever, focal neurological impairments, headache, seizures, and motor deficits.⁹³

Evidence supports that the neurotoxic effect of HIV is more likely to affect the basal ganglia, the frontal neocortex, the white matter tracts connecting the regions (such as the fronto-striato-thalamocortical loops), the temporal cortices (including the hippocampus), and the parietal cortices.⁹⁶ A relationship between stroke and AIDS has been reported.^{97,98} The most common cause of cerebral infarction in both clinical and autopsy series was nonbacterial thrombotic endocarditis. Intracerebral hemorrhages were

usually associated with thrombocytopenia, primary CNS lymphoma, and metastatic KS.

HIV-related conditions in the spinal cord include not only HIV myelitis, opportunistic infections, and lymphomas but also vacuolar myelopathy, which affects predominantly the dorsolateral white matter tracts. The cause of vacuolar myelopathy is not understood, and it has not been unequivocally linked with HIV infection.⁹⁹ Vacuolar myelopathy may affect up to 30% of untreated adults with advanced HIV/AIDS, and the incidence may be even higher in children infected with HIV.¹⁰⁰ Unless it is treated with effective antiretroviral therapy, vacuolar myelopathy of the spinal cord associated with moderate clinical disability develops in many patients with AIDS.¹⁰¹

Treatment for CNS impairments includes an eclectic blend of rehabilitation strategies. Neuromuscular disturbances may first appear as movement disorders. Subtleties of altered movement can be detected early and during subsequent treatment phases. A neurological examination can be performed to determine a diagnosis and prognosis. This may include the level of the lesion, neuromuscular deficits, need for assistive devices, ability to perform ADLs, and functional abilities. Various quality-of-life assessments used with the HIV population can be found in Table 31-9.

Peripheral Nervous System. Possible neurological complications associated with HIV disease that may affect the PNS include meningitis, ataxia, myelopathy, and encephalitis. PNS diseases have been reported in up to 50% of HIV-infected individuals, resulting in distal polyneuropathy, Guillain-Barré syndrome, and mononeuropathy.¹⁰²

Distal symmetrical polyneuropathy (DSP) is the most common form of neuropathy in HIV infection. The most frequent complaints in DSP are numbness, burning, and paresthesias in the feet. These symptoms are typically symmetrical and often so severe that patients have contact hypersensitivity and gait disturbances. Involvement of the upper extremities and distal weakness may occur later in the course of DSP. Neurological examination shows sensory loss to pain and

TABLE 31-8 ■ COMMON OPPORTUNISTIC DISEASES IN HIV INFECTION

DISEASE AND PATHOGEN	SITES OF INFECTION	SYMPTOMS	MEDICATIONS AND SIDE EFFECTS	DISEASE-SPECIFIC PRECAUTIONS
PCP— <i>Pneumocystis jiroveci</i> , a protozoan found in air, water, and soil, carried by domestic animals, and possibly latent in most people.	Lungs; sometimes spreads to the spleen, lymph nodes, and blood in late disease	Fever, cough, shortness of breath, chills, chest pain, sputum production	Trimethoprim-sulfamethoxazole: rash, itching, Stevens-Johnson syndrome, extreme fatigue, dysphagia, fever, leukopenia, sore throat, thrombocytopenia, hepatitis, hematuria, diarrhea, dizziness, headache, anorexia, nausea, vomiting Intramuscular or intravenous pentamidine isethionate: azotemia, serum creatinine elevations, pain and induration at intramuscular sites, abscess or necrosis at injection sites, elevated liver function test results, leukopenia, nausea, vomiting, hypotension, syncope, blood sugar imbalances Aerosolized pentamidine isethionate: investigational Dapsone: nausea, vomiting, abdominal pain, vertigo, blurred vision, tinnitus, insomnia, fever, headache, phototoxicity, lupus, anemia Sulfadoxine-pyrimethamine: allergic skin reactions, nausea and vomiting, glossitis, stomatitis, headache, peripheral neuritis, mental depression, fatigue, weakness	None
Toxoplasmosis— <i>Toxoplasma gondii</i> , a protozoan found in air, water, soil, and some cats and other animals. Most often acquired by ingestion of uncooked infected lamb or pork, unpasteurized dairy products, raw eggs, or vegetables. Mothers can give it to unborn children. Other human-human transmission does not occur.	Produces lesions in the CNS; may also involve heart and lungs	Fever, chills, headache, visual disturbances, lethargy, confusion, hemiparesis, seizures	Sulfadiazine: same as for trimethoprim-sulfamethoxazole Pyrimethamine: anorexia, vomiting, megaloblastic anemia, leukopenia, thrombocytopenia, glossitis	None
Cryptosporidiosis— <i>Cryptosporidium</i> , a protozoan primarily acquired through oral contact with feces of an infected animal, or oral sexual contact with an infected person	GI tract	Copious diarrhea, abdominal pain, anorexia, nausea, vomiting, dehydration, weight loss, weakness, fever	Spiramycin: nausea, vomiting, diarrhea, abdominal pain Eflornithine: investigational	Gloves and gown or apron when handling feces Private room when patient has poor hygiene

TABLE 31-8 ■ COMMON OPPORTUNISTIC DISEASES IN HIV INFECTION—cont'd

DISEASE AND PATHOGEN	SITES OF INFECTION	SYMPTOMS	MEDICATIONS AND SIDE EFFECTS	DISEASE-SPECIFIC PRECAUTIONS
Isosporiasis— <i>Isospora belli</i> , a protozoan primarily acquired through eating uncooked beef or pork or through oral sexual contact with an infected person	GI tract	Diarrhea, abdominal pain, nausea, vomiting, anorexia, weight loss, weakness, fever	Trimethoprim-sulfamethoxazole: see under PCP— <i>P. jiroveci</i>	Gloves and gown or apron when handling feces Private room when patient has poor hygiene
<i>Mycobacterium avium-intracellulare</i> infection— <i>M. avium-intracellulare</i> , a bacterium found in soil, water, animals, eggs, and unpasteurized dairy products and other foods. Infection is atypical and noncommunicable.	Disseminated	Fever, malaise, night sweats, anorexia, diarrhea, weight loss	Isoniazid: paresthesia and peripheral neuropathy, elevated liver function test values, anorexia, nausea, vomiting, fatigue, malaise, weakness Rifabutin: hepatotoxicity, neutropenia, nausea, vomiting, diarrhea, rash, itching Clofazimine: reddish-brown discoloration of skin, conjunctiva, sweat, hair, urine, and feces; abdominal pain, diarrhea Ethambutol: reversible blurring of vision, anaphylaxis, skin irritation, nausea, vomiting, fever Cycloserine: convulsions, drowsiness, headache, tremor, other CNS disturbances Ethionamide: nausea, vomiting, peripheral and optic neuritis, mental depression, postural hypotension, rash Rifampin: urine discoloration, heartburn, nausea, vomiting, abdominal cramps, headache, drowsiness, fatigue Streptomycin: nausea, vomiting, vertigo, numbness of the face, rash, fever, itching, elevated white blood cell count	Gloves and gown or apron when handling wound drainage
Candidiasis— <i>Candida albicans</i> , a fungus that inhabits the oropharynx, vagina, large intestine, and skin, causing no harm as long as immunity remains undamaged; may occur as a secondary infection in conjunction with herpes simplex virus lesions.	Anywhere skin or mucous membrane is damaged, including through intravenous therapy and pressure monitoring sites	Thrush, esophageal, perianal irritation, vaginitis, proctitis; inflammation around fingernails can be disseminated	Clotrimazole: abdominal pain, diarrhea, nausea, vomiting Nystatin: diarrhea, nausea, vomiting, stomach pain Ketoconazole: hepatitis, gynecomastia, nausea, vomiting, decreased libido, diarrhea, dizziness, drowsiness, photophobia, rash, itching, sleepiness Amphotericin B: fever, shaking chills, hypotension, anorexia, nausea, vomiting, headache and tachypnea	None

Continued

TABLE 31-8 ■ COMMON OPPORTUNISTIC DISEASES IN HIV INFECTION—cont'd

DISEASE AND PATHOGEN	SITES OF INFECTION	SYMPTOMS	MEDICATIONS AND SIDE EFFECTS	DISEASE-SPECIFIC PRECAUTIONS
Cryptococcosis— <i>Cryptococcus neoformans</i> , a fungus found in air, water, soil, raw fruits and vegetables, and pigeon droppings found on window ledges and nesting places; acquired by inhalation.	CNS, lungs; can be disseminated	Altered cognition, low-grade fever, headache, nausea, vomiting, meningeal signs	Amphotericin B: fever, shaking chills, hypotension, anorexia, nausea, vomiting, headache and tachypnea Ketoconazole: see under Candidiasis	None
CMV infection— cytomegalovirus, an organism found in saliva, semen, cervical secretions, urine, feces, blood, breast milk. It causes problems only when immunity is compromised.	Disseminated	Fever, profound fatigue, muscle and joint aches, night sweats, impaired vision, cough, dyspnea, abdominal pain, diarrhea	Ganciclovir: leukopenia, bone marrow depression, elevated liver enzymes, edema, nausea, muscle aches, headaches, anorexia, disorientation, rash, phlebitis	Private room if the patient has enteritis and poor hygiene. Gloves and gown or apron for handling excretions and secretions if soiling is likely
Herpes simplex virus (HSV) infection—HSV-1 is spread by contact with infected oral secretions. HSV-2 is spread by contact with infected genital secretions. Patient can spread either variety by touching lesions then touching other body parts.	Mouth, perianal area; can be disseminated	Painful burning, itching vesicular lesions; sometimes colitis, pericarditis, esophageal infection	Acyclovir: rash, diarrhea, light-headedness, headache, nausea, vomiting, thirst, fatigue	Gloves and gown or apron for handling secretions from lesions Private room if infection is disseminated or severe
Progressive multifocal leukoencephalopathy (PML)—JC virus; transmission routes unclear	Brain	Impaired speech, vision, and thought; ataxia and limb weakness; advanced disease can cause profound dementia	No known effective treatment	None

CMV, Cytomegalovirus; CNS, central nervous system; GI, gastrointestinal.

TABLE 31-9 ■ QUALITY-OF-LIFE ASSESSMENTS IN HIV DISEASE

INSTRUMENT	AUTHOR	DIMENSIONS	LENGTH	ADMINISTRATION
AIDS Health Assessment Questionnaire (AIDS-HAQ)	Lubeck and Fries (1991-1992)	Physical function, mental health, cognitive function, social health, energy and fatigue	30 items	Self-administered (5 minutes)
AIDS Specific Functional Assessment (ASFA)	Rapkin et al (1991-1993)	Evaluates usefulness of functional assessment	Varies	Self-administered, care provider
Idiographic Functional Status Assessment (IFSA)	Rapkin et al (1991-1992)	Patient-generated activities associated with pursuit of following goal types: a. achievement b. problem-solving c. avoidance-prevention d. maintenance e. disengagement	75 items	Self-administered

TABLE 31-9 ■ QUALITY-OF-LIFE ASSESSMENTS IN HIV DISEASE—cont'd

INSTRUMENT	AUTHOR	DIMENSIONS	LENGTH	ADMINISTRATION
Medical Outcomes Study HIV Instrument (MOS-HIV or MOS-30)	Wu et al (1991)	Health, pain, physical functioning, role functioning, social functioning, mental health, fatigue, energy, health distress, cognitive functioning, health transition, general quality of life	30 items	Self-administered (5 minutes)
HIV Patient-Assessed Report of Status and Experience (HIV-PARSE)	Berry et al (1991)	Physical health, mental health, general health	38 items	Self-administered (5 minutes)
Functional Multidimensional Evaluation of People with HIV (VFM/HIV)	Marazzi et al (1992)	Self-sufficiency with ADL, economic resources, social resources, physical health, mental health	12 items	Self-administered
Neuropsychiatric AIDS Rating Scale (NARS)	Boccellari et al (1992)	Assesses patient's orientation, memory, motor ability, behavioral changes, problem-solving ability, and ADL	Varies	Health care provider
HIV Overview of Problems Evaluation System (HOPES)	Schag et al (1992)	Global, physical, psychosocial, medical interaction, significant others, sexual components	139 items	Self-administered (15 minutes)
HIV-Related Quality-of-Life Questions (HIV-QOL)	Cleary et al (1993)	Mental health, energy and fatigue, fever, limitations of basic ADL and intermediate ADL, disability days, all symptoms, sleep symptoms, neurological symptoms, memory symptoms, pain	30 items	Self-administered (5 minutes)
HIV Quality Audit Marker (HIV-QAM)	Holzemer et al (1993)	Captures nurse data collector's judgment of status of patient based on observations, interviews, and recorded interviews	Varies based on duration of interview	Nurse
HIV Visual Analog Scale	Nokes et al (1994)	Rates HIV-related symptom severity and general well-being	Varies	Nurse
HIV Assessment Tool (HAT)	Nokes et al (1994)	Physical symptoms related to HIV disease, social and role functioning, psychological well-being, and personal attitudes related to well-being	34 items	Self-administered Self-administered
Multidimensional Quality of Life Questionnaire for Persons with HIV (MQOL-HIV)	Avis and Smith (1994)	Mental health, physical health, physical functioning, social functioning, social support, cognitive functioning, financial status, partner intimacy, sexual functioning, medical care	40 items	Self-administered (10 minutes)
Medical Outcomes Study HIV Health Survey (MOS-HIV)	Wu, Rivicki, Jacobson, and Maltz (1997)	General health perceptions, role functioning, mental health, quality of life, pain, social functioning, health distress, physical functioning, energy and fatigue, cognitive function, and health transition	35 items	Self-administered or via interview (5-10 minutes)

TABLE 31-9 ■ QUALITY-OF-LIFE ASSESSMENTS IN HIV DISEASE—cont'd

INSTRUMENT	AUTHOR	DIMENSIONS	LENGTH	ADMINISTRATION
HIV/AIDS-Targeted Quality of Life (HAT-QoL) Instrument	Holmes and Shea (1998)	Overall function, sexual function, disclosure worries, health worries, financial worries, HIV mastery, life satisfaction, medication concerns, provider trust	42 items	Self-administered (15 minutes)
World Health Organization-Quality of Life HIV Instrument (WHOQOL-HIV)	Mental Health: Evidence and Research Department of Mental Health and Substance Dependence, World Health Organization, Geneva	Physical, psychological, level of independence, social, environmental, spiritual, general quality of life and health, symptoms of HIV, social inclusion, death and dying, forgiveness and fear of death	115 items	Self-administered
Functional Assessment of Chronic Illness Therapy—Spiritual Well-Being (FACIT-Sp-12)	Brady et al; Peterman (2002)	Faith, meaning, and peace	12 items	Self-administered
The Self-Efficacy for Managing Chronic Disease 6-Item Scale	Lorig and Sobel (2001)	Covers several domains that are common across many chronic diseases—symptom control, role function, emotional functioning, and communicating with physicians—with less subject burden than other surveys	6 items	Self-administered

temperature in a stocking-glove distribution, increased vibratory thresholds, and diminished ankle reflexes compared with knee reflexes.^{85,103} Patients with AIDS frequently have concurrent CNS disorders and neuropathy, characterized by hyperactive knee reflexes and depressed ankle reflexes.

The incidence of DSP increases with advancing immunosuppression, in parallel with decreased CD4 counts.¹⁰⁴ Thirty-five percent of patients with AIDS may have electrophysiological or clinical abnormalities.¹⁰⁵ Furthermore, pathological evidence of DSP is present in almost all patients who die of AIDS.¹⁰⁶ Various theories regarding the mechanism of DSP have been proposed. It was formerly thought that direct HIV invasion of the nervous system caused DSP⁹⁴; however, most investigators now believe that this is not the sole cause.¹⁰⁴ A “dying-back” neuropathy affecting all fiber types, with prominent macrophage infiltration of the peripheral nerve, has been described.¹⁰⁶ Additional theories include HAART drug toxicity, neurotoxic effects of cytokines, toxicity of HIV proteins, and mitochondrial damage.¹⁰⁷ Cytokines, tumor necrosis factor, and interleukin-1 have been identified in the peripheral nerves of patients with AIDS.¹⁰⁸

Balance and Postural Mechanisms. Balance disturbances may be seen with HIV involvement of either the CNS or the PNS. Polyneuropathy caused by AZT (AZT polyneuropathy) and CMV, which is a common pathogen in AIDS (inflammatory polyneuropathy), may manifest in the

form of a generalized asymmetrical demyelination and chronic denervation of muscles.¹⁰⁹ Demyelination and denervation of nerves that supply postural muscles may weaken such muscles and result in balance problems (e.g., distal pain, paresthesia, numbness, or core weakness). It is also possible that, apart from muscle demyelination and denervation, the pathological process, which also includes macrophage infiltration of neural structures, could spread to affect the vestibular neural complex of the inner ear, which is important in the maintenance of both static and dynamic balance. Our clinical experience shows that sensory changes are common in the lower limbs of neuropathic HIV/AIDS patients. The balance problems of these patients are likely to be connected to a lack of adequate proprioception from the legs during stance, and it is well known that diminished sensory information makes gait control more difficult. Refer to Chapter 22 for a discussion of balance dysfunction.

Peripheral neuropathy weakens the neuromuscular system and causes a limitation in functional activities. These effects on the neuromuscular system manifest in disturbances of postural control. An appropriate posture should be regarded as the starting position for a functional activity. However, compromise of the postural pattern is so characteristic of HIV peripheral neuropathy that it is diagnostic for HIV-1 infection.¹¹⁰ The neurological abnormality resulting from peripheral neuropathy in HIV/AIDS produces postural disturbances¹¹¹ that may take various forms that worsen with

the severity of the neuropathy¹¹² and compromise functional activity at various levels. This means that as the condition of HIV/AIDS patients deteriorates, balance deficits may increase.

According to Husstedt and colleagues,¹¹³ peripheral neuropathy in HIV disease progresses much more rapidly than that associated with diabetes or hereditary polyneuropathies. Again, because of demyelination as the HIV infection progresses, distal symmetrical peripheral neuropathy increases, resulting in a depression of certain motor functions such as gait and manual dexterity, and a worsening of the condition is caused by demyelination.¹¹³ There is therefore a need to treat HIV neuropathy as soon as it is diagnosed, to avoid complications that lead to impairments in functional mobility.

One group⁶¹ has identified peripheral neuropathy and its complications as causes of functional limitations in individuals with HIV disease. A patient who, for instance, has balance impairment resulting from peripheral neuropathy may not function effectively with ADLs. Functional impairments may impede a patient's ability to return to gainful employment. For individuals with HIV disease, peripheral neuropathy and its resulting pain may be a limiting factor in the ability to return to work. Any intervention that can aid in the reduction of functional limitations should be incorporated into the rehabilitation plan of care.

Pain

A factor closely related to HIV neuropathy is pain. Pain is one of the most prominent and distressing symptoms in patients with HIV disease, and it has a significant effect on quality of life and psychological state. Pain may affect patients at any stage of the disease process; however, it is more frequent during the advanced stages. The occurrence of pain during HIV infection varies from 30% to 80%. Pain is the result of a complex process that involves psychological and neurophysiological mechanisms, and therefore it should be assessed with use of sensitive tools that examine its multidimensional nature. One model that evaluates the evaluative, affective, and sensory aspects of pain is the McGill Pain Questionnaire. This assessment tool is useful in evaluating HIV disease-related pain because different causes and non-sensorial factors related to the disease often make clinical assessment of pain difficult.¹¹⁴

Most HIV patients require various pain treatment interventions. Distal symmetrical peripheral neuropathy has been shown to be the most common peripheral neuropathy complaint in patients with HIV-1 infection.¹¹⁵⁻¹¹⁷ Peripheral neuropathy is one of the most common types of pain in HIV-infected men,¹¹⁸ and peripheral neuropathies occur in as many as 40% to 60% of patients with HIV disease. Peripheral neuropathy is the most prevalent neurological complication associated with HIV. CNS or PNS involvement has been found in 30% to 63% of patients across the arena of HIV and is often related to antiretroviral therapy.¹¹⁹ When neuropathy results in distal painful paresthesia, imbalance in stance and gait may result from compensatory measures aimed at relieving pain in dynamic standing activities. Postural compensations may further exacerbate musculoskeletal, cervical, thoracic, or lumbosacral back pain.

Pain management is a critical part of the overall care of individuals with HIV disease. Pain is the second most

common reason for hospitalization of patients with AIDS.¹²⁰ A study of 72 AIDS patients found that 97% had pain related to the disease process.¹²¹ Newshan and Wainapel,¹²¹ who surveyed 100 patients who had pain associated with AIDS, showed that the two reported pain types were abdominal and neuropathic pain. In a longitudinal study of HIV-positive men, painful peripheral neuropathy was one of the most common types of pain.¹¹⁸

DSP results in painful paresthesias that are challenging to treat with pharmacological interventions. Oral gabapentin and cutaneous lidocaine patches are often prescribed to manage pain associated with peripheral neuropathy. Clinical experience shows that conventional transcutaneous electrical nerve stimulation may exacerbate or relieve peripheral pain in patients with HIV infection. Another consideration for treatment is low-voltage electroacupuncture.¹²² Manual therapy to improve ankle and foot range of motion along with other compensatory areas is recommended for pain management and return to function. (See Chapters 32 and 39 for additional information.)

Psychopathology

Medical and neuropsychiatric sequelae of HIV infection present a spectrum of diagnostic and treatment challenges to health care practitioners. Both HIV infection and the various opportunistic infections that manifest in patients as the result of an immunocompromised state can affect the CNS. Epidemiological studies indicate that greater than 60% of HIV-positive individuals will experience at least one major psychiatric disorder during the course of their infection. Depression is the most common disorder, closely followed by anxiety and substance abuse disorders.¹²³ Therefore therapists need to be familiar with the diagnosis and management of HIV infection-related medical and psychiatric disorders. These disorders have a great impact on the outcomes of rehabilitation.

Careful consideration of psychological function is warranted during clinical encounters with HIV-infected persons. AIDS-related psychopathologies mimic many previously described consequences of primary HIV infection, opportunistic infections, and drug side effects. These psychiatric complications can be affective or organic. Indicators include disturbances in sleep and appetite patterns, diminished memory and energy, psychomotor retardation, withdrawal, apathy, and emotional lability. Anxiety disorders (particularly post-traumatic stress disorder), adjustment reactions, reactive and endogenous depressions, and obsessive disorders frequently result.¹²⁴⁻¹²⁶ Refer to Chapter 6 for additional recommendations regarding psychological adaptation and adjustments to nervous system dysfunction.

With use of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision, one study found Axis I disorders (excluding substance abuse) in 61.9% of the subjects.¹²⁷ Indeed, the virus's affinity with subcortical structures of the CNS that regulate affect and mood supports research indicating a prevalence of manic episodes that is 10 times higher than in the general population.¹²⁸ Manic episodes have been identified at all stages of the disease process and may also occur in response to AZT therapy.^{16,46,129} When associated with HIV infection, mania appears to be secondary to structural CNS changes.^{130,131} Described manic

episodes generally respond well to psychiatric medications and may not recur.^{46,132-134}

Analyses of new-onset psychosis among HIV-positive individuals yielded the following information. Psychotic episodes are preceded by a period (days to months) of affective and behavioral changes.¹³⁵ Admitting diagnoses to psychiatric units included “undifferentiated schizophrenia, schizophreniform disorder, ‘reactive psychosis,’ atypical psychosis, depression with psychotic features and mania.”¹³⁵ Some psychiatric diagnoses were revised during the course of hospitalization to “AIDS encephalitis, cryptococcal meningitis, or ‘organic psychosis.’”¹³⁶ Eighty-seven percent of the subjects in one study displayed delusions that were usually persecutory, grandiose, or somatic. Affective disturbances were present in 81% of the subjects. Hallucinations and thought process disorders were each prominent in 61% of patients. Several subjects received the diagnosis of AIDS during their psychiatric hospitalization.¹³⁶

Remarkable progress has been made in recent years in the therapeutics of HIV-associated dementia. Viral replication in and outside the CNS has been reduced by HAART. This has resulted in partial repair of cellular immune function with improvement in, and prevention of, neurological deficits associated with HIV disease.¹³⁷ Extensive use of PIs is associated with dramatic declines in overall mortality and morbidity, including HIV-associated dementia.^{37,138}

Neuropathological abnormalities seen in the brain tissue of patients with HIV-associated dementia are usually diffuse and predominantly localized to the white and deep gray matter regions. Myelin pallor and inflammatory infiltrates composed of macrophages and multinucleated giant cells are the hallmarks of this disease process, although a spectrum of lesions has been identified from encephalitis to leukoencephalopathy.^{139,140} The characteristic clinical feature of HIV-associated dementia is disabling cognitive impairment, often accompanied by behavioral changes, motor dysfunction, or both.¹⁴⁰ Degrees of impairment have been recorded, and a five-part staging system was subsequently developed.¹⁴¹⁻¹⁴³ Motoric manifestations of AIDS dementia complex include gait disturbances, intention tremor, and abnormal release of reflexes.

Differentiation between psychiatric and physiological manifestations is complicated. Psychiatric and organic disorders are initially indistinguishable on the basis of behavior and may exist concurrently. Furthermore, other primary disease processes and drug reactions imitate psychopathological conditions. Differentiation is nonetheless essential because many disorders respond well to established therapies, both psychological and pharmacological, once differential diagnoses have been established. Awareness of the intricate interplay of all factors is essential for competent rehabilitative efforts for those infected with HIV.

Pediatric HIV Infection

Pediatric HIV infection differs from that most commonly seen in adults. Symptoms develop much earlier in pediatric patients compared with adults. Children infected with HIV may be classified as “rapid progressors” or “slow progressors.” Rapid progressors are children infected with HIV who manifest symptoms within the first 12 to 24 months of life. These children progress quickly to

AIDS-defining conditions and have a rapid decline in CD4 count. Children who are slow progressors have a more gradual progression of symptoms and are likely to show evidence of immune system compromise by 7 to 8 years of age. A small percentage of children remain healthy and have only nominal or no symptoms of the disease and a normal to slightly decreased CD4 count through 9 to 10 years of age.¹⁴⁴

The prediction of 6 million pregnant women and 5 to 10 million children infected with HIV-1 by the year 2000¹⁴⁵ may have been an underestimate. An accurate understanding of the timing of HIV transmission from mother to fetus is important for the design of intervention strategies. The AIDS Clinical Trial Group Study (ACTG) 076 trial, which included treatment from the fourteenth week of gestation in women with CD4 counts of more than 200/mm³, prompts other considerations.¹⁴⁶ Onset of HIV-1 infection in children has a wide spectrum of clinical manifestations.¹⁴⁷ Thus prevention of transmission from mother to fetus via HAART is a critical component of managing this worldwide epidemic.

Pediatric HIV is neurotrophic in nature in that the virus most often initially affects the CNS rather than the PNS. As the virus spreads, pediatric HIV patients can have CNS disorders that include encephalopathy, pyramidal tract signs, receptive and expressive language difficulties, cognitive deficits, psychomotor impairments, and upper respiratory infections.¹⁴⁴ Neuroimaging shows HIV has an influence on neurological function in the basal ganglia, frontal cortex, and other connecting structures in the CNS. Studies also support that there is an environmental component which contributes to developmental and behavioral issues in HIV-positive children.¹⁴⁸

In the first year of life, severe immunodeficiency develops in 15% to 20% of pediatric patients with serious recurrent infections or neurological dysfunction, whereas in school-age children the disease progresses more slowly and the risk for development of HIV-related encephalopathy becomes less.¹⁴⁹ Some infants have features of severe immunodeficiency, whereas others have nonspecific findings, such as hepatosplenomegaly, failure to thrive, unexplained fever, parotitis, and recurrent gastroenteritis. Adenopathy is common, and salivary gland enlargement occurs more frequently than in adults. Otitis media and measles, despite immunization, are also more frequent complications in children.^{56,81} Cardiac involvement in children with HIV infection is a well-known entity and occurs clinically more often in patients with advanced disease.¹⁵⁰

Studies have shown that children with HIV demonstrate behaviors often associated with attention-deficit/hyperactivity disorder (ADHD) including impulsivity, hyperactivity, difficulty attending, and decreased ability to focus on stimuli. In one study, the most common behavioral issues were psychosomatic disorders (28%), learning disorders (25%), hyperactivity (20%), impulsive-hyperactive disorder (19%), conduct problems (16%), and anxiety (8%); standardized intelligence scores were lower compared with established population norms. Hyperactivity was more common in children with a Wechsler IQ lower than 90, anxiety issues were more common in children older than 9 years, and conduct disorders were more often seen in children with CD4 counts less than 660 cells/mL.¹⁴⁸

Children are susceptible to disorders seen in adults—herpesvirus infection, pneumonia, toxoplasmosis, meningitis, and encephalitis. HIV encephalopathy is noted to have the most serious side effects because of its progressive deteriorating pattern and associated CNS abnormalities,¹⁷ although static encephalopathy can be characterized by severely delayed cognitive functioning and neuromotor skills without deterioration.¹⁵¹ Manifestations in children include cerebral atrophy, ataxia, rigidity, hyperreflexia, and the inability to achieve or sustain developmental milestones. Although the HIV neurodevelopmental involvement causes a prognostic worsening, most studies of pediatric cases of neuro-AIDS demonstrate that an early diagnosis followed by adequate antiretroviral therapeutic regimens can lead to significant, even if temporary, improvement.¹⁴⁹

Rehabilitation of the pediatric patient requires a multidisciplinary approach to meet the medical, emotional, and psychosocial needs of these children and their families. Children are encouraged to give form to their psychological experiences through play, writing or telling stories, and creating works of art.¹⁵²

REHABILITATION INTERVENTIONS

The examination procedures for HIV illness are broadly outlined in the following paragraphs. Of course, each case varies and the evaluation process is individualized according to the specific needs of the client (Box 31-3).

What is the relationship of the person with HIV infection to the environment, both at present and in the future? The rehabilitation therapist should keep this question in mind throughout the examination process. In this context the term *environment* is meant to include not only the physical aspects of surroundings but also the psychological and emotional climate in which the individual functions (see Table 31-1).

The examination process has a different focus for different stages of the disease. If the client is in the early stages of the disease, the therapist should determine whether she or he is still managing in accustomed life roles. Important issues may include new or adapted vocational and leisure skills. During the advanced stage, the focus may change to more basic daily functional concerns. The therapist must remember, however, that the client may place more importance on participation in avocational interests than on independent self-care. This choice not only is valid but must be respected and supported by health care professionals. If the patient is evaluated in an inpatient setting, another crucial determination to be made is whether the person is to be discharged to home or some other supervised setting. It is critical to determine what kind of community-based support networks are available to the individual. Case managers are often adept at identifying home and community resources available and will assist in setting up these resources before the patient's discharge.

Astute evaluative questions about the psychosocial status of the client include the following:

- Does the client's perception of his or her status and prognosis agree with that of the treatment team?
- What is the client's predominant coping style?
- Who are the client's caregivers?
- What is the social support system?
- What is the client's home environment?
- What is the client's prior level of function?

The support system can be a critical issue for many people with HIV infection, especially those who are part of the high-risk groups, such as homosexual and bisexual men and intravenous drug users.¹⁵³ Many of these people have traditional networks of family, spouse, and friends; a significant number have equally strong nontraditional support systems. Some

will be lacking in the kinds of support needed to cope with the devastating physical and emotional effects of the disease.

It is possible to use models developed for oncology and progressive neurological disorders for HIV involvement of the CNS and PNS. An orthopedic approach may be taken when pain is a presenting factor or biomechanical alterations are a result of other disease processes. Functional fluctuations that characterize HIV infection and secondary infections must be understood; therefore the therapist must appreciate the effects that HIV infection has on various systemic complications.

The examination of an individual who has HIV disease should include standard cognitive, perceptual, and motor function evaluative tools. The idiosyncratic nature of the disease may necessitate more detailed evaluation of these specific areas. Recommended cognitive and perceptual evaluations are both formal and observational. Safety, judgment, functional mobility, ADL management, community management skills, and independent financial management skills need to be assessed. Evaluation of the systemic complications of HIV infection is necessary for optimal rehabilitative planning and treatment team efficacy.

The ADL evaluation is best made within the context of the immediate and projected life roles of the individual. Maximal independent functioning is the goal of rehabilitation, whatever the stage of illness. If the person is at home or is being discharged to home, a crucial component of the ADL examination is the assessment of community management skills; consider an individual's access to transportation, socialization opportunities, shopping, and banking. The ability to negotiate health care and insurance systems and participate in community activities is critical to returning to independence. Many people with HIV infection and their caregivers have minimal experience with disability because of their age or social status. This, combined with the stressors of illness, can create unrealistic expectations and unnecessary frustrations.

Treatment Process

The neuromuscular rehabilitation treatment procedures for HIV infection and an overview of treatment techniques for opportunistic infections are presented in Boxes 31-4 and 31-5.

Cognitive deficits in attention, concentration, and memory necessitate consistency, structure, and environmental cues to minimize confusion. Safety and judgment deficits can be countered by environmental adaptations. Lethargic clients benefit from sensory enhancement. Maintenance of endurance, strength, and passive and active range of motion are important components of any motor function treatment plan. Neuromuscular facilitation and inhibition, positioning, and splinting are feasible modalities to normalize tone as needed. Gait training, the use of assistive devices, training in motor planning, balance activities, and endurance exercises may be appropriate.

In addition to techniques and modalities, active listening, empathy, and unconditional positive regard are important aspects of the therapeutic process. The clinician must set aside personal biases and beliefs to accurately hear the perspective of the individual client. The use of expressive modalities facilitates the development of coping skills while providing appropriate exploration and release of powerful emotions. Human touch can counter the powerful and isolating effect of fear of contagion. Rehabilitation therapists can demonstrate and educate caregivers about the safety and benefit of touch.

Motoric manifestations of AIDS dementia complex include gait disturbances, intention tremor, and abnormal release of reflexes. Rehabilitation and progression of independent functional mobility become more complex in these patients secondary to the cognitive involvement.

Pain management is best approached with a behavioral and a physical approach. Pain reduction is achieved through training in breathing techniques, visualization, progressive muscle relaxation, autogenics, music, meditation, and engagement in meaningful activities. Various forms of electrotherapy such as

BOX 31-5 ■ MOST COMMON OPPORTUNISTIC INFECTIONS AND REHABILITATION INTERVENTIONS IN HIV-INFECTED PATIENTS

PCP—Most common opportunistic infection. Infectious agent unclear but probable latent infection; 65% to 85% of healthy adults possess PCP antibodies. Fever, dyspnea, and hypoxia → diaphragmatic breathing, energy conservation.*

Candida albicans—Present in healthy people, immunocompromised status → yeast infections of oral, esophageal, and vaginal mucosal tissues → teach good oral care with soft brush, bland diet, salt water rinses.

Cryptococcus neoformans—A yeast that manifests in CNS as abscesses and meningitis. Headache, altered mental status, nausea, vertigo, somnolence, seizures, and coma → pain management, safety and gait training, cognitive and sensory stimulation.

Cryptosporidiosis—Infects GI tract → chronic diarrhea and malabsorption, contributes to wasting syndrome → nutritional and hydration strategies.

Wasting syndrome—Involuntary loss of 10% of baseline body weight, weakness, chronic diarrhea, and unexplained fever → Nutrition, hydration, energy conservation.

Toxoplasmosis—Affects CNS in 30% to 40% of cases; headache, altered cognition, encephalitis, seizures, focal deficits → imposed structure, concrete tasks, pain management.

CMV—Present in 40% to 100% of healthy adults. Can affect GI and respiratory tracts but most often affects ocular structures → unilateral or bilateral decreased visual acuity, field cuts and blindness → compensatory

skills, safety tasks and mobilities, home evaluation, supportive service referrals.

Mycobacterial infections—Two are most pertinent: *Mycobacterium avium* complex (MAC) and *Mycobacterium tuberculosis* (causes TB). MAC affects 18% to 56% of those with HIV, but autopsies reveal that this is a low estimate. MAC infection is not latent but is a primary infection. It appears late in HIV infection, begins in the GI or respiratory tract, and then disseminates. Pneumonia, fever, weight loss, malaise, sweats, anorexia, abdominal pain, and/or diarrhea may occur. TB appears early, with latent reactivation in 90% of HIV-infected patients. Pulmonary TB affects an estimated 75% to 100% of HIV-infected persons infected with the TB bacillus. It also infects lymph nodes and bone marrow in 60% of these patients, and it also infects CNS, cardiac, and mucosal tissues. Fever, weight loss, malaise, cough, lymph node tenderness, and night sweats → energy conservation, nutrition, hydration, and caregiver and patient education in safe management of infection. The infection is communicable; wear a mask, follow respiratory isolation protocol.

AIDS-KS—Frequent neoplasm and most frequent in homosexual men; it is rare in women and intravenous drug users. Purple skin or visceral lesions are present. Associated are deficient lymphatic transport, nodal tumors, and lymphedema → swollen, painful lower extremities. Nutrition, pain management, task simplification, mobility, and training in ADLs.

ADLs, Activities of daily living; AIDS-KS, AIDS-Kaposi sarcoma; CMV, cytomegalovirus; CNS, central nervous system; GI, gastrointestinal; PCP, *Pneumocystis jirovecii* pneumonia; TB, tuberculosis.

electroacupuncture, thermal agents, and manual therapy are useful therapeutic tools. (See Chapters 9, 32, and 39 for additional treatment ideas.)

The impact of HIV infection can be evident in cerebral, emotional, psychosocial, and other physical domains, affecting the patient infected with HIV and those around her or him. The prognosis and psychological and physical consequences of HIV infection are associated with significant emotional distress and clinical syndromes, such as adjustment disorders, depression, and anxiety in some patients.¹⁵⁴ Increasing focus is being placed on the potential impact of HIV infection-related stress on the course of infection because of the observed and postulated relationship between psychosocial stress, neuropsychological functioning, and immune status.¹⁵⁵ Minimizing stressful events throughout the management of chronic HIV infection can be approached in various ways, such as meditation, relaxation, and various forms of exercise.

Exercise

Exercise is an intervention commonly used by movement specialists to address a multitude of impairment and functional limitations. Thus, understanding of the implications of the HIV disease process on exercise prescription is

important. A review of published studies¹⁵⁶ on the effects of exercise on individuals with HIV disease revealed the following: (1) although intense bouts of exercise may result in transient immunosuppression, there is no evidence that regular exercise by individuals with HIV disease results in a detrimental effect on the immune system over time, (2) some studies have shown actual improvement in immune system function in response to regular exercise, (3) improved cardiovascular function has been observed in response to aerobic exercise, and (4) resisted exercise may be effective in counteracting the effects of wasting syndrome and improving strength and lean body mass. A systematic review of progressive resistive exercise (PRE) showed that PRE or a combination of PRE and aerobic exercises lead to statistically significant increases in weight, arm girth, and thigh girth. Trends were also found supporting an improvement in submaximum heart rate and exercise time. In addition, PRE was found to contribute to improved strength and psychological status. PRE was found to be safe and beneficial for medically stable HIV-positive adults.¹⁵⁷

From a psychoneuroimmunological perspective, psychological stress has been implicated among the cofactors that contribute to the immunological decline in HIV disease. Good evidence supports the stress management role of exercise

training as a means to explain a buffering of these suppressive stressor effects, thereby facilitating a return of the CD4 cells. Early intervention with exercise, in compliance with guidelines, is most prudent to stave off opportunistic infections throughout the spectrum of HIV disease.

Precautions and Concerns during Exercise

It is important to address any orthopedic or neurological concerns before embarking on an exercise or movement therapy program. If musculoskeletal problems exist or other pain symptoms are present, a concerted effort to modulate pain is necessary for the successful completion of an exercise regimen.¹⁵⁸ If HIV-related peripheral neuropathy exists, it is important to implement proper foot care and supportive shoes when weight-bearing activities are performed.^{61,159} In addition, appropriate safety measures, such as guarding during balance activities, should take place when working on exercise programs with patients who have decreased stability.

There is some concern about aerobic exercise increasing the body's metabolic rate and thus increasing additional muscle loss. However, with a balanced diet and incorporation of a sound nutritional program, this should not pose a problem for the asymptomatic person with HIV disease. If wasting is present, the cause needs to be addressed and treatment rendered.⁴⁷ One study determined the contribution of total energy expenditure to weight changes in individuals with HIV infection–related wasting. The researchers observed a significant positive relation between total energy expenditure and the rate of weight change. During rapid weight loss, total energy expenditure fell from an average 2750 kcal per day to 2189 kcal per day. The key determinant of weight loss in HIV infection–related wasting, they concluded, was reduced energy intake, not increased energy expenditure.¹⁶⁰

If fatigue is present as a symptom, a differential diagnosis for anemia, low testosterone levels, or specific vitamin deficiencies must be made before any exercise regimen is begun. Proper caloric intake must be adequate to meet the energy expenditure required for the activity. Seeking the advice of a nutritionist is recommended for proper guidance.

Evidence of autonomic neuropathy (a peripheral neuropathy that affects involuntary body functions including heart rate, blood pressure, perspiration, and digestive functions) on provocative testing is common in HIV infection, with estimates of incidence ranging from 30% to 60%.^{161,162} Underlying cardiac parasympathetic dysfunction may need to be assessed throughout the course of HIV disease. One method described by Mallet and co-workers¹⁶³ is the use of the 4-second exercise test, which consists of pedaling an uploaded ergometer at maximal individual speed from the fourth to the eighth second of a 12-second maximal inspiratory apnea. From an electrocardiogram, vagal activity is estimated through a ratio. In that study, subjects were subjected to respiratory sinus arrhythmia, which is a valid method to detect vagal dysfunction. The researchers found that there was a tendency for lower values of the vagal function test in HIV-positive subjects. Vital sign monitoring is prudent throughout any exercise regimen. Exercise can help control long-term side effects including altered body composition; elevated cholesterol, triglyceride, and blood glucose levels; and elevated blood pressure.¹⁶⁴ Certain comorbidities associated with HIV disease, such as inflammatory myopathy, acute infectious arthritis, or compromised cardiac status may result in restrictions on exercise prescription.¹⁵⁶

A supervised training program should be consistent with recommendations of the American College of Sports Medicine. Guidelines have been established for the spectrum of the stages of HIV disease.²⁵ During the stage of asymptomatic HIV disease, there are no limitations on maximum graded exercise testing. Exercise should consist of resistance training, cardiovascular training, flexibility training, balance training, and mind-body training.¹⁶⁴ In this stage, all metabolic parameters are within normal limits for most individuals. Thus, unrestricted activity is generally encouraged. Most sports do not pose a significant risk of HIV transmission. However, sports such as boxing, in which there is a risk of open wounds and contamination with infected blood, should be viewed with great caution.¹⁵⁶

Exercise is safe and beneficial for most individuals with HIV disease; however, caution is warranted with symptomatic HIV disease and advanced HIV disease. In symptomatic HIV disease, there may be reduced exercise capacity, $\dot{V}O_2$ max, and oxygen (O_2) pulse max. There may also be other cardiovascular and pulmonary problems, anemia, and peripheral muscle abnormalities. Pain, side effects of medications, psychosocial issues, and unplanned events may also create obstacles to exercise for individuals in the symptomatic stage of HIV disease. For individuals with cardiac myopathy or hyperlipidemia, submaximal aerobic capacity testing should be followed with a staged cardiac rehabilitation program⁹² because of the risk of cardiac failure in patients with compromised cardiac status.¹⁶⁵

Patients with AIDS have dramatically reduced exercise capacity, vital capacity, $\dot{V}O_2$ max, and O_2 pulse max. Elevated heart rate and breathing reserve persist in this stage. Neurological dysfunction, opportunistic infections, and progressive disability indicate a need for careful monitoring of the exercise program during this stage of the disease. In general, individuals with advanced HIV disease should remain physically active and exercise on a symptom-limited basis. Precautions related to comorbidities should be implemented. Individuals in this stage of the disease are at greater risk for exercise-induced injuries as a result of chronic tissue changes in both muscle and peripheral nerve. For individuals with severe morbidity and extensive disability, treatment should emphasize enhancement of basic functional tasks, ADLs, and energy conservation.¹⁵⁶

Psychoneuroimmunology: Prevention and Wellness in HIV Infection

Psychoneuroimmunology is the field that investigates the interrelationships among psychological constructs (e.g., stressors and mood states) of the neuroendocrine and immune systems. Although all the precise mechanistic links among these varied components of psychoneuroimmunology are not yet fully elucidated, psychoneuroimmunology does offer a useful framework for our understanding of how stressors play a role in immunomodulation. The progression of HIV disease can be modulated by psychosocial factors and by factors such as the viral strain, genetic characteristics of the host immune system, co-infections with other pathogenic organisms, and health maintenance habits (diet, exercise, medical treatments).¹⁶⁶ These factors may have a profound influence on the occurrence and progression of ill health in chronic diseases such as HIV infection or AIDS.

Findings of studies related to psychoneuroimmunology suggest that it may be useful to evaluate the influence of behavioral factors on immune functioning and disease progression in HIV-infected individuals.¹⁶⁷⁻¹⁶⁹ The stress response is physiologically mediated by certain immune parameters (catecholamines and glucocorticoid hormones). A study by Leserman and colleagues¹⁷⁰ in 2002 concluded that “stressful life events, dysphoric mood, and limited social support” are correlated to the increased rate of progression from HIV to AIDS.¹⁷⁰ Behavioral interventions with immunomodulatory capabilities may help restore competence and thereby slow the progression of HIV disease, especially at the earliest stages of the infectious continuum.

A growing body of literature indicates that many different stressors have deleterious effects on the immune system.¹⁷¹ It has been well documented in healthy individuals that changes in immune function and disease susceptibility are correlated with times of “psychic distress.”¹⁶⁶ These stressors in the case of people living with HIV infection may be attenuated by an exercise training program. Research indicates that continued aerobic exercise training may result in increased CD4 cell counts, heightened immune surveillance, and a potential for a slowing of disease progression.¹⁶⁹ Other researchers have demonstrated similar benefits of exercise for individuals infected with HIV who are at more advanced stages of disease. However, these are studies conducted on traditional modes of exercise and do not investigate alternative activities such as yoga or tai chi. Exercise within the context of psychoneuroimmunology appears to be a promising approach in the treatment of illness and promotion of health in chronic HIV disease.

Complementary Therapies in HIV Infection

There is substantial evidence to suggest that traditional exercise, particularly aerobic exercise, can provide notable physiological and psychological benefits for most individuals, especially those with chronic diseases. However, the mode, duration, and intensity of many traditional standardized exercise programs may not always be entirely appropriate during chronic illness. The stage of disease and the type of illness itself may preclude more strenuous exercise activities at various times. During such times, less traditional movement therapies may prove to be more appropriate and efficacious. In fact, movement therapy includes a number of similar constructs used in physical therapy and can be quite complementary to an individual’s program of more traditional exercise.^{172,173} Refer to Chapter 39 for additional information.

The HIV epidemic has resulted in an increasing use of alternative therapies, some more traditional than others.¹⁶⁵ Estimates show that 53% of HIV-positive individuals in the United States report the use of at least one complementary and alternative medicine (CAM) therapy.¹⁷⁴ The exploration outside the medical model has fostered investigations by the Office of Alternative Medicine at the National Institutes of Health.¹⁷⁵ Eisenberg and colleagues¹⁷⁶ reported that prayer and exercise combined accounted for more than 60% of all alternative therapies used. Other therapies include relaxation techniques (13%), massage (7%), imagery (4%), and spiritual healing (4%). Traditional exercise such as aerobic and weight training is incorporated in the medical model through exercise physiology and rehabilitation. However, various movement therapies (such as martial arts) are often viewed

as less traditional and outside the established medical model. In a study by Bastyr University (1998), various movement therapies were used by people living with HIV disease. This study evaluated the use of alternative therapies within the previous 6 months. Yoga had been used by 15.5%, tai chi by 4.8%, and qi gong by 3.6% of the participants. Research¹⁷² demonstrated beneficial physiological and psychological effects of the use of tai chi and aerobic exercise (see Chapter 39). In 1993 researchers at the University of Maryland School of Nursing in Baltimore concluded that there was a positive correlation between patient health and participation in prayer and meditation. Relevant factors included participants’ “perception of their physical, emotional, and spiritual health; and their participation in exercise and the use of special diets.”¹⁷⁷ A study done at Rutgers University in 1999 looked at guided imagery and progressive muscle relaxation on HIV. Health status was significantly different after treatment. Guided imagery produced the most positive effects in the middle stage of the disease. The combination of imagery and muscle relaxation is suggested to improve health status, and it should be initiated early in the disease process.¹⁷⁸ Recent studies indicate that pain level is a good predictor of the use of CAM therapies; individuals with pain decreased by CAM therapy are less likely to use illegal or untested drugs. Patients experiencing depression were more likely to use illegal or untested drugs and therapies.¹⁷⁴

Social Interactions and the Association with Disease Management

The process of grieving is often mistakenly associated solely with the death of another. It is a natural reaction to loss, including the loss of one’s own health and diminished independence. Loss of abstract human qualities, such as perceived attractiveness and productivity, results in grief. Such emotions are often difficult for a client to articulate. It is the therapist’s responsibility to be sensitive to the client’s individualized grief pattern (see Chapter 6).

Placement issues accompany discharge planning from acute health care facilities. The rehabilitation professional is often called on to make recommendations regarding the level of assistance the client will need. All of the previously discussed areas of cognitive-perceptual, sensorimotor, and ADL management combined with available psychosocial and practical support influence these recommendations. Options include a return to independent living and work, assisted independent living with help from a loved one, home with supportive services (often supplied by community-based AIDS organizations), home with hospital-based home care, hospice, Level I (inpatient acute) rehabilitation, Level II (subacute) rehabilitation, and an extended care facility.

Literature on long-term survivors with AIDS is replete with anecdotal evidence linking survival to one or more of the following: (1) holding a positive attitude toward the illness, (2) participating in health-promoting behaviors, (3) engaging in spiritual activities, and (4) taking part in advocacy activities related to the HIV community.^{141,179-180} Positive relationships have been demonstrated between hardiness and perception of physical, emotional, and spiritual health and participation in exercise and the use of special diets.¹⁸¹⁻¹⁸³

Research provides support for the hypothesis that interpersonal relationships influence patterns of physiological

functions. Data from experimental studies have shown that social contact can serve to reduce physiological stress responses.^{184,185} Community-based studies have also shown negative associations between reported levels of support and physiological parameters such as serum cholesterol, uric acid, and urinary epinephrine levels.¹⁸⁵ Studies of immune function have demonstrated that social relationships have both positive and negative impacts on immune function. Loss of a partner to cancer or HIV infection, family caregiving for patients with Alzheimer disease, and divorce or poor marital quality all show negative associations with immune function, whereas more supportive relationships are associated with better immune function.¹⁷¹

Exercise and movement therapy in a group context may provide the socialization necessary to foster these physiological changes and adherence to an exercise regimen. Another area of potential socialization is the workplace. The quality-of-life issues for people with HIV/AIDS are becoming more complicated as more people with the disease achieve higher CD4 counts and lower viral load levels. Improvement in health status is directly related to the improved effectiveness of newer treatment regimens, and many individuals are improving enough to either continue working or reenter the work force. Exercise and movement therapy may augment the stress and fatigue that may be associated with the adjustment to the workplace.

SUMMARY

Research and resultant treatments are extending lives so that more people require rehabilitative services that maximize function and quality of life. Medical management has focused on the treatment of reducing viral load, preventing secondary illnesses, and improving the immunological status of chronic HIV disease. Examination of the neuromusculoskeletal system and interventions for individuals with HIV disease are similar to those for other progressive neuromusculoskeletal disorders. HIV disease should be addressed like other life-altering diseases such as cancer, but with an emphasis on cognitive and perceptual function. Rehabilitation interventions focus on specific impairments, disabilities, and psychosocial ramifications of the disease. Adaptive compensations, mobility, ADL retraining, pain control, and community management skills constitute a well-developed treatment plan.

The epidemic is a major challenge on a personal as well as a professional level because of the continued natural fear of contagion. The illness originally appeared in subcultures that are often disenfranchised. Social, racial, and economic status

and controversial behaviors contribute to prejudice, fear, and limited access to health care. Rehabilitation professionals have responded significantly to this challenge. Continued advocacy and compassion combined with professional enlightenment will, in a small way, alter the course of the disease.

Future Directions for Research

The issue of HIV disability warrants a careful investigation into our current health care system. Some long-term survivors of HIV disease who formerly received disability ranking are potentially ready to return to work. However, their grave concern about the long absence from work, reflected in the resume, and fears about potential opportunistic infections while on the job require specific strategies. Vocational rehabilitation and on-the-job counseling are necessary for optimal return to work. The systemic issues of acquisition of disability and the loss of all benefits when one relinquishes disability are quite complicated and overwhelming. The diagnosis of advanced HIV disease is the determining factor for disability, and many people living with HIV disease with CD4 counts less than 200/mcL have experienced considerable improvement in their immunological status with a concomitant drop in viral load. Prognosis for these individuals has great variability. Promoting quality of life may be greatly enhanced through the use of complementary therapies. An integral aspect of self-perception is often the role played in society. The workplace affords individuals a sense of identity and a self-sustaining purposefulness. Therefore our health and governmental systems need to conduct further research on return-to-work outcomes, with ease of transition and on-the-job accommodations when necessary. Future directions in the AIDS epidemic as we see people living longer will be the full return to function in all domains of ADLs and return to productive work.

CASE STUDIES

Three case studies are presented to help the reader understand and identify various stages of this clinical problem and how each stage may require a different therapeutic focus.

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 192 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

CASE STUDY 31-1 ■ ASYMPTOMATIC HIV DISEASE VERSUS SYMPTOMATIC HIV DISEASE: MARIO

EXAMINATION

History

Mario is a 48-year-old male chemistry teacher who tested positive for HIV 6 years ago. Currently, his absolute CD4⁺ cell count is 475/mcL, and his viral load (HIV RNA) is 40,000 copies/mL. Mario runs 5 miles three times per week for exercise. Recently he began to experience some pain and tingling in the soles of his feet that is most noticeable after running. His weight has

been stable. He has noticed a mild deficit in short-term memory over the past year, which he attributes to middle age. He has a history of rotator cuff tendonitis but is otherwise healthy and denies other symptoms. His wife and 28-year-old son serve as his primary emotional support system. The rest of his family lives in Italy, his native country. He is a Roman Catholic and attends church regularly. Current medications include aspirin as needed after running.

CASE STUDY 31-1 ■ ASYMPTOMATIC HIV DISEASE VERSUS SYMPTOMATIC HIV DISEASE: MARIO—cont'd

Tests and Measurements

Left extremity sensation testing with Semmes-Weinstein monofilaments¹⁸⁶ reveals diminished light touch sensation over the distribution of the medial plantar nerves bilaterally. A lower-extremity neural tension test (straight leg raise with dorsiflexion) and a Tinel test over the tarsal tunnel have positive results bilaterally and reproduce tingling along the medial arches of the feet. Screening of the lumbar spine, hips, and knees is negative. Foot and ankle range of motion and strength are normal. Pain is not provoked with passive stretching of the plantar fascia. Lower-extremity reflexes are normal, and no abnormal reflexes are present. Excessive pronation is noted during the gait cycle; gait is otherwise normal. In standing, an excessive calcaneal valgus angle is noted; normal medial arches are observed in non-weight bearing. Foot pain on a visual analog scale is 0/10 at rest and 5/10 after running.

EVALUATION AND DIAGNOSIS

Bilateral distal sensory disturbances may be caused by DSP in individuals with HIV disease. However, this is typically associated with side effects of HAART, and the patient has not yet been placed on these drugs. Furthermore, sensory loss with DSP typically involves multiple peripheral nerves and occurs first in the most distal distribution. The patient's toes have no sensory impairment. Myelopathy should be considered in patients with chronic HIV disease who appear to have peripheral neurological symptoms; however, Mario does not demonstrate any signs that would suggest myelopathy as the cause of his foot symptoms. Examination is significant for signs and symptoms of flexible pes planus, which may be contributing to tarsal tunnel syndrome bilaterally. His gait pattern of excessive pronation is likely contributing to

compression on the tibial nerve within the tarsal tunnel when he runs.

Prognosis, Goals, and Outcomes

Mario is expected to have full recovery with interventions directed at reducing biomechanical stress on the tarsal tunnel during running. Mario's goal is to run for 5 miles without any symptoms. Outcomes will be measured with patient's self-report of global improvement, the visual analog scale for pain associated with running, and changes in clinical signs (lower-extremity neural tension test, Tinel test, and monofilament sensory testing).

Intervention Plan and Recommendations

Mario will receive low Dye taping¹⁸⁷ to decrease his pronation and provide temporary relief of symptoms. Orthotics will be fabricated to reduce pronation and adverse stress on the tarsal tunnel. Mario will replace running with aerobic training on a stationary bike until his orthotics are adequately broken in, after which he can resume running. Before discharge he will receive instruction in general lower-extremity and plantar fascia flexibility exercises. If foot symptoms are recalcitrant to biomechanically based interventions, further consultation with Mario's HIV specialist will be warranted to rule out possible tibial nerve mononeuropathy related to his HIV disease. The therapist will encourage Mario to see a mental health professional because of the complaints of memory loss. A mental health professional may use the HIV Dementia Scale,¹⁸⁸ or other instruments may be used to assess the patient's cognitive function and rule out the possibility of early signs of HIV dementia. If any of Mario's symptoms are determined to be related to his HIV disease, he will be re-staged to symptomatic HIV disease.

CASE STUDY 31-2 ■ ADVANCED HIV DISEASE (AIDS) AND A PLAN FOR THE FUTURE: RUBY

EXAMINATION

History

Ruby is a 23-year-old woman of African American and Hispanic descent. Ruby has an 8-year history of intravenous drug abuse and bipolar disorder. She was tested for HIV disease 5 years ago, at which time she was hospitalized with a diagnosis of *P. carinii* pneumonia and oral thrush. At that time, her absolute CD4⁺ cell count was 15/mcL and her viral load was 750,000 copies/mL. Her opportunistic infections were successfully treated with antibiotics, and HAART was initiated. Within a few months, her viral load was undetectable and her absolute CD4⁺ level had climbed to 400/mm³. Since then she has had intermittent periods of homelessness and is currently residing with a friend. She stopped adhering to her HAART regimen several months ago, during a period of depression. Recently Ruby has worked as a prostitute to earn money for crack cocaine. Ruby was admitted to the hospital 12 days ago with complaints of abdominal bloating and severe left shoulder pain. Her behavior was clearly agitated. A large abscess was

present over the left deltoid. Medical workup revealed that Ruby had a staphylococcal infection in the left anterior deltoid and infectious arthritis of the left glenohumeral joint. It was determined that she was 4 months pregnant. Her psychiatric status was significant for a manic episode. Her CD4⁺ count was 175/mcL and viral load was 200,000 copies/mL. Ruby's shoulder infection was treated with intravenous methicillin, and recent magnetic resonance imaging of the shoulder region was negative for osteomyelitis. Medical clearance for examination and interventions for the shoulder was obtained from her infectious disease physician. She was placed on psychotropic medication for mood stabilization. Pending results of genotype testing, Ruby was placed on a new regimen of HAART. Genotype testing is needed because she likely has mutant strains of the virus as a result of poor adherence to the previous course of HAART. HAART will be implemented quickly, with the goal of achieving undetectable viral loads by the time of birth. Consultation with nutrition services was ordered to ensure adequate nutrition during the remainder of her pregnancy.

Continued

CASE STUDY 31-2 ■ ADVANCED HIV DISEASE (AIDS) AND A PLAN FOR THE FUTURE: RUBY—cont'd

Ruby has disclosed that her arm infection was probably caused by injecting drugs. She has been referred to see an addiction counselor and the social worker. Current medications: none.

Tests and Measurements

Ruby has a nonhealing wound over the left anterior deltoid region that was 1.5 cm × 1.1 cm with a depth of 0.5 cm. The wound appears to be clean with 100% granulation tissue, and the most recent laboratory report is negative for *Staphylococcus*. Ruby reports that the swelling and redness in her left shoulder have resolved, and no swelling or redness is observed during the examination. Left shoulder strength is 3/5 (fair) for abduction, internal rotation, and external rotation and 4/5 (good) for other motions. Passive range of motion (PROM) of the left side is limited as follows: external rotation 70 degrees, abduction 160 degrees, and internal rotation 45 degrees. Her score on the Disabilities of the Arm, Shoulder and Hand questionnaire (DASH)¹⁸⁹ is 85/100 for the left upper extremity. Screening examination of the cervical spine is clear; however, hypertonicity is noted in the elbow and wrist and the finger flexors on the left side. PROM of the elbow, wrist, and hand is within normal limits; however, slight resistance is noted with quick passive stretching of flexor muscles. Ruby has weakness in grasp and demonstrates a mild flexor synergy pattern with attempts to elevate the left arm.

EVALUATION AND DIAGNOSIS

As a result of the findings of the examination, neurology is immediately consulted and brain magnetic resonance imaging (MRI) is performed. The MRI reveals a mild right cerebrovascular accident involving the middle cerebral artery. Physical and occupational therapy will be initiated to address the following findings: impaired integumentary integrity associated with partial-thickness skin involvement over the left anterior deltoid region; impaired glenohumeral joint mobility, muscle performance, and range of motion associated with connective tissue dysfunction (adhesive capsulitis as sequela of infectious arthritis); and impaired motor function (spasticity and weakness in the left upper extremity) associated with nonprogressive disorder (right cerebrovascular accident) of the CNS.

Prognosis, Goals, and Outcomes

Ruby's outcomes will be strongly influenced by her complex psychosocial status. She states that she is highly motivated to have a healthy baby and learn how to become a stable provider, which may help her adherence to HAART and drug rehabilitation. Continuing communication among all team members (infectious disease, obstetrics-gynecology, social work, addictions counseling, physical therapy, and occupational therapy) will be critical to optimize her care. Because of multisystem involvement and multiple impairments, it is expected that Ruby will require 6 to 8 weeks of therapy. Goals specific to physical therapy include the following: facilitate wound healing and prevent reoccurrence of infection, restore full PROM to the left shoulder, improve strength and function throughout the left upper extremity, achieve independence in performance of ADLs with the left upper extremity, improve the DASH score,¹⁸⁹ and minimal functional limitation as per the Barthel Index score.¹⁹⁰ Outcomes will be measured with continuing assessment of wound characteristics, the DASH score,¹⁸⁹ the Barthel Index score,¹⁹⁰ shoulder PROM measurements, and strength assessment of upper-extremity musculature.

Intervention Plan

Wound healing will be facilitated with dressing changes and use of topical agents as prescribed by her physician. Glenohumeral impairments will be addressed with joint mobilization, therapeutic exercises, and functional retraining. Upper-extremity impairments involving tone and weakness will be addressed with motor learning techniques, functional activities, and strengthening exercises. Ruby will receive daily physical and occupational therapy until she is discharged from the hospital. Social work will facilitate discharge to a structured group home for women because Ruby's current roommate is using drugs and working as a prostitute. On discharge from the hospital, Ruby will return for outpatient therapy at a frequency of three times per week. She will continue to follow up with the social worker regarding vocational counseling.

CASE STUDY 31-3 ■ ADVANCED HIV DISEASE (AIDS) AT THE END STAGE OF LIFE: WALTER

EXAMINATION

History

Walter is a 68-year-old man who was diagnosed with AIDS in 1987. He lost his life partner to the same disease in 1990. He has no living relatives. At the time of his diagnosis, Walter had toxoplasmosis, KS, AIDS wasting syndrome, and anemia. He was one of the first patients to receive AZT, which, along with other medications used to treat the opportunistic infections, proved to be lifesaving. As new classes of drugs became available and were added to his regimen, Walter's viral loads and CD4⁺ cell counts were usually stable. Over time, viral resistance developed to many of the drugs. Recently, he was

placed on enfuvirtide (Fuzeon), an injectable receptor site inhibitor that is used when other drugs and salvage therapy have been exhausted. His current CD4⁺ count is 25/mcL with a viral load of 200,000 copies/mL. Walter has multiple side effects and complications of long-term HIV survival, including peripheral neuropathy in the hands and feet, chronic fibromyalgia, myelopathy, liver toxicity, and severe lipodystrophy. He has marked wasting of fat in the face and extremities, severe truncal obesity, and a dorsocervical fat mass. Walter has also been undergoing treatment for hypertension and hyperlipidemia. Over the past decade, Walter's Medical Outcomes Study HIV Health Survey¹⁹¹ scores have indicated progressive

CASE STUDY 31-3 ■ ADVANCED HIV DISEASE (AIDS) AT THE END STAGE OF LIFE: WALTER—cont'd

disability and worsening quality of life. Walter has been hopeless and depressed about his physical appearance and level of function. Before admission to the hospital, Walter lived alone in a modest studio apartment. He employed a daily home health aide to assist with food preparation and personal hygiene. Walter had been ambulating short distances in his apartment, often using a walker because of fatigue and unsteadiness. Walter's gait became increasingly ataxic over the past month. Last week, he had a seizure that resulted in admission to the hospital. Testing revealed progressive multifocal leukoencephalopathy (PML). Walter's physician expects that this brain infection, combined with his immunosuppression, will lead to death within a few months. Current medications: Fuzeon (enfuvirtide; HAART component), Kaletra (lopinavir and ritonavir; HAART component), Truvada (emtricitabine and tenofovir disoproxil fumarate; HAART component), Oxycontin (oxycodone; for chronic pain), Norpramin (desipramine; a tricyclic antidepressant), Pravachol (pravastatin; a cholesterol-lowering agent), and Prinivil (lisinopril; an angiotensin-converting enzyme inhibitor and diuretic).

Tests and Measurements

Inspection of the integumentary system reveals redness over the sacrum; otherwise the skin is intact. Diminished light touch sensation is noted in a stocking-glove distribution over the hands and feet. A Hoffman reflex, consistent with his myelopathy, is present in the upper extremities. Walter rates his pain at rest as ranging from 4/10 to 6/10. His pain drawing indicates low back, bilateral hand, and bilateral foot pain. Pulse oximetry reveals 96% oxygen saturation. Vital signs sitting: heart rate 70 beats/min, blood pressure 130/70 mm Hg, and respiratory rate 16 breaths/min with no apparent distress. Rate of perceived exertion at rest (RPE, Borg Scale) is 1/10. Pitting edema (+1) is noted in the ankles and feet.

Walter is independent with all bed mobility. Sitting balance is good. Standing balance is fair. Contact guard is required for sit-stand transfer and for ambulation a distance of 10 feet with a rolling walker. Vital signs after ambulating 10 feet: heart rate 110 bpm, blood pressure 150/70 mm Hg, respiratory rate 24 breaths/min, RPE 5/10, and oxygen saturation 96%. He demonstrates erratic foot placement and a wide base of support during gait. His Functional Independence Measure (FIM)¹⁹² score is a 4. Because of fatigue and pain, strength and range-of-motion assessments are abbreviated. The following strength data are obtained (all measured bilaterally): shoulder abduction 3/5 (fair), elbow extension 4/5 (good), knee extension 3/5 (fair), and dorsiflexion and plantarflexion 4/5 (good). Passive range of motion data (bilateral): dorsiflexion 5 degrees; knee flexion 125 degrees (full knee extension not available,

10-degree flexion contracture noted); hip flexion 120 degrees; hip extension 10 degrees; shoulder flexion and abduction 140 degrees; and elbow, wrist, hand within normal limits.

EVALUATION AND DIAGNOSIS

Walter exhibits multiple impairments related to his advanced HIV disease (affecting multiple systems) and PML (a progressive disorder of the CNS). Summary: impaired integumentary integrity associated with superficial skin involvement, pain, impaired sensory integrity, impaired joint mobility and range of motion (knees, shoulders), impaired muscle performance, impaired gait, impaired balance, and impaired endurance.

Prognosis, Goals, and Outcomes

Walter's prognosis for survival is poor. It is likely that he will deteriorate slowly over the upcoming months. Goals and outcomes will thus focus on optimizing quality of life during Walter's remaining days. Specifically, goals are to reduce pain; prevent sequelae of immobility (such as pressure wounds, pneumonia, deep venous thrombosis, joint contracture, deconditioning, and atrophy); achieve independent sit-stand transfers and short-distance (15 feet) ambulation with a wheeled walker; improve endurance (RPE of 2 to 3 after ambulation); maintain independence with bed mobility; and promote safety.

Intervention Plan

Physical therapy will first be provided at bedside. If the patient wishes, treatment may be provided in the physical therapy department. Interventions will include relaxation techniques, passive range of motion and grade I joint mobilization (knees and shoulders), gait training with a wheeled walker, balance activities, and gentle strengthening and endurance exercises as tolerated. Occupational therapy will be consulted to address bed mobility and self-care tasks. Walter's vital signs will be closely monitored during therapy because it is possible that his ANS dysfunction may become evolved as a result of the CNS infection.

Walter's physician will be contacted regarding Walter's pain ratings. It is likely that increased dosage of pain medication is warranted as a result of reports of moderate pain at the current dosage. Walter will be seen by a dietician. The social worker will plan for transfer to a hospice setting.

In hospice care, physical therapy will focus on basic functional activities, such as transfers, gait, and endurance. Palliative interventions (moist heat, gentle massage) will be provided as needed for pain control. Caregiver education will be provided regarding prevention of the effects of immobility and safe functional mobility. In the hospice setting, Walter will have the opportunity to work with a spiritual counselor. Walter has expressed an interest in exploring Eastern medicine for pain control. Therefore a consultation with an acupuncturist will be arranged.

CHAPTER 32 Pain Management

ANNIE BURKE-DOE, PT, MPT, PhD

KEY TERMS

ANS pain: complex regional pain syndrome
acute pain
behavioral manipulations: exercise, operant conditioning, hypnosis, biofeedback
chronic pain
CNS pain: thalamic pain
cognitive strategies: relaxation exercises, body scanning, humor
nociceptor
pain intensity measurements: visual analog scale (VAS), simple descriptive pain scale (SDPS), pain estimate, faces pain scale
pain localization tools: pain drawing
pain modulation: gate control theory, neurotransmitters, neuromodulators
pain pathway
pain quality measurements: McGill Pain Questionnaire (MPQ), pediatric verbal descriptor scale, caregiver checklists
point stimulation

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe the pain pathways.
2. Describe how pain is modulated within the nervous system.
3. Identify the causes of acute and chronic pain.
4. List the signs and symptoms of CNS, ANS, and peripheral pain and give an example of each.
5. Perform a comprehensive pain evaluation, including taking a pain history, measuring pain intensity, measuring pain character, and examining the client.
6. Design a comprehensive pain management program that addresses the objective and subjective aspects of the pain experience.

Chronic pain has a profound impact on all aspects of an individual's life. It influences relationships with family members, friends, co-workers, and health care providers. It affects the ability to fulfill responsibilities, to work, and to participate in social activities. Perhaps more than any other factor, the presence of chronic pain and the response to it determine the overall quality of an individual's life.

Chronic pain is prevalent. The National Institutes of Health (NIH) estimate that 100 million Americans suffer from chronic pain.¹ The prevalence of chronic noncancer pain in patients seen in the primary care setting shows an approximate range of 5% to 33%,² and a 2006 American Pain Foundation survey found that fewer than 40% of people with chronic noncancer pain reported that their pain was under control.³ Studies of physicians, nurses, and therapists who treat individuals with chronic pain show that most do not have even a basic understanding of the concepts of pain management.⁴⁻⁶ The result is inadequate or inappropriate care⁶⁻⁸ of individuals who report having pain.

The use of the International Classification of Functioning, Disability and Health (ICF) model as a framework for understanding the relationship among impairments, activity limitations, and participation restrictions has been covered previously (refer to Chapter 1 as well as many chapters in the second section of this text). In terms of the application of the ICF model to pain, the clinician must understand that many impairments

within various body systems cause pain and can limit activity and participation. The ability to identify appropriate rehabilitation approaches to improve activity and participation depends to a great extent on the clinician's ability to identify different impairments that cause pain, or the resulting impairments and activity and participation problems caused by pain.

This chapter deals with the complex issue of acute and chronic pain management. In the first section, an overview of the anatomy and physiology of pain is presented. In the second section, examination and evaluation of pain are explained. In the third section, a number of treatment interventions are suggested. Finally, case studies are presented to guide clinicians through the problem-solving process for designing pain management programs.

DEFINING PAIN

The primary purpose of pain is to protect the body. It occurs whenever there is tissue damage, and it causes the individual to react to remove the painful stimulus. Pain is also a sensation with more than one dimension. To the individual, pain is both an objective and a subjective experience. The objective dimension is the physiological tissue damage causing the pain. The subjective dimensions include the following⁹:

- A perceptual component: the client's awareness of the location, quality, intensity, and duration of the pain stimulus

- An affective component: the psychological factors surrounding the client's pain experience, including the client's personality and emotional state
- A cognitive component: what the client knows and believes about the pain resulting from his or her cultural background and past pain experiences (both personal pain experiences and those of others)
- A behavioral component: how the client expresses the pain to others through communication and behavior

All of these components taken together constitute the client's pain experience. Thus all must be addressed for a successful pain management program. When the subjective components of the pain experience are ignored, it is entirely possible that the client's underlying tissue damage may be corrected without her or his pain perception being cured.

In addition, recognizing that pain is more than simply a physical injury or disease process helps clinicians explain some of the inconsistencies observed in patients with chronic pain. Why is a client's pain report out of proportion to the magnitude and duration of the injury? Why is pain intolerable to one person and merely uncomfortable to another? And why is pain tolerable in one instance but overwhelming to the same individual when experienced at a different time?

The answers lie in the interconnectedness of the nervous system and the fact that pain transmission involves several higher centers. To select the most appropriate intervention, it is important for clinicians to have at least a general idea of the pain pathways. An overview of pain anatomy and physiology is discussed next.

PAIN ANATOMY

Pain arises from the stimulation of specialized peripheral free nerve endings called *nociceptors*. Injurious stimulation to the skin, muscle, joint, viscera, or tissue can trigger these peripheral terminals, whose cell bodies are located in the dorsal root ganglia and trigeminal ganglia. The density of nociceptors varies between as well as within these tissues. Nociceptors are extremely heterogeneous, differing in the neurotransmitters they contain, the receptors and ion channels they express, their speed of conduction, their response properties to noxious stimuli, and their capacity to be sensitized during inflammation, injury, and disease.¹⁰

Nociceptors found in interstitial tissues become excited with extreme mechanical, thermal, and chemical stimulation,¹¹ whereas nociceptors found in vessel walls become excited with these stimuli plus marked constriction and dilation of the vessels.¹² These receptors respond directly to some noxious stimuli and indirectly to others by means of one or more chemicals (histamine, potassium, bradykinin) released from cells in the traumatized tissues.¹³

Thermal nociceptors are triggered by intense hot or cold temperatures (>45° C or <5° C). They have fibers that are of small diameter and thinly myelinated with moderately fast conduction signals of 5 to 30 m/s. Mechanical nociceptors are triggered by intense pressures applied to the skin, such as a pinch. They also have thinly myelinated, moderately conducting fibers with speeds of 5 to 30 m/s.

Polymodal nociceptors are triggered by more than one sensory modality (mechanical, chemical, or thermal). These nociceptors have small-diameter, nonmyelinated fibers that conduct more slowly, generally at velocities less than 1.0 m/s. Stimulation of these receptors causes sensations of diffuse

burning or aching pain. The difference in the fibers' size and lamination determines the speed at which impulses will travel to the brain.

These three types of nociceptors are broadly distributed in the skin and tissues and may work together. One example would be hitting one's shin against a table: a sharp "first pain" is felt immediately, followed later by a more prolonged aching, sometimes burning, "second pain."¹³ The fast, sharp pain is transmitted by A delta fibers that carry information from thermal and mechanical nociceptors. The slow, dull pain is transmitted by C fibers that are activated by polymodal nociceptors.

Nociceptive input travels on A delta and C fibers into the dorsal horn of the spinal cord, where the gray matter is laminated and organized by cytological features. The first-order A delta and C fibers synapse with second-order neurons in lamina I (marginal layer), II (the substantia gelatinosa [SG]), and V. The second-order neurons do one of three things. A small number synapse with motor neurons, causing reflex movements (e.g., withdrawing the hand from a hot object). Others synapse with autonomic fibers, causing responses such as changes in heart rate and blood pressure and localized vasodilation, piloerection, and sweating. Most, however, travel a multisynaptic route to the higher centers by means of the ascending tracts.^{11,14}

There are four major classes of neurons¹⁵ responding to pain in the dorsal horn: low-threshold nociceptive-specific neurons designated class I; wide dynamic range (WDR) neurons designated class II; high-threshold nociceptive neurons designated class III; and a fourth, nonresponder group of neurons that develop spontaneous activity with exposure to endogenous inflammatory cytokines, designated class IV. Nociceptive-specific neurons are most abundant in superficial lamina; their receptor fields are discrete and vary from one to several square centimeters.¹⁶ WDR neurons, in contrast, respond to a wide range of stimuli from A delta, A beta, and C fibers in a graded manner (i.e., the rate of firing escalates with increasing intensity of stimulation), can be found in all lamina, and are the most prevalent cells in the dorsal horn.¹⁶ Because of their unique response to innocuous or nociceptive input, as well as their larger receptor field, WDR neurons play an important role in the central sensitization and the plasticity of the spinal cord.¹⁶

Nociceptive input crosses at the cord level to the anterolateral quadrant of the ascending contralateral spinothalamic tract (Figure 32-1). The axons of the anterolateral quadrant are arranged so that the sacral segments are most lateral, with the lumbar segments more medial and the cervical segments most central. This arrangement may be important clinically in that symptoms may be provoked according to dermatomal maps to some degree.¹⁷ Pain dermatomes overlap to several adjacent dorsal roots so boundaries can be less distinct, requiring the clinician to distinguish the pain and dysfunction.

The anterolateral tract is divided into three ascending pathways: the spinothalamic, spinoreticular, and spinomesencephalic. The spinothalamic tract conveys information about painful and thermal stimulation (location and intensity) directly to the ventral posterior lateral nucleus of the thalamus, as well as sending collaterals off at the brain stem to join the spinoreticular tract. Axons within the spinoreticular tract synapse on neurons of the reticular formation of

Figure 32-1 ■ Pain pathway. (From Gould BE: *Pathophysiology for the health professions*, ed 2, Philadelphia, 2002, WB Saunders.)

the medulla and pons, which relay information to the intralaminar and posterior nuclei of the thalamus and to other structures in the diencephalon, such as the hypothalamus (emotional response to pain).

Axons in the spinomesencephalic tract relay information to the mesencephalic reticular formation and periaqueductal gray matter by way of the spinoparabrachial tract. It then projects to the limbic system, which is involved with the affective component of pain (central modulation of pain).

The thalamus processes and relays information to several higher centers.¹² Each projection serves a specific purpose. Axons of the spinothalamic tract project information to both the lateral and medial nuclear groups of the thalamus. The lateral nuclear group of the thalamus is where information about the location of an injury is thought to be mediated.¹³ Injury to the spinothalamic tract and the lateral nuclear group of the thalamus causes central neuropathic pain, which is discussed in further detail later.

Projections from the spinoreticular tract to the medial nuclear group of the thalamus are concerned with processing information about nociception, and they also activate nonspecific arousal systems. These pathways project from the thalamus to the basal ganglia and many cortical areas.

Projections to the postcentral gyrus (sensory cortex) are responsible for pain perception. It is from this projection that pain can be localized and characterized. Projections from the thalamus to the frontal lobes and limbic system are concerned with pain interpretation. It is from all these projections that an individual perceives pain as hurting. Projections from the thalamus, as well as from the limbic system and sensory cortical areas, to the temporal lobes are responsible for pain memory; and projections from the thalamus to the hypothalamus are responsible for the autonomic response to pain.

PAIN TRANSMISSION

Ascending transmission of pain impulses is mediated by the action of the chemical excitatory neurotransmitter glutamate (A delta and C fibers) and tachykinins such as substance P (C fibers). Glutamate and neuropeptides have distinct actions on postsynaptic neurons, but they act together to regulate the firing properties postsynaptically.¹³ Tachykinins' activity is thought to prolong the action of glutamate, as levels are increased in persistent pain conditions.¹⁶ The substrates of nociception that exist at the spinal level are complex in that more than 30 different neurotransmitters acting on more than 50 different receptors have been identified in the spinal cord and associated with some pain-related phenomenon.¹⁸ Modulation of these substrates will assist in the effectiveness of therapeutic interventions and will be discussed next.

PAIN MODULATION

Nociceptive transmission is modulated at several points along the neural pathway by both ascending and descending systems.

The Gate Control Theory

The SG contains an ascending gating mechanism to block nociceptive impulses from leaving the dorsal horn of the spinal cord. The first-order neurons for both nociceptive and nonnociceptive information synapse with second-order

neurons in the SG. The second-order neurons for both types of information project to specialized neurons named *T cells* (transmission cells) in lamina V. For pain transmission to occur, T cells must be stimulated while the SG is inhibited. The input from A delta and C fibers stimulates the T cells and inhibits the SG (Figure 32-2). Therefore A delta and C fiber input opens the gate, allowing pain transmission to the higher centers. On the other hand, when the SG and T cells are both stimulated, the T cells are inhibited and the gate is closed to pain transmission. The input from nonnociceptive A beta fibers carrying information from pressoreceptors and mechanoreceptors stimulates both the T cells and the SG. Therefore A beta fiber input closes the gate, blocking pain transmission.¹⁷

One example that illustrates the gate control theory is the use of transcutaneous electrical nerve stimulation (TENS) in an area that overlaps the injury. It works to reduce pain by activation of large-diameter A beta fibers that “closes the gate,” thereby preventing pain transmission to the higher centers of the brain. This is also why shaking (vibrating) your hand after hitting your thumb with a hammer temporarily relieves pain.

Descending Pain Modulation System

There are at least two descending pain modulation systems. One involves the action of neurotransmitters, including serotonin, dopamine, norepinephrine, and substance P. High concentrations of brain serotonin¹⁰⁸ and L-dopa (a precursor of dopamine)¹⁹ have been found to inhibit nociception, whereas norepinephrine appears to enhance nociception.²⁰⁻²³ The spinal mediators of descending nociceptive inhibitory influences include serotonin, norepinephrine, and acetylcholine (ACh). This may be relevant to the action of antidepressants in relieving pain in the absence of depression. Substance P is

Figure 32-2 ■ Schematic representation of spinal structures involved in the gate control theory of pain transmission. Afferent input by means of both large- and small-diameter fibers is theorized to influence the transmission cell (*T*) directly and through small internuncial neurons located within the substantia gelatinosa (*SG*). (From Nolan MF: Anatomic and physiologic organization of neural structures involved in pain transmission, modulation, and perception. In Echtertnach JL, editor: *Pain*, New York, 1987, Churchill Livingstone.)

thought to be the neurotransmitter for neurons transmitting chronic pain.²⁴

The second descending modulating system is mediated by neuromodulators—chemicals capable of directly affecting pain transmission. The neuromodulators include enkephalin and β -endorphin, which are referred to as *endogenous opiates* because they have morphine-like actions and are found in areas of the central nervous system (CNS) that correspond to opiate-binding sites. Endogenous opiates are believed to modulate pain by inhibiting the release of substance P. They have been shown to have a profound effect on nociception and mood.²⁵⁻²⁷ Their levels in the brain and spinal cord rise in response to emotional stress, causing an increase in the pain threshold and providing a possible reason that acute stress decreases acute pain.^{28,29}

Although serotonin is not classified as an endogenous opiate, it exerts a profound effect on analgesia and enhances analgesic drug potency. High concentrations of serotonin lead to decreased pain by inhibiting transmission of nociceptive information within the dorsal horn,^{30,31} whereas low concentrations result in depression, sleep disturbances, and increased pain.

The success of several therapeutic modalities, including noxious counterirritation (e.g., brief intense TENS or acupuncture) and diversion (including hypnosis), is attributed to raising the level of endogenous opiates in the body.²⁹

CATEGORIZING PAIN

Pain is grouped into several categories: acute, chronic, referred, central neuropathic, autonomic, and peripheral.

Acute pain is the normal predicted physiological response and serves as a warning. It alerts the individual that tissues are exposed to damaging or potentially damaging noxious stimuli. Acute pain is localized, occurs in proportion to the intensity of the stimuli, and lasts only as long as the stimuli or the tissue damage exists (1 to 6 months).³² Although acute pain is associated with anxiety and increased autonomic activity (increased muscle tone, heart rate, and blood pressure),³³ it is usually relieved by interventions directed at correcting the injury. The pain experience is usually limited to the individual.³⁴

Chronic pain is usually referred to as *intractable pain* if it persists for 6 or more months. It is defined as pain that continues after the stimulus has been removed or the tissue damage heals. Physiologically, chronic pain is believed to result from hypersensitization of the pain receptors and enlargement of the receptor field in response to the localized inflammation that follows tissue damage.³⁵ Chronic pain is poorly localized, has an ill-defined time of onset, and is strongly associated with the subjective components outlined previously. It does not respond well to interventions directed solely at correcting the injury. Chronic pain patients frequently report other symptoms, such as depression, difficulty sleeping, poor mental and physical function, and fatigue. The effects of the pain experience extend beyond the individual and affect the family, the workplace, and the social sphere of the individual.³⁴

Referred pain is felt at a point other than its origin. Pain can be referred from an internal organ, a joint, a trigger point, or a peripheral nerve to a remote musculoskeletal structure. Referred pain usually follows a specific pattern. For example, cardiac pain is frequently referred to the left arm or jaw; the referral pattern for trigger points is exact

enough to be used as a diagnostic tool and is often used by physicians to diagnose pathology. Referred pain is the result of a convergence of the primary afferent neurons from deep structures and muscles to secondary neurons that also have a cutaneous receptive field.^{36,37}

Although it is now recognized that all neuropathic pain results in abnormal activity within the CNS,³⁸ pain initiated or caused by a primary lesion or dysfunction of the CNS³⁹ is referred to as *central neuropathic pain*. The involvement of the nervous system can be at many levels: nerves, nerve roots, and central pain pathways in the spinal cord and brain. In this circumstance, there is permanent damage to the nervous system (usually a peripheral nerve) and likely anatomical reorganization of spinal terminations of surviving axons or ectopic activity from a neuroma that contributes paroxysmal, persistent input to the spinal cord.⁴⁰ In addition to anatomical reorganization in the spinal cord, there could be some reorganization in the rostroventral medulla (RVM) as well, but more likely there is prolonged input to the RVM that sustains facilitatory influences that descend to the spinal cord. Less appreciated, descending facilitatory influences on spinal sensory processing could also be important to maintenance of chronic pain conditions, particularly those that persist in the absence of obvious tissue pathology.⁴⁰

Central neuropathic pain is medically diagnosed by its defining neurological signs and symptoms; it is verified with neuroimaging tests that identify a CNS lesion and rule out other causes. It is important that the therapist be able to localize the level and differentiate between central and peripheral pain. Central neuropathic pain can be caused by vascular insult; traumatic, neoplastic, and demyelinating diseases; and surgery (including vascular compromise during surgery). Central neuropathic pain is distinct from nociceptive pain (nonneuronal tissue damage).

The onset of central neuropathic pain is usually delayed after the occurrence of the initial episode that results in damage to the CNS; onset of pain may occur during the phase of recovery from neurological deficits.⁴¹ Pain originating from a cerebrovascular incident and spinal cord injury usually begins weeks or months after the insult, whereas pain originating from tumors may take years to begin.³⁸

Individuals with central neuropathic pain may have difficulty describing their pain and report burning, aching, pricking, squeezing, or cutting pain after cutaneous stimulation, movement, heat, cold, or vibration. A normally nonnoxious stimulus, such as moving clothing across skin, becomes agonizing. In some cases the pain begins spontaneously.⁴² Pain intensity varies, but it does seem to be associated to some degree with the location of the lesion.³⁸ Allodynia (pain from normally nonnoxious stimuli) and dysesthesia are common, and one of the characteristic features of central neuropathic pain is that the clinical symptoms persist long after the stimulus has been removed.

Central neuropathic pain is topographical. The site of the lesion determines the location of the symptoms. The pain may involve half the body, an entire extremity, or a small portion of one extremity.³⁸ It is frequently migratory. Thalamic pain is the classic example of central neuropathic pain.

Central neuropathic pain is difficult to treat. Surgery is not helpful for most individuals with central neuropathic pain, and medications have not been effective in permanently

relieving the symptoms.¹¹ Therefore the treatment of clients with central neuropathic pain stresses coping strategies and prevention of loss of activity and participation. The ideal management of a chronic pain patient is by a multidisciplinary approach, including disciplines such as internal medicine, neurology, anesthesia, nursing, psychology, pharmacy, rehabilitation medicine, physical therapy, occupational therapy, and others. The limitation of this approach is that access to such a wide range of specialists is often available only at large medical centers and special pain clinics, which restricts access to a limited number of patients.

Under normal conditions there is a fine balance between the parasympathetic and sympathetic branches of the autonomic nervous system (ANS). Parasympathetic activity maintains homeostasis, whereas sympathetic activity functions to make “fight-or-flight” changes in response to stress. Stimulation of the autonomic efferent fibers is not normally painful. However, the balance between afferent input and the descending sympathetic nervous system (SNS) is disrupted when there is injury, resulting in exaggerated and prolonged sympathetic activity, allodynia, and hyperalgesia (increased response to normally painful stimuli)—hence, autonomic pain.

Allodynia is a product of the phenomenon of central sensitization.⁴³ After injury, new axons sprout from the sympathetic efferent neurons. These fire spontaneously and, because they synapse on the cell bodies of the primary afferent neurons, cause them to fire as well. In addition, the dorsal horn neurons themselves become more excitable. They show an enlargement in their receptive field and become more sensitive to mechanical, thermal, and chemical stimulation. The result is an increase in the neuronal barrage into the CNS and the perception of pain with usually nonpainful stimuli.¹³

Complex regional pain syndrome (CRPS) is an example of pain that arises from abnormal activity within the ANS.⁴⁴ CRPS has been classified into two distinct types³⁹: CRPS type I (formerly *reflex sympathetic dystrophy*) follows mild trauma without nerve injury, and CRPS type II (formerly *causalgia*) follows trauma with nerve injury. CRPS type I generally begins within the month after the injury, whereas CRPS type II can occur any time after the injury.⁴⁵

The main features of CRPS type I are constant burning pain that fluctuates in intensity and increases with movement, constant stimulation, or stress. There are also allodynia and hyperalgesia, edema, abnormal sweating, abnormal blood flow and trophic changes in the area of pain, and impaired motor function. CRPS type I is relieved by blocking the SNS, indicating that the pain is sympathetically maintained.⁴⁵

CRPS type II occurs in the region of a limb innervated by an injured nerve. The nerves most commonly involved in CRPS type II are the median, sciatic, tibial, and ulnar; involvement of the radial nerve is rare. Pain is described as spontaneous, constant, and burning and is exacerbated by light touch, stress, temperature change, movement, visual and auditory stimuli, and emotional disturbances. Allodynia and hyperalgesia are common and may involve the distribution of more than one peripheral nerve. As with CRPS type I, edema, abnormal sweating, abnormal blood flow, trophic changes, and impaired motor function occur. The symptoms spread proximally and can involve other areas of the body.

Evidence also points to sympathetic involvement in CRPS type II.⁴⁵

The treatment of CRPS is complex and must be carefully coordinated among members of an interdisciplinary team including the neurologist (medications), psychologist (behavior), anesthesiologist (injections), and therapist (functional recovery). The therapist provides the core treatment to improve function. Therapists need to pay close attention to the following aspects of the disorder: (1) the degree of motor abnormalities, including restricted active range of motion (ROM), abnormal posturing, spasm, tremor, and dystonia; (2) true passive range restriction; (3) hyperesthesia and allodynia; (4) swelling and vasomotor changes; and (5) evidence of osteoporosis by radiograph.⁴⁶ Please refer to **Case Study 32-1** for interventions for clients with CRPS.

Peripheral pain results from noxious irritation of the nociceptors. The character of peripheral pain depends on the location and intensity of the noxious stimulation, as well as which fibers carry the information into the dorsal gray matter. As noted previously, information carried on A delta fibers is sharp and well localized, begins rapidly, and lasts only as long as the stimulus is present, whereas information carried on C fibers is dull and diffuse, has a delayed onset, and lasts longer than the duration of the stimulus. The treatment of peripheral pain is covered in detail in Chapter 18.

The management of central versus peripheral pain is determined by the type of pain—acute or chronic—and the clinical features present, including clinical localization; time of onset; laboratory study localization; response to analgesics, including narcotics; response to antidepressants; and response to nerve block or neurectomy.⁴¹ Differentiation among features will drive the treatment plan, but because some peripheral and central forms can coexist, diagnosis may be difficult.

The multidimensional aspects of chronic pain make it important to evaluate the causes as well as the emotional and cognitive sequelae.⁴⁷ Persistent pain is now considered to have a psychogenic component.⁴⁸ The longer an individual has pain, the more a psychological component may become dominant. Many emotional factors can strongly influence pain, such as pain thresholds, past experiences with pain, coping styles, and social roles. The emotional experience that we perceive with pain reflects the interaction of higher brain centers and subcortical regions, such as the amygdala and cingulate gyrus (limbic system).⁴⁹ Positron emission tomography of patients with chronic neuropathic pain demonstrates a shift of acute pain activity in the sensory cortex to regions such as the anterior cingulate gyrus.⁵⁰ Understanding the physical limitations imposed by chronic pain is an area that therapists commonly assess; it is the mind-body connection that is often less articulated by the client and more difficult for the practitioner.

Treatment of chronic pain should include a patient-centered approach, given the unique manifestations that occur in an individual's response to pain. Patient-centered models, such as the ICF model, provide a framework that embraces a multidisciplinary team approach practiced in pain clinics. In such models, chronic pain has been noted to include psychological factors such as feelings of fear, anxiety, and depression,⁵¹ which are known to have the ability to modulate and exacerbate the physical pain experience.⁵² For example, a client with chronic pain who has the

fear that movement will increase pain may alter his activity, causing muscular shortening, spasms, and a spiraling course of more pain and disability. The focus in treating clients with chronic pain should be on improving functional physical activity, decreasing peripheral nociception and central facilitation, and providing cognitive and behavioral strategies to help in resuming normal activities.

EXAMINATION OF THE CLIENT WITH PAIN

The examination of a client with pain can be challenging because the therapist must frequently weed through the individual's emotions, behaviors, and secondary gains in an attempt to identify the source of the symptoms. Many clients are not referred to therapy until they have participated in weeks, months, or even years of failed interventions, and their expectations and patience are at low levels. They often approach therapy anticipating more instructions, more frustration, and more pain. Despite these obstacles, therapists must strive to complete pain evaluations that include measurable, reproducible information that identifies the source of pain and provides direction toward treatment that is both beneficial and cost-effective and that assists in establishing attainable goals. The time allotted for the examination may be dependent on the type of practice setting; many therapists send a comprehensive questionnaire to the client or ask the client to arrive early to complete important paperwork. It is essential to develop a trusting relationship, ensuring that the client feels that the therapist has listened to his or her concerns and has acknowledged his or her fears, and will participate in a plan for improving his or her physical, mental, and functional abilities.

Pain History

Every evaluation of a client with pain should begin with a comprehensive pain history. It is important to have a standardized format to decrease chances of missing important information and to minimize having the client "lead the interview." The following alphabetical mnemonic device may prove helpful (OPQRST):

- **Observation:** Observation of the client from the moment of entry until (and sometimes beyond) the moment of exit from the clinic. By observing the client outside of the evaluation, the therapist is able to assess the client's movement. The patient's nervous system will accurately express itself to the therapist, especially when the patient is asked to focus attention on a topic other than pain and the patient is not aware that movement is being observed.
- **Origin and onset:** Date and circumstances of the onset of pain. How did the pain start? Gradually or suddenly? Was there a precipitating injury? If so, what was the mechanism of injury? If not, can the client correlate the onset to a particular activity or posture?
- **Position:** Location of the pain. Have the client demonstrate where the pain is located rather than relying on description alone. In addition to being more accurate, demonstration allows another observation of the client's ability and willingness to move. Clients can also be asked to draw their symptoms on a schematic, such as the pain drawing, which is described later.
- **Pattern:** Pattern of the pain. Is the pain constant or periodic? Does it travel or radiate? Which activities and

postures increase or decrease the pain? Does medication or time of day have any effect on the pain? Have there been any recent changes in the pattern? Does the client believe that the pain is improving, worsening, or remaining the same?

- **Quality:** Characteristics of the pain. Does the client use adjectives indicating mechanical (pressing, bursting, stabbing), chemical (burning), neural (numb, "pins and needles"), or vascular (throbbing) origin? Two tools for describing pain character are described later.
- **Quantity:** Intensity of the pain. How has the pain intensity changed since the onset? Several methods that allow for monitoring change in pain intensity are presented later.
- **Radiation:** Characteristics of pain radiation. Does the pain radiate? What causes the pain to radiate? Can the radiation be reversed? How?
- **Signs and symptoms:** Functional and psychological components of the pain. Has the pain resulted in any functional limitations? Has it caused any changes in the client's ability to participate in life, including employment and recreational activities? Does the client's personality contribute to the pain, or has the pain caused changes in the client's emotional stability? Does the client benefit from the pain? How? It may be necessary to interview the client's significant others or family members for an accurate picture.
- **Treatment:** Previous and current medical and therapeutic treatment and its effectiveness, including medications, home remedies, and recommendations for movement activities. It is also important to determine the client's attitude and expectations concerning therapy in addition to obtaining a treatment history.
- **Visceral symptoms:** Physical symptoms of visceral origin that can accompany and be responsible for the pain (Box 32-1). Visceral causes of pain require referral to the client's physician for further investigation before the initiation of treatment by a therapist.

Pain Measurement

Research has shown that pain memory does not provide an accurate measure of pain intensity.⁵³ Therefore pain measurement tools are designed to provide information about the intensity, location, and character of a client's symptoms at the time of the evaluation. This information can then be merged with the pain history, the disease or pathology history, and the physical findings to identify the cause of the pain. The disease or pathology management and its pain measurement will be the responsibility of the physician, whereas the movement limitations caused by the pain are the responsibility of the therapist. A number of pain measurement tools are available. These tools are used by professionals whose focus is pathology, as well as professionals whose responsibility is helping the patient to regain functional activities and life participation. The applications and limitations of several are discussed.

Measuring Pain Intensity

Pain intensity rating tools are scales that have the client rate the current level of pain by marking a continuum or assigning a numerical value to the pain intensity (Figure 32-3).

BOX 32-1 ■ VISCEROGENIC BACK PAIN

GENERAL SIGNS AND SYMPTOMS

- Pain does not increase with spinal stresses or strains.
- Pain is not relieved with rest.
- Visceral symptoms accompany back pain.

GASTROINTESTINAL TRACT SIGNS AND SYMPTOMS

- Pain is accompanied by altered bowel habits.
- Pain is related to eating.
- Peptic pain is relieved with vomiting.

KIDNEY SIGNS AND SYMPTOMS

- Increased pain with diuresis indicates hydronephrosis.

PELVIC SIGNS AND SYMPTOMS

- Low back pain associated with vaginal bleeding or discharge.

PROSTATE SIGNS AND SYMPTOMS

- Low back discomfort associated with micturition.

LUNG SIGNS AND SYMPTOMS

- Posterior thoracic pain associated with respiration in chronic obstructive pulmonary disease.

VASCULAR SIGNS AND SYMPTOMS

- Deep, boring, pulsating low back pain associated with a palpable abdominal aortic aneurysm.
- Back pain with or without calf pain after walking and relieved with standing still; possibly impaired lower extremity pulses and trophic skin changes associated with occlusive disease of the internal iliac artery or its branches.

Modified from Makofsky H, Willis GC: Non-mechanical and pathological causes of low back pain. *Phys Ther Forum* May 15, p 12, 1989.

Each of the first three tools described here has been found to be reliable over time when used to measure pain that is present at the time of the rating. In general, however, clients who are depressed or anxious tend to report higher levels of pain and clients who are not depressed or anxious tend to report lower levels of pain on all three of these scales.⁵⁴

Visual Analog Scale. With the visual analog scale (VAS), the client rates the pain on a continuum that begins with “no pain” and ends with “maximum pain tolerable.” This tool provides an infinite number of points between the extremes, making it sensitive to small changes in pain intensity. However, it has not been found reliable for individuals who have impaired abstract thinking skills⁵⁵ and may be unable to translate their pain intensity into a corresponding point on a line.

Simple Descriptive Pain Scale. With a simple descriptive pain scale (SDPS), the client rates the pain on a continuum that is subdivided using descriptors that gradually increase in intensity. Sample descriptors are “no pain,” “mild pain,” “moderate pain,” “severe pain,” and “maximum pain tolerable.” This tool is more useful than the VAS for clients with impaired abstract thinking because it is easier for them to identify with the pain descriptors than with the line found in the VAS. However, clients have been found to favor the points corresponding to each descriptor rather than points between, resulting in a less sensitive tool than the VAS.⁵⁶

Pain Estimate. With a pain estimate, the client assigns a numerical rating to the pain, staying within defined limits (most commonly between 0 and 100, where 0 represents no pain and 100 represents maximum pain tolerable). Because it provides a numerical range of scores, this tool is valuable for statistical analysis purposes. However, whereas some clients find assigning a numerical rating to their pain intensity easy,

Figure 32-3 ■ Rating scales for measuring pain intensity. **A**, Simple descriptive pain scale (SDPS). **B**, Visual analog scale (VAS). **C**, Pain estimate. **D**, Faces pain scale. (D Reprinted from Bieri D, Reeve DA, Champion GD, et al: The faces pain scale for the self-assessment of the severity of pain experienced by children: development, initial validation, and preliminary investigation for the ratio scale properties. *Pain* 41:139–150, 1990, with permission from Elsevier Science.)

clients with impaired abstract thinking may have difficulty similar to that encountered with the VAS.

Faces Pain Scale. With the Faces Pain Scale, the client selects one of seven schematic faces representing gradually increasing pain intensities. The scale begins with a face representing no pain and ends with a face representing the most pain possible. This tool is designed for use with young children who do not have the ability to use any of the three previous tools. The Faces Pain Scale has been found to be valid across cultural lines⁵⁷ and to have a strong correlation with other pain measures.⁵⁶ It is simple to use, does not require verbal skills, and requires little instruction. It has been used successfully with children as young as age 3 and with individuals who are limited in verbal expression.

Localizing Pain Symptoms

Pain Drawings. The client is asked to draw his or her symptoms on a schematic of the human body using a provided list of symbols (Figure 32-4). The result is a diagram describing the nature and location of the client's pain, which can be compared with the client's verbal report. In addition to providing a database, the pain drawing has been found to be useful in identifying individuals who have a heavy psychological or emotional component to their pain, making it helpful also in identifying clients who would benefit from further psychological evaluation.⁵⁸

Describing Pain Quality

McGill Pain Questionnaire (MPQ). One of the most popular scales to rate pain quality is the McGill Pain Questionnaire (MPQ), which includes 20 categories of descriptive words covering the sensory (numbers 1 to 10), affective (numbers 11 to 15), and evaluative (number 16) properties of pain (Figure 32-5). Sensory properties are measured using temporal, thermal, spatial, and pressure descriptors. Affective properties are measured using fear, tension, and autonomic descriptors. Evaluative properties are measured using pain experience descriptors.⁵⁹ Each word has a numerical value based on its position within its category.

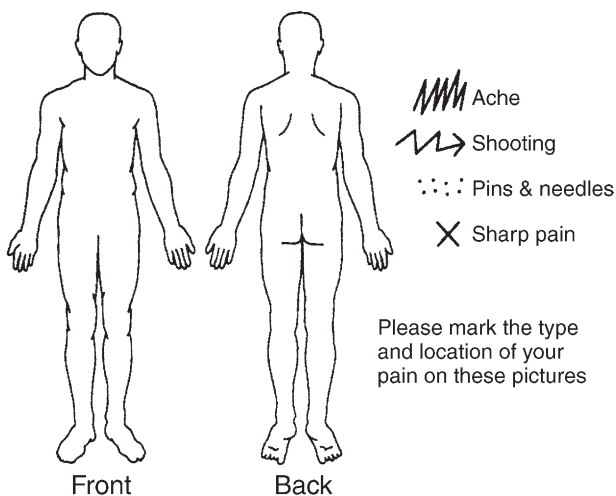

Figure 32-4 ■ Pain drawing for describing the nature and location of a client's pain symptoms. (From Cameron MH, editor: *Physical agents in rehabilitation*, Philadelphia, 1999, WB Saunders.)

The client is instructed to “select the word in each category that best describes the pain you have now. If there is no word in the category that describes the pain, skip the category. If there is more than one word that describes the pain, select the word that best describes the pain.”⁵⁹

The MPQ can provide the following types of information⁵⁹:

- A pain-rating index based on the sum of the values of all the words selected
- A pain-rating index based on the sum of the values of all the words in a given category
- The total number of words chosen

The MPQ has been studied extensively and found valid for adults with acute and chronic pain as well as for those with a variety of specific pathological states.⁶⁰⁻⁶² It provides clues into the specific cause of pain because it describes the client's symptoms.

However, the MPQ does pose some disadvantages. It is time-consuming, requiring more time to complete than any of the previously described rating scales. Thus it is not appropriate for quick estimates of pain after treatment. Clients, especially children, are frequently unfamiliar with some of the descriptors and ask the evaluator to assist by defining words. However, reliability and validity of this test are based on examiner objectivity, and care must be taken to avoid the introduction of evaluator bias by helping the client to select appropriate descriptors.⁵⁹ This issue can be dealt with by telling the client, “If you do not recognize a word, it probably does not apply to you.”

Pediatric Verbal Descriptor Scale. Because a child's description of pain is limited by a smaller vocabulary, Wilkie and associates⁶³ have developed a verbal descriptor scale specifically for use with children (Table 32-1). Their list includes 56 words commonly used by children aged 8 to 17 to describe their pain experience. The word list is divided into the four categories found in the MPQ. The evaluators' research has shown the list to be useful for children with a variety of diagnoses because it is relatively free of gender, ethnic, and developmental bias.

Caregiver Checklist. Clients who are unable to communicate verbally because of neurological disabilities may be unable to use any of the just-described pain measurement scales. However, because of pain associated with their medical conditions, extensive and repeated surgery, and behavioral oddities that might limit pain expression, these individuals are at high risk for having their pain go unrecognized. McGrath and colleagues⁶⁴ have attempted to develop and categorize a checklist of demonstrated pain behaviors identified by caregivers of severely handicapped individuals. Although their list did not pass validity criteria, the researchers propose that clinicians develop a client-specific checklist that could be used to gauge changes in the client's pain from the information gained during the caregiver interview portion of the evaluation of nonverbal handicapped clients.

In addition to qualifying and quantifying the client's pain, pain measurement tools have an additional value. They can be used to identify inconsistencies between a client's pain report and the clinician's objective findings. For example, a client with normal objective findings would not be expected to give a high pain report or draw symptoms over the entire pain drawing. Conversely, a client with a multitude of objective findings within the severe range would be expected to

What Does Your Pain Feel Like?

Some of the words below describe your present pain. Circle ONLY those words that best describe it. Leave out any category that is not suitable. Use only a single word in each appropriate category—the one that applies best.

1 Flickering Quivering Pulsing Throbbing Beating Pounding	2 Jumping Flashing Shooting	3 Pricking Boring Drilling Stabbing Lancing	4 Sharp Cutting Lacerating
5 Pinching Pressing Gnawing Cramping Crushing	6 Tugging Pulling Wrenching	7 Hot Burning Scalding Searing	8 Tingling Itchy Smarting Stinging
9 Dull Sore Hurting Aching Heavy	10 Tender Taut Rasping Splitting	11 Tiring Exhausting	12 Sickening Suffocating
13 Fearful Frightful Terrifying	14 Punishing Grueling Cruel Vicious Killing	15 Wretched Blinding	16 Annoying Troublesome Miserable Intense Unbearable
17 Spreading Radiating Penetrating Piercing	18 Tight Numb Drawing Squeezing Tearing	19 Cool Cold Freezing	20 Nagging Nauseating Agonizing Dreadful Torturing

Figure 32-5 ■ The McGill Pain Questionnaire used to rate pain quality. (Reprinted from Melzack R: The McGill Pain Questionnaire: major properties and scoring methods. *Pain* 1:277, 1975, with permission from Elsevier Science.)

provide a high pain rating. In addition, as objective symptoms subside, it is expected that the client will report a similar decline on the rating scales. Inconsistencies between the client's pain descriptions and the therapist's findings should serve to alert the clinician that the client might require cognitive or affective intervention in addition to physical treatment.

PSYCHOSOCIAL ASSESSMENT

Psychosocial factors are key variables in the comprehensive assessment of chronic pain. Davidson and colleagues⁶⁵ determined seven factors using a "prototypical" pain assessment battery that included pain and disability, pain description, affective distress, support, positive coping strategies, negative coping strategies, and activity. Irving and Squire⁶⁶ described two key individual personality features that affect pain: catastrophizing and health-related anxiety. Persons who catastrophically misinterpret innocuous bodily sensations, including pain, are likely to become fearful of pain, which results in pain-related fear. Pain-related fear is associated with avoidance of movement and physical activity, which directly affects

recovery of function. Pain-related fear is also associated with increased pain levels and an exacerbated painful experience. Two validated tools to screen for these features include the Pain Catastrophizing Scale (PCS) and the Tampa Scale of Kinesophobia (TKS).⁶⁷

EXAMINATION OF THE CLIENT

The clinical examination should begin the moment the client enters the door. Clients frequently change posture and affect when they are being formally evaluated, and it is important to gain an accurate view of pain behavior during spontaneous activities to assess the validity of complaints. The following should be included in the examination:

- Observation of gait and movement patterns, including the use of assistive devices.
- Notation of body type and anomalies.
- Examination of sitting and standing posture, including both the normal posture and that assumed because of the pain. (Observe the client during activities, if possible, to differentiate movement patterns altered by intent versus automatic adjustments.)

TABLE 32-1 ■ PEDIATRIC VERBAL DESCRIPTOR SCALE

DIMENSION	WORD	DIMENSION	WORD	DIMENSION	WORD	DIMENSION	WORD
A	Annoying	S	Biting	S	Itching	A	Crying

S, Sensory; A, affective; E, evaluative.

- Inspection of the skin for pliability, trophic changes, scar tissue, and other abnormalities.
- Palpation of the soft tissue structures to identify changes in temperature, swelling, tenderness, and areas of discomfort.
- Palpation of the anatomical structures to determine end feel—the sensation felt at the end of the available movement.⁶⁸
 - Bone to bone: hard normal, for example, at the end range of elbow extension.
 - Spasm: muscular resistance abnormal.
 - Capsular feel: rubbery normal at the extreme of full ROM; abnormal when encountered before the end of ROM.
 - Springy block: rebound abnormal.
 - Tissue approximation: soft tissue normal at the extremes of full passive flexion.
 - Empty feel: no physiological resistance, but client resists movement because of pain.
- Examination of ROM: active ROM testing is performed to assess the client's willingness to move and to identify any limitations or painful areas; passive ROM testing is used to further refine the observations.⁶⁸
 - When active and passive movements are painful and restricted in the same direction and the pain appears at the limit of motion, the problem is most likely arthrogenic.
 - When active and passive movements are painful or restricted in opposite directions, the problem is most likely muscular.
- When there is relative restriction of passive movement in the capsular pattern, the problem may be arthritic in nature.
- When there is no restriction of passive movement but the client cannot perform the movement actively, the muscle may not be functioning, either from intrinsic problems within the muscle or interruption in the neural pathway (central or peripheral).
- Examination of muscle strength⁶⁸:
 - When the movement is strong and painful, there is a minor lesion in the muscle or tendon.
 - When the movement is weak and increases the pain, there is a major lesion that needs to be identified with further testing.
 - When the movement is weak but does not increase the pain, there is the possibility of either complete rupture of the muscle or tendon or a neurological disorder.
 - When all resisted movements are painful, the pain may be organic or the patient may be emotionally hypersensitive.
 - When movement is strong and painless, the test results are normal.
- Assessment of bilateral neurological function:
 - Reflexes: peripheral lesions tend to diminish deep tendon reflexes (DTRs). CNS lesions tend to intensify DTRs, and testing frequently elicits a clonic reaction.⁶⁹ Note any asymmetries in response.
 - Sensation: test light touch, sharp (noxious) touch, and vibration. Pressure on a nerve usually affects

conduction on the large, myelinated fibers first. Therefore vibration is the first sensation to be diminished. Where there is decreased perception of touch and noxious stimuli, the lesion is more severe.⁷⁰ Note any asymmetries in response.

- Allodynia and hyperalgesia: delineate areas of allodynia and hyperalgesia to touch, hot, and cold. Exact descriptions of these areas, along with areas of decreased perception of vibration, will provide information concerning A beta versus C fiber involvement in the production of pain.⁷⁰
- Stretch and pressure tests to nerve trunks.

It is not always possible to complete a pain evaluation in one session. Clients may not be able to tolerate all the required activities at one time, or there may be enough inconsistencies for the therapist to want a second appointment to refocus on specific tests. However, with the limitations on number of visits common with managed care, the therapist may feel pressured to identify a cause for the client's pain in the initial visit. This is not necessary. It is far better to take more than one visit and be accurate than to take only one visit and develop a treatment plan that is not appropriate for the client's needs.

REHABILITATION MANAGEMENT OF THE CLIENT WITH PAIN

There are three broad avenues of intervention for pain management: physical interventions, cognitive strategies, and behavioral manipulations.⁷¹ Each avenue addresses a different aspect of the pain experience, and each requires a different level of participation from the client.

Physical interventions are directed at the client's body with the goal of healing the tissue injury. Examples include medication, surgery, and the therapy modalities. Physical interventions are of use most frequently with acute pain or recurrent pain resulting from reinjury. Physical interventions are often passive and, for the most part, soothing. When used long term, they promote dependence on the clinician. Therefore it is best to use them as a short-term adjunct in the overall treatment program.

Cognitive strategies are directed at the client's thoughts with the goal of changing the client's pain paradigms. Cognitive strategies include body scanning and reinterpretation of self-statements. Cognitive strategies are self-initiated and performed independently; therefore they encourage personal responsibility and independence.

Behavioral manipulations involve a behavioral change on the part of the client to bring about the desired response. They include exercise, biofeedback, hypnosis, relaxation exercises, and operant conditioning. There is usually a brief learning period until the client becomes proficient with these techniques; however, once learned, behavioral manipulations can be initiated and performed independently. Behavioral manipulations also encourage personal responsibility and independence.

A brief review of the benefits, indications, contraindications, and precautions for many of the interventions provided by therapists should provide an overview of the complexity of pain management. The purpose of this section is to provide guidance in the selection of one treatment option over another so that intervention will be based on sound physiological principles. Readers who wish to explore an

intervention in greater depth are directed to the references listed at the end of this chapter.

Physical Interventions

Thermotherapy

The physiological effects of heat depend on the method of application, the depth of penetration, and the rate and magnitude of temperature change. In terms of the use of thermotherapy to control pain, several mechanisms have been established. Muscle spasm decreases as a result of decreased activity in gamma motor efferents, decreased excitability of muscle spindles, and increased activity of Golgi tendon organs.^{72,73} This modality will often decrease peripheral pain. Ischemic pain is relieved by the influx of oxygen-rich blood into the dilated vessels, and muscle tension pain is decreased by interruption of the pain-spasm cycle. In addition, the pain threshold itself rises through gating at the spinal cord level.^{74,75}

Several textbooks⁷⁶⁻⁸⁰ on physical agents and rehabilitation discuss the physiological effects, precautions, contraindications, and method of application for these modalities. The reader is advised to refer to the textbooks for details.

Superficial heat can be applied by conduction, convection, or radiation. Conductive heating involves the exchange of heat down a temperature gradient by two objects that are in contact. The depth of penetration with conductive heating is usually 1 cm or less.⁸¹ Moist heat packs and paraffin are examples of therapeutic conductive heating. Convective heating involves heat transfer through the flow of hot fluid. Therapeutic convective heating takes place during hydrotherapy and Fluidotherapy (Encore Medical Corporation, Austin, Texas). Molecules with a temperature greater than absolute zero are in an excited state and emit energy, thus creating radiant heat. Objects that are warmed by the energy are heated by radiation. Therapeutic radiant heat is applied with infrared or ultraviolet light. Because of the contraindications of ultraviolet light, this type of radiant heat is seldom used by therapists today in rehabilitation settings.

Clients can be taught how and when to apply superficial heat independently. Once they have demonstrated independence, responsibility for the application of superficial heat should be transferred to the client or her or his caregiver.

The deeper tissues can be heated using conversion, the alteration of one form of energy into another. Examples of heating by conversion include use of shortwave diathermy or ultrasound.

During shortwave diathermy, the client is placed into an oscillating magnetic field. The systemic ions create friction as they attempt to line up with the continuously reversing current, resulting in an increase in tissue temperature deep within the body. Shortwave diathermy is contraindicated for clients with metal implants because of the potential for the implant to become hot and burn the surrounding tissues. It is also contraindicated for clients with cardiac pacemakers because of the pacemaker's metal components and because the electromagnetic radiation may interfere with the pacemaker's operation. Shortwave diathermy should not be used for clients with cancer or multiple sclerosis or who are pregnant, and it should not be used over the eyes, the reproductive organs, or growing epiphyses. Female therapists should avoid prolonged exposure to shortwave diathermy because

some research has demonstrated a possible negative effect on pregnancy outcome and fetal development.⁸²

Ultrasound is another modality that heats deep tissues by conversion. As its name implies, ultrasound consists of sound waves delivered at a frequency too high to be perceived by human hearing. Sound waves are repeatedly refracted as they encounter tissues of differing acoustical resistance while traveling through the skin toward the bone (Figure 32-6). Tissues with high collagen content (tendon, ligament, fascia, and joint capsule) are heated more efficiently than tissues with low collagen content (fat, muscle). The extent of the temperature increase is related to the dose of ultrasound energy delivered. As the dose of ultrasound energy is increased by increasing the treatment duration or intensity, more energy is available to the tissues and the heating effect increases.²¹ Moreover, the higher the frequency of ultrasound delivered, the more superficial the effect. Ultrasound delivered at 1 MHz heats tissues at depths to 5 cm, whereas ultrasound delivered at 3 MHz heats tissues in the upper 2 cm.⁸³

The thermal effects of ultrasound can be used to increase tissue extensibility, cellular metabolic processes, and circulation; decrease pain and muscle spasm; and change nerve conduction velocity. The number of impulses traveling along the nerve decreases at low doses but begins to rise slowly beginning at 1.9 W/cm². Sounding of C fibers yields pain relief distal to the point of application, whereas sounding of large-diameter A fibers brings relief of spasm by changing gamma fiber activity, making the muscle fibers less sensitive to stretch.⁸⁴ Because it is impossible to treat C or A fibers selectively, ultrasound provides both pain relief and relief from muscle spasm, making it effective in the treatment of peripheral neuropathies, neuroma, and muscle spasm associated with musculoskeletal pathology, including sprains, strains, and contusions.⁸⁵

In addition to thermal effects, ultrasound has nonthermal effects that come from the mechanical effects of the ultrasound wave on the tissues. Ultrasound causes cavitation, the development and growth of gas-filled bubbles, in the tissues. Ultrasound also causes tissue fluid to move or stream. The

Figure 32-6 ■ The longitudinal wave of ultrasound is refracted at tissue interfaces where it encounters tissues of differing acoustical resistance. When the wave changes direction, energy is transferred to the tissues, resulting in the production of heat.

movement of fluid around the gas bubbles formed by cavitation is called microstreaming, and the movement of fluid within the ultrasound delivery area is called acoustic streaming. The nonthermal effects of ultrasound include accelerating metabolic processes, enzyme activity, and the rate of ion exchange, as well as increasing cell membrane permeability and the rate and volume of diffusion across cell membranes. These effects are thought to explain the role of ultrasound in enhancing the healing of soft tissue and bone.⁸⁶⁻⁸⁸ The nonthermal effects of ultrasound can be achieved without raising tissue temperature by applying ultrasound in the pulsed mode.

Phonophoresis is the use of ultrasound to deliver pain-relieving chemicals to the tissues. Chemicals are delivered to the cells by the ultrasound wave, where they are broken down into ions and taken up into the cells (Figure 32-7). Common pain-relieving chemicals that can be administered with phonophoresis include 5% lidocaine ointment (Xylocaine) for acute conditions in which immediate pain relief is the primary goal, and 10% hydrocortisone cream or ointment for conditions in which pain is the result of inflammation.⁸⁹

After phonophoresis, measurable quantities of these molecules have been found at tissue depths of up to 2 inches.⁹⁰ The contraindication to use of any chemical during phonophoresis is having an allergy to that chemical. Clients should be questioned about any adverse reactions to dental local anesthesia (lidocaine) or aspirin.

Cryotherapy

The physiological effects of cold make it superior to heat for acute pain from inflammatory conditions, for the period immediately after tissue trauma, and for treating muscle spasm and abnormal tone. Peripheral nerve conduction velocity in both large myelinated and small unmyelinated fibers decreases 2.4 m per degree centigrade of cooling. As a result, pain perception and muscle contractility diminish.⁹¹ Peripheral receptors become less excitable.⁹¹ Muscle spindle responsiveness to stretch decreases; as a result, muscle spasm diminishes.⁸⁴

Local blood flow initially decreases, local edema decreases, the inflammatory response decreases, and hemorrhage is minimized. However, cold application for longer

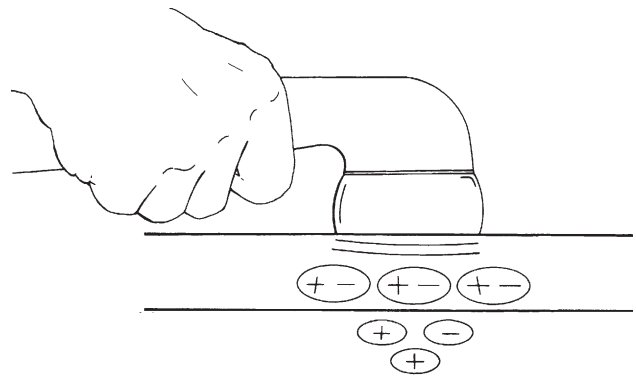

Figure 32-7 ■ Phonophoresis. Molecules of a substance are driven into the tissues by the ultrasound wavefront. They are not free for use by the body until they are broken down into chemical ions.

than 15 minutes results in increased local blood flow. Known as the “hunting response,” this protective mechanism brings core temperature blood to the surface and prevents tissue injury resulting from prolonged cooling.⁸¹ Cellular metabolic activities slow. The oxygen requirements of the cell decrease.⁹¹

As with heat, several precautions must be taken when using cold as a therapeutic modality. Cryotherapy is contraindicated in individuals with Raynaud phenomenon or cold allergy. Cryotherapy should not be used in individuals with rheumatic disease who, with the application of cold, have increased joint pain and stiffness. Cryotherapy should be used with caution in young, frail, or elderly individuals and those with peripheral vascular disease, circulatory pathological processes, or sensory loss.⁹²

Cryotherapy is applied in three ways. Convective cooling involves movement of air over the skin (fanning) and is rarely used therapeutically. Evaporative cooling results when a substance applied to the skin uses thermal energy to evaporate, thereby lowering surface temperature. Most commonly, this substance is a vapocoolant spray. Conductive cooling uses local application of cold via ice packs, ice massage, or immersion. Cooling is accomplished as heat from the higher-temperature object is transferred to the colder object down a temperature gradient. Conductive cooling is the most commonly used form of therapeutic cold application.

Because muscles, tendons, and joints respond differently, the best method of cold application depends on which tissues are causing the pain.⁹³ Acute injuries are best treated with cryotherapy along with rest, compression, and elevation (RICE). Muscle spasm is decreased with cold packs and stretching. Trigger points, irritable foci within muscles, are best treated with vapocoolant spray, deep friction massage, and stretching. Tendinitis responds well to ice massage and exercise. Cold packs are often the only source of pain relief in acute disc pathology. The inflamed joints of rheumatoid arthritis frequently respond to cold packs or ice massage with decreased inflammation, increased function, and long-lasting pain relief.^{92,94}

Clients and caregivers can be taught how and when to perform cryotherapy independently. Once they have demonstrated their proficiency, responsibility for the use of cryotherapy should be transferred to the client or the client's caregiver.

Transcutaneous Electrical Nerve Stimulation

TENS is the use of electricity to control the perception of pain. It appears that at a high rate TENS selectively stimulates the low-threshold, large-diameter A beta fibers, resulting in presynaptic inhibition within the dorsal horns,⁹⁵ either directly through the gating mechanism or indirectly through stimulation of the tonic descending pain-inhibiting pathways.⁹⁶ Research has shown that the neurons in the brain stem fire in synchrony with the TENS stimulation frequency,⁹⁷ and although the significance of this is not known at this time, it does indicate that the action of high-rate TENS is not limited to the dorsal columns. TENS delivered at a low rate is thought to facilitate elevation of the level of endogenous opiates in the CNS.⁹⁸

Stimulation frequencies of 1 to 250 pulses per second (pps) decrease pain. Frequencies of 50 to 100 pps have proven most effective for sensory-level (high-rate) TENS,

and frequencies of 2 to 3 pps are most effective for motor level (low-rate) TENS.³¹ Stimulation at exactly 2 pps causes an increase in the pain threshold.⁵³ As the frequency is decreased, more time is needed before the onset of relief, but the effects are more long-lasting.⁹⁹ Pulse width duration determines which nerves are stimulated. Sensory nerves are stimulated at widths of 20 to 100 ms, and motor nerves at 100 to 600 ms.¹⁰⁰

There is a variety of modes of TENS delivery. Each mode relieves pain through a specific physiological mechanism and is therefore most beneficial for a specific type of pain.

When TENS impulses are generated at a high rate (greater than or equal to 50 pps) with a relatively short duration, the stimulation is referred to as *sensory-level* or *conventional* or *high-rate TENS*. Sensory-level TENS produces mild to moderate paresthesia without muscle contraction throughout the treatment area. Sensory-level TENS is thought to control pain through the gating mechanism in the spinal cord. The onset of relief is fast (seconds to 15 minutes)³¹ because the gate is closed at the onset of stimulation. The duration of relief after stimulation stops is short-lived (at best up to a few hours). Sensory-level TENS has been found to be beneficial for acute pain syndromes and for some deep, aching chronic pain syndromes. (Refer to Chapter 33.)

Stimulation using high-rate and long-duration impulses is called *brief-intense TENS*. Brief-intense TENS decreases the conduction velocity of A delta and C fibers, producing a peripheral blockade to transmission.³¹ Brief-intense TENS is useful in the clinical setting for short-term anesthesia during wound debridement, suture removal, friction massage, joint mobilization, or other painful procedures.

When the impulses are generated at a low rate (less than or equal to 20 pps) and have a relatively long duration (100 to 300 microseconds), the stimulation is referred to as *motor-level* or *acupuncture-like* or *low-rate TENS*. Motor-level TENS produces strong muscle contractions in the treatment area with or without the perception of paresthesia. Motor-level TENS is associated with deployment of endogenous opiates within the CNS. The onset of relief is delayed 20 to 30 minutes, presumably the time it takes to deploy the opiates. Relief frequently lasts hours or days after treatment. Because motor nerves are not stimulated in isolation, sensory fibers are also excited, causing the gating mechanism to come into play.¹⁰⁰ Motor-level TENS has been found to be beneficial for chronic pain syndromes and when sensory-level TENS has not been successful.

Modulating TENS parameters is one way to avoid the negative aspects of each of the treatment modes. Rate modulation is most commonly used to avoid neural accommodation during TENS. By setting the initial pulse rate so that, even with the programmed decrement, it will remain within the treatment range, there will be continuous variation in the stimulus, and neural accommodation will be avoided.

Width modulation is most commonly used with motor-level TENS. By setting the initial pulse duration so that, even with the programmed decrement, the impulses are able to recruit the desired motor units, there will be a continuous variation in perceived strength of the muscle contraction, rendering motor-level TENS more tolerable.

Stimulation in which the impulses are generated in pulse trains is called *burst TENS*. Burst TENS is another form of TENS modulation. The stimulator generates low-rate carrier

impulses, each of which contains a series of high-rate pulses. Because burst TENS is a combination of high-rate and low-rate TENS, it provides the benefits of each. The low-rate carrier impulse stimulates endorphin release, and the high-rate pulse trains provide an overlay of paresthesia. The advantage to burst TENS is that muscle contractions occur at a lower, more comfortable amplitude, and accommodation does not occur. Burst TENS is beneficial whenever motor-level TENS cannot be tolerated and sensory-level TENS is ineffective because of neural accommodation.¹⁰¹

TENS, like all electrical stimulation, is contraindicated for clients with pacemakers, in the low back and pelvic regions of pregnant women, and over areas with thrombus. TENS should be used with caution for clients who have decreased sensation in the area being stimulated and for clients who have difficulty with understanding or expression. TENS electrodes should not be placed over areas of skin irritation, the eyes, or the carotid sinuses. It also should not be used in the immediate area of an operating diathermy unit.

TENS appears to be of greatest benefit for acute conditions with focal pain, chronic pain syndromes, postoperative incision pain, and during delivery. It has been found least effective with psychogenic pain¹⁰² and pain of central origin.¹⁰³ For additional information on TENS, see Chapter 33.

Clients and caregivers can be taught how and when to apply TENS independently. Once they have demonstrated independence, responsibility for the use of TENS can be transferred to the client or to the caregiver.

Iontophoresis

Iontophoresis is a process in which chemical ions are driven through the skin by a small electrical current. Ionizable compounds are placed on the skin under an electrode that, when polarized by a direct (galvanic) current, repels the ion of like charge into the tissues. Once subcutaneous, the ions are free to combine with the physiological ions, resulting in a physiological effect dependent on the characteristics of the ion (Figure 32-8). Ionizable substances that are known to be effective analgesics include the following¹⁰⁴:

- Five-percent lidocaine ointment (Xylocaine) administered under the positive electrode for an immediate, although short-lived, decrease in pain. Iontophoresis with lidocaine is recommended before ROM exercises, stretching, and joint mobilization and when immediate relief of acute pain (as in bursitis) is the object of treatment.
- One-percent to 10% hydrocortisone and dexamethasone administered under the positive electrode for relief

of inflammatory pain in conditions such as arthritis, bursitis, or entrapment syndromes. Iontophoresis with hydrocortisone has a delayed onset but a prolonged effect, and it frequently eliminates the underlying cause of pain.

- Two-percent magnesium (from Epsom salts) administered under the positive electrode for relief of pain from muscle spasm or localized ischemia. High levels of extracellular magnesium inhibit muscle contraction, including the smooth muscle found in the walls of the vessels, leading to localized vasodilation.
- Iodine (from Iodex ointment [Lee Pharmaceuticals, South El Monte, California]) administered under the negative pole for relief of pain caused by adhesions or scar tissue. Iodine “softens” fibrotic, sclerotic tissue, thereby increasing tissue pliability.
- Salicylate (from Iodex with Methyl Salicylate [Lee Pharmaceuticals] or Gordogesic Creme [Gordon Laboratories, Upper Darby, Pennsylvania]) administered under the negative pole for relief of pain from inflammation. Salicylate is effective for arthritic joint inflammation, myalgia, and entrapment syndromes.
- Two-percent acetic acid administered under the negative pole to dissolve calcium deposits.
- Two-percent lithium chloride or lithium carbonate administered under the positive pole to dissolve gouty tophi. In both acetic acid and lithium iontophoresis, the insoluble radicals in the deposits are replaced by soluble chemical radicals so the deposits can be broken down through natural processes.

The contraindication to the use of any ion is an allergy to that ion. Because most clients will not have had iontophoresis previously, it is important to inquire about experiences that might indicate an allergy. For example, intolerance to shellfish may be the result of an allergy to iodine, and a poor reaction to dental local anesthesia may indicate a problem with lidocaine. Moreover, because iontophoresis involves the application of direct current, the likelihood of polar reactions under each electrode is greater than with electrical stimulations using alternating current (for example, TENS), and therefore the risk for skin burns is greater.

Massage

Massage has been recognized as a remedy for pain for at least 3000 years. Evidence of its beneficial effects first appeared in ancient Chinese literature, and then in the writings of the Hindus, Persians, Egyptians, and Greeks. Hippocrates advocated massage for sprains and dislocations as well as for constipation.¹⁰⁵

Massage decreases pain through both direct and indirect means. Massage movements increase circulation through mechanical compression of the tissues, resulting in reflex relaxation of muscle tissue and direct relief from ischemic pain. Massage also indirectly stimulates A delta and A beta fibers, causing activation of the gating mechanism and the descending pain-modulating system.³⁴

Massage movements are classified by pressure and the part of the hand that is used.¹⁰⁶ The two massage movements that may cause a decrease in pain include stroking (effleurage) and compression (kneading or pétrissage). Stroking involves running the entire hand over large portions of the body. Stroking causes muscle relaxation and elimination of

Figure 32-8 ■ Iontophoresis. Chemical ions are driven into the tissues by a small electrical current. Once subcutaneous, they are immediately free to take part in chemical reactions within the body.

muscle spasm or improved circulation depending on the depth and force of the strokes. Compression is applied with intermittent pressure using lifting, rolling, or pressing movements meant to stretch shortened tissues, loosen adhesions, and assist with circulation.

Massage is useful in any condition in which pain relief will follow the reduction of swelling or the mobilization of the tissues. These include arthritis, bursitis, neuritis, fibrositis, low back pain, hemiplegia, paraplegia, quadriplegia, and joint sprains, strains, and contusions. Massage is contraindicated over infected areas, diseased skin, and thrombophlebitic regions.

Clients or caregivers can be taught how and when to perform massage. Once they have demonstrated independence in the appropriate technique, responsibility for the performance of massage should be given to the client or caregiver.

A specialized massage technique is lymphatic massage, which consists of light-pressure rhythmic strokes to encourage organizational flow of the lymphatic system. This type of massage can be beneficial with clients who have peripheral swelling with or without pain. A popular form of lymph massage called *manual lymphatic drainage* (MLD) is used after surgical procedures to reduce swelling (for example, mastectomy for breast cancer). Evidence-based studies show conflicting results regarding the efficacy of this technique, and more research needs to be done to validate it.¹⁰⁷⁻¹⁰⁹

Myofascial Release

Myofascial release (MFR) techniques are used to release the built-in imbalances and restrictions within the fascia and to reintegrate the fascial mechanism. The therapist palpates the various tissue layers, beginning with the most superficial and working systematically toward the deepest, looking for movement restrictions and asymmetry. Areas of altered structure and function are then “normalized” through the systematic application of pressure and stretching applied in specific directions to bring about decreased myofascial tension, myofascial lengthening, and myofascial softening,¹¹⁰ thereby restoring pain-free motion in normal patterns of movement. MFR is useful in treating musculoskeletal injuries, chronic pain, headaches, and adhesions or adherent scars.¹¹¹ MFR has been shown to be effective in the treatment of chronic prostatitis (CP) and chronic pelvic pain syndrome (CPPS) in conjunction with paradoxical relaxation therapy (PRT).¹¹² More research is needed to provide evidence regarding the efficacy of MFR in pain control.

MFR is contraindicated over areas with infection, diseased skin, thromboembolus, cellulitis, osteomyelitis, and open wounds. In addition, it should not be used with clients who have osteoporosis, advanced degenerative changes, acute circulatory conditions, acute joint pathology, advanced diabetes, obstructive edema, or hypersensitive skin.¹¹¹ (See Chapter 39 for more in-depth information regarding MFR.)

Joint Mobilization

Joint mobilization consists of passive oscillations that restore normal accessory movements.¹¹³ In addition, the rhythmical repetition of the motions provides pain relief through the spinal gating mechanism.¹¹⁴

The oscillations involved in joint mobilization are presented in Chapters 9 and 18. Grades I and II oscillations are performed to maintain joint mobility and for pain relief, making them the choice for subacute conditions in which pain and potential loss of motion are the primary considerations. Grades III and IV oscillations are performed to increase joint mobility and are indicated for chronic conditions in which regaining lost motion is the goal. Grade V thrusts are performed to regain full joint mobility.¹¹³

Joint mobilization is contraindicated with rheumatoid arthritis, bone disease, advanced osteoporosis, and pregnancy (pelvic mobilization), as well as in the presence of malignancy, vascular disease, or infection in the area to be mobilized.⁵³

Light Therapy

Light therapy is described by Bot and Bouter¹¹⁵ as a light source that generates extremely pure infrared light of a single wavelength. When applied to the skin, infrared laser light produces no sensation and it does not burn the skin. Because of the low absorption, it is hypothesized that the energy can penetrate deeply into the tissues, where it is assumed to have a biostimulative effect.^{77,115,116} It has been suggested that laser therapy may act by stimulating ligament repair,^{117,118} producing antiinflammatory effects,¹¹⁹ increasing production of endogenous opioids,¹²⁰ reducing swelling,¹²¹ and influencing nerve conduction velocity.¹²² To promote wound healing and manage pain, rehabilitation centers use lasers with power outputs less than 500 mW at a power density of 50 mW/cm² and wavelengths ranging from 600 to 1500 nm.⁷⁷ Contraindications to light therapy include exposing photosensitive areas, hemorrhagic areas, any area that has undergone 4 to 6 months of radiation treatment,¹¹⁶ neoplastic lesions, and unclosed fontanelles in children; the abdomen of pregnant women; areas over the heart, the vagus nerve, or sympathetic innervations routes to the heart of cardiac patients; or, locally, endocrine glands.^{77,116,123,124} In addition, exposure to the cornea of the eye is contraindicated, so protective eye equipment should be worn by the patient and the therapist. Caution should be used for areas with compromised somatosensation, the epiphyseal plates in children, the gonads, and infected areas and with patients displaying fever, epilepsy, or mental confusion.^{77,116,123}

Therapeutic Touch

A description of therapeutic touch can be found in Chapter 39. Therapeutic touch has been effective in treating painful conditions resulting from anxiety and tension. In a report by Keller and Bzdek, 90% of individuals treated with therapeutic touch experienced tension headache relief, and 70% had continued relief for more than 4 hours; only 37% of the placebo group expressed sustained relief.¹²⁵ A meta-analysis and systematic review on therapeutic touch revealed that the available studies have varying approaches and protocols on therapeutic touch, subject selection, and description. Although most of these studies confirm the efficacy of the technique, several studies also have demonstrated negative or mixed results.¹²⁶ Therapeutic touch, as well as other approaches, are being more widely accepted; however, the therapist must continue to be diligent in using outcome studies to substantiate the use of any complementary therapy. (See Chapter 39 for additional information.)

Point Stimulation

Refer to Chapter 39 for an in-depth discussion of point stimulation. It is interesting to note that acupuncture points frequently correspond in location to trigger points, which are tight, elevated bands of tissue that are extremely sensitive when palpated and have a characteristic pattern of radiation to remote regions of the body. Trigger points appear to be areas of “focal irritability” that are myofascial in origin and are usually the site of small aggregations of nerve fibers that produce continuous afferent input when stimulated.

Needling therapies include trigger point injections and trigger point dry needling and are used in myofascial pain conditions. Trigger point injections are usually restricted to medical doctors and their professional support staff.¹²⁷ Trigger point dry needling consists of superficial and deep dry needling, and the exact mechanism of pain relief is not known. It is thought that needling and injections may trigger changes in the end plate cholinesterase and ACh receptors,¹²⁷ may involve central pain mechanisms, and may activate enkephalinergic, serotonergic, and noradrenergic inhibitory systems in association with A delta fibers through segmental inhibition.¹²⁷ Acupressure (i.e., finger pressure applied to acupuncture or trigger points) is thought to decrease their sensitivity through the same mechanism. The therapist applies deep pressure in a circular motion to each point for 1 to 5 minutes, until the sensitivity subsides. Pressure must be applied directly to each point for the treatment to be effective. Acupressure can be accompanied by the use of a vapocoolant spray to provide additional sensory stimulation.

Sensitive points also can be stimulated using electricity. A point locator is used to identify points along the appropriate meridians that are sensitive to stimulation or more conductive to electricity. Each is then stimulated at the client’s level of pain tolerance for 30 to 45 seconds. The points farthest from the site of pain are treated first.

Points that are most sensitive to stimulation are beneficial sites for TENS electrode placement. When point stimulation alone does not provide sufficient pain relief, TENS can be used between sessions for continuous stimulation for more prolonged relief. (See Chapter 39 for additional information on electrical acupuncture.)

Cognitive Strategies, Including Cognitive Behavioral Therapy

The extent to which an individual perceives and expresses pain is a result of his or her emotional state, expectations, personality, and cognitive view. Each individual feels and responds to pain differently. Melzack and Wall¹¹⁴ identified the following three nonphysical components of pain that interact and determine how an individual will respond to pain:

- The individual’s sensory and discriminative interpretation of the pain
- The individual’s motivation and attitudes relating to the pain
- The individual’s cognitive and evaluative thoughts and beliefs concerning the pain experience

Cognitive strategies are part of a holistic approach to health that looks at the total person and the interaction among the three components of body, mind, and spirit. Cognitive strategies recognize that the mind is not separate from the body, accept that there is a mental component to pain,

and use the inner resources of the mind to influence the pain experience.

Cognitive strategies work in two ways. First, they activate the descending cortical modulating systems, and, second, they teach the individual to control, rather than be controlled by, the pain. Used in conjunction with other modalities necessary for physical relief, these approaches can play a significant role in long-term pain management and should not be overlooked in seeking a viable pain management alternative.

As mentioned previously, current research has given the medical community a much deeper understanding of chronic pain. Many new intervention approaches have been developed based on these new theories, and physical rehabilitation clinicians play a significant role in these new interventions. Of particular importance is the increasing role of clinicians in using cognitive behavioral therapy (CBT) in the management of individuals with chronic pain.¹²⁸ CBT for pain management involves the integration of cognitive, affective, and behavioral factors into the case conceptualization and treatment.¹²⁸ It is thought that a person’s beliefs about pain are associated with various functional outcomes^{129,130} and that changes in patients’ beliefs about pain are related to changes in functioning.^{131,132} Techniques potentially used may include coping skills, education and rationale about the course of an illness, relaxation, imagery, goal setting, pacing, distraction, and cognitive restructuring as well as homework assignments. A thorough discussion of this approach as it applies to physical rehabilitation is beyond the scope of this text. The work of Butler and Moseley provides clinicians a great resource on how to better explain pain to patients and clients, as well as to use the most current evidence on pain science and chronic pain management in treating individuals with chronic pain.^{133,134}

Relaxation Exercises

People who are in pain experience stress. Chronic stress can trigger increased pain. Both pain and stress cause an increase in SNS activity, including increased muscle tension. Relaxation exercises can bring about muscle relaxation and a generalized parasympathetic response.¹³⁵ Benson¹³⁶ has named this effect the *relaxation response* and reports that it is accompanied by an increase in alpha brain waves.

Relaxation reduces ischemic pain by normalizing blood flow to the muscles by making way for more oxygen to be delivered to the tissues. In addition, relaxation reduces muscle tension, resulting in an interruption in the pain-spasm cycle.¹³⁷

Relaxation exercises all have two elements in common: a single focus and a passive attitude toward intruding thoughts and distractions. The end product of relaxation is a lowered arousal of the SNS and a lessening of the symptoms caused by or worsened by stress.¹³⁸

Deep relaxation can be achieved through progressive relaxation and attention-diversion exercises. Progressive relaxation involves alternately tensing and relaxing the muscles until, eventually, the entire body is relaxed. This activity teaches the individual how to recognize and relieve muscle tension within the body.

Attention diversion is an active process in which the individual directs her or his attention to nonnoxious events or stimuli in the immediate environment to achieve distraction

from the pain. Attention diversion is categorized as passive or active. Passive attention diversion includes meditation and involves concentrating on a visual or auditory stimulus rather than the painful sensation, whereas active attention diversion involves active participation in a task (e.g., serial subtraction).

Meditation involves quieting the mind and focusing the attention on a thought, word, phrase, object, or movement. The individual becomes more alert to the constant stream of conversation taking place within the mind. Meditation calms the body through the relaxation response and keeps the attention focused in the present moment. Individuals in Eastern cultures have traditionally focused on a mantra, a word with spiritual meaning; however, there are no rules for where to focus the attention. The word or object should bring the individual a sense of peace and should allow the attention to be pleasantly directed toward the immediate moment.

Imagery is another form of attention diversion. During imagery the individual uses his or her imagination to produce images with pain-weakening potential. This can take two forms. In one, the individual imagines experiences that are inconsistent with the pain (e.g., imagining rolling in snow to alleviate burning pain). In the other, the individual imagines experiences that modify specific features of the pain experience (e.g., imagining that the pain is the result of a sports injury or that the sensation is “numbness” rather than pain).

Attention diversion works by activating the relaxation response and by diverting the individual’s attention from the pain. However, attention diversion also has been found to activate the higher brain centers and may have an inhibitory effect on pain through the spinal gating mechanisms.^{44,71} Lautenbacher and colleagues¹³⁹ found that individuals who used attention diversion for pain management reported decreased intensity and unpleasantness of their pain.

Clients can be taught to perform relaxation exercises independently and should be encouraged to perform them regularly because the benefits of these exercises are gained through regular practice.

Body Scanning

Clients with chronic pain frequently become one with their suffering; they do not view themselves as individuals with pain, but rather as painful individuals. Body scanning is a technique that endeavors to separate the individual from the pain.¹⁴⁰

During body scanning, the client is taught to achieve a meditative state, then focus attention on each body area, one area at a time. The client is instructed to breathe into and out from each area, relaxing more deeply with each exhalation. When the area is completely relaxed, the client “lets go” of the region and dwells in the stillness for a few breaths before continuing. Painful areas are scanned in an identical manner as nonpainful areas. The client notes, but does not judge, changes in sensation, thoughts, and emotions during scanning of each area.

Individuals who practice this technique report new levels of insight and understanding concerning their pain experience. They separate the pain experience into the following three parts¹⁴⁰:

- An awareness of the pain sensation and their thoughts and feelings about it
- An awareness of a separation between the pain sensation and their thoughts and feelings about it

- An awareness of a separation between themselves and their pain, because they are able to examine objectively the sensation and their thoughts and feelings about it

Once clients have accepted that they are not their pain or their reaction to the pain, they can determine how much influence and control pain will have in their lives.

Studies of chronic pain patients at the Stress Reduction Clinic at the University of Massachusetts Medical Center revealed that 72% of patients who used body scanning along with traditional medical interventions experienced at least a 33% reduction on their McGill-Melzack Pain Rating Index score.¹⁴⁰ In addition, at the end of an 8-week training period, the individuals perceived their bodies in a more positive light, experienced an increase in positive mood states, and reported major improvements in anxiety, depression, hostility, and the tendency to be overly occupied with their bodily sensations.

Humor

Ever since Cousins¹⁴¹ reported in his book *Anatomy of an Illness* that he used humor to manage pain and enhance sleep during his illness, the role of humor in healing has been well studied. Humor has been found beneficial for both acute and chronic pain management.^{96,142}

Laughter increases blood oxygen content by increasing ventilation. It helps to exercise the heart muscle by speeding up the heart rate and enhancing arterial and venous circulation, resulting in more oxygen and nutrients being delivered to the tissues.¹⁴³ Laughter decreases serum cortisol levels (cortisol levels increase with stress and are thought to have a negative effect on the immune response)^{144,145} and increases the concentration of circulating antibodies.¹⁴³ As little as 10 minutes of belly laughter a day has been found to decrease the erythrocyte sedimentation rate and provide 2 hours of pain-free sleep.¹⁴⁴ Finally, laughter releases energy and emotional tension and is followed by generalized muscle relaxation.^{143,146}

Therapeutic humor can be used to provide distraction from pain and as a coping mechanism to decrease the anxiety and tension associated with chronic pain. The muscle-relaxing effect can be used to interrupt the pain-spasm cycle.

Therapeutic humor should not be used with individuals who do poorly with humor. This includes individuals who despise or misunderstand humor, individuals who find joy threatening or guilt inducing, and narcoleptic individuals who become cataleptic with laughter.¹⁴⁷

Very few clients will benefit from all these cognitive strategies, and it may take some trial and error to find the appropriate cognitive strategy for an individual client. Some clients will have no difficulty learning and practicing cognitive strategies, whereas others will not be able to perform any of these techniques independently. It may be beneficial to provide the client with an individualized relaxation tape or to have the client repeat coping affirmations over and over throughout the day. The success of cognitive strategies is dependent on applying the appropriate strategy to the appropriate client and fine-tuning the strategy so that it matches the client’s needs.

In conclusion, it is important to reemphasize that all individuals with chronic pain have some degree of emotional or cognitive involvement, or both, in their pain experience. Many clients will live with pain regardless of the treatment

they receive. Therefore it is imperative for health care practitioners to address the emotional and cognitive components of each client's pain to allow her or him to function at the highest level and as comfortably as possible and to find joy in each day.

General Conditioning through Exercise

Deconditioning is a major source of disability with chronic pain. Pain causes an intolerance for activity, which in turn leads to physiological and pathological changes in the organ systems. Exercise improves overall functional performance by improving ROM, muscle strength, neuromuscular control, coordination, and aerobic capacity, as well as offering higher self-esteem.

All three types of exercise are beneficial for pain management. ROM and stretching exercises restore normal joint mobility and correct muscle tightness. The joints are held in normal alignment and are subjected to normal stresses during movement. ROM and stretching exercises are indicated where there is decreased mobility.

Strengthening exercises increase muscle strength and cardiovascular endurance. When performed with high intensity for a short duration, strengthening exercises result in increased muscle mass, improved neuromuscular control, and improved coordination. When performed at low intensity for a long duration, they increase the aerobic capacity of the muscles.

Aerobic exercises improve cardiovascular fitness. More oxygen is supplied to the tissues because there is an increase in the number and size of capillaries and a decrease in the diffusion distance between the capillaries and the muscles. The tissues use oxygen more efficiently, and the individual has a higher energy level.

All exercise has an analgesic effect through the gating mechanism by stimulation of the A delta neurons and a pain-modulating effect through activation of the descending systems. Exercise of sufficient intensity has been known to increase circulating β -endorphin levels, but exercise-induced β -endorphin alterations are related to the type of exercise and special populations tested and may differ in individuals with health problems.^{148,149}

It is important to include exercise in all pain management programs. Clients should be taught the appropriate exercises beginning with the first treatment session and encouraged to perform the exercises consistently when not at therapy. The ultimate end product of movement intervention is to empower the client to modulate and control all functional activities, enabling that individual to participate in life.

Operant Conditioning

Coping strategies are learned. Individuals with chronic pain express their pain with behaviors that provide them with consistent positive rewards. For example, wincing might result in attention from a family member, or limping might allow the individual to avoid performing a particular task. Over time, the individual with pain becomes conditioned to perform certain behaviors for the behavior's rewards rather than as a reaction to the pain. Similarly, individuals with chronic pain also can condition their nervous systems through learning. If an individual expects to experience pain as the result of a particular level of activity, the individual will always experience pain at that level of activity.

Operant conditioning addresses the learned (or conditioned) aspects of pain.¹⁵⁰ Operant conditioning involves unlearning or separating the behavior and the response from the pain experience. If the goal of treatment is to lessen social reinforcement of the client's pain behaviors (and thus extinguish those behaviors), the client and the family or other involved individuals are shown how their behaviors and responses provide social reinforcement for the client's reaction to pain. The involved individuals are provided with specific new responses to the client's behavior. Family members might be instructed to ignore wincing, groaning, or the verbal report of pain. They might be told not to perform activities that are the client's responsibility just because the client reports pain. In time, the client will become conditioned to the new response, and pain in those situations will diminish.

If the goal of treatment is to increase the client's pain-free activity level, operant conditioning can be used to condition the nervous system to a higher level of activity before responding with pain. If the client's usual pattern is to remain active until the onset of pain (negative reinforcement for activity) and then rest (positive reinforcement for pain), the client is instructed to remain active to just below the pain threshold and then rest (positive reinforcement for activity). In this way the nervous system unlearns the connection between activity and pain, and the client's activity level increases.

Hypnosis

Hypnosis is a state in which the body and conscious mind are deeply relaxed while the subconscious mind remains alert, focused, and open to suggestion.¹³⁸ This has been demonstrated physiologically by electroencephalography (EEG), which shows an increase in the number of theta waves, which are associated with enhanced attention.¹⁵¹ When a hypnotized individual is given a suggestion that is in alignment with his or her existing belief system, it is accepted by the subconscious mind as reality. The suggestion is not filtered through the conscious mind, which is critical and judgmental. Hypnosis allows the individual to bypass her or his critical beliefs.¹⁵² For example, if the individual believes that a certain activity will cause pain (critical belief), that activity is sure to cause pain. If, however, during hypnosis, the individual accepts the suggestion that the activity does not cause pain, the pain may decrease and even disappear.

When hypnosis is used for pain management, a client is first assisted to achieve complete relaxation, then given suggestions that reinterpret the pain experience. For example, a client might be guided to reframe the pain into a messenger and then be encouraged to listen to its message to gain understanding of the meaning behind the pain. Or a client might be guided to view the pain as an indication to stop a particular activity to avoid being injured. Or a client might be instructed to feel less pain. Finally, where harmless activities have become painful through learning, the client can be guided to disconnect the activity from his or her pain.

Biofeedback

Biofeedback is a training process in which the client becomes aware of and learns to selectively change physiological processes with the aid of an external monitor. A monitoring

instrument is placed on the appropriate area of the body. The machine provides an initial readout. The client is instructed how to change the monitored process, and as change occurs, the machine “feeds back” that information. By mentally changing a biological function, the client learns to gain control over it. In time, the client learns to control the process without needing an assist from the instrument.

Muscle tension, pulse rate, blood pressure, skin temperature, and electromyography (EMG) and EEG readings are some of the physiological processes that can be consciously modified with biofeedback.¹³⁵

Biofeedback is proving to be an effective pain management tool for headaches, muscle spasms, and other physical dysfunction that leads to or increases chronic pain (see Chapters 33 and 39).

GENERAL TREATMENT GUIDELINES

As noted earlier, chronic pain management using the medical model has not been found effective. Treatment limited to correcting pathology promotes dependence on the therapist, as well as making full resolution of symptoms the measure of success.

The ICF model addresses the functional losses associated with impairments. Therapeutic interventions are not focused on pathology, but they are directed at improving the individual’s function and preventing or improving disability. This does not mean that the impairment is ignored, however. Most times, addressing the individual’s functional losses involves treating the impairments that caused them.

For example, clients with chronic pain frequently become sedentary, leading to the impairments of limited ROM, muscle weakness, and deconditioning. These factors can then, of themselves, cause pain, creating a cycle that spirals upward until the individual becomes disabled. During therapy, interventions are directed at the impairments with the goal of restoring function. Therapeutic interventions are

selected based on their ability to improve functional outcome. Impairments that do not affect function do not become the focus of therapy; therapeutic interventions that do not address functional deficits are not used.

The development of an appropriate treatment plan may seem overwhelming when the therapist is confronted with a client who has chronic pain that has not responded to previous interventions or who has a chronic condition that has pain as one of its characteristics. The key is to identify the client’s functional deficits and then develop a treatment plan that addresses the causes of those deficits. In some cases this may mean not treating the pain itself but rather its causative factors.

For example, if the client has chronic pain because of joint hypomobility, the treatment plan includes interventions to increase joint mobility. Conversely, if the client’s pain is caused by joint hypermobility, the treatment plan includes interventions to increase support around the hypermobile joints. Merely addressing the joint pain by applying modalities will do little to resolve the pain because it does nothing to correct the precipitating cause.

When a client has pain because of a chronic disease and the treatment plan will include instruction in pain-relieving interventions, it is important for the therapist to understand the specific causes of the pain to select the appropriate intervention. For example, pain from rheumatoid arthritis most commonly is the result of either joint inflammation or biomechanical stress on unstable joints. A client would be instructed in pain-relieving modalities for the former and instructed to wear splints to support the joints for the latter. One intervention would not be appropriate for both causes.

CASE STUDIES

Case Studies 32-1, 32-2, and 32-3 demonstrate a problem-solving approach to the treatment of clients with chronic pain.

CASE STUDY 32-1 ■ FIBROMYALGIA

K. E. is a 35-year-old computer programmer with a diagnosis of fibromyalgia. She reports a 6-month history of generalized muscular pain and fatigue that increase when she performs repetitive motions or holds a position for a prolonged period. K. E. is currently unable to work because she is no longer able to perform data entry without increased neck and shoulder pain. She states she awakens from pain and leg cramps several times during the night. She awakens each morning with a headache and low back pain; she does not get much relief from pain medication. K. E. states she has not been out with friends in several months. She states she is “nervous, unable to concentrate, and depressed.” She has been evaluated by several physicians. All medical test results are negative.

K. E.’s objective examination reveals pain on digital palpation of distinct points in the muscles of her neck and shoulder girdles, over both lateral epicondyles and greater trochanters, in her gluteal muscles, and just above the medial joint lines of the knees. Pain is referred from the tender points distally. K. E. sits and stands with a forward head and elevated protracted shoulders, and her cervical ROM is restricted slightly at end range

because of her posture and muscle guarding. Muscle strength is 4/5 throughout. All other musculoskeletal and neurological test findings are normal.

K. E. demonstrates the impairments of pain, poor posture, decreased cervical and shoulder ROM, and decreased endurance, resulting in the activity limitations of interrupted sleep and decreased tolerance for activity and participation restrictions of inability to work at her profession.

The long-term goals of treatment for K. E. are independence with self-management of pain, normalization of posture, restoration of normal sleep, independence with a home exercise program, and return to work and appropriate social activities. The short-term goals include decreasing K. E.’s pain, helping her to achieve proper sleep positioning, correcting her postural abnormalities, improving her limited endurance, and assessing and correcting the ergonomics of her workstation. K. E. also needs intervention to address the emotional and cognitive aspects of her condition.

The lowered pain threshold and magnified pain perception seen with fibromyalgia result from a complex combination of

CASE STUDY 32-1 ■ FIBROMYALGIA—cont'd

muscle tissue microtrauma, neuroendocrine abnormalities, and changes in the levels of CNS neurotransmitters. The muscles of individuals with fibromyalgia show abnormal energy metabolism, poor tissue oxygenation, and localized hypoxia. Their blood shows decreased levels of the inhibitory neurotransmitter serotonin and increased levels of the facilitatory neurotransmitter substance P. This combination, which is unique to fibromyalgia, is thought to cause changes in the dorsal horn neurons and eventually in the areas of the brain responsible for the sensory-discriminative and affective-motivational aspects of pain.⁴²

Fibromyalgia pain has been shown to respond favorably to interventions that work through the gating mechanism. These include sensory-level TENS, light massage, muscle warming, and gentle stretching. K. E. can be taught to apply localized heat or to take a warm bath before gentle stretching of her tight muscles. She should be cautioned to stretch slowly to the point of resistance and to hold the stretch for 60 seconds to allow the Golgi tendon organs time to signal the muscle fibers to relax. Quick stretching to the point of pain will cause increased tightness and pain through the pain-spasm cycle. It is important for K. E. to understand that these measures address the pain of fibromyalgia but do not have any long-term effect on the course of her condition.

Individuals with fibromyalgia, and most individuals with chronic pain, experience a variety of emotions, including depression, anger, fear, withdrawal, and anxiety.¹⁵³ These individuals have been helped with hypnosis, biofeedback, and cognitive restructuring.^{42,153} In addition to giving them a sense of control over their pain, these interventions are known to bring about an increase in the individual's level of endogenous opiates, thereby activating one of the descending pain modulation systems. K. E. can be taught to perform these techniques independently.

K. E. should be asked to demonstrate her sleeping posture. Because the muscles of individuals with fibromyalgia do not relax easily, K. E. should be shown how to use pillows to support her neck and back so that they are encouraged to relax while she sleeps. This will help to decrease the frequency of morning headaches and back pain and help her to sleep through the night. She might also benefit from a warm bath before going to bed.

K. E.'s therapist can use gentle MFR to help correct the biomechanical imbalances causing her poor posture. K. E. can then be taught to selectively stretch the shortened muscles of her neck and shoulder girdles using the technique already described and to selectively strengthen their weakened antagonists using light resistance. To counter deconditioning, K. E. should be placed on a nonimpact aerobic program (walking, pool exercises, or stationary bicycle) with a goal of 30 minutes three to four times a week at 70% maximum heart rate (220 minus her age). If she is unable to tolerate 30 minutes of exercise at one time, she can be started at 3 to 5 minutes twice or three times daily and gradually progressed to three sessions of 10 minutes, then two sessions of 15 minutes, and finally one session of 30 minutes. K. E. may require a significant amount of coaxing and education to motivate her to participate in exercise; many individuals with fibromyalgia do not wish to move because movement initially increases their pain.

Before she returns to work, K. E. should be assisted with the ergonomics of her workstation. Research¹⁵⁴ has shown that individuals who work at computers need to vary their positions throughout the day even if their sitting posture is appropriate. Further research^{72,155,156} has shown that correct mouse placement is important to minimize stress to the arms and shoulders.

CASE STUDY 32-2 ■ PHANTOM LIMB PAIN

A. R. is a 60-year-old carpenter who underwent below-knee amputation of his right leg 4 weeks ago after a motor vehicle accident. He now reports a constant burning, piercing, throbbing sensation in the distal portion of his missing limb. He states that immediately after the amputation, he was aware of an itching or tickling in the missing portion of the leg, but the sensation gradually changed to pain. He notes that the leg feels as if it is shortening, as if the missing foot is moving closer and closer to his hip. A. R. has been fitted with a shrinker but does not wear it because of fear of increasing the pain. He does not believe he will be able to wear a prosthesis and is concerned because his employer will be unable to find work for him if he is wheelchair bound.

A. R.'s objective examination reveals a healing surgical incision and a poorly shaped stump. Right lower-extremity hip and knee strength are 3/5 and 2+/5, respectively. Sensation to light touch is diminished in the area of the incision. All other musculoskeletal and neurological test findings are normal. A. R. ambulates short distances using a walker but relies on a wheelchair for locomotion outside his home.

A. R. has the diagnosis of a below-knee amputation and demonstrates the impairments of phantom limb pain and decreased strength in the right lower extremity, resulting in the functional limitations of inability to prepare his leg for a prosthesis, inability to ambulate, and inability to work in his profession.

The long-term goals of treatment for A. R. are independent use of a prosthesis and return to work with modified job tasks. The short-term goals include resolution of his phantom limb pain, preparation of his stump for a prosthesis, at least 4/5 right hip and knee strength, and, when appropriate, gait and balance training with the prosthesis.

There are two theories of the cause for phantom limb pain. At one time it was thought that it occurred as the result of the formation of a terminal neuroma at the site of the amputation¹¹; however, this theory did not explain phantom phenomena in individuals with congenital amputations or individuals with complete spinal cord injuries who also experience painful and nonpainful sensations in their missing or anesthetic limbs. This led researchers to look at the role of the CNS in phantom phenomena, and the latest theories suggest the previously

Continued

CASE STUDY 32-2 ■ PHANTOM LIMB PAIN—cont'd

described changes in the dorsal horn neurons and changes in the spinal cord caused by the sudden loss of afferent impulses after amputation.¹⁵⁷

These theories are supported by the effectiveness of interventions that stimulate the large nerve fibers and provide inhibitory input through the gating mechanism. Phantom limb pain is relieved by stroking, vibration, TENS, ultrasound, heat applications, and the use of a prosthesis. A. R. can be taught a progressive desensitization program. He should be encouraged to wear the shrinker both to prepare his stump for a prosthesis and to decrease pain. Because phantom limb pain is adversely affected by emotional stress, exposure to cold, and local

irritants, he should be taught to avoid these factors as much as possible.

A. R.'s adjustment to a changed body image, a changed lifestyle, and the use of a prosthesis can be aided with any of the cognitive strategies described previously. He might also benefit from referral to an amputee support group.

It is important for A. R. to be aware of his abilities and limitations so that he remains safe when he returns to work. If appropriate, the therapist should accompany A. R. to his job and perform a job task analysis, making suggestions for necessary modifications. If this is not possible, the therapist could discuss needed modifications with A. R. based on his descriptions of his job tasks.

CASE STUDY 32-3 ■ COMPLEX REGIONAL PAIN SYNDROME

P. S. is a 45-year-old right-handed secretary who sustained a Colles fracture of the right wrist 6 months ago. The wrist was placed in a cast for 6 weeks, during which time P. S. avoided using the extremity. Two weeks after the cast was removed, P. S. developed pain, swelling, and stiffness in the wrist and hand. She returned to her physician who diagnosed CRPS type I. She has received four sympathetic nerve blockades. The first provided 4 weeks of pain relief. The second and third provided 2 weeks of relief each. She has just received her fourth injection along with a referral for therapy.

P. S. is wearing a sling. She has 30-degree flexion contractions of her right fingers, along with swelling and stiffness of the wrist and hand. Her right wrist, elbow, and shoulder show limited motion as well. P. S. describes constant burning pain that becomes worse with any stimulation, even air blowing over the skin. She rates her pain as 4/10 since the block, but she states that the pain had slowly been escalating toward 10/10 before the injection. Her hand and wrist are cool, and the skin appears mottled and shiny. P. S. states that she is not using her arm and needs assistance at home for activities of daily living and household chores.

P. S. demonstrates the impairments of pain, swelling, stiffness, and decreased ROM of the right wrist and hand. These impairments cause activity limitations, decreasing her ability to use the right upper extremity for any functional activities, including activities of daily living, job tasks, and homemaking activities. In addition, because she is not using the extremity and carries the arm in a sling, P. S. is at risk for developing shoulder-hand syndrome.

The long-term goal of treatment for P. S. is restoration of pain-free use of her right upper extremity. The short-term goals include quieting the SNS, decreasing P. S.'s pain and edema, and restoring normal ROM of the shoulder, elbow, wrist, and hand.

Successful treatment of CRPS involves a coordinated effort by the physician and the therapist. The treatment of choice is interruption of sympathetic activity with nerve blocks and movement therapy.¹⁵⁸

Interventions included in a pain management program for CRPS should be chosen for their ability to quiet the SNS as

well as accomplish the desired outcome. For example, thermotherapy is more beneficial than cryotherapy because of its ability to decrease pain without stimulating a sympathetic response.¹⁵⁸

A successful rehabilitation program for CRPS cannot be limited to therapy visits. Clients need to be instructed in interventions that they then perform three, four, or even five times daily. Therefore the therapist needs to become a guide, with the responsibility for performing the pain management program given over to the client or caregiver.

Pain reduction is the first priority. This can be accomplished through the gating mechanism or through the deployment of endogenous opiates. Thermotherapy and TENS have both been found effective for pain management with CRPS. If P. S. cannot tolerate electrode placement on the right arm, the electrodes can be placed on the opposite arm or along the spinal roots of the involved segments.^{31,104} P. S. can be instructed in any of the superficial heating modalities. Stroking massage along the paravertebral muscles beginning in the cervical region and continuing to the coccyx has also been found effective in quieting the SNS.

Before P. S. can regain mobility of her wrist and fingers, the edema must be resolved. This can be accomplished with elevation, massage, lymphatic drainage, and compression. P. S. can wear a compression glove or, if she is able to tolerate it, receive intermittent compression to the arm. She should be instructed to keep the arm above heart level as much as possible.

P. S. should be advised to discontinue use of the sling and begin frequent weight bearing through her arm. Immobility increases the symptoms of CRPS. Movement of the extremity is important to increase proprioception and circulation, both of which have an inhibitory effect on the SNS.¹⁵⁸ Therefore P. S. should be encouraged to begin using her hand as much as possible throughout the day. If she is reluctant to use the arm, the therapist can design a functional activity program that allows her to use the arm during simple activities, which can be progressed as her symptoms improve.

There are two forms of exercise that are beneficial in CRPS. The first is active ROM exercises, which should be performed

CASE STUDY 32-3 ■ COMPLEX REGIONAL PAIN SYNDROME—cont'd

frequently throughout the day within the pain-free range to regain motion, increase circulation, and provide nonnociceptive input. Exercise of the specific ROM should be within functional activities. The activity itself will encourage ROM while the patient is concentrating on successfully completing the activity itself. The second form of exercise is stress loading,¹⁵⁹ which involves active compression and traction activities without joint motion. For example, P. S. can use a coarse-bristled brush to scrub a piece of plywood and apply as much pressure as possible without causing pain (compression activity). Or she can carry a briefcase or purse in her affected hand (traction

activity). Compression and traction both provide increased proprioceptive input.

P. S. should also begin performing desensitization activities, which can be modified as she is able to tolerate more stimulation to her extremity. P. S. may benefit from biofeedback to gain control over the circulation in her arm and from relaxation activities to stimulate the relaxation response and enhance parasympathetic function.

Once P. S. becomes independent in the performance of her program, therapy can be decreased to once or twice weekly to monitor and modify her pain management regimen.

Acknowledgments

We would like to acknowledge the contribution of Linda Mirabelli-Susens to the writing of this chapter in the fourth edition of the textbook.

Electrophysiological Testing and Electrical Stimulation in Neurological Rehabilitation

ALAIN CLAUDEL, PT, DPT, ECS, ROLANDO T. LAZARO, PT, PhD, DPT, GCS,
GEORGE WOLFE, PT, PhD, and JANET MARIE ADAMS, PT, MS, DPT

KEY TERMS

electromyographic feedback
electroneuromyography
functional electrical stimulation
kinesiographical electromyography
nerve conduction velocity
neuromuscular electrical stimulation

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify electrophysiological tests performed on clients with neurological disorders.
2. Describe the instrumentation and general procedures for electrophysiological testing.
3. Recognize normal and abnormal findings of various electrophysiological tests.
4. Recognize the differences in instrumentation, signal processing, and interpretation when performing electrophysiological testing versus kinesiographical electromyographic testing.
5. Differentiate the basic mechanism underlying functional neuromuscular stimulation, electrical stimulation, and electromyographic biofeedback.
6. Describe the appropriate instrumentation, signal processing, and interpretation for kinesiographical electromyographic testing.
7. Describe the indications and contraindication for the use of neuromuscular stimulation, electrical stimulation, and electromyographic biofeedback.

The goal of this chapter is to enhance the clinician's ability to recognize indications for the most commonly used electrophysiological tests and to integrate knowledge of these test indications and findings into the management of clients with neuropathological dysfunction. The first section presents a basic description of the electrophysiological tests, including nerve conduction studies (NCSs), electromyography (EMG), kinesiographical electromyography (KEMG), and the underlying neuroanatomical structures being tested. Normal and abnormal findings are discussed, with emphasis on how knowledge of these tests can assist the therapist in client evaluation. The second section provides an introduction to the physiology, indications, contraindications, equipment, and applications of electrical muscle stimulation (EMS), neuromuscular electrical stimulation (NMES), and electromyographic biofeedback (EMGBF). The information integrates electrotherapeutic interventions into program planning for common neurological body system problems, their subsequent functional limitations, and perceived decrease in quality of life. Published evidence examining efficacy is included to assist the therapist in making choices about the use of these tools in the clinic. The third section provides a series of four case studies that illustrate the usefulness of electromyographic testing in patients with a variety of medical diagnoses.

ELECTROPHYSIOLOGICAL TESTING

Physical therapists (PTs) are uniquely positioned to understand and perform electrophysiological testing. This is because PTs examine patients with pain, numbness, and/or weakness and also because they have a superior knowledge of neural and muscular anatomy and physiology. Electrophysiological testing is a sensitive and specific tool designed to assist in the diagnosis and the development of treatment

plans for patients with diseases of the peripheral nervous system (PNS) and of the muscle itself.

An informed perspective on the application of these tests will benefit the therapist's interaction and communication with other members of the medical and health management community. At the completion of the electrophysiological consultation, the clinician who performed the test generates a report. Understanding this report can guide decisions in planning and modification of intervention programs or will assist in referring to other health care practitioners. A review of components of such report follows.

Electrophysiological tests are usually performed by neurologists, physiatrists, and PTs who have education, training, and experience in these procedures. Most PTs practicing in the area of clinical electrophysiology are board certified by the American Board of Physical Therapy Specialties.¹ Some states (such as California) require additional licensing.

The general goal of electrophysiological testing is to answer the following questions:

- Is there a lesion in the PNS and/or muscles?
- Where precisely is that lesion?
- What is the extent of the lesion?

Most of the electrophysiological tests described involve the application of an external electrical stimulus to a nerve or muscle and observation and assessment of the muscle or nerve response. Other tests such as needle EMG and single-fiber electromyography (SFEMG) involve the monitoring and recording of the electrical activity produced by the muscle tissue at rest or during contraction.

The electrophysiological tests most commonly used are motor and sensory NCSs, including F-wave and H-reflex latency measurements; repetitive stimulation; somatosensory evoked potential (SSEP) tests; and needle EMG. Most

often, a patient referred for electrophysiological testing will undergo at least two motor nerve conduction tests, at least two sensory conduction tests, and at least one limb needle EMG. The American Association of Neuromuscular and Electrodiagnostic Medicine (AANEM) has published evidence-based guidelines, which may be found on the AANEM website at www.aanem.org/Practice/Practice-Guidelines.aspx.² A review of the client's history, a relevant systems review, and a physical examination guide the examiner in the selection and sequencing of appropriate tests. In other words, muscle strength and tone, sensation, range of motion (ROM), neurological signs, and cognition are crucial in selecting and administering electrophysiological tests. Electrophysiological testing is considered by all authors on the subject as an extension of the clinical examination.^{3,4} It does not replace a careful history and physical examination of the patient. It does, however, establish the precise state of the nerves and muscles and can thus determine the location of a lesion more precisely than the clinical examination alone, particularly in cases of mild weakness or ill-defined sensory changes. In very clearly defined pathologies, electrophysiological tests are not necessary (except perhaps for medicolegal reasons). For example, in the case of a unilateral ankle dorsiflexion weakness coupled with a clearly defined L5 nerve root compression on magnetic resonance imaging (MRI) of the lumbar spine, the electrophysiological test may be of little added value. However, for a similar clinical presentation (foot drop) and no clear-cut imaging, the electrophysiological tests will differentiate between a peroneal palsy, a sciatic nerve neuropathy, a lumbosacral plexopathy, or an L5 radiculopathy.

Finally, evidence-based practice recommends that the practitioner have a good understanding of the implication of the sensitivity and specificity of each test to rule it in or out for a specific condition.⁵

Anatomical Review

In order to best understand the systematic interpretation of data from the electrophysiological examination of nerves, the reader is invited to review the following foundational principles. These are explored in much greater detail elsewhere in this text.

At the Cellular Level

A nerve is composed of axons covered with a sheath of myelin. Depolarization inside the axon is an “all-or-nothing” phenomenon in which an action potential moves along the surface of the cell membrane. This action potential is an electrical wave caused by a flow of ions across the cell membrane. A local current opens a sodium channel, allowing Na⁺ ions to rush inside the cell. The electrical resistance to this wave is inversely proportional to the diameter of the axon. Larger nerves conduct faster than smaller nerves. In order for efficiency as an organism to be achieved, nerve conduction must be fast. In complex organisms with billions of axons, increasing the nerve diameter is not a viable option; hence, the role of the myelin sheath. The myelin is produced by Schwann cells. These are special satellite cells that separate axons from the endoneurial fluid. The myelin acts as a capacitor: the conduction “jumps” between gaps in the myelin called *nodes of Ranvier*. This saltatory conduction allows human nerves to be 50 times

smaller but conduct four times faster than unmyelinated nerves.⁶ Consequently, recording and analyzing the *conduction velocity* of nerves primarily reflects on the state of the myelin. The amplitude of the response (if a supra-maximal stimulation is delivered) is a reflection of the number of axons available to the stimulation.

The physiology of the nerve is such that when there is an injury to the axon, the portion of the axon distal to the injury will degenerate (wallerian degeneration). This is important because all muscles innervated by branches of the nerve distal to the lesion will show signs of denervation approximately 11 days after the lesion. Consequently, assessing a patient too early after a lesion may lead to false-negative results.^{6,7}

At the Anatomical Level

The accurate performance and interpretation of the electrophysiological test—particularly the needle EMG—is significantly contingent on knowledge of the precise innervation of each muscle. As an example, an ulnar neuropathy at the elbow (UNE) clinically may be indistinguishable from a C8 radiculopathy. However, the astute clinician will remember that the cell body of the sensory nerve lies in the dorsal root ganglion, which is typically not involved in a radiculopathy. The therapist will also know that the abductor pollicis brevis is a C8- and median nerve–innervated muscle. Consequently, an ulnar nerve neuropathy is distinguishable from a C8 radiculopathy in that the ulnar sensory test will have decreased amplitude in the UNE and the abductor pollicis brevis will be denervated in the C8 radiculopathy. As a matter of fact, the clinician will keep in mind the innervation of each muscle while conducting the test. Electrophysiological testing is hence a dynamic process during which the choice of the next nerve to test or muscle to sample is predicated on the result of the previous test.^{6,7}

As a result, the electrophysiological examination is not a single, stereotyped investigation but an evolutionary one during which several tests (nerve conduction, both sensory and motor, and EMG of several muscles) can be applied to a clinical presentation.^{3,8}

Nerve Conduction Tests

A general overview of NCSs is presented to provide an understanding of their application and indications. Many excellent texts are available for details of the techniques.⁹⁻¹³

Motor and sensory NCSs can provide data that are helpful in establishing the presence and location of pathological conditions in the PNS. The tests may indicate the anatomical level, such as a plexopathy, versus a localized peripheral mononeuropathy. Individual and multiple nerves may be assessed, and the findings compared with responses of the same nerves contralaterally. The site of pathology may be localized, such as median nerve compression at the wrist versus a lesion of the lateral cord of the brachial plexus.

Nerve conduction velocity is faster in myelinated fibers because of saltatory conduction. Disorders involving peripheral demyelination can thus be differentiated from impairments primarily involving axonal degeneration. A mild localized compressive disorder (neurapraxia) may be distinguished from a more severe lesion in which the axons and surrounding connective tissue have been completely disrupted (neurotmesis).^{11,14} In the event that the findings of

NCS and EMG are normal, the clinician may be able to rule out most conditions involving the PNS and look for central nervous system (CNS) or other pathology. Knowledge of the rationale for NCSs and EMG should help the therapist decide when the tests may be indicated and understand the reasoning behind reports of tests that have already been performed on clients.

Motor Nerve Conduction

In motor NCSs the peripheral nerve is stimulated at various sites and the evoked electrical response is recorded from a distal muscle supplied by the nerve (a measure of orthodromic conduction). Surface electrodes are usually used for both stimulating and recording. An example of electrode configuration for a motor NCS is shown in Figure 33-1 (ulnar nerve study). The response represents the electrical activity of muscle fibers under the recording electrodes and is called the *compound muscle action potential* (CMAP). It is also called the *M wave* or *M response*. Measurements are taken of the latency (the time in milliseconds required for the impulse to travel from each stimulus site to the recording site) and the amplitude of the response in millivolts (mV). The shape and duration of the response are assessed, and motor nerve conduction velocity is calculated for each segment of interest by dividing the distance between stimulus sites (in millimeters) by the difference in latency measured at each respective site.

Velocities, latencies, and the shape and amplitude of the responses (Figure 33-2) are studied and compared with established normal values and often with values taken from tests of the uninvolved extremity (when possible). In infants and children, nerve conduction is slower than in adults and reaches adult values by age 4 years.¹³ Nerve conduction

velocities gradually slow after age 60 years but generally remain within the outer limits of normal.^{11,13}

Sensory Nerve Conduction

Sensory nerve conduction can be measured from many superficial sensory nerves, such as the superficial radial and sural nerves. It can also be measured from mixed motor and sensory nerves. The stimulus is applied over the nerve in question, and the recordings taken from electrodes placed over a distal sensory branch of the nerve. The recordings are called *sensory nerve action potentials* (SNAPs). An example of recording and stimulation sites is shown in Figure 33-3. Both orthodromic and antidromic conduction can be assessed. Response latencies and amplitudes are measured, and sensory nerve conduction velocities are calculated for each segment by dividing the distance between two adjacent stimulus and recording sites, or two stimulus sites, by the latency (conduction time) between these same sites. Sensory nerve responses are considerably smaller than motor responses. Their amplitudes are generally measured in microvolts (μV). Sensory recordings are more sensitive than motor recordings in cases of mixed sensory-motor neuropathies.

F-Wave Latency

When a motor nerve is stimulated in the periphery, both orthodromic (peripherally to the muscle) and antidromic (centrally toward the spinal cord) impulses are generated. A proportion of the antidromic impulses will, as it were, “bounce off” the axon hillock and return as a recurrent discharge along the same neurons to activate the muscle from which the recording is taken. This activity is termed the *F wave* (Figure 33-4), and it is observed as a small wave occurring after the M wave.^{11,13,14} No synapse is involved.

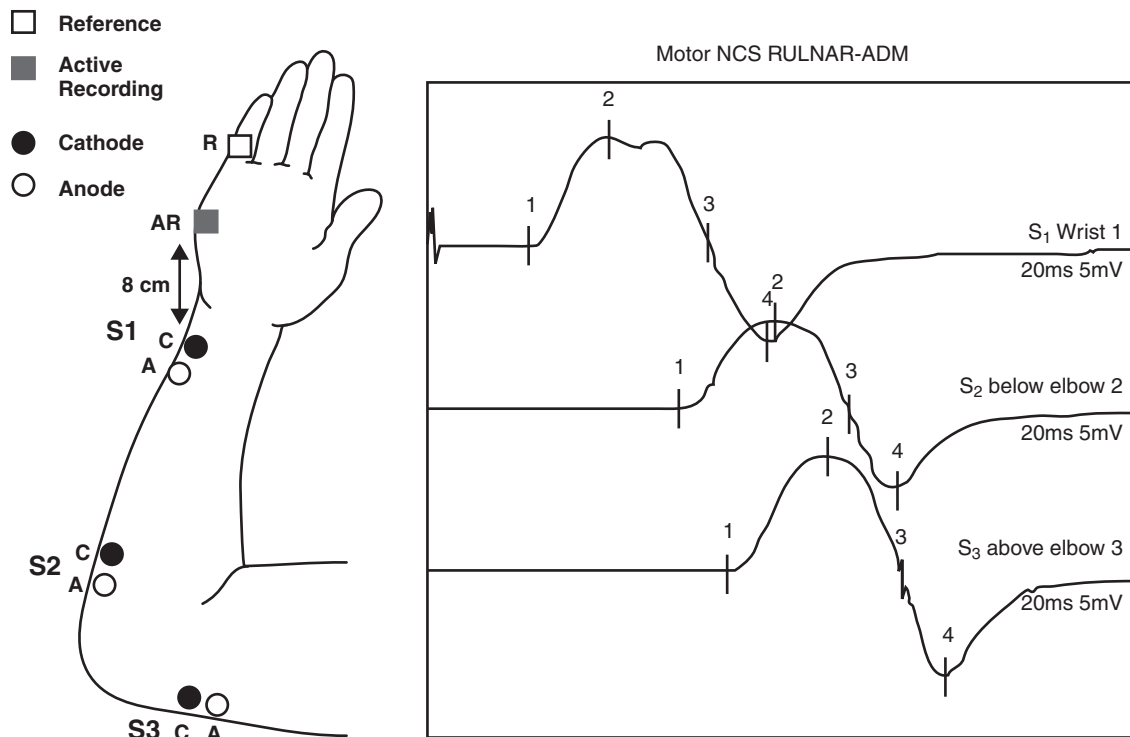

Figure 33-1 ■ Electrode location for ulnar motor nerve conduction.

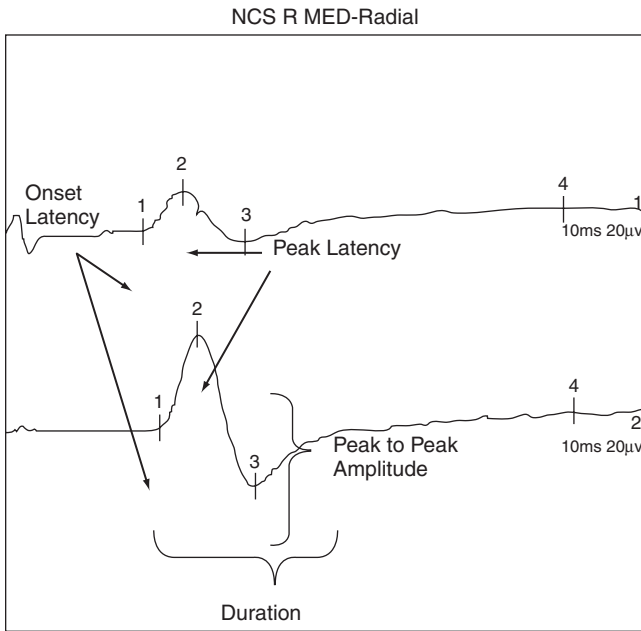

Figure 33-2 ■ Velocities, latencies, and the shape and amplitude of the responses.

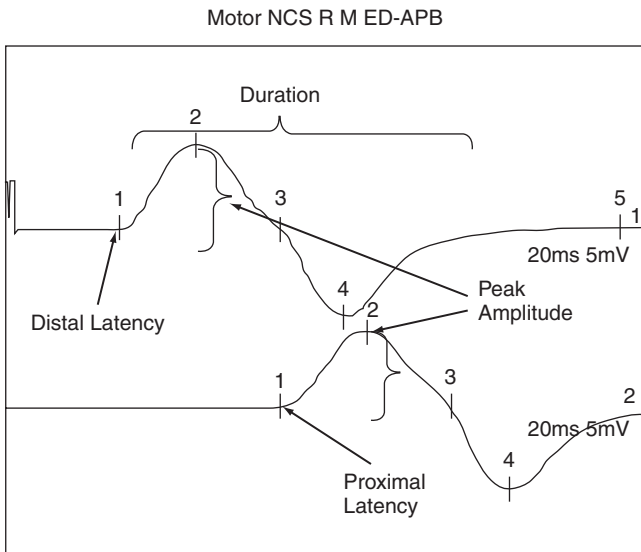

Figure 33-3 ■ Example of recording and stimulation sites.

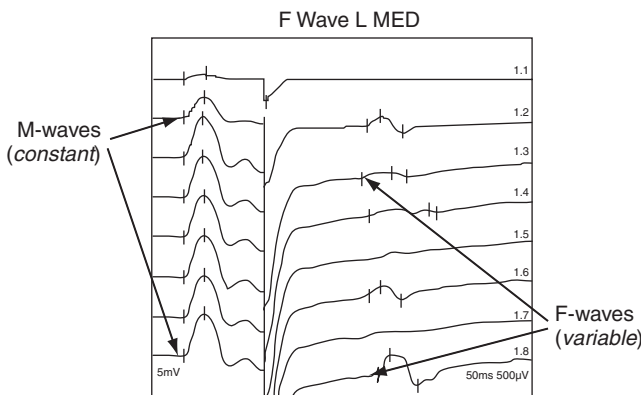

Figure 33-4 ■ Example of F-wave study.

Thus the F wave is not a reflex response, but rather only a measure of conduction along the motor neuron. Specific conditions of electropotential must exist at the soma-dendritic cell membrane to reactivate the efferent axon; therefore the occurrence of the F-wave response is inconsistent and variable in latency and waveform.¹⁵

The F-wave latency can be useful in evaluating conduction in conditions usually involving the proximal portions of the peripheral neurons (e.g., radiculopathy, Guillain-Barré syndrome [refer to Chapter 17], or thoracic outlet syndrome [refer to Chapter 18]). Its value, however, has been questioned by some authors because of its variability. Normal values of F-wave latency are 22 to 34 ms in the upper extremity (stimulating at the wrist) and 40 to 58 ms in the lower extremity (stimulating at the ankle), depending on the height of the subject, with a bilateral difference in latency of no greater than 1 ms.¹⁶

H-Reflex Response

The H-reflex response latency (Figure 33-5) is a measure of the time for action potentials elicited by stimulating a nerve in the periphery to be propagated centrally over the Ia afferent neurons to the spinal cord, to be transmitted across the synapse to alpha motor neurons, and then to travel distally over these neurons to activate the muscle. The response therefore measures conduction in both the afferent and efferent neurons.^{11,13} It is also referred to as a “late” response (the other being the F wave).

The H reflex is constant in latency and waveform, and it occurs with a stimulus usually below the threshold level required to elicit the M-wave response (Ia afferent fibers are larger in diameter than alpha motor neurons and thus more sensitive to electrical stimulation). This monosynaptic reflex response is most easily found by stimulating the tibial nerve at the popliteal area and recording from the soleus muscle. Braddom and Johnson¹⁷ reported a mean latency of 29.8 ms (± 2.74 ms) for the tibial nerve in normal adults, and a bilateral difference of no more than 1.2 ms. The H-reflex latency is a valuable measure of conduction over the S1 nerve root in differentiating suspected proximal plexopathy and radiculopathy from a herniated disc or foraminal impingement. Sabbahi and Khalil¹⁸ have reported a technique for recording the H reflex from the flexor carpi radialis muscle when stimulating the median nerve. In normal human beings older than 1 year, the H reflex is usually seen only in the tibial, femoral, and median nerves. It can be elicited from several nerves in infants and in conditions of CNS dysfunction in adults.

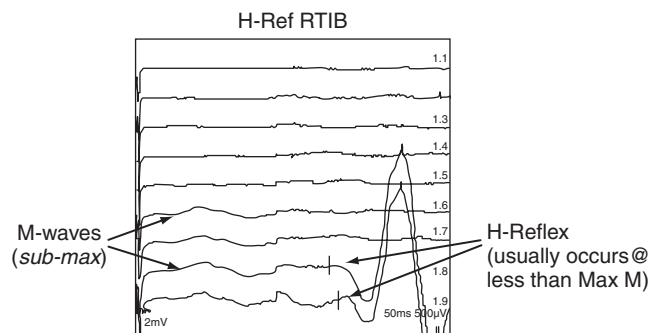

Figure 33-5 ■ Example of H-reflex study.

Repetitive Stimulation Tests

The repetitive nerve stimulation (RNS) test is used to evaluate transmission at the neuromuscular junction (motor synapse) in patients with diffuse weakness. RNS tests are helpful in the differential diagnosis of disorders such as myasthenia gravis and Lambert-Eaton myasthenic syndrome (LEMS). One protocol uses a series of supramaximal electrical stimuli applied to a peripheral nerve at a distal site (e.g., median or ulnar nerve at the wrist) at a rate of three to five per second for five to seven responses. Changes in amplitude of the muscle response are assessed. Precise technical requirements are specified to prevent movement artifacts and other testing errors. Detailed descriptions of the RNS test can be found in other texts.^{11,19} Under normal conditions the amplitude does not change more than 10% from that of the initial response in a series of 10 stimuli recorded before and after resistive exercise. An amplitude decrease in the fifth or sixth response of more than 10% is considered abnormal and is compatible with a physiological defect at the postsynaptic receptor site of the neuromuscular junction, as in myasthenia gravis.

In another RNS protocol, stimuli are applied to a nerve, first at a slow rate, then at a faster rate, usually 10 to 20 per second for up to 10 seconds. Normally, the amplitude can decrease up to 40% from the initial amplitude. In some defects at the presynaptic site, the response may be lower than normal during a slow stimulation rate but show a significant amplitude increase at the higher rate. Increases in amplitude greater than 100% over the initial response are consistent with presynaptic neuromuscular junction defects such as seen in LEMS, which has a strong association with small-cell bronchogenic carcinoma, and in botulism. In 1957 Eaton and Lambert²⁰ reported this phenomenon as a myasthenic syndrome.

Gilchrist and Sanders²¹ reported another protocol referred to as a *double-step RNS test*. This test measures amplitude before and after a temporarily induced ischemia of the extremity. They found the double-step RNS test to be slightly more sensitive than the routine RNS test, but only 60% as sensitive as the SFEMG technique. The RNS test is a good alternative test for neuromuscular transmission when the SFEMG is not available, but the examiner must meticulously adhere to technical details when conducting the test.

Blink Reflex

In some conditions (e.g., facial palsy) or to establish the presence of a widespread neuropathy, it may be necessary to assess the conduction in the cranial nerves. The stimulation of the supraorbital nerve (branch of the trigeminal nerve, cranial nerve V) elicits two separate responses of the orbicularis oculi muscles, one early and ipsilateral (R1) and one late and bilateral (R2), via the facial nerve (cranial nerve VII). The early R1 response involves a synapse in the pons, whereas the late bilateral R2 responses involve a more complex pathway involving the pons and lateral medulla. Analysis of the respective latencies of each response will help in determination of the following:

- Trigeminal neuralgia (cranial nerve V) or Guillain-Barré: all responses delayed
- Acoustic neuroma or Bell palsy (cranial nerve VII): ipsilateral responses delayed
- Pontine lesion: absence of R1
- Medullar lesion: absence of R2
- Others

Hence, the blink reflex is a nerve conduction test that assesses a portion of the CNS and has shown some utility in assisting in the diagnosis of multiple sclerosis (see Chapter 19) and Wallenberg syndrome.⁷

Clinical Evoked Potentials

Electrical potentials elicited by stimulation of nerves or sense organs in the periphery can be recorded from various sites as the impulses are transmitted centrally along the neuronal pathway and from the representative area of the brain.^{11,22-24} SSEP procedures are particularly useful in assessing the integrity of afferent pathways in the CNS. They are helpful in differentiating among lesions in areas such as the plexus, spinal cord, brain stem, thalamus, and cerebral cortex. Evoked potential tests have the advantage of providing data about the integrity of both peripheral and central neuronal pathways, including transmission across axodendritic synapses.

The SSEP is valuable in assessing damage and continuity of spinal cord tracts in early spinal cord injury (SCI). For example, if an electrical stimulus is applied at the popliteal area over the tibial nerve, responses can be recorded with surface electrodes placed over the spine at the L3 and C7 spinal segments and from the lumbar representation of the contralateral sensory cortical area. Conduction time and other parameters of the response waveforms can be measured from the recordings.

This simplified example of an SSEP illustrates how conduction over sensory peripheral nerves and afferent pathways to the cerebrum can be studied. The median nerve is usually tested to evaluate the integrity of peripheral and central pathways and their synaptic connections as the impulses travel from the upper extremity to the contralateral cortical area.

In visual evoked potential (VEP) procedures, visual stimuli such as variable light flashes of changing patterns are applied to one or both eyes under highly controlled conditions. The response is recorded from the scalp over the representative area of the cerebral cortex.^{11,23,24} The term *pattern reversal evoked potentials* (PREPs), a more descriptive term for these procedures, is recommended by the American Electroencephalographic Society.²² These tests and other VEP procedures are useful in assessing pathology of retinal photoreceptors, the optic nerve, and postchiasm pathways. Abnormal conduction findings have been reported when VEP studies are used in demyelinating disorders such as multiple sclerosis and optic neuritis. The examiner may conclude that the patient is cortically blind because no response is recorded on the visual cortex. Although many causes for a stimulus not reaching the visual cortex are possible, the end result is considered blindness. If the cause for cortical inactivity is swelling or a neurochemical imbalance within a nuclear relay structure, once corrected, the individual may experience normal vision. A change in the reaction of the patient to the visual environment may reflect increased awareness and a change in coma scale rating. Similarly, just because an individual turns toward a light or visual stimulus does not mean an evoked potential reaches the visual cortex. Instead, the eyes as receptors and the visual tract to the brain stem may be intact even though a problem in the synaptic connections between or within the thalamus and visual cortex may exist.

Auditory evoked potential tests are used to evaluate neurological function of the cochlear division of the auditory nerve (eighth cranial nerve), central auditory pathways and synapses in the brain stem, and the receptor areas on the cerebral cortex.^{11,22-24} Brain stem auditory evoked potentials are frequently referred to as BAEPs. A series of high-intensity clicks is applied to auditory receptors in the ears through headphones, and several components of the response waveforms are recorded by using surface electrodes over the representative cortical areas. The BAEP is an effective test procedure for localizing and evaluating acoustic neuromas and other space-occupying lesions in the brain stem. This test is also used for assessment of brain damage in patients who are comatose as a result of traumatic brain injury (TBI). Robinson and Rudge²⁵ recommend caution in using BAEP tests for this purpose because other factors, such as defective receptor organs, can cause abnormalities in BAEPs.

The evoked potential tests described in this chapter all require application of appropriate external stimuli that are rapidly repeated many times. The response is electronically averaged to sort out the desired signal from interference signals. The conduction times (latencies), waveform shape and amplitude, and sometimes conduction velocities are measured and compared with normal values. Absence of a response, increased latencies, decreased amplitudes, and slowing of conduction velocities are all abnormal findings. Normal values and details of techniques for the evoked potential tests are described elsewhere.^{11,22-24}

Therapists with special interest and training administer the SSEP tests for neurological applications more frequently than other types of evoked potential tests. Because of the highly specialized techniques necessary to administer VEP tests for ophthalmological applications and BAEP tests for hearing dysfunction, they are usually performed by persons who specialize in these procedures.

Needle Electromyography

Needle EMG complements the motor and sensory NCSs; it is most sensitive in the detection of denervation.

Unlike NCSs, which use the electrical stimulation of the motor nerves to elicit muscle contraction, the needle EMG is used to record and analyze muscle activity at rest and during voluntary activation. It is particularly useful in identifying pathology of the lower motor neurons and of the muscle itself. EMG can also be used to identify abnormalities of motor neuron recruitment that are associated with certain disorders of the CNS especially when NCS findings are normal—as would be the case in radiculopathies. The primary recording studied is the insertional activity, along with activity at rest and the motor unit action potential (MUAP), which is produced by the depolarization of single motor units during voluntary or reflex activity. Spontaneous electrical activity of single muscle fibers at rest is termed *fibrillation* and is diagnostic of denervation. For recording of muscle activity, small-diameter needles are inserted within the muscles to be studied. Three electrodes are required: active (negative), reference (positive), and ground. The needles may be *monopolar*, requiring a second needle or surface electrode for reference, or *bipolar*, containing both the active and reference electrodes (usually concentric in cross section). The ground electrode is typically placed

on the surface of the skin. Most commonly the needles used are disposable. The activity detected in the muscle is displayed on the video display terminal of a computer (and can be stored and printed later). It is simultaneously played through an audio amplifier. The electromyographer can often identify pathological conditions by the characteristic “sounds” of the electrical activity of the muscle. Many excellent resources are available for readers interested in details of the equipment and procedures for EMG.^{9-11,26,27} Details of contraindications and special precautions are described by Currier and colleagues.²⁷

In an EMG examination, four conditions are evaluated at each location: (1) activity during needle insertion (normally a brief burst (250 ms) of high-frequency activity that abates when the needle ceases motion), (2) activity during rest (electrical silence is normal unless an electrode is placed directly over a motor endplate), (3) activity during minimal and gradually increasing voluntary contraction (biphasic or triphasic MUAPs of small amplitude composed of slow-twitch type I fibers that increase in frequency and are joined by higher-amplitude potentials as larger, predominantly fast-twitch type II motor units are recruited), and (4) activity during maximal activation (an *interference pattern* caused by the blending of potentials in which individual MUAPs cannot be identified), characterized as full (complete), reduced, or absent. Several locations in an individual muscle may be studied. The specific muscles to be studied are determined by clinical findings, and results must always be interpreted in the context of the total complex of signs and symptoms. In determining the specific location of a lesion, muscles located both proximally and distally to the suspected lesion site must be assessed. Studies may be repeated at intervals to determine if changes consistent with recovery (such as reinnervation) or exacerbation are present. EMG is typically used to help determine the presence (and extent) of the following:

- Denervation
- Reinnervation
- Myopathic or neuropathic signs
- Distribution or specific location of peripheral nerve pathology

Needle EMG is sensitive in determining the state of the axons. When axons are interrupted, there is denervation of the muscle cell. The findings in denervation and partial denervation include increased insertional activity, fibrillation potentials or positive sharp waves at rest, and a reduced or absent interference pattern. CNS dysfunction can result in no resting potentials, but if motor control was impaired a decreased or abnormal interference pattern might be apparent because of difficulty in recruitment (Figure 33-6). Needle EMG also informs the clinician about muscle cell disorders such as myopathies. The primary finding in the case of a myopathy is fibrillation potentials and small-amplitude polyphasic MUAPs.

Although client cooperation during EMG testing is important, some aspects of muscle electrical activity can be studied in the client who is very young (infant), who is unable to move, or who has only involuntary or reflex activity. Insertional and resting potentials can always be evaluated. MUAPs appear during the contraction of muscle fibers activated both voluntarily and involuntarily in both isotonic or isometric conditions. In normal conditions MUAPs are seen with

EMG FINDINGS

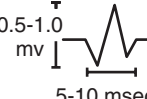

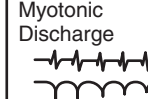

EMG Steps \ LESION	NORMAL	NEUROGENIC LESION		MYOGENIC LESION		
		Lower Motor	Upper Motor	Myopathy	Myotonia	Polymyositis
1 Insertional Activity	Normal 	Increased 	Normal 	Normal 	Myotonic Discharge 	Increased 
2 Spontaneous Activity	—	Fibrillation Positive Wave 	—	—	—	Fibrillation Positive Wave 
3 Motor Unit Potential	0.5-1.0 mv 5-10 msec 	Large Unit Limited Recruitment 	Normal 	Small Unit Early Recruitment 	Myotonic Discharge 	Small Unit Early Recruitment 
4 Interference Pattern	Full 	Reduced Fast Firing Rate 	Reduced Slow Firing Rate 	Full Low Amplitude 	Full Low Amplitude 	Full Low Amplitude 

Figure 33-6 ■ Typical findings in lower and upper motor neuron disorders and myogenic lesions. Myotonia shares many features common to myopathy in general in addition to myotonic discharges triggered by insertion of the needle or with voluntary effort to contract the muscle. Polymyositis shows combined features of myopathy and neuropathy, including (1) prolonged insertional activity, (2) abundant spontaneous discharges, (3) low-amplitude, short-duration, polyphasic motor unit potentials, and (4) early recruitment leading to a low-amplitude, full-interference pattern. (From Kimura J: *Electrodiagnosis in diseases of nerve and muscle: principles and practice*, ed 3, New York, 2001, Oxford University Press.)

voluntary movement; however, reflex activation of muscle also produces MUAPs with certain normal characteristics. In CNS disorders hypertonic or spastic muscles will produce recognizable MUAPs when they are actively contracting. The electromyographer can elicit a contraction by tapping on the muscle or tendon. For example, consider a client who is recovering from a traumatic head injury with residual spastic hemiplegia. She is unable to cooperate with the EMG exam. The client has abnormal extensor responses in the lower extremity with the exception of the ankle and foot, which appear flaccid. An EMG of the leg and foot muscles detects abnormal resting potentials, including fibrillation and positive sharp waves in muscles innervated by the peroneal nerve. Tapping on the muscles fails to elicit MUAPs. Muscles in the tibial nerve distribution have no resting potentials and respond with bursts of identifiable MUAPs when the tendon is tapped. These findings would guide the physician and therapist in looking for a possible peripheral nerve lesion in addition to the CNS dysfunction. The treatment program in this situation would differ from that for a client without peripheral nerve pathology.

In summary, results of the needle EMG are best presented in the form of a table that indicates the following:

- Insertional activity: may be increased in acute denervation and myopathic processes
- Spontaneous activity at rest: present (positive sharp waves and fibrillation potentials) in denervation
- Fasciculations: may be present in motor neuron disorders
- Analysis of MUAPs:
 - Amplitude: Low amplitude is seen in myopathy or nascent potential; large amplitude is a sign of chronicity.

- Phases: Normal MUAPs are biphasic or triphasic. Polyphasia is indicative of denervation-reinnervation.
- Recruitment pattern: A less-than-full recruitment is indicative of fewer motor units discharging, as can be seen in axon loss.
- Firing rate: If elevated, fewer motor units are contracting more often to provide the same tension in a denervated muscle.

Justification and analysis of the basic principles and results after EMG studies should assist therapists managing clients with neurological dysfunction in planning and modifying therapeutic management programs. As electrical tests are being conducted, the findings are continuously studied and used by the physician and examiner as a guide in continuing with or modifying the plan for future tests based on whether they fit the characteristics usually identified with specific pathological conditions. As previously stated, the results of the electrodiagnostic tests must be correlated with other clinical findings and data.

Summary of Clinical Electroneuromyographic and Nerve Conduction Studies

Instruments with computer-assisted analysis are now commonplace for studying electromyographic signals in great detail.^{11,28-30} Parameters of the waveform, including amplitude, duration, frequency spectrum, number of turns, or phase polarity reversals and area (the integral or total voltage of the waveform) can be automatically analyzed. The data are then compared electronically with predetermined patterns of electrical changes, which correlate with categories of neuromuscular disorders such as myelopathies and neuropathies.

The following is a summary of the more characteristic EMG and nerve conduction changes associated with selected groupings of neurological disorders. The intent is to assist in the understanding of reports of these studies and recognize changes that may be seen in sequential tests during the course of the disorders. The following is a simplified grouping of electrical changes; actual electrodiagnostic studies show considerably more detail and frequent variations of these findings.^{9-11,26,27}

Electrical testing in CNS disorders typically shows normal motor and sensory nerve conduction. In the EMG, spontaneous activity is typically not seen, and individual motor units seen on muscle contraction usually have normal parameters. The recruitment pattern may show a slower-than-normal MUAP discharge frequency with an incomplete and irregular interference pattern. In the presence of tremor and other involuntary movements, bursts of MUAPs occur, consistent with the muscle contraction pattern. In cases involving the brain stem, the blink reflex may show abnormalities.⁷ The tests are important in differential diagnosis between a CNS and a PNS problem, but often they are not used when clinical examinations demonstrate the problem to be definitively in the CNS.

In myelopathies, which include upper and lower motor neuron disorders (e.g., amyotrophic lateral sclerosis [ALS], poliomyelitis, cervical spondylitis, and syringomyelia), motor and sensory nerve conduction is usually normal, although mild slowing may be present.¹¹ The characteristic EMG changes, which usually appear in the more chronic stages of the disorders, are increased amplitude and duration of MUAPs because of the variable impulse conduction time in sprouting axon terminals. An increased number of polyphasic potentials with increased duration is usually found. Spontaneous activity is often seen, and on strong contraction fewer rapidly firing large MUAPs are recruited, resulting in a single-unit or partial interference pattern. In ALS, fasciculations and denervation potentials are typically found. The distribution of the EMG abnormalities determines the extent of the condition.

Peripheral neuropathies show a variety of electrical changes depending on the type and location of the pathology. In a proximal pathology (e.g., radiculopathy), motor and sensory nerve conduction generally remain normal, except F waves and H-reflex responses in specific spinal segments. If motor nerve roots are compromised, spontaneous activity and increased polyphasic potentials appear, and reduced recruitment of MUAPs results in an incomplete interference pattern. In more chronic stages MUAP amplitude and duration can be increased. As the lesion improves, spontaneous activity decreases and the recruitment patterns become more normal. If only sensory roots are injured, no EMG changes occur. Again, the distribution of the EMG abnormalities (all in one myotome) is pathognomonic, especially in the presence of denervation potentials in the corresponding paraspinal muscles.³¹

Lesions of peripheral nerves, which range from a focal mononeuropathy to plexopathy, frequently show abnormalities in motor and sensory nerve conduction depending on which components of the nerve are involved. In the EMG, spontaneous activity, particularly fibrillation and positive sharp waves, is common. If the lesion is complete, no MUAPs are found. The presence of even a few MUAPs suggests a

more optimistic prognosis. Often the location of the lesion can be identified by the distribution of the electrical changes. With regenerating axons, low-amplitude polyphasic MUAPs gradually appear. In the chronic stage, the amplitude and duration of MUAPs are often increased. Spontaneous activity decreases with reinnervation, but it may persist for several years.

Generalized, systemic peripheral polyradiculoneuropathies can be divided into primarily demyelinating, primarily axon loss, or mixed axonal-demyelinating polyneuropathies. Some involve mostly sensory nerves (e.g., hereditary sensory neuropathy types I to IV, Sjögren syndrome, Friedreich ataxia), and others mostly motor nerves (e.g., chronic inflammatory demyelinating polyneuropathy [CIDP], lead neuropathy), but most involve both sensory and motor nerves. In the primarily demyelinating type, such as Guillain-Barré syndrome, motor and sensory nerve conduction and F waves become markedly slow. EMG changes usually do not occur, except for a reduced recruitment pattern consistent with weak muscle contraction or conduction block (when the demyelination is such that the impulse does not propagate). With primarily axonal polyneuropathies, such as uremic neuropathy, isoniazid or cisplatin toxicity, and lead poisoning, motor and sensory nerve conduction is mildly slowed or may remain normal. The duration and amplitude of the response, however, decrease. During advanced stages, many polyneuropathies develop both demyelinating and axonal pathology (e.g., diabetic neuropathy, which is by far the most commonly encountered polyneuropathy). On EMG, spontaneous activity is commonly seen. These electrical changes generally become more severe with worsening of the pathology, but they also improve if the pathology is reversed. From a patient management standpoint, remyelination occurs at a much more expedient pace than reinnervation.³²⁻³⁴

Again, the scope of the NCS electromyographic test is to determine the presence and extent of a neurological dysfunction. Attributing a cause to the dysfunction (e.g., diabetes versus alcoholism) requires other tests.

With myopathic disorders, motor and sensory nerve conduction are generally normal unless neural tissue is also affected. In advanced stages, however, severely atrophied muscles can produce decreased amplitude and distorted nerve conduction responses. The characteristic findings on EMG are short-duration, low-amplitude potentials. Some spontaneous potentials, particularly fibrillations and positive sharp waves, may be found but are much more frequent in the inflammatory myopathies such as polymyositis. Specific myotonic potentials appear in certain myopathic disorders (e.g., myotonia congenita). The recruitment pattern shows many low-amplitude MUAPs, appearing in a full pattern, with little voluntary effort. This type of recruitment pattern is referred to as *early recruitment*.

Neuromuscular junction disorders involve the synapse between axons and myocytes. In LEMS the pathology is in the presynaptic membrane (decreased release of acetylcholine [ACh]), whereas in myasthenia gravis the pathology involves the postsynaptic membrane. The two are differentiated by the response to RNS or jitter with single-fiber EMG (see later). In LEMS the amplitude of the responses increases with repetitive stimulation (more quanta of ACh released), whereas in myasthenia gravis the responses

decrease (all ACh receptors saturated). Sensory NCS findings are typically normal.

Table 33-1 provides a summary of typical findings.

Single-Fiber Electromyography

Electrical activity can be recorded from two or more muscle fibers innervated by the same motor unit by using a specially designed single-fiber needle electrode. SFEMG is, at this time, the most sensitive test for evaluation of neuromuscular transmission defects such as myasthenia gravis and myasthenic syndrome. It is also used to evaluate peripheral neuropathies, motor neuron diseases, and myopathies. It is typically provided only in tertiary centers and requires a high level of patient participation.

During a carefully controlled minimal voluntary contraction, a 25- μm -diameter needle is inserted into the muscle, and several potentials from muscle fibers within the recording area are stored. Equipment with a trigger and delay line is necessary to “time lock” the tracings of the potentials. The slightly different conduction time or interpulse interval (IPI) required for impulses to be transmitted from a single motor neuron to each of its terminal endplates, cross the neuromuscular junction, and activate the muscle fiber is called *jitter*. This time difference is collected from several tracings and is converted into a mean consecutive time difference (MCD), which normally ranges from 5 to 55 ms. Values shorter or longer than this range are considered abnormal. The impulses from some axons to their muscle fibers may fail to be transmitted. This is referred to as *blocking*. Another capability of SFEMG is the measure of fiber density, that is, the average number of muscle fibers within the needle recording area. Fiber density is increased in reinnervation and also with certain myopathies because of axonal collateralization or splitting.²⁸

Macroelectromyography

A variation of SFEMG uses a macroelectrode to record the majority of muscle fibers of a single motor unit as they are triggered by an initial potential, which is then time locked

with all the other muscle fiber potentials recorded from a different part of the same or a nearby needle.^{11,29,30,35,36} Two recording channels are used. Maximal amplitude of the potentials from several muscles has been reported by Stalberg.³⁵ The findings are analyzed, along with findings of jitter, fiber density, and conventional EMG, to evaluate the status and prognosis of various neurological and neuromuscular disorders, such as motor neuron disease, peripheral nerve lesions, and myopathies.

In summary, the astute PT in the presence of a patient reporting weakness and/or numbness will refer that patient appropriately for electrophysiological testing based on the findings of a judicious clinical examination. In reading the report of an electrophysiological consultation, the PT will first correlate the results with the findings of the physical examination of the patient, determine whether the studies performed are complete (i.e., there are sufficient data to rule in the condition but also sufficient data to rule out other conditions), and correlate the findings with the conclusion. There is evidence that PTs performing NCSs and EMG tend to follow guidelines consistently.³⁷

Kinesiological Electromyography

KEMG measures muscle activation during movement, whether it is purposeful, involuntary, dynamic, or relatively static. It is the method by which the therapist-examiner determines a muscle's (or muscle group's) onset, cessation, relative intensity, and activation sequencing during functional activities such as walking. Because normal movement depends on the CNS's ability to execute motor programs through muscle action, KEMG provides the therapist with insight, in real time, into motor function, motor control, and motor learning.

Persons with neuromuscular disorders typically exhibit control errors, including the inability to initiate, execute, or terminate movement. Selective control may be absent or abnormal with errors in muscle timing, intensity, and sequencing. Spasticity or synergistic muscle action may impede smooth execution of tasks and prevent purposeful movement. With

TABLE 33-1 ■ SUMMARY OF TYPICAL FINDINGS

DISORDER	MOTOR CONDUCTION	SENSORY CONDUCTION	ELECTROMYOGRAPHY
Motor neuron disease (e.g., amyotrophic lateral sclerosis [ALS])	Reduced amplitudes	Normal	Acute plus chronic neurogenic changes, fasciculations
Radiculopathies	Normal	Normal	Acute neurogenic changes in myotome
Plexopathies	Reduced amplitudes	Reduced amplitudes	Acute neurogenic changes in specific pattern
Axonal neuropathy	Reduced amplitude in affected nerve(s)	Reduced amplitude in affected nerve(s)	Acute neurogenic changes in affected nerve
Demyelinating neuropathy	Reduced conduction in affected nerve	Reduced conduction in affected nerve	Normal
Neuromuscular junction disorder	Decrement (myasthenia gravis [MG]) or increment (Lambert-Eaton myasthenic syndrome [LEMS]) with repetitive stimulation	Normal	Occasional myopathic motor unit action potentials (MUAPs)
Myopathies	Normal	Normal	Small-amplitude polyphasic MUAPs

increased emphasis on evidence-based practice, KEMG can provide objective documentation of abnormal control and intervention outcomes and provide insight into optimizing strategies for improved functional performance. Many orthopedic surgeons rely on KEMG testing to supplement clinical evaluation in planning surgical interventions (muscle transfers and releases) in children with cerebral palsy,³⁸ in patients with TBI,³⁹ and in those who have had a stroke.⁴⁰

KEMG interpretation depends on the examiner's understanding of the instrumentation chosen for testing, including electrode selection, recording techniques, signal processing, and time and intensity normalization.⁴¹ Coupled with three-dimensional motion (infrared camera and motion capture) and force plate analysis, external moments are calculated that define internal force demands on muscles during functional activities such as walking. KEMG delineates the muscles that participate in meeting the internal force demand.

Recording Instrumentation

KEMG can be performed by using surface or fine wire electrodes (intramuscular). Controversy exists about the choice of electrodes, with the selection dependent on the clinical or research question. If the examiner is interested in "muscle groups" (e.g., dorsiflexors, quadriceps) then surface electrodes are appropriate. Fine wire electrodes are optimal if activation of individual or deep muscles is desired (e.g., posterior tibialis, iliacus). Fine wire allows for specificity of muscle action required for surgical decisions related to muscle transfers, releases, or muscle lengthening.^{38,39,42}

Needle or Fine Wire Electrodes (Indwelling or Intramuscular). A pair of 50- μ g fine wire electrodes, also referred to as *indwelling* or *intramuscular electrodes*, are introduced through the skin and into the muscle with a 25-gauge hypodermic needle. The 50- μ g, Teflon-coated wires are threaded through the needle's core; 2 to 3 mm of the wire's distal end are stripped of insulation and, once inserted, record adjacent motor unit activity. Before insertion the electrodes are sterilized. Inserted through the skin and into the muscle of interest, the barbed end "hooks" the muscle fibers when the needle is withdrawn. Accurate placement requires that the examiner have extensive knowledge of three-dimensional anatomy and excellent palpation skills. A maximal concentric voluntary contraction is elicited to anchor the wires into the muscle fibers, preventing displacement during subsequent contraction. This ensures sampling the same motor unit pool during subsequent tasks, trials, or conditions. Electrical stimulation is an essential testing element to verify electrode location. Wire electrodes allow a more precise definition of muscle timing (onset and cessation) by reducing the incidence of intramuscular crosstalk.⁴³ Disadvantages include decreased reliability and insertional pain caused by skin penetration.⁴⁴⁻⁴⁶ In several states the examiner must possess specialized KEMG licensure to penetrate the skin with a needle.

Surface Electrodes. When the clinical question can be answered by using surface electrodes, electrical stimulation of motor points often defines optimal electrode placement over the muscle or group of muscles of interest. A maximal voluntary contraction (MVC) is elicited to confirm that optimal placement has been achieved. Standardizing electrode

placement, size, interelectrode distance, and skin preparation enhances test-retest repeatability,⁴⁷ with submaximal contractions more reliable than maximal contractions.⁴⁸ Skin displacement under the recording site may introduce movement artifact, which can be minimized by securing the electrodes to the skin with tape. To improve interday reliability, electrode placement should be marked (with ink) and standardized electrodes used. When both recording electrodes are contained in the same housing, interelectrode distance is standardized and movement artifact attenuated. Advantages of using surface electrodes include improved reliability and the ease with which they can be applied without causing patient discomfort.⁴⁴⁻⁴⁶ Specialized licensure is not required.

Instrumentation for Kinesiological Electromyography Acquisition

KEMG signal acquisition requires either a telemetry unit (FM modulation) or a hard-wired system that relies on a "cable" tethered to the subject to transmit signals from the electrode site to the receiver. The subject's performance and nature of movement strategies performed may be altered by the cabling. Telemetry allows the subject unrestricted movement; KEMG signals are transmitted through the air from a small unit worn around the subject's waist. The optimal characteristics of the receiver include a bandwidth frequency of 40 to 1000 Hz and an overall gain of 1000 Hz.⁴¹

Signal Processing. KEMG processing has become highly automated with the advent of high-speed computers and customized software. Once the signal has been acquired, it is stored digitally and processed by various computer programs. The "raw" signal is full wave rectified (all the negative values become positive), and a linear envelope is generated within a designated time interval. The area under the curve is mathematically integrated, and an average EMG profile is generated. Muscle-specific onset, cessation, and relative intensity are defined with a variety of software. According to a recent study, KEMG timing (onset and cessation) is optimally identified by using the intensity filtered average (IFA) and packet analysis (PAC) when compared with ensemble average (EAV).⁴⁹ Despite a smaller recording volume with wires, Bogey and colleagues⁴⁹ demonstrated no significant difference in signal amplitude when multiple insertion sites within the same muscle were compared.

Normalization. Any acquired "raw" EMG signal needs to be referenced to a standard value. This is accomplished by dividing the raw EMG during a functional task such as walking by a reference value. The MVC serves this purpose. Subjects exert a maximal voluntary effort for each muscle that determines the maximal EMG activity possible. All subsequent efforts are compared with this maximal effort and expressed as a percentage of maximum (%MVC). In patients with neurological dysfunction who lack selective motor control, a maximal effort can be elicited in either an extensor or flexor synergy by using the upright motor control (UMC) test developed at Rancho Los Amigos National Rehabilitation Center, grading the effort as "weak," "moderate," or "strong" in synergy.⁵⁰ Maximal efforts are elicited for 3 to 5 seconds, and the software determines the maximal activity for a 1-second interval. The muscles' activation during a functional activity is subsequently expressed as a percentage of MVC.

Interpretation of Kinesiological Electromyography

Kinesiological Electromyography and Strength.

KEMG testing does not directly measure muscle strength, and the examiner should resist equating raw EMG signal amplitude directly with muscle force or torque output. Grading the strength (manual muscle testing [MMT] or UMC test) of each maximal effort must accompany the interpretation of the muscle participation during a functional task.⁵¹ For example, patients with postpolio syndrome (refer to Chapter 35) produce large-amplitude KEMG signals that often reflect the maximal exertion of a “weak” muscle (e.g., “MMT—Poor” or 2/5). Large-amplitude EMG signals represent activation of large motor units typical of reinnervation, not force output. Despite large-amplitude signals, the muscle is functionally weak. In other words, a 100% MVC normalized KEMG record for a muscle may represent the maximal effort of a “poor” or 2/5 muscle.

Muscle Tone versus Spasticity. Therapists should resist making inferences about *tone* from KEMG testing. As previously stated, KEMG reflects the contractile activity of motor units. Muscle tone refers to the amount of *resting* tension in a muscle because of its viscoelastic properties. Because tone is not a function of motor unit activity, it cannot be measured with KEMG.⁴¹ In contrast, spasticity, defined as a hyperactive quick stretch response, can be recorded by KEMG because it reflects prolonged muscle activation (>0.1 s). Clonus has a distinct frequency characterized by a prolonged 5- to 8-Hz signal. Using signal duration in response to quick stretch, Cahan and colleagues⁵² identified significant decreases in spasticity in selected lower-extremity muscles in children with cerebral palsy after selective dorsal rhizotomy. In these children spasticity interfered with agonist activation during walking.

In conclusion, KEMG is useful for delineating patterns of muscle activation in motor performance, reflecting the integrity of the neuromuscular control mechanism. The examiner’s interpretation should also consider additional factors such as the type of contraction; speed of movement; joint acceleration; and a host of physiological, biomechanical, anatomical, and neurological elements beyond the scope of this chapter.

ELECTRICAL STIMULATION AND ELECTROMYOGRAPHIC BIOFEEDBACK

NMES and EMGBF are often used as tools in the management of neurological dysfunction. EMGBF can be used both alone and in conjunction with stimulation. The primary goal of use is improvement of function by improving voluntary motor control. To that end, strengthening and alteration of abnormal tone are also common goals of treatment. EMGBF is discussed later in this chapter. More detailed explication of treatment protocols is included in a variety of published work.⁵³⁻⁶⁴

Electrical stimulators used in physical rehabilitation practice may be either small, portable, battery-operated units or larger line-powered clinical instruments. The clinical units often will offer a variety of stimulus forms and options for modulation of currents. Portable units provide the ability for patients and caregivers to carry out prescribed stimulation at home. Clinical units allow the therapist to customize programs to optimize treatment outcomes.

Neuromuscular Electrical Stimulation

In NMES, muscle contraction is elicited by depolarization of the motor neurons. Electrodes may be placed over the muscle to be stimulated or over the motor nerve that controls the muscle. Firing order of neurons is a result of neuronal size, proximity of the electrical stimulus, and the intensity of stimulation.⁶⁵ Muscle recruitment patterns triggered by electrical stimulation differ from those observed in normal muscle activation. In a voluntary muscle contraction, motor units fire asynchronously, with a larger proportion of type I, fatigue-resistant muscle fibers of the smaller motor units being recruited first. The order of muscle fiber firing occurs as a result of motor neuron size and the anatomy of synaptic connections.⁶⁶ Conversely, an electrically stimulated muscle contraction elicits initial responses from larger motor units, which contain a greater number of fatigable, type II muscle fibers. The type II fibers are innervated by larger-diameter neurons that have a lower threshold for electrical stimulation than smaller neurons.⁶⁷ A study of healthy subjects demonstrated recruitment of these higher-threshold motor units at relatively low NMES training levels. In voluntary exercise a much greater exercise intensity is required for activation of these larger motor units.⁶⁷

Synchronous recruitment of muscle fibers is obtained with electrical stimulation. This does not occur with volitional activation. During a sustained volitional contraction motor units periodically “drop out” and then “drop in” to reduce fatigue. With NMES, once recruited the motor units will continue to fire until the stimulus is ended. This, coupled with the early recruitment of fatigable motor units, accounts for fatigue being a major problem in the use of NMES. It also is one reason functional activities performed under control by stimulation are much less smooth and balanced than when they are performed volitionally. At the same time, relatively low levels of NMES can recruit motor units that volitionally would be recruited only with maximal effort. This provides support for observed increases in strength with low NMES training intensities.⁶⁸ Numerous potential benefits have been identified for NMES. Among them are improvement in ROM, edema reduction, treatment of disuse atrophy, and improvement of muscle recruitment for muscle reeducation.⁵⁶

Parameters of Stimulation

With any electrical stimulation used for patients with neuromuscular dysfunction, three parameters must be considered within the waveform: pulse (or phase) duration, pulse frequency, and pulse amplitude. Depending on the intent of the electrical stimulation, instruments are available that allow all of these to be independently adjusted.

Waveform

NMES units use alternating currents. The waveform of the stimulus produced by most NMES units is either a symmetrical or an asymmetrical biphasic pulse. The two phases of each pulse continually alternate in direction between positive and negative polarity. Although an ideal waveform has not been identified, most studies have shown the symmetrical biphasic waveform to be more comfortable than either the asymmetrical biphasic or the monophasic waveform.^{53,69,70}

Duration

Phase or pulse duration (also called *pulse width*) refers to the amount of time of a single pulse or phase. Stimulators with a pulse duration of 1 to 300 μs (0.3 ms) can be used to activate muscles with intact innervation. Waveforms of shorter durations require a greater current amplitude to produce a muscle contraction (because the current is on for a shorter period of time). They may be more comfortable but may not possess enough charge for good contraction levels. Longer-phase durations may be used but are less comfortable. In NMES units, pulse durations may be started at 100 μs , then increased to 200 to 300 μs if tolerated well by the patient.^{71,72} Denervated muscles require significantly longer phase durations (20 to 100 ms) because of the longer chronaxy of muscle cells compared with motor neurons.

Frequency

Pulse frequency (or *pulse rate*) refers to the number of electrical pulses applied per unit time. In applications seeking to provide muscle contraction, the stimulus rate should be 35 to 50 pps. This is a typical critical frequency at which a muscle will respond with a smooth contraction (also called a *tetanic frequency*). Higher frequencies than this can result in early onset of fatigue. NMES used for spasm reduction may use a higher frequency, with the intent of fatiguing the muscle and decreasing spasm, which will result in decreased pain levels.

Amplitude

The amplitude (intensity) of the stimulus should be sufficient to achieve the desired strength of contraction. Battery-operated units usually indicate the amplitude only in a relative way (nonquantitatively) because the output of the battery declines over time. Depending on the impedance of the electrodes, coupling agent, skin and soft tissue, the amount of current required at one location could be quite different than at another to produce the same degree of muscle contraction. This is why the amplitude of the stimulus is usually described according to the strength of the sensation felt by the patient. *Mild, moderate, or maximum sensory* refers to the intensity of the stimulation as felt by the patient, without eliciting a motor contraction. Similarly, *mild, moderate, and maximum motor* describe the amplitude of the stimulus needed to produce those visible muscular contractions using electrical stimulation. If

the intent is to strengthen the muscle or increase endurance, the client is usually asked to participate by voluntarily contracting the muscle being stimulated when the stimulation is on. The amplitude of stimulation should be graded based on the response of the patient, aiming at production of the clinically desired force output.

Additional Parameters: Ramp Time and On-Off Time Ratio

On Time and Off Time. NMES for facilitation of muscle contraction should be used to supplement exercise, and goals for stimulation should be consistent with the goals of the exercise program. To simulate isotonic or isometric muscle contractions, as in voluntary movement for exercise, the stimulator must have the capability of setting cycles of on and off times. Each period of muscle contraction is followed by a period of relaxation (Figure 33-7).^{2,56} In most cases a shorter on time than off time is desirable to avoid fatigue. For example, a 10-second on time may be followed by a 50-second off time in a cycle, resulting in an on-off ratio of 1:5. Packman-Braun⁷³ investigated ratios of stimulation to rest time with NMES for wrist extension in a group of hemiplegic patients. Results supported the on-off time of 1:5 as being the most beneficial in training programs of 20 to 30 minutes because of the deleterious effects of fatigue with lower ratios (1:1, 1:2, 1:3, 1:4). If the goal is to reduce edema by providing a muscle pumping action, a ratio of 1:1 or 1:2 may be preferred,⁷³ as the intent is to decrease the edema by continuous muscle pumping action. Lower ratios may be used when the goal is neuromuscular reeducation or endurance training.

Ramping. Ramping is another modulation that can be set by the therapist. Ramp-up is the time it takes each train of pulses to increase amplitude or intensity sequentially from zero to maximum. Ramp-off is the period set at the end of the train of maximal intensity pulses to decrease sequentially from maximum to zero amplitude (see Figure 33-7). Ramp time can be adjusted so that the stimulation more nearly resembles a pattern of gradually contracting and relaxing muscles. For clients with hypertonicity or spasticity and a goal of facilitation and strengthening the antagonist muscle, a longer ramp-up time may avoid or minimize activation of the stretch reflex in the hyperactive agonist muscle.

Duty Cycle. The term *duty cycle* is sometimes confused with the on-off time ratio. Duty cycle is the percentage of

Figure 33-7 ■ Example of the relation between ramp times and on/off times. Each division on the horizontal axis equals 2 seconds. Note that the ramp-up time is considered part of the on time, whereas the ramp-down time is considered part of the off time. (Reprinted from DeVahl J: NMES in rehabilitation. In Gersh MR, editor: *Electrotherapy in rehabilitation*, Philadelphia, 1992, FA Davis.)

time a series or train of pulses is on out of the total on and off time in a cycle.^{2,53} For example, if the train of pulses is on 10 seconds and off 30 seconds, the total cycle time is 40 seconds. The duty cycle would be 25% (10 seconds of the total 40-second cycle). The actual on time and off time of the pulses in a cycle is a more informative description than either the duty cycle or the on-off ratio.

Muscle Reeducation

After an insult or injury affecting the CNS, problems with motor control frequently manifest. One of the common goals of therapy is to facilitate movement in the areas where control is lacking. If active movement is not present, NMES allows movement to occur by stimulation, which may be followed by resumption of active movement, possibly triggered by the sensory (visual and proprioceptive, among others) experience that accompanies the stimulation. When active movement is present but is weak or not well controlled, the therapist may choose to use NMES to supplement and strengthen the muscular contraction already present. Some evidence exists that NMES can increase activity in the somatosensory cortex and that the cortical activity is correlated with improvement in functional tasks.⁷⁴ In the presence of hypertonicity, the muscles serving as antagonists to the spastic muscle may be targeted for NMES, not only to strengthen the antagonist but to inhibit the spastic muscle by reciprocal inhibition.

Functional Electrical Stimulation

The term *functional electrical stimulation* (FES) has been used casually to describe various applications of NMES. However, FES is defined by the Electrotherapy Standards Committee of the Section on Clinical Electrophysiology of the American Physical Therapy Association as the use of NMES (on innervated muscles) for orthotic substitution.² Baker and Parker⁷⁵ use the term to describe external control of innervated, paretic, or paralytic muscles “to achieve functional and purposeful movements.” Although NMES is generally considered to have therapeutic applications, such as increasing ROM, facilitation of muscle activation, and muscle strengthening, the key to application of FES is to enhance or facilitate functional control. It is used with clients with SCI, TBI, cerebrovascular accident (CVA), and other CNS dysfunction who have intact peripheral innervation.

An example of FES application is the electrical stimulation of the peroneal nerve to enhance ankle dorsiflexion during gait in patients with hemiplegia.⁷⁶ Two of the more common applications of FES on the market include the WalkAide system (Innovative Neurotronics, Austin, Texas) and Bioness (Bioness, Valencia, California). In terms of neurological dysfunctions, research has been published that indicates efficacy of these devices and FES in general in improving functional performance in people with CVA,⁷⁷⁻⁸⁰ multiple sclerosis, TBI, SCI,^{81,82} and cerebral palsy.⁸³ Moreover, numerous other uses of FES have been described, ranging from isolated motor control activities, such as decreasing shoulder subluxation and reducing scoliosis, to highly technical computerized gait and bicycling capabilities, sometimes referred to as *computerized FES* (CFES).⁸⁴⁻⁹² The trigger that activates muscle contraction in synchrony with the functional activity can be manually

initiated by the client, set within the stimulator to automatically trigger on and off cycles, or programmed into a complex computer system for bicycling or gait.

Stimulation is generally applied in short-duration pulses with a frequency sufficient to provide smooth, tetanizing muscle contractions and adjusted to cycle on and off, with adequate ramp functions, as indicated by the speed and time needed to synchronize the stimulation with the functional activity. The length of the intervention depends on the purpose and may vary from a few contractions during the functional activity, building to multiple 30-minute sessions working up to several hours, repeated daily or three to five times per week. With the more complex computerized systems used with clients with complete spinal cord lesions, electrically activated functional movements are the mechanism to achieve physiological and psychological benefits. In some situations, assisted function is also an important goal, although functional community ambulation is not yet a reality.^{88,90,93-100} Hooker and co-workers⁹⁴ evaluated the physiological effects of use of FES-assisted leg cycling in SCI. Compared with resting levels, significant increases were found in cardiac output, heart rate, stroke volume, respiratory exchange rate, pulmonary ventilation, and other physiological phenomena. CFES for cycle ergometry and ambulation has also been shown to increase muscle mass, electrically induce muscle strength and endurance,^{89,101,102} increase circulation and aerobic capacity, decrease edema, and have a beneficial impact on self-image.^{90,102,103} Jacobs and colleagues¹⁰⁰ compared the metabolic stress of FES-assisted standing versus frame-supported standing. Cardio-respiratory stress was significantly higher with FES, and the authors concluded that FES-assisted standing alone may provide a stress sufficient to meet minimal requirements for exercise conditioning.

The demonstrated benefits of FES clearly indicate that it is a valuable tool for supplementing functional activities. The practicality and cost of applications of the more complex computerized systems need further study, especially in terms of function in community activities. (Refer to Chapter 38 for additional discussion.)

Electromyographic Biofeedback

Biofeedback is a general term used to describe the use of visual or auditory representation of physiological processes to allow an individual to modify those processes. EMGBF makes available to the client information regarding the electrical activity of muscle. EMGBF has several well documented applications, including alteration of physiological responses such as heart rate, temperature, and muscle tension.⁵⁴ These applications may prove beneficial for clients with neurological dysfunction. An example would be relaxation to modify pain perception. The focus of this review is the use of EMGBF for improvement of active movement, which may include reduction of hypertonicity in addition to muscle reeducation. EMGBF units range from basic single-channel portable models to clinical units with multiple channels and multiple options for provision of feedback.

EMGBF may be used to assist a client in attaining greater levels of muscle activation in paretic muscle, decrease levels of muscle activation in spastic muscle, or attain a balance between agonist and antagonist muscle pairs.¹⁰⁴ For most practicing clinicians, EMG levels are monitored through the

use of surface electrodes. Monitoring of activation of deep muscles is often not feasible. Attention to size and specific electrode placement is critical to ensure feedback that will be useful. Smaller electrodes allow specific placement, although higher impedance will be encountered. Skin must be carefully prepared to take this into account.¹⁰⁵ Because the EMG information recorded represents the sum of action potentials from motor units between the electrodes, large interelectrode distance will increase the area of muscle recorded. This may be desirable for large muscle groups or when minimal activity is present.

Smaller interelectrode distances are preferable if interference from “crosstalk” or “volume conduction” from muscles or motor units not part of the target group is a risk. Basmajian and Blumenstein¹⁰⁵ provide an excellent review of electrode placements.

Reduction of Hypertonicity

DeBacher¹⁰⁶ described a progression of intervention with EMGBF designed to reduce spasticity. The program uses three stages of intervention: (1) relaxation of spastic muscles at rest even in the presence of distraction, mental effort, or use of muscles not targeted for EMGBF training; (2) inhibition of muscle activity during passive static and dynamic stretch of the spastic muscle, beginning with static stretch at the extremes of motion, then progressing to passive movement speed at a speed of 15 degrees per second; and (3) isometric contractions of the antagonist to the spastic muscle, with relaxation of the spastic muscle, progressing to prompt muscle contraction and relaxation of the spastic muscle, and grading of muscle contractions with movement for various force output requirements. Use of the technique in a small sample of young adults with cerebral palsy demonstrated improvement in resting levels of involuntary muscle activity.¹⁰⁷ Improvements in function, however, were not demonstrated.

Inhibition of a spastic muscle alone may not be enough to improve function. Often the spastic muscle itself, once hypertonicity has diminished, is weak or has low functional tone. Weak antagonists to the affected muscle may contribute to the functional limitation. EMGBF to reinforce activity in the weak muscle may be done concurrently with its use to modify the tone in the agonist.¹⁰⁸ EMGBF can be useful in helping a client decrease abnormal muscle activation, but persistence of control problems may be related to lack of force production, deficits in speed of muscle activation, and lack of reciprocal interaction of muscle groups.¹⁰⁹

Muscle Reeducation

Therapists may opt to use biofeedback to provide information about the quality of the muscle contraction directly to the client. The client can then attempt to alter the contraction in accordance with guidelines provided by the therapist, whether the focus is to facilitate stronger contraction, decrease apparent hyperactivity, or modulate a balance of muscle activity during a functional task.

Concurrent assessment of muscle activity (CAMA) is an application of EMGBF in which the therapist uses biofeedback as an adjunct in evaluation of client response to therapeutic exercise.¹¹⁰ In this procedure the therapist decides which muscle group(s) are desired for activation and adjusts the position of the client or the therapist intervention accordingly

to get the correct responses. CAMA allows for the judgment of the effectiveness of a particular activity based on actual EMG responses rather than presumptions of what the intervention should cause. In a placebo-controlled study of hemiplegic patients, the addition of EMGBF to hand exercises based on the Brunnstrom approach resulted in significant improvement in active ROM in those using biofeedback compared with sham.¹¹¹

Several authors suggest the use of biofeedback signals from homologous extremity muscles as a model for what the hemiplegic client needs to alter muscle activity in a particular function.^{112,113} This has been described as a “motor copy” and was compared with a more targeted training procedure. Indications showed that the motor copy resulted in better carryover in function than the comparison therapy in follow-up evaluations. A similar training study showed indications of benefits of the procedure, but the results were not statistically significant because of the small group size.¹¹² At least two studies support patterning or copying EMG from other muscles as a potentially useful tool for individuals with C4-7 SCI.^{114,115} A meta-analysis that compared EMGBF with conventional physical therapy for upper-extremity function in individuals after stroke reviewed only six studies and concluded that neither approach was superior to the other.¹¹⁶

Feedback Considerations

EMGBF has the benefit of being provided simultaneously with the client’s movement, consisting of accurate and objective information about muscle activity (given careful electrode application), and not requiring the same level of therapist skill as verbal feedback provision. EMGBF therefore may be beneficial for clients with deficient sensory feedback systems. The frequency of feedback provision, however, may require close scrutiny by the therapist.

Experiments examining feedback frequency in the learning of motor tasks support the use of less than 100% relative frequency for the subject to learn the task. Feedback provided on every trial may improve performance but degrades learning in normal subjects.¹¹⁷ In a study of stroke patients attempting a pursuit tracking task, biofeedback was used for the experimental group (electrodes over the spastic biceps), whereas the control group performed the task without feedback.¹¹⁸ Posttests revealed that the use of continuous feedback had a negative transfer effect on learning of the movement task, suggesting that the experimental learners became dependent on the external feedback in performance of the task. The clinician must therefore carefully structure the use of external feedback so the client begins to develop a sense of muscle activation or relaxation that is present without the EMGBF apparatus. This may be accomplished by turning the screen away from the client and turning off the auditory signal as the patient progresses.

Integrating Neuromuscular Electrical Stimulation and Electromyographic Biofeedback

The use of EMG-triggered NMES, in which NMES is initiated once the client has achieved a predetermined level of EMG activity in the targeted muscles, is an application that has been shown to have merit,^{119,120} although a more recent systematic review showed no statistically significant

differences between EMG-NMES and usual care in improving upper-extremity function of the affected extremity in people who had had a stroke.¹²¹ Threshold levels of EMG activity could gradually be increased as the client gains the ability to activate muscles independently, with eventual discontinuance of the NMES as strength and active control allow. The success of this application has been shown in patients with hemiplegia in terms of increasing EMG activity and subsequent improvement in ROM and function in the involved arm and leg.¹¹⁹ In another study, patients who had had a stroke more than 1 year previously significantly improved wrist and finger extension strength and function after treatment with EMG-triggered stimulation compared with controls.¹²⁰

A variation of this application is NMES triggered by positional feedback, such that NMES is initiated once the patient actively moves through a portion of the available ROM at a joint.¹²² The therapist may set the threshold angle in accordance with the patient's goals and abilities. This method has been shown to be effective in improving wrist motion after stroke, although it was not as effective in altering control of the knee in a similar patient group.¹²³

Although discussions of EMGBF, NMES, and FES are often presented separately, the use of these modalities can be intertwined to achieve desired muscle control. NMES or FES may be initiated in the absence of active control (although lower levels of muscle activation may be discovered and facilitated with EMGBF). Once return of active control begins, EMGBF may be used to refine the control. An increase in muscle EMG should not be assumed to translate automatically to an improvement in functional use of that muscle in daily activities. Consequently, NMES and EMGBF need to be integrated into daily functional activities so that appropriate muscle activity is elicited and used in its appropriate functional context.

Applications

The application of the common principles of EMGBF and NMES to different patient populations emphasizes the role of the therapist in tailoring intervention to meet specific client needs.

Many investigators have evaluated the use of NMES and EMGBF in clients who have had a stroke.^{108,124-126} FES has been used extensively with clients with SCI. Other populations that demonstrate neuromuscular impairment or dysfunction have not been as thoroughly studied. This may be because the heterogeneity of these groups may create difficulty in research design.

Upper-Extremity Management

Electromyographic Biofeedback

EMGBF has been extensively studied, but success of the treatment is mixed, with difficulty in interpretation. A reduction in co-contraction has been observed,¹²⁷ as well as improvement in several neuromuscular variables^{124,128,129}; however, a lack of significant improvement in functional skill was noted. Given the challenge of improving upper-extremity functional ability after stroke, Wolf and Binder-Macleod¹²⁹ suggested consideration of several key factors in predicting which clients may benefit from EMGBF: "Those patients who achieve the most substantial improvement in manipulative abilities initially

possess voluntary finger extension; comparatively greater active ROM about the shoulder, elbow, and wrist; and comparatively less hyperactivity in muscles usually considered as major contributors to the typical flexor synergy." Attention to the chronicity of motor dysfunction also appears critical in anticipating success with EMGBF, as clients 2 to 3 months after stroke demonstrated stronger functional gains after intervention with biofeedback compared with clients 4 to 5 months after stroke. A placebo-controlled study of EMGBF showed statistically significant improvement in active ROM of the hand in clients who received EMGBF in addition to exercise.¹¹¹ A study by Doğan-Aslan¹³⁰ and colleagues found improvements in the Ashworth scale, Brunnstrom stage, upper-extremity function test, wrist extension ROM, and surface EMG potentials in their subjects who were treated with EMGBF in conjunction with neurodevelopmental treatment (NDT) and conventional treatment in a population of subjects with hemiplegia secondary to stroke.

Neuromuscular Electrical Stimulation

Common upper-extremity applications of NMES for the patient with a stroke include reduction of shoulder subluxation (FES) and facilitation of elbow, wrist, and finger extension and motor control.

FES for shoulder subluxation reduction appears beneficial for prevention of pain and subluxation, especially if used during the early stages of recovery. The functional benefits over the long term are not always clear, and cost-benefit ratios need to be considered. Baker and Parker,⁷⁵ Faghri and colleagues,⁸⁵ and Chantraine and colleagues¹³¹ have reported success in management of shoulder subluxation after stroke by using gradually increasing stimulation times that ultimately reached 6 to 7 hours per day. On-off ratios were typically 1:3.

Use of NMES after stroke to facilitate motor control and function has been studied, but many studies lack controls. The extensors of the fingers and wrist are typically the targeted muscle groups. de Kroon and colleagues⁶¹ reported a systematic review of literature that included six randomized controlled trials. A variety of stimulation parameters were used. Three studies tested subjects with acute conditions, and three tested subjects with chronic conditions. Outcome measures for motor control included the Fugl-Meyer Motor Assessment (four studies) and strength (two studies). Functional outcomes were reported by two studies, one using the Action Research Arm test and one using the Box and Block test. The authors concluded that there was a positive effect of stimulation on motor control. Only two studies reported functional outcomes, but both were positive. Of significance is the fact that only six studies met the criteria for review in terms of rigor.^{119,120,122,132-134}

FES has also been investigated as an upper-extremity orthosis after hemiplegia, using movement of the uninvolved shoulder to trigger stimulation of elbow extension and hand opening.¹³⁵ After an extensive training period, patients were able to demonstrate functional use of the involved hand for basic reach and grasp.

Systems with more than two channels of stimulation have proved difficult for patients to use.¹³⁶ Popovic and colleagues¹³⁷ reported two studies in which they used NMES to treat patients after stroke. They termed the intervention

functional electrical therapy (FET). The stimulation was used during an exercise program composed of voluntary arm movements and opening and closing, holding and releasing objects with the stimulation serving as an electric prosthesis. Treatment was 30 minutes daily for 3 weeks in one study¹³⁷ and 6 months in the other.¹³⁸ Outcomes were reported as better than controls. Initially higher-functioning subjects benefited more than those who were rated as low functioning. Unfortunately, outcome measures in these studies were not standardized.

A study of use of daily NMES in the form of neuroprosthetic FES (NESS Handmaster) stimulation of hand and finger extensors in patients with subacute strokes (6 to 12 months after onset) was reported by Ring and Rosenthal.¹³⁹ All subjects were receiving physical and occupational therapy three times a week. The stimulator was used at home. Those receiving stimulation had significantly greater improvements in spasticity, active ROM, and functional hand test scores compared with control subjects. The authors concluded that supplementation of outpatient rehabilitation with NMES improves upper-limb outcomes.¹³⁹

Three-month interventions with EMG-triggered NMES, low-intensity NMES, proprioceptive neuromuscular facilitation (PNF) exercise, or no treatment were compared in a group of chronic stroke patients.¹⁴⁰ At 3 and 9 months after treatment, Fugl-Meyer scores improved 18% for the PNF group, 25% for the patients receiving low-intensity NMES, and 42% for the group receiving EMG-triggered NMES. The control group did not change.

These findings lend support to the use of NMES and EMGBF and NMES alone as adjuncts to physical therapy. Typically, higher-functioning patients have shown the greatest impact. Results have tended to show greater effect in patients with acute or subacute conditions, but longer-term patients sometimes benefited as well.

With the advent of the use of technology in neurological rehabilitation (see Chapter 38), an increasing number of investigations have been done to incorporate new technology with electrical stimulation to improve functional performance. Sayenko¹⁴¹ described the use of a video game-based training system combined with NMES in a person with chronic SCI. Results indicated improvement in the strength and endurance of the paralyzed lower extremities of the individual after the intervention.

Lower-Extremity Management

Electromyographic Biofeedback

Several studies evaluating EMGBF for retraining lower-extremity control after stroke have focused on improvement of tibialis anterior control and reduction of gastrocnemius muscle activity. Results support increases in strength and ROM in ankle dorsiflexion with carryover into ambulation and maintenance of this improvement on follow-up evaluation.¹⁴²⁻¹⁴⁴

Wolf and Binder-Macleod¹²⁴ examined a number of variables at the hip, knee, and ankle in a controlled group study of the effects of EMGBF. Subjects were assigned to one of four groups: lower-extremity EMGBF, upper-extremity EMGBF, general relaxation training, and no treatment. No significant changes were observed between experimental and control groups for EMG levels and ROM at the hip, but improvements were noted in knee and ankle

active motion for the experimental group. Although subjects in the experimental group increased their gait speed, these changes were not significantly different from findings in the comparison groups.

Use of EMGBF with the intent of improving ambulation may require use of feedback during the task of ambulation instead of during static activity, as demonstrated by this study. Positional biofeedback regarding ankle position and traditional EMGBF were compared in a group of hemiplegic subjects.¹⁴⁵ A computerized system provided audiovisual feedback during ambulation for both groups. Pretreatment and posttreatment measures of ankle motion, gait, and perceived exertion were conducted for the two treatment groups and a control group. The group receiving positional feedback increased walking speeds relative to the other groups, with improvements maintained at follow-up intervals of up to 3 months. The consideration of integrating feedback into functional ambulation bears further investigation.

Neuromuscular Electrical Stimulation

Peroneal nerve stimulation has been documented as an assistance for patients with hemiplegia to improve ambulation.^{76,146-148} Long-term stimulation with implanted electrodes has proved effective in improving gait patterns, but difficulties in achieving balanced dorsiflexion, infection, and equipment maintenance were drawbacks.^{148,149}

Shorter-term use of peroneal nerve stimulation as an adjunct to traditional physical therapy may be considered. In a controlled study examining the use of 20 minutes of peroneal nerve stimulation six times per week for 4 weeks, the stimulated group demonstrated dorsiflexion recovery three times greater than the control group, as measured by an average of 10 maximal dorsiflexion contractions. These improvements were regardless of site of lesion, age, or time since lesion.¹⁴⁶ Surface electrode stimulation is effective, and gait parameters can be improved with its use.^{150,151} If, however, a foot drop is the only major impediment to ambulation, lightweight plastic orthoses are a functional and much less expensive choice of intervention.

Multichannel electrical stimulation has been used in the management of ambulation in patients who have had a stroke.^{140,152-155} Although more effective than traditional gait training in some cases in terms of gait velocity and stride length, at follow-up evaluations 8 to 9 months after therapy the difference between groups had faded. However, the expense and availability of such systems make their use unlikely at this time.

NMES used for ankle dorsiflexion triggered by heel switch during gait and biofeedback to improve active recruitment of ankle dorsiflexors or relaxation of ankle plantar flexors has been studied in hemiplegic clients.¹⁵⁶ Patients who received a combination of these interventions demonstrated significantly improved knee and ankle range parameters more rapidly than those using a single modality. This improvement was maintained over a 1-month period. Although all groups improved in gait cycle times, results in the combined intervention group were better. This may be attributable to the synergy of biofeedback and stimulation.⁵¹ Granat and colleagues¹⁵⁷ also studied peroneal muscle stimulation effects on gait parameters after stroke. After intervention the subjects showed significant control of eversion on all surfaces. The Barthel Index score also improved

after intervention. However, no improvement occurred when the patients were not using the stimulator.

Evidence-Based Practice

Much of the literature evaluating the use of EMGBF and NMES involves patients with CVA. Although these studies have shown many significant results, interpretation of these findings in relation to what is recommended for clinical intervention is not as clear-cut. Improvements in generation of EMG activity and active movement are well documented, but the functional implications of these gains are not as well established. Clearly, in the current practice environment much of the focus is on function, so these techniques to improve muscle activation patterns must be put to functional use in the context of therapy. The therapist must consider the relevant factors that may predict success and critically evaluate outcomes during trial use of these modalities. Cost-benefit analyses must accompany any intervention using technology with the goal of regaining movement as quickly as possible and eliminating the use of equipment when practical.

Stroke (See Chapter 23)

Wolf and Binder-Macleod¹²⁴ examined client characteristics that are critical to success with biofeedback training for upper- and lower-extremity control after stroke. In a group of 52 clients with stroke, no significant relations between outcome and age, sex, number of EMGBF treatments, or side of hemiparesis were found. Lower-extremity treatment was associated with a greater probability of success, and this success did not seem related to chronicity of stroke sequelae. In contrast, success of upper-extremity treatment did appear to be related to length of time since onset of stroke, and poorer outcomes were noted if clients had received therapy to the involved arm for more than 1 year before EMGBF training. Improvements in elbow and shoulder function were obtained in this group of patients, but improvement in functional use of the hand was limited. Aphasia imposed a slight limitation to achieving improvement, but proprioceptive deficits were more significant in restricting functional gains. The role of client motivation in success with EMGBF training was emphasized. On follow-up over a 12-month period, the improvements made in the initial intervention were maintained in 33 of 34 clients evaluated.

A number of studies have been published discussing the muscle recruitment problems observed after CVA.^{108,125,126} Knowledge of these problems is a prerequisite for determination of the appropriate application of EMGBF and NMES. Delayed recruitment of the agonist and antagonist is a relatively consistent finding. Other findings include delayed termination of muscle activity once initiated,¹⁵⁸ presence of co-contraction of agonist and antagonist muscles,^{125,126} lack of co-contraction,¹⁰⁸ and maintenance of agonist muscle contractions.¹²⁵ These reports emphasize the potential value of EMGBF in determining the best mode of intervention.

Jonsdottir and colleagues¹⁵⁹ found that the application of EMGBF in a task-oriented manner, incorporating motor learning principles, resulted in improvements in gait velocity, stride length, and peak ankle power in a population of individuals with hemiparesis. Sander and colleagues¹⁶⁰ found that NMES application to the tibialis anterior muscle

for 30 minutes three times a week for 4 weeks was effective in improving strength of the affected lower extremity.

Lourencao and colleagues¹⁶¹ studied the effects of biofeedback with FES and occupational therapy on upper-extremity function of individuals with hemiplegia. Results indicated significant improvements in upper-extremity ROM and functional recovery with the addition of biofeedback in the treatment regimen.

Lastly, a systematic review was conducted by Woodford and Price¹⁶² on the use of EMGBF for recovery of motor function in individuals with stroke. The authors found evidence from a number of small studies that indicate that EMGBF resulted in improvement in gait, function, and muscle power compared with the usual physiotherapy interventions. The authors emphasized limitations in the results because of the small amount of evidence and problems with methodological designs and differing outcome measures.

Traumatic Spinal Cord Injury (See Chapter 16)

NMES has a variety of applications for clients who have sustained SCI. Muscle strengthening may occur for muscles innervated by segments just above a complete SCI, or a variety of strengthening applications may be appropriate in the case of incomplete SCI. EMGBF may be used to identify muscle activity in weak musculature, as a tool to judge improvement in muscle activation, and as a method of facilitating increased strength.¹⁶³ Applications of EMGBF for individuals with SCI also include facilitation of unassisted ventilation in high-level quadriplegia¹⁶⁴ and use of biofeedback for muscle reeducation with incomplete SCI in the acute stages when immobilization may be required.¹⁶⁵

The use of NMES, EMGBF, and other physical therapy was examined in a group of clients with incomplete cervical SCIs over a total treatment period of 16 weeks. Clients were randomly assigned to one of four groups receiving physical exercise, NMES, or EMGBF. Group 1 received EMGBF followed by physical exercise, group 2 received EMGBF followed by NMES, group 3 received NMES followed by physical exercise, and group 4 received 16 weeks of exercise only. Measurements of muscle strength, self-care ratings, mobility scores, and voluntary EMG were conducted at baseline, treatment midpoint, and conclusion of all interventions. All groups demonstrated improvement across the treatment period on all measures except voluntary EMG; however, no significant differences were seen among the four groups.¹⁶⁶ At least one other study compared conventional intervention, EMGBF, electrical stimulation, and combined stimulation with biofeedback over a 6-week period in individuals with quadriplegia. An examiner who was blinded to the intervention protocol evaluated 45 subjects in the four treatment groups. All groups improved in the parameters evaluated, and no significant difference among groups was noted.¹⁶⁷ These results again emphasize the need to consider carefully cost as well as time and effort for setup and equipment operation in intervention planning.

A study by Carvalho and colleagues¹⁶⁸ studied the use of treadmill gait training with NMES to improve bone mass in people with SCI. Their research study included 21 males with chronic quadriplegia between C4 to C8, randomly assigned to a control and treatment groups. Those in the treatment group received treadmill training with NMES, unweighting the body of 30% to 50% of body weight. The training was done

for 20 minutes, twice a week for 6 months. Results showed that gait training with NMES, even with 30% to 50% unweighting, resulted in the improvement of bone mass in the subjects with chronic quadriplegia. In another study also by Carvalho,¹⁶⁹ NMES with partial body weight support resulted in hypertrophy of the quadriceps femoris muscle also in a population of subjects with quadriplegia. In both studies, NMES was helpful in producing stimulation that allowed for the subjects to advance their lower extremities while walking with body weight supported on the treadmill.

In a few studies, the application of NMES appears to be beneficial in improving impairments associated with SCI. Bittar and Cliquet¹⁷⁰ found that the use of NMES on the quadriceps and anterior tibialis of individuals with SCI was beneficial in that it allowed the feet and ankles to be placed in a better biomechanical position for ambulation. In addition, a study by de Abreu and colleagues¹⁷¹ found improvements in the cross-sectional area of the quadriceps after NMES to these muscles.

In a study by De Biase¹⁷² EMGBF training was noted to have resulted in increased EMG response of the rectus femoris muscle in 20 subjects with chronic SCI.

Upper-Extremity Management

The use of electrically stimulated hand orthotic systems for patients with C6 or higher level SCI have been refined to allow greater functional independence for a select group of patients.^{87,96,97,115,173-175} Because hand function does not occur in a cyclical pattern, the onset and termination of stimulation must be controlled by the patient in some manner, with a myoelectric or contact closing switch.⁹⁶ Multichannel stimulation is then applied with intramuscular electrodes for the flexors and extensors of the fingers and thumb, with computer-configured interplay between the different muscles to achieve a functional grasp. A chest-mounted position transducer (operated by shoulder elevation or depression and protraction or retraction) allows the user to initiate stimulation and lock the stimulation to maintain a grasp as well as unlock it for release. A toggle switch mounted on the chest allows a choice between electronically stimulated lateral or palmar grasp patterns.^{87,97} Some investigators have used contralateral shoulder slings as well as elbow accelerometers to trigger the needed stimulation.^{176,177} Multiple authors have described successful implantation and use, with a few drawbacks, of upper-extremity FES prostheses.¹⁷⁸⁻¹⁸¹ Use of this type of system may allow patients with SCI at the C5 level to operate at the same level of independence (or even a higher level) as those with C6 quadriplegia with tenodesis, gaining the ability to perform more activities of daily living (ADLs) without an attendant. Patients with SCI at the C6 level may be able to manipulate a greater variety of objects without special adaptations.

Lower-Extremity Management

Standing. In an excellent review of the use of FES for the purpose of standing patients with SCI, Gardner and Baker¹⁸² described the easiest approach to stimulating the quadriceps femoris to allow paraplegic clients to stand. More complex systems may incorporate stimulation of the gluteus maximus, gluteus medius, hamstring, adductor magnus, gastrocnemius, and soleus muscles for longer-duration and better-quality standing performance. Multichannel surface and

implantable systems have been and continue to be developed for assistance in sit-stand and transfer activities.¹⁸³⁻¹⁸⁵ Surgical procedures, client selection, and technology are also factors cited in successful interventions. Despite these efforts, the duration of standing with electrically stimulated systems ranges from a few minutes to several hours. The client with SCI may be able to use this technology to perform functional activities that require standing. The use of these systems depends on the functions unavailable to a client without use of the technology, and the ease with which a system can be used and maintained. Peripheral to, but no less important, are the reactions of joints to these interventions. Two studies^{186,187} have reported positive benefits to the structure and functions of lower-extremity joints of adolescents with SCI after participating in FES programs. A recent study has also identified that the physiological responses to standing in SCI may provide a cardiorespiratory stress sufficient to meet minimal requirements for exercise conditioning.¹⁰⁰

Cycling. The use of systems to stimulate reciprocal lower limb motions electrically has increased for stationary cycling. The benefits of these interventions for the client with SCI may relate to prevention of cardiovascular disease in the wheelchair-dependent client. Physiological changes noted with electrically stimulated cycling include improvement of peripheral muscular and cardiovascular fitness, as demonstrated by increased power output after training with leg cycle ergometry.^{85,94,95,101,102} Combining FES and lower-extremity cycling with upper-extremity ergometry induced a higher level of cardiovascular fitness than lower-extremity ergometry alone.¹⁸⁸ Exercise session frequency as little as two times a week induced positive changes in cardiovascular fitness.¹⁸⁹ When testing of clients with paraplegia or quadriplegia is conducted with arm crank ergometry after a training program with electrically stimulated leg cycle ergometry, clients do not demonstrate differences in pretest and posttest measures of hemodynamic and pulmonary responses. These findings may relate to the specificity of the leg exercise training or the presence of a peripheral rather than a central circulatory response to the training procedure.⁹⁵ As previously noted, many cardiovascular factors can be improved and the improvements retained for at least 8 weeks after a program of FES ergometry.

Ambulation. As technology continues to progress, the use of electrically stimulated systems for ambulation may become more practical and useful for the patient with SCI.^{98,190,191} Acceptance and use of the systems by clients outside the clinic have been mixed, but the systems have been shown to have positive effects on characteristics of ambulation.^{149,192} Improvements in functional applications and use will also take place as the ability to select appropriate candidates improves.^{193,194} Benefits of these systems may include increased muscle bulk, a reduced risk of pressure sores and osteoporosis, and psychological benefit. Generally, improvements in functional ability are expected to produce positive psychological factors. Addressing these factors directly, Bradley,¹⁹⁵ in a study measuring the effects of participation in an FES program on the affect of 37 individuals with SCI, demonstrated that positive affect was not significantly altered. Significant changes in negative affect occurred, however, with particular items of hostility and depression evident in those individuals in the treatment group who had unrealistic expectations. The author noted

that these individuals need to be identified and monitored through the course of rehabilitation. Other drawbacks relate to the expense of the equipment and personnel and the lack of long-term efficacy studies. The speed with which a client with a complete SCI is able to walk with electrically stimulated systems remains relatively low (2 to 54 m/min) compared with normal rates of 78 to 90 m/min.^{196,197} Many of the published reports do not provide information on the maximal distance patients are able to walk with these systems, but reported distances range from 100 to 400 m.

Some clients may perceive the technology of electrically stimulated standing and walking as moving them toward a cure for their paralysis. With a complete injury, however, the stimulation occurs passively, without expectation that voluntary control will return.¹⁹⁵ In cases of incomplete injury, electrically stimulated ambulation may assist the client in using and bolstering active control so that movement without the stimulation is more feasible. In considering use of electrically stimulated cycling and ambulation, discussion of the goals of treatment and the costs of the procedure must be conducted openly with the client to allow an educated choice to be made about the use of this expensive technology.

Traumatic Brain Injury (See Chapter 24)

NMES may be a useful tool with clients having sustained brain injury, with potential benefits of managing contractures by increasing ROM, facilitating active control, and reducing spasticity by strengthening the antagonist of a spastic muscle.¹⁹⁸ In cases in which an understanding of the purpose and principles of NMES is not feasible for a client, the comfort of the stimulation may be critical in ensuring its continued use. Comfort may be enhanced by increasing the ramp-on time and selecting waveforms that allow stimulation at lower amplitudes yet still obtain the desired contraction.³⁶ Use of NMES with a client at Rancho Level IV and below is not appropriate because the client may not be able to understand the purpose and meaning of the stimulus and thereby may perceive the stimulus as noxious.

EMGBF applications for clients with brain injury can be similar to those used with stroke, given similar motor presentations.¹⁹⁹ Therapists must consider residual cognitive deficits after brain injury in determining the appropriateness of EMGBF.

Guillain-Barré Syndrome (See Chapter 17)

EMGBF in clients with Guillain-Barré syndrome demonstrated improvements in muscle strength in upper and lower extremities, although inconsistent improvement in functional use of the upper extremities was noted.^{200,201} Treatment regimens consisted of EMGBF for 10 trials per muscle conducted in 45-minute treatment sessions twice a week, in one case for 78 weeks and in the other case for 46 weeks.²⁰¹

Multiple Sclerosis (See Chapter 19)

In a case series, Wahls and colleagues²⁰² found improvements in ambulation of patients with primary or secondary progressive multiple sclerosis. The authors cited the possible positive effects of NMES application on muscle spasm, muscle pain, and disuse atrophy as possible reasons behind the improvements in ambulatory function in their subjects.

Pediatric Applications

Special considerations for pediatric clients need to be understood when addressing the use of electricity. Although contraindications and precautions are the same as for adults, acceptance and tolerance of these devices are not. Fear and apprehension of electricity, for both child and parent, must be addressed. The clinician must take extra care in explanation and demonstration, perhaps on themselves and possibly the parent, before placing the device on the child. Allowing the child as much control as possible in device operation may assist with acceptance. Of course, the attention span of the child must also be addressed.

Cerebral Palsy (See Chapter 12)

The use of NMES with children with cerebral palsy has been addressed to some degree, with several case study reports.²⁰³⁻²⁰⁵ Carmick^{203,204} described a variety of applications with children at 1.6, 6.7, and 10 years of age, integrating NMES into a treatment regimen that focused on a “task-oriented model of motor learning.” Improvements were noted in upper- and lower-extremity movement and functional use across a variety of tasks appropriate to the age and the movement dysfunction each child demonstrated. In a study by Nunes and colleagues,²⁰⁶ the once-a-week application of NMES on the tibialis anterior muscle of 10 children with spastic hemiplegia resulted in improvements in gross motor function, passive ROM of ankle dorsiflexion, and muscle strength.

Ozer and colleagues²⁰⁷ studied the effect of using NMES combined with dynamic bracing and found the intervention to be more effective than either alone in reducing upper-extremity spasticity in their sample of children with spastic hemiplegic cerebral palsy. A similar study by Postans and colleagues²⁰⁸ found that NMES combined with dynamic splinting reduced upper-limb contractures in children with cerebral palsy. In another study,²⁰⁹ the application of NMES to the gluteus medius improved gait parameters in children with spastic diplegia.

Advancements in technology have allowed the use of EMGBF in increasing contexts, such as the computer-assisted feedback (CAF) system, which can be used to provide feedback about muscle activity during ambulation.²¹⁰ Data examining use of this system to provide feedback about the level of triceps surae activity during gait of children with cerebral palsy suggest potential improvements in gait symmetry, velocity, and appropriate muscle activation patterns as a result of this intervention. Use of this modality as an adjunct to physical therapy may prove beneficial.

Spina Bifida (See Chapter 15)

Five subjects with spina bifida (aged 5 to 21 years) were treated with daily NMES over an 8-week period to strengthen the quadriceps femoris muscles. Increases in maximal quadriceps torque production were observed in two of the five subjects in the treated limb. Improvements in functional activity speeds were noted for all of the subjects. Lack of improvement in torque production by three subjects was speculated to be related to lack of adherence to the exercise regimen and the heterogeneity of the subject sample.²¹¹

Spinal Muscular Atrophy (See Chapter 13)

One study has reported the use of low-intensity electrical stimulation in children with types II and III spinal muscular atrophy in an attempt to determine any effect on arm

strength and function. After 6 to 12 months of stimulation no statistically significant differences were noted between experimental and placebo-control arms in strength, muscle mass, or function.²¹²

Scoliosis

Axelgaard and Brown⁸⁴ demonstrated in the 1970s that surface NMES could reduce idiopathic scoliosis. Criteria for this treatment required curves measuring 20 to 45 degrees by the Cobb method, at least 1 year of growth remaining, idiopathic and progressive nature of the curve, cooperative and psychologically stable and compliant patient, and tolerance of the stimulation. Electrodes were placed laterally over the midaxillary line on the convex side. A paraspinous location on the convex side was sometimes used. Settings included a pulse duration of 220 μ s, frequency of 25 pps, and an on-off ratio of 6 seconds on and 6 seconds off. The treatment time was gradually increased to 8 hours of stimulation per day (the stimulation was typically done at night if tolerated). High success and low dropout rates were reported.²¹³ Others, however, reported much lower success rates.²¹⁴ Intolerance of the treatment resulting in low compliance may be the cause of these differences. This disorder is much more common in adolescent girls. When NMES first was introduced for scoliosis, the uncomfortable and cosmetically undesirable Milwaukee brace was still the norm for treatment. With more advanced materials and orthotic management that is much more acceptable cosmetically, the use of NMES in scoliosis management has significantly declined.

Contraindications and Precautions

Any electrical stimulation application is contraindicated for clients who have epilepsy or demand-type pacemakers. In addition, contraindications exist to applications over the transthoracic area or the uterus in pregnancy as well as in a cancerous area and the carotid sinus. Other factors require precaution but are not strict contraindications, such as sensory deficits, skin problems (sensitivity to stimulation, electrodes, or gel; edema; open wounds), tolerance of stimulation intensity sufficient to elicit muscle contraction, client's capability to participate in the training process, and financial considerations.^{56-58,215}

Matthews and colleagues²¹⁶ reported changes in blood pressure and heart rate suggestive of autonomic hyperreflexia when electrical stimulation was applied in seven subjects with SCI above the T6 level. FES to the quadriceps produced the noted changes as stimulation intensity was increased. The mechanism for this reaction is unclear. Clinicians should monitor vital signs in clients with SCI (and possibly all clients), at least during the initial application of electrical stimulation.

Use of stimulation modalities by clients outside clinical therapy sessions requires a degree of cooperation and motivation to take care of the stimulation unit, use it as instructed, and observe precautions. Long-term use of NMES (e.g., FES) may not be feasible for clients who do not have the financial resources (insurance or otherwise) to rent or purchase a unit

or do not have reasonable access to support for equipment maintenance.

EMGBF does not require as many precautions because the procedure only monitors muscle activity. This form of feedback by the client requires a basic level of attention and cognitive skill to understand the meaning of, as well as act on, the feedback to change muscle performance. Client motivation and interest in use of this modality are also required because the client must be able to develop sensitivity to the degree of muscle activation independently so that feedback is no longer required. EMGBF may be used in some instances that do not require the cognitive skills of the client to use this information, such as an evaluative tool for the therapist to gather information about muscle activation to plan intervention strategies.

SUMMARY

The concepts, descriptions, and applications of electrodiagnosis presented in this chapter are intended to enrich the therapist's comprehension of these studies as applied to clients with neurological conditions. Integration of the results of these tests in differential diagnosis and in subsequent planning of intervention is invaluable.

Clearly the use of NMES and EMGBF has numerous possibilities with clients of all ages who have sustained neurological insult or injury. Improvement of motor control has been supported in some applications, although well controlled group research in populations other than stroke and adult SCI is lacking. This underscores the need for further investigation to support the evidence for these modalities. As the therapy environment continues to change in response to time and funding constraints, therapists must carefully evaluate the benefits of a variety of available tools to assist their clients in regaining motor control and functional ability. A benefit of FES or EMGBF is the ability of the client to work autonomously (i.e., at home) after becoming familiar with the treatment regimen, with the therapist periodically updating a home program. This protocol allows physical and occupational therapy time to be used for direct intervention. NMES and EMGBF may efficiently assist in attaining improvement in control, and may also be used in the context of functional activities, but these tools alone will not create functional changes. The case studies that follow further integrate these concepts in actual cases.

CASE STUDIES

Part 1: Electrodiagnosis

The following are cases studies from patients seen in the electrophysiology lab. The reader will receive the full benefit of studying the cases by first reading the evaluation and establishing a set of differential possible diagnoses and dysfunctions of the nervous system. The reader can then progress through the report, test by test and challenge the differential diagnoses. The conclusion of the study is provided. NOTE: Please refer to [Appendix 33-A](#) for a key to all the abbreviations found in the figures and tables used in the Case Studies.

CASE STUDY 33-1

The patient is a right-handed 55-year-old general contractor. He reports that 3 months prior, he purchased an exercise cycle which he started using quite vehemently. Following this bout of exercise, he started noticing muscle soreness in his hamstrings and right calf. He now reports fatigue and twitching of the muscles in both shoulders and right leg. He also has an achy back in the middle of his thoracic spine. There is no numbness. He does not have any particular stressors except for the decrease in business brought about by the change in the economy. He never lost control of his sphincters. His thinking is clear.

Prior medical history is significant only for skin cancers which were excised from his back last year and a meniscal tear. He has no known allergies and is lactose intolerant. On questioning, the patient does report hunting and eating the game he kills but has no other exposure to heavy metals.

Physical examination shows that walks unassisted but has a slight foot drop on the right side. From an orthopedic standpoint there is some crepitus with mobilization of the left shoulder; otherwise, ROM is full, including in the cervical spine. There is no Lhermitte sign. Inspection shows significant fasciculations in the right quadriceps and both upper arms; a mild facial asymmetry from a previously fractured upper maxilla on the left side; easily palpated dorsalis pedis pulse on both sides; and mild atrophy of the right calf, which is 1.5 cm smaller than that of the left side. Grip strength is 80 lb on the right side and 60 lb on the left side. MMT reveals a decrease in the strength of the extensor and flexor hallucis longus on the right side, 3+/5 (4/5 on the left side); right tibialis anterior, 3/5 (4/5 on the left side); right to gastrocnemius, 3-/5; right quadriceps, 4-/5; and intrinsic muscles, 4/5 on both sides. The patient fully detects the 3.61 Semmes-Weinstein monofilament in the lower extremities and the 2.83 monofilament in the upper extremities, which is normal. Muscle stretch reflexes are 2+ in the upper extremities and 1+ in the lower extremities; there is no Hoffmann sign in either hand; plantar cutaneous reflex is equivocal; cranial nerve scan is normal including extraocular movements. Speech is normal.

SUMMARY OF NERVE CONDUCTION FINDINGS

Motor distal latencies are normal in all nerves tested. Conduction velocities in all segments are normal. Amplitudes of the

responses are slightly decreased or at the lower limit of normal. Sensory distal latencies, amplitudes, and conduction velocities are all within normal limits.

F-wave latencies are slightly delayed in the right peroneal and tibial nerves and normal in the left peroneal and right median nerves.

H-reflex latencies are delayed on both sides.

SUMMARY OF ELECTROMYOGRAPHIC FINDINGS

Insertional activity was increased in the right vastus medialis, tibialis anterior, gastrocnemius, extensor feature brevis, and left tibialis anterior. Fasciculations were found in the right deltoid, triceps, first dorsal interosseous, vastus medialis, and extensor digitorum brevis, as well as in the left gastrocnemius and thoracic paraspinals. Denervation potentials were found in every muscle sampled (including the tongue) except the right biceps. Analysis of the MUAPs showed them to be polyphasic in the first dorsal interosseous of the right hand, right tibialis anterior, right gastrocnemius, left extensor digitorum brevis, and left tibialis anterior. Recruitment pattern was reduced in the right biceps and in the tibialis anterior, gastrocnemius, and extensor digitorum brevis on both sides. Firing rate of the MUAPs was fast in the extensor digitorum brevis on both sides as well as in the right gastrocnemius and tibialis anterior. Refer to Tables 33-2 to 33-6, and Figures 33-7 and 33-8 for a summary of various nerve conduction studies performed on this patient.

CONCLUSIONS

The results of this study are abnormal. Findings include normal sensory distal latencies, nerve conduction, and amplitudes; normal motor distal latencies and nerve conduction, slightly reduced amplitudes; widespread denervation potentials in three limbs, paraspinals, and the tongue; fasciculations. This is consistent with an acquired motor neuron disorder.

Based on this study, laboratory tests, and the physical examination, the referring neurologist diagnosed patient 1 with ALS.

PROGNOSIS

Poor.

INTERVENTIONS

The patient was issued ankle-foot orthoses, first on the right side, then the left. He later required a walker, then a powered wheelchair and CPAP. He died 12 months after this study.

CASE STUDY 33-2

The patient is a right-handed, 49-year-old administrative assistant. She reports a 1-year history of numbness in the right hand. Initially, this numbness was present only intermittently. The numbness involves mostly the thumb and index and long fingers. Recently the numbness has been present every morning. This impairs her ability to sleep. The patient also reports difficulty with writing. She has a positive flick sign. Finally, she reports that ibuprofen has been of some help in the sense

that she no longer wakes up in the middle of the night. She has no numbness in her toes. There are no complaints regarding her cervical spine.

Prior medical history is essentially unremarkable and includes only uterine fibroids. The patient has had a hysterectomy. There are no known allergies.

Physical examination shows that the patient walks unassisted with a normal gait pattern. Inspection shows slight

CASE STUDY 33-2—cont'd

arthritic changes at the base of the right thumb but no noticeable muscle atrophy in the intrinsic muscles or thenar eminence. Grip strength is 45 lb on the left side and 55 lb on the right side. Sensation is slightly decreased: the patient detects the 3.61 Semmes-Weinstein monofilament at the tip of the fingers of the right hand. Result of the Phalen test is positive, and the reverse Phalen test causes wrist pain; the Finkelstein test also causes wrist pain. “Okay” sign is normal. Cervical ROM is full in all directions; result of the Spurling test is negative. Muscle stretch reflexes are 2+ and symmetrical. Cranial nerve scan is normal.

Based on this physical examination, what is your clinical impression?

SUMMARY OF NERVE CONDUCTION FINDINGS

The median motor distal latency is prolonged compared with the ipsilateral ulnar motor distal latency (2.05 ms difference). Amplitudes of the median motor responses are decreased. The ulnar motor distal latency, amplitudes, and conduction velocities are within normal limits.

The median sensory distal latencies are significantly delayed. Radial and ulnar sensory distal latencies are normal. The combined sensory index (CSI) is 7.1 (cutoff value for normal conduction for the CSI is 1.3).

Median F-wave latencies are at the upper limit of normal for a patient this height. Ulnar F-wave latencies are normal.

SUMMARY OF ELECTROMYOGRAPHIC FINDINGS

Insertional activity was normal in all muscles sampled. A few denervation potentials were found at rest in the abductor

pollicis brevis (fibrillation potentials). Analysis of the MUAPs showed them to be of normal configuration, phases, and recruitment in all muscles tested except in the abductor pollicis brevis. In this muscle, motor units were slightly polyphasic. Refer to [Figure 33-9](#), and to [Tables 33-7 to 33-10](#) for a summary of various nerve conduction studies performed on this patient.

CONCLUSIONS

This study is abnormal. Findings are consistent with a moderate to severe mononeuropathic process involving the right median nerve at or distal to the wrist. This is evidenced by delayed median motor and sensory distal latencies, decreased amplitudes of the median motor responses, and abnormal electromyographic findings in the abductor pollicis brevis only.

Because the ipsilateral ulnar motor and ulnar and radial sensory NCS findings are normal and because the needle EMG findings are limited to the abductor pollicis brevis, a polyneuropathic, plexopathic, or a radiculopathic process is unlikely in the right upper extremity.

PROGNOSIS

Excellent. The patient and her surgeon elected to go ahead with a carpal tunnel release.

INTERVENTIONS

The patient started rehabilitation after surgery and went on to a full recovery in 2 months.

Figure 33-9 ■ Sensory nerve action potential (SNAP) difference: median (*above*) and ulnar (*below*).

CASE STUDY 33-3

The patient is a right-handed, 86-year-old retired internist. He consults today for assessment of the strength in his lower extremities and numbness in his right hand. He reports having difficulty going up the 13 steps he has at home and states that his right thumb and index and middle fingers feel like “Band-Aids are on too tight at the tip of the fingers.”

Prior medical history includes Waldenström macroglobulinemia, gastrectomy for recurrent bleeding, 7+ years of taking amiodarone, hypothyroid.

Physical examination shows that the patient walks with a bilateral foot drop and increased base of support. MMT shows decrease in the strength of ankle dorsiflexors on both sides, noted 3+/5; right quadriceps, 4/5; foot intrinsic muscles, 3/5; hand intrinsic muscles, 3+/5; right triceps muscle, 3+/5. All other muscles groups have normal strength. Grip strength is 30 lb on the right side and 35 lb on the left side. Sensation is decreased to the 3.61 Semmes-Weinstein monofilament at the sole of the right foot; the patient detects the 4.31 filament. It is also decreased to the 2.83 monofilament at the palm of the right hand; the patient detects the 3.61 filament. ROM of the left shoulder is impaired in abduction. Cervical ROM is within normal limits. Spurling’s test is negative. Toes are down-going

with the plantar cutaneous reflex; there is no Hoffmann sign in the hands. Muscle stretch reflexes are 2+ in the quadriceps and upper extremities, 1+ at the ankle. Cranial nerve scan is normal. Romberg sign is positive. Refer to [Figure 33-10](#), and [Tables 33-11 to 33-15](#) for a summary of various nerve conduction studies performed on this patient.

CONCLUSIONS

The study findings are abnormal. Findings are consistent with an axonal loss, mixed sensorimotor polyneuropathic process. This is evidenced by normal motor and sensory distal latencies, absent or significantly reduced amplitudes in both motor and sensory responses, delayed F-wave and H-reflex latencies, denervation in the distal more than the proximal muscles, and no findings in the lumbar paraspinals.

PROGNOSIS

Fair to good. Improvement expected over the next 4 to 6 months with medical management of the polyneuropathy.

INTERVENTIONS

The patient started balance rehabilitation and muscle strengthening and ultimately met his goal of safely climbing up and down his stairs.

Figure 33-10 ■ Needle electromyography. **A**, Polyphasic motor unit action potentials (MUAPs) in the right peroneus longus. **B**, Essentially one MUAP in the foot dorsal interossei.

Part 2: Neuromuscular Electrical Stimulation and Electromyographic Biofeedback

CASE STUDY 33-4

A 68-year-old woman is referred 3 weeks after left middle cerebral artery CVA with residual right hemiparesis affecting the upper extremity to a greater degree than the lower extremity. The client's left extremities appear well controlled with at least functional strength. She exhibits a two-fingerbreadth right shoulder subluxation, with pain at the extremes of shoulder flexion (150 degrees), abduction (135 degrees), and external rotation (30 degrees), and hypertonicity in a stereotypical flexor synergy pattern affecting the shoulder horizontal adductors and internal rotators and elbow, wrist, and finger flexors. She is beginning to develop upper-extremity movement with the ability to shrug her shoulder, abduct, and flex through partial range (with elbow flexed), full-range elbow flexion, partial-range elbow extension against gravity, and no wrist or finger extension. Right lower-extremity ROM is within normal limits, although control is limited at the ankle (dorsiflexion only with hip and knee flexion, no eversion actively) and knee control is decreased (reduced eccentric quadriceps control, difficulty isolating knee flexion with hip extension). Ambulation is

accomplished with the use of a quad cane and an articulating AFO on the right for limited distances with standby assistance. This client lives at home with her husband, who is very supportive of her rehabilitation. Both of them are retired, but they have an active calendar of participation in volunteer and leisure activities. Insurance coverage is good.

PROGNOSIS

Independent or isolated motor function is promising for continued improvement in the condition of the client. Lower-extremity impairments are expected to be minimized as the return of motor control progresses. Quad cane use should continue until isolated hip and knee action improves. A need for AFO is expected for an indefinite time period.

INTERVENTION

Interventions including EMG or NMES would assist in accelerating improvement in functional control. [Table 33-16](#) provides the various intervention options using NMES-EMGBF for this patient.

TABLE 33-16 ■ NMES/EMGBF OPTIONS

CLIENT PROBLEM	GOALS	MODALITY PARAMETERS	MEASURES TO DETERMINE EFFICACY	CONSIDERATIONS
Shoulder subluxation	Decrease subluxation to 1 finger-width, with pain manageable within patient's daily routine.	Portable FES for home use, begin with 10:30 second on-off ratio for 15-minute periods tid, amplitude to generate muscle contraction without shoulder elevation. Increase on time and treatment time as tolerated so that reduction is maintained majority of day.	Trial use for 1 month. Measure amount of palpable subluxation, pain-free ROM; if improvement is not observed, discontinue FES, with instruction to maintain shoulder flexibility, consider lapboard or arm tray when sitting, support when standing.	<ol style="list-style-type: none"> 1. Requires rental of portable FES unit; patient/family compliance is needed for success in home program. 2. Cost of rental of FES and supplies. 3. Frequent use for reduction of subluxation requires close monitoring of skin for possible reactions to stimulation, gel, or electrodes. 4. Integrate scapular movement and stabilization exercises into program
Lack of active ankle dorsiflexion	Increase active control of ankle dorsiflexion with knee extended, allowing heel-strike without AFO for short-distance ambulation.	FES twice daily for 15-minute duration; 10:20 second on-off ratio with slow ramping on-off; as active movement improves, consider EMGBF to further focus attention on balanced dorsiflexion (with eversion). Use of heelswitch requires decreased ramp time to minimum patient can tolerate. Switch should activate at heel-off to control dorsiflexion through the swing phase.	Monitor each session for increased active dorsiflexion in sitting, standing, and ambulation. Integrate use of heelswitch during ambulation without AFO. Trial use over 2 to 3 weeks. Discontinue if not seeing increase in voluntary control; compensate with AFO.	<ol style="list-style-type: none"> 1. If client rents unit for shoulder subluxation, may also use stimulator at home instead of requiring time during therapy session. 2. Similar cost, convenience issues as above. 3. Additional education necessary if stimulator settings are to be switched for dorsiflexion and shoulder subluxation interventions.

Continued

TABLE 33-16 ■ NMES/EMGBF OPTIONS—cont'd

CLIENT PROBLEM	GOALS	MODALITY PARAMETERS	MEASURES TO DETERMINE EFFICACY	CONSIDERATIONS
Lack of full active wrist and finger extension	Control of active wrist and finger extension to allow release in gross grasp.	NMES and/or EMGBF twice a day for 10-minute sessions initially, with gradual increase in duration up to 20 minutes if fatigue does not alter the quality of the contractions. Other parameters as described for ankle dorsiflexion.	Trial period of 2 to 3 weeks; discontinue if voluntary motion is not changing significantly. Active movement in finger extensors with wrist in neutral position. Functional ability to release grasp of objects of varying shapes and sizes.	May use portable stimulator as described for ankle or shoulder interventions, with similar considerations.
Muscle imbalance, lack of right upper-extremity functional movement	Decrease hypertonicity in flexor muscle groups; increase extensor control for gross arm movements (e.g., positioning).	EMGBF to decrease flexor muscle activity (resting and with passive movement) and increase extensor activity.	Speed and control with reciprocal elbow motions, especially with extension. Use of this motion for functional activity (e.g., positioning the arm, reaching activity).	Focus on increased extensor control may prove more effective than simply decreasing flexor hyperactivity.

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will,

when available, provide a link for the reader to a Medline abstract for the article cited. There are 216 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

APPENDIX 33-A ■ Key to Abbreviations

The following is a key to the abbreviations used in the Case Studies in this chapter.

μV = microvolts

ABD POLL BREVIS = abductor pollicis brevis

ADM = abductor digiti minimi

Amp PK-PK = peak to peak amplitude

AMP = amplitude

APB = abductor pollicis brevis

AR = active recording

bel. = below

ab. = above

CM = centimeters

COMM PERONEAL = common peroneal nerve

D INTEROSS = dorsal interosseus

EDB = extensor digitorum brevis

EMG = electromyography

EXT DIG BREV = extensor digitorum brevis

EXT DIG COMM = extensor digitorum communis

FASC = fasciculation potentials

FLEX CARPI RAD = flexor carpi radialis

FHB = flexor hallucis brevis

FIB = fibrillation potentials

Fib head = head of the fibula

FIRST D INTEROSS = first dorsal interosseus

GASTROCN = gastrocnemius

H AMP = H reflex amplitude

H LAT = H reflex latency

H/M APLM = Ratio between the amplitudes of the H-reflex and the M wave or motor response

IA = insertional activity

L = left

LAT MALLEOLUS = lateral malleolus

LAT = latency

LL = lower leg

LUMB PSP = lumbar paraspinals

M/S = meters per second

MAX F AMP = maximum F wave amplitude

MAX F LAT = maximum F wave latency

MAX F-M = Maximum difference in F wave and M latencies

Med = median

MIN F LAT = minimum F wave latency

MIN F-M = Minimum difference in F wave and M latencies

msec = milliseconds

MUAP = motor unit action potentials

MV = millivolts

PERON LONGUS = peroneus longus

POLYPH = polyphasic

CERV PSP = cervical

PSW = positive sharp waves

R = right REC SITE = recording site

SNAP = sensory nerve action potential

TEMP = temperature

THOR PSP = thoracic paraspinals

TIB ANTERIOR = tibialis anterior

VAST MED = vastus medialis

VEL PK = peak velocity

VEL = velocity

vs = versus

Uln = ulnar

KEY TERMS

ankle-foot orthosis (AFO)
 knee-ankle-foot orthosis (KAFO)
 thoracolumbosacral orthosis (TLSO)
 anterior or toe lever arm
 double-adjustable ankle joint

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify and analyze the force systems produced by the use of an orthosis.
2. Comprehend the prescription rationale gained from an orthotic evaluation for individuals with neuromuscular dysfunctions.
3. Identify and differentiate the variables considered by the orthotist to optimize outcomes during orthotic intervention.

OVERVIEW

An orthosis is an external device that produces a force that biomechanically affects the body to correct, support, or stabilize the trunk, the head, and/or an extremity. The goals in patient care with orthotic use vary from temporary application to permanent usage to maintain improvement. Orthoses are named by the sections of the body to which they are applied. For example, an orthosis that controls and covers the ankle and foot is called an *ankle-foot orthosis* (AFO). The abbreviations for the device are used by professionals in clinical documentation. Many factors enter into the decision regarding use and type of orthosis, and these will be discussed later. It is essential that the least complicated and most cost-effective orthosis be applied to the patient. The rehabilitation team must build a priority list of desired outcomes and accept that sometimes all of the items on the list may not be achieved by either the orthosis or the patient-team combination. At the very least, care must be attempted in stages because the patient's condition changes or other medical concerns may arise. For example, an excessive number of custom-made and custom-fit plastic AFOs have been issued because they are "more cosmetic and lighter" than AFOs made of metal and leather material. There are times when all higher-priority goals can be achieved so that down the list the goals of cosmesis and light weight can be considered (Table 34-1). However, in the case of neuropathy of the foot, significant risk would be incurred by providing a total contact AFO made of plastic to keep it lightweight. A double-upright metal AFO with a well-fitting extra-depth shoe with a custom accommodative insert would fit the patient's needs and take into consideration the sensory and motor changes within the lower extremity. Effective coordination and communication between health professionals in development of patient goals is essential during the evaluation process. For example, a design criteria omission as simple as placing a loop closure on the side that the patient cannot reach will prohibit the use of the orthotic device. A sound understanding of biomechanical and orthotic principles as well as

skilled patient management techniques must be used to be successful with patients who require orthoses.

There are similarities in orthotic management of orthopedic and neurologically impaired patients; however, the neurological population presents additional factors that challenge prescription criteria and outcomes for the rehabilitation team. Lack of proprioception, impairments in sensation, and spasticity are some of these special considerations. Concurrent medical issues, problems with communication, and caregivers may complicate patient management.

The advancements in and access to medical technology have had a profound effect in the field of orthotics. The evolution of plastic, composite, and metals fabrication technology has dramatically improved the ability to control, support, and protect all areas of the human body. Today, patients are fit for custom and prefabricated orthotic devices that provide a variety of functions in both a timely and cost-effective manner. These factors have led physicians to routinely prescribe orthoses for a wide range of medical conditions, whereas in prior decades lack of availability and shortage of experienced orthotists restricted patient access and narrowed the use of orthoses.¹ Orthoses are important options for postoperative management, acute fracture management, and adjunct treatment, in addition to more traditional uses. For many, the proliferation of the prefabricated orthosis signaled a dilution of quality orthotic care, but in reality it has had the opposite effect. These readily available, cost-effective orthoses have not taken orthoses out of the hands of the orthotist but rather have moved them into the minds of treating professionals. There has been continued growth of new and improved orthoses and expansion into other areas of treatment previously lacking in orthotic management. For example, positional and corrective orthoses can be used for premature and newborn infants, and a wide range of sizes of orthoses that previously were made only in adult sizes have become available for pediatric patients. As with any new technological advancement, there has been incorrect application and use. It is not that many of these prefabricated orthoses are difficult to

TABLE 34-1 ■ COMPARISON OF METAL AND PLASTIC ORTHOSES

FACTOR	METAL AND LEATHER	POLYPROPYLENE	LAMINATION OR GRAPHITE	POLYETHYLENE
Adjustability	Yes	Yes, with heat	No	Yes, with heat
Patient changes shoes	No	Yes	Yes	Yes
Weight-bearing strength	Yes	Yes	Yes	No
Skin at risk	Yes	Yes, close observation	No	Yes
Best spinal use	No	Yes	No	Yes
Long-term wear	Yes	Less	Yes	Least
Weight (lightest at 1)	4	2	3	1
Adjustability to changing clinical picture	Yes	Limited unless initial articulation fabricated	No	No
Short-term need	Yes	Yes	Yes	Yes
Requires corrective force with good patient sensation	Fair	Good	Fair	Good
Patient compliance, ability, or direction	Best	Questionable	No	Fair
Ability of clinician to change angulation, ankle or knee	Best	Limited*	No	Not indicated for weight bearing
Upper-extremity fabrication—direct mold highest frequency	Limited	Yes	Limited	Yes

*Use in combination with metal joints produces best results.

apply; rather, there has been lack of a clear understanding of the indications, contraindications, and limitations these devices present to the orthotist and other health professionals such as occupational and physical therapists.

Advancements in technology have allowed the use of lighter, stronger materials in the fabrication of lower-extremity orthotics. Specifically, the substance called *pre-impregnated carbon* is a graphite fabric with an exact amount of resin and catalyst already incorporated into the material. With the fibers properly directed over a model, it can be formed with heat. Graphite in other forms has been used in both prosthetics and orthotics for years. However, it had limited acceptance in orthotics because it did not significantly reduce the weight of the orthosis compared with other materials. It also lacked the properties to enable modification of the orthosis after the lamination process. The preimpregnated graphite has a dramatically reduced weight, still maintains its strength, and gives the orthotist the opportunity to use the dynamics of loading and response during the gait cycle. This allows for assistance in both the swing and stance phases of gait (Figure 34-1). A clinical example at the end of this chapter demonstrates this need in patient management.

Another significant advancement in component technology has been the introduction of weight-activated orthotic knee joints. Although available in prosthetics for decades, the development of a lightweight, compact knee joint that would allow a patient to have knee stability during stance² and clearance during swing phase has been elusive until recently. Before this, the available knee joints for knee-ankle-foot orthoses (KAFOs) involved some type of locking mechanism that remained locked throughout the gait cycle. The joint provided stabilization of the weak quadriceps

Figure 34-1 ■ New lightweight materials. (Courtesy Otto Bock Healthcare.)

musculature during stance but kept the knee in a fully extended position, making advancement of the limb in swing more difficult for the patient. There are specific indications and contraindications for stance control KAFOs, but early results are promising. This feature can significantly reduce energy output,³ as it is not necessary to raise the center of gravity to clear the locked knee during swing phase. This improves patient safety when walking on uneven surfaces. New technology for externally powered knee orthoses has just entered the market. These “bionic legs” are robotic aids worn during therapy sessions for gait training. They assist and augment the strength of the patient’s muscle and are most typically used in post–cerebrovascular accident (CVA) rehabilitation. Once the patient has achieved functional improvements, the use of the orthosis is discontinued.

Other advancements in orthotic technology include the development of neuroprosthetic devices. These devices act through circuitry and programming to substitute for a deficit in the neural system. Functional electrical stimulation (FES) is a method of applying low-level electrical currents to motor nerves to restore function. In the 1960s the application of FES for foot drop was demonstrated by using a simple single channel to stimulate the common peroneal nerve to activate the ankle dorsiflexors. FES has widespread applications in many other neuroprosthetic devices such as cardiac pacemakers, cochlear stimulators, bladder stimulators, and phrenic nerve stimulators. Until recently, FES devices to provide ambulation assistance were large, unreliable, complex, and restricted to use in a therapy setting. The FES used in neurological rehabilitation attempts to unmask existing voluntary control (if any) and/or initiate dormant activity of the nerves and muscles. For FES to be used, the patient must have an upper motor neuron lesion. This means the nerve-to-muscle pathway is intact and the reflex arc is undamaged. Goals of FES address many rehabilitative outcomes. FES can reduce spasticity, synergy patterns, swelling, and blood clot formation as well as maintaining range of motion (ROM). FES used in gait can improve overall walking abilities by dorsiflexing the foot during swing to provide foot clearance, control initial contact, increase safety, decrease energy expenditure, and retrain muscles. FES has some application in the upper extremity as well, although at this time it is purely in a therapeutic setting. Currently, there are several FES units for foot drop on the market. These devices are used by patients in their daily lives and are not limited to the rehabilitation setting. The WalkAide from Innovative Neurotronics (Figure 34-2) and NESS L300 from Bioness (Figure 34-3) both function to provide dorsiflexion during the swing phase by stimulating the peroneal nerve. An ideal candidate for these devices must have an upper motor neuron lesion, good control of the knee joint, and drop foot. Common neurological conditions in which these devices are used are CVA and multiple sclerosis (MS). Both devices involve some sort of sensor to determine when the patient is initializing the swing phase of the gait cycle and send an electrical stimulus to the nerve to dorsiflex the foot. Advantages of functional FES over traditional orthotic management for foot drop are that it shifts an orthotic device from being a passive support to providing active assistance. FES stimulates the patient’s muscles to lift the foot, rather than acting as a passive splint to hold the foot.

Future developments in the field of orthotics will provide external power and support for patients lacking muscular control. There are already prototypes of systems that can be applied to a patient with paraplegia to allow him or her to stand and walk. “Bionic” orthotics will incorporate microchips and computer programming to provide a degree of artificial intelligence to devices. This will allow the orthosis to change its setting according to the patient’s input or position during the specific task or part of the gait cycle. In more traditional types of orthotics, the materials used will continue to become lighter, stronger, and more versatile.

Figure 34-3 ■ The NESS L300 Foot Drop System.

No discussion of the delivery of health care services within the United States would be complete or accurate without acknowledging the effects of governmental and private regulations. The earlier discussion regarding a dramatic increase in usage has raised the medical justification debate about the use of orthotic intervention.

Governmental regulations have dramatically changed the course of the orthotic profession, beginning with the Medicare program, to diagnosis-related groups (DRGs), managed care, and, soon, qualified providers. Medicare was the first national program to cover the cost of both orthotic and prosthetic devices. Before that time only a special few had access to “braces and limbs.” DRGs put the responsibility of paying for prescribed orthoses into the hands of the local hospital. Once a specific diagnosis was made, the government would pay a specified amount as reimbursement, leaving the decision of how to manage the patient’s care with the physician and hospital. This policy change created many new innovations. Hospitals, interested in reducing the length of hospital stays, challenged physicians to change the way they treated their patients. Patients are no longer immobilized for long periods in hospital beds and are sent home sooner, or sent to a less acute setting or a skilled nursing facility. The use of orthotic devices to expedite care and for precautionary care during hospitalization has increased dramatically. The use of halo fixation systems, thoracolumbosacral orthoses (TLSOs), fracture orthoses, and contracture-preventing orthoses are a few examples of orthotic care that is helping to reduce length of stay. Another significant effect of the DRG decade on orthotics was the need to reduce delivery times and be as cost-effective as possible. Orthoses needed to be delivered in hours, not days. Careful evaluation developed to determine whether a prefabricated, custom-fit,

or custom-made orthosis was most appropriate. A prefabricated orthosis is one that is available in “off-the-shelf” sizing and is intended for temporary use. Commonly used prefabricated items are commonly kept in stock by the orthotic provider. Custom-fit orthoses are customizable devices that can be modified to optimize the fit to each individual patient. These devices are intended for use on a more definitive basis, and are often appropriate when the patient has adequate sensation and normal anatomy. Custom-made orthoses require very specific measurements or models of the patient to be obtained for the most specific fit and to accommodate any deformity. These devices are time and labor intensive and are worn definitively when the patient’s condition is permanent or when his or her condition or anatomy does not facilitate fitting of a more basic device. Challenges to improve traditional methods of fabrication, better materials, and higher usage spawned the rapid growth of a wide range of orthoses for patient care. There is no reason to believe that this trend will slow as the population ages.

Professional relationships between physical and occupational therapy and orthotics are critical as the evolution of managed care continues. Identifying patient functional goals and a variety of evidence-based care is critical for patient care and clinical outcomes. Orthotic use must be based on proven evidence-based care specific to the profession. In that spirit, a broad overview of the evaluation, prognosis, and intervention of orthotics in neurological rehabilitation is presented.

BASIC ORTHOTIC FUNCTIONS

Alignment

Alignment of the extremities and spine is a common function in orthotic prescription. The orthosis can provide either temporary or permanent function. A TLSO may be prescribed for stabilizing alignment after spinal fusion in the case of an unstable spinal cord injury (refer to Chapter 16). A supramalleolar orthosis (SMO) is commonly prescribed to hold the foot in proper alignment. When the goal of orthotic intervention is to correct alignment to a position well tolerated by the overlying soft tissue and/or the malalignment is a result of a muscle weakness, the new position should stabilize the joint. Clinicians need to remember that aligning one joint may result in the proximal or distal joint being placed in malalignment. An example of this is a genu valgum knee, which may seem easily corrected. However, changes in alignment result in adjustments by the other joints up and down the kinetic chain. Questions such as “Does the subtalar joint have the mobility to pronate?” must be asked and answered.

Stability

Stability is often required for the patient with neurological deficits. These patients frequently lack the muscle control and strength necessary to maintain trunk balance or to ambulate. Patients with muscular dystrophy benefit from TLSOs to help maintain trunk stability, achieve sitting balance, and perform safer transfers. However, the decision regarding an orthosis must take into consideration maximum stability and flexibility while not restraining breathing capacity. An AFO that limits both dorsiflexion and plantarflexion can stabilize the ankle and the knee for the patient

who has had a CVA. Although this patient may initially require medial and lateral ankle stability, controlling the anterior posterior lever arms at the ankle can also provide knee stability and prevent future knee impairments. The orthosis functions in the sagittal plane by producing a posterior force that extends the knee during the stance phase of gait, as most patients requiring this type of stabilization have a foot-flat gait instead of a normal initial heel-strike pattern.

Contracture Reduction

Contracture reduction is the goal for many orthotic applications in patients with neurological involvement. The increase in the use of these types of orthoses has been dramatic, as even slight increases in contractures can make the difference between nonambulatory function and ambulatory community participation. Increased awareness and proactive use of prefabricated orthoses have become routine during periods of inactivity, associated surgical procedures, and “sound side” prevention. These types of orthoses can be either dynamic or static and are used in conjunction with various therapeutic modalities to reduce the contracture. Dynamic contracture-reducing orthoses use a spring-type mechanism that applies a low force to a joint over an extended period of time to gain ROM. Static-type orthoses range from serial casts, in which a manual stretch is placed over the joint, to custom-made cylindrical devices designed to spread force over larger areas, to custom-fit devices with some type of quick adjustability. Dynamic-type orthoses are usually contraindicated for the patient with a neurological disorder. Low-tension stretch can trigger spasticity and create skin breakdown because of the high pressure on localized skin areas. The exception for this would be individuals with lower motor neuron impairments and residual hypotonicity. Any tension orthosis needs to be monitored when there is sensory loss, regardless of the cause. To achieve results in contracture reduction, one must be cautiously aggressive, as the amount of force required to improve ROM often threatens the soft tissue’s ability to tolerate the pressure of the orthosis. Experience, frequent sessions, and close communication with other members of the rehabilitation team and the family and patient are critical factors in the success of the use of orthotic devices.

EVALUATION

The examination and evaluation of the neurologically impaired patient must be comprehensive. One must not read a diagnosis and assume a total clinical picture. The diagnosis should alert the evaluator to movement patterns associated with the impairment, and these should be used to confirm potential findings. Complete patient evaluations do not end with determination of ROM, muscle testing findings, assessment of proprioception, skin sensitivity evaluation, or assessment of the integrity of the affected limb or spine. The individual ordering an orthotic device must assess the total picture to determine what limitations orthotic care may impose on other important functions, activities, and patient participation in life. The evaluation must include a patient management assessment. What is the patient’s or family’s motivation? How much equipment can the patient tolerate, and with how much can he or she function? What chance of

success does the patient or family have once they have left the clinical setting? How significant are the risks associated with orthotic intervention? As stated, the total evaluation of the patient and the patient’s environment is important in developing the treatment plan, as is the communication among the physical therapist, occupational therapist, and orthotist. Whether done together or (more realistically) at separate sites, the details of the treatment plan must be discussed. The patient with neurological impairment often presents a series of complex issues: biomechanical, communication, visualization, and so on. Incomplete information or a lack of effort at communication among these professionals will not lead to a comprehensive treatment plan and ultimate outcome optimization.

During evaluation, review of the diagnosis and gathering of patient history are extremely valuable. A complete medical diagnosis will indicate important information to the team. For example, if a patient with poliomyelitis is to be seen, the orthotist is aware that it is a lower motor neuron lesion and that proprioception is intact (see Chapters 17 and 35). These patients have the benefit of skeletal balance in standing and ambulation and therefore require durable orthotic construction. Compare this with a similar result in muscle testing and ROM assessment for an individual with T12 level paraplegia. Assuming this is a complete lesion, patients with this upper motor neuron lesion lack proprioception. They require other means to get feedback about standing balance and require a lightweight orthosis, as they rarely use orthoses as a major means of locomotion. Although gathering patient history is a vital part of the evaluation, it is, more importantly, an opportunity to establish a productive patient management environment. Patients and family members have important information regarding the initial injury, previous medical care, reasons they sought additional care, and desired outcomes of new treatment. Most of this information can be gathered efficiently as either the therapist or the orthotist begins other professional evaluations. These are important patient and family management skills. One must hear from the patient or family why they came to see the health care professional and their expectations of care. The therapist should not assume the family’s goals without asking, as often patient and family goals are higher than the clinicians’ expectations. Communicating at a level that is understandable both is vital and demonstrates to the patient and family that the therapist is a concerned professional, thereby engendering trust and confidence. Complete and timely documentation of these findings is becoming increasingly vital to the evaluation and treatment plan. Whether communicating with others on the rehabilitation team, insurance carriers, or legal professionals, documentation and building medical justification are essential in treating all patients.

Evaluation of the Spine

Each area of the spinal column presents various combinations of motion and function. Beginning at the lumbar level as the base for upright position, the spinal column (1) protects vital organs, (2) serves as a supporting structure for the lungs to expand, (3) provides a base for the upper extremities to reach from, (4) acts as a scaffold for objects to be carried, (5) protects the nervous system pathway for the body, (6) and controls the upright position and motions of

the head. The individual segments of the spine have relatively few complicated orthotic challenges. However, it is rare that only one segment is involved in the patient with neuropathic impairments. It is more common for two or more segments of the spine to be involved in orthotic fitting. For example, supporting the head in a functional position is a major goal of orthotic intervention, but to accomplish this the orthosis must encompass the thoracic as well as the cervical spine in order to distribute the forces to minimize skin pressures.

When evaluating the cervical spine and head, one must (in addition to muscle testing) determine at what angulations an upright position of the head cannot be recovered. Limiting the head from assuming nonfunctional positions such as extreme extension is an easier orthotic function than holding the head upright. Many patients with neurological problems may have the strength to move in a 15- to 20-degree range of flexion and extension, lateral bend, and rotation but do not have the strength to recover the head from greater angles. Even the most pressure-tolerant soft tissue about the head does not tolerate long-term pressure from an orthosis; intermittent control and relief are a critical part of the design. Pressure directly on the ear is not tolerated at any time.

The thoracic and lumbar spine is almost always treated concurrently with an orthosis in the patient with a neurological deficit. The major reasons for orthotic intervention in this area are to stabilize the trunk for balance, to protect surgical correction or stabilization, and to maintain respiration. The pelvis is generally used as a base to prevent distal migration of the orthosis whether the patient is sitting or standing. For this reason, one must closely evaluate the degree of deformity, prominence of bony structure, skin sensation, and condition of soft tissue coverage. Many neurologically impaired patients also have other medical issues that need to be considered in orthotic design, such as a colostomy, gastrointestinal (GI) tubes, pressure sores, and other factors. Scoliosis and kyphosis are common biomechanical impairments within this patient group. Balance between correcting the spinal deformity to maintain respiratory function by use of a tightly fitting TLSO and the skin pressure it creates must be reached by the rehabilitation team. The evaluation of the spine and potential need for orthotic intervention would not be complete without recognizing the effect the desired orthosis may have on the extremities, whether the patient is ambulatory or non-weight bearing. What movements of the spine are present during ambulation, and would immobilizing the spine significantly affect the patient? Will the orthosis restrict needed shoulder elevation and arm movements? Variation in materials used for fabrication of a spinal orthosis can often significantly improve the desired outcome, increase the wear time, ease the donning process, and improve skin care. From a patient and family management standpoint, one must consider many variables in potential design of the orthosis. Can the patient or family apply the orthosis and remove it when appropriate? Do they understand potential areas of pressure? What is the home situation like?

Evaluation of the Upper Extremities

Evaluation of the upper extremities requires multiple inputs from health care professionals, patients, family, and teachers because of the wide range of specific functions an individual

performs daily. Unique to the upper extremity, multiple functions generally require multiple orthotic devices for activities of daily living (ADLs). Typical functions of orthoses of the upper extremity include maintenance of functional wrist and hand position, reduction of contracture or tone, transfer of force available in one area to another, and support of subluxations resulting from denervation. It is common for the neurologically impaired patient to require several orthoses with different functions for use throughout the day. Strength, ROM, condition of soft tissues, and sensation are all important evaluation factors. In addition, ambulatory status, bilateral or unilateral condition, status of vision, and condition of the spine and head must be factored into the indications and contraindications in assessment of the orthotic needs of the patient. Much more critical muscle tests must be performed in the upper extremity as opposed to the lower extremity, as minor increases or decreases in strength will dramatically alter orthotic need. For example, the C5 quadriplegic has the ability to function with a wrist-hand orthosis by providing enough wrist extension to use the tenodesis effect, which can produce a three-jaw-chuck type of grip. The difference between a functioning and nonfunctioning orthosis is minor, not only because there is limited muscle strength, but also because minor inefficiencies in the tenodesis splint (from friction or malalignment) could reduce function to below acceptable levels. Patients with unilateral involvement have far different needs than the bilaterally involved. The patient with a CVA with unilateral involvement may have an intervention of a positional wrist-hand orthosis to prevent contracture and injury and a supportive shoulder orthosis to prevent shoulder subluxation (Figures 34-4 and 34-5). In these cases the other extremity becomes dominant, and there is little need to fabricate complex orthoses for the use of the affected extremity. The patient with bilateral involvement presents a much different picture. Consideration for grooming, feeding, mobility, and so on must be factored into the desired expectation during evaluation. The case of the patient with neurological impairments who requires orthotic intervention is complex, as this patient typically has involvement in the trunk, head, and

Figure 34-4 ■ Resting hand splint.

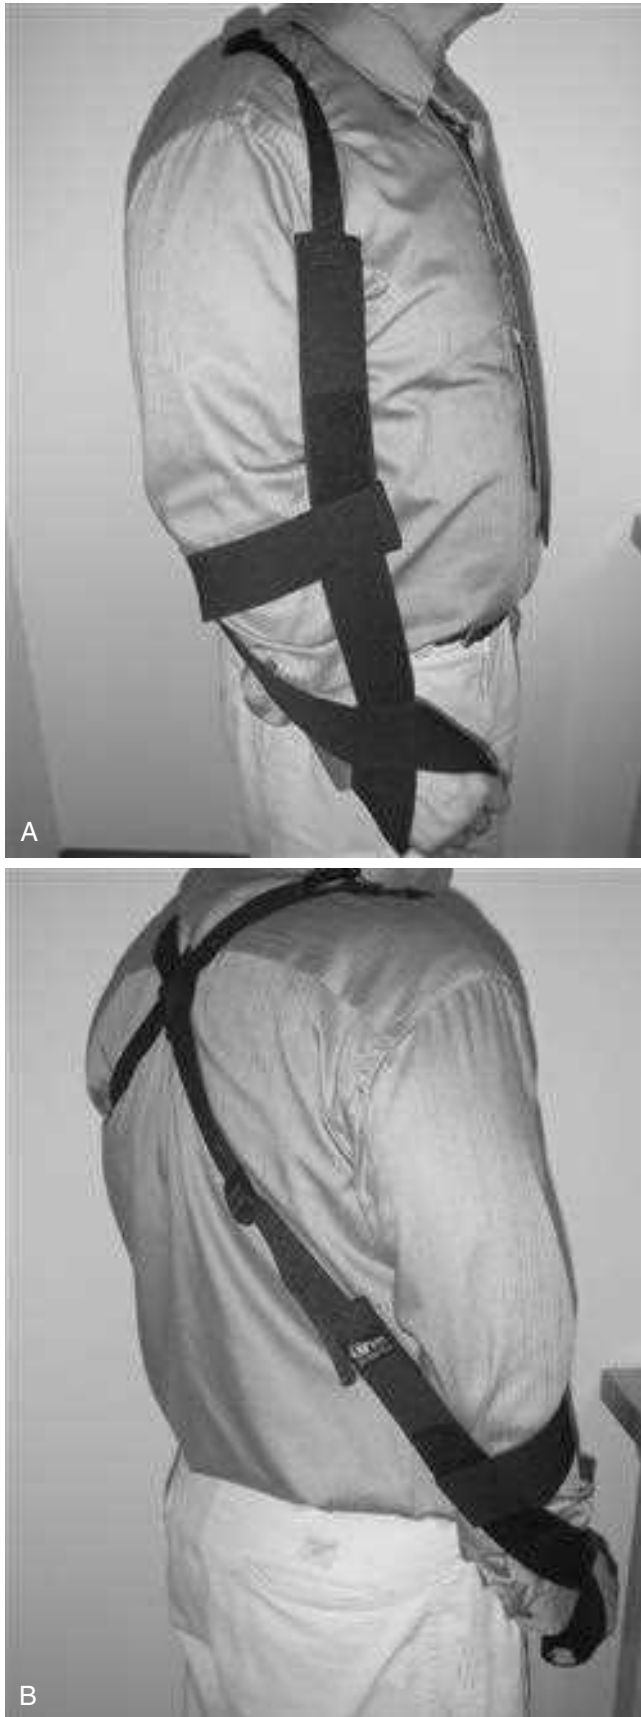

Figure 34-5 ■ Shoulder splint to support the shoulder against subluxation and pain. **A**, Sagittal view. **B**, Posterior view.

lower extremity. These patients require specialized wheelchairs and seating systems. Evaluation is most effective with all rehabilitation team members present to establish a treatment plan. Orthotic treatments maximize what limited muscle strength and ROM the patient may have. Orthoses that are used during the day to maximize function are often replaced with positional orthoses at night to preserve gains and prevent decline in ROM. The occupational therapist provides most of the functional and positional orthoses for the upper extremity. In today's rehabilitation environment, many occupational therapists work directly with orthopedic hand specialists and trauma physicians. They use low-temperature materials to mold custom devices specifically designed for protecting surgical reconstruction or promoting or maintaining ROM or for use as assistive devices.

Evaluation of the Lower Extremities

Evaluation of the lower extremity offers additional challenges owing to the role of ambulation and its value to independence for the patient and family members. ROM, strength, existing deformity, proprioception, muscle tone, and soft tissue condition and sensation must be evaluated. Where appropriate, weight-bearing evaluation and gait analysis are completed. Patient and family assessment as it relates to the ability to comprehend and follow instructions is extremely important, as the potential for injury may outweigh the benefit of orthotic intervention to transform a patient from being non-weight bearing to having limited ambulation. Lack of ROM at the hip and knee will significantly decrease the duration of potential ambulation or may totally inhibit ambulation. Lack of ROM at the hip and knee is more critical than lack of strength. In the foot and ankle, the need for normal ROM is even more critical for efficient standing balance and ambulation. Orthoses of the lower extremity provide a combination of force lever arms acting about a joint axis at the knee, hip, or ankle. These joints are significantly compromised by the lack of ROM. These force lever arms within the lower extremities substitute for the lack of strength. For example, by blocking dorsiflexion of the ankle, the toe or anterior lever arm provides a posteriorly directed force in the sagittal plane during stance that stabilizes the knee. If the patient lacks the ability to get the ankle even to neutral, this tightness provides its own lever arm, which will result in a variety of undesirable forces and actions. Genu recurvatum, foot or ankle varus, a shortened stride length on the nonaffected side, and the heel rising out of the shoe are common signs of this problem. These issues are further complicated when lack of proprioception, spasticity, and lack of sensation are present. Lack of ROM at the ankle creates many symptoms in the lower extremity but is often overlooked during evaluation as the cause of these problems. Genu varus and genu recurvatum are common deformities of the patient with neurological impairments. A number of factors create these problems. In addition to the ankle ROM, leg length differences, lack of quadriceps strength, and lack of proprioception can create deformities about the knee. The patient with poliomyelitis may have both a short extremity and weak knee extensors, which lead to genu recurvatum and genu valgus. However, reducing the genu recurvatum without protecting against undesirable knee flexion would be a mistake. Patients with lower motor neuron disease have excellent proprioception, which is the reason they protect the unstable knee by

hyperextending it. They may even use force from their upper extremity by pushing posteriorly on the femur with the hand. A similar patient with upper neuron impairments, for example a patient who has had a CVA, has a similar knee presentation. However, the usual cause of this patient's deformity is different. Reduced or lack of strength and ROM limitations about the hip limit effective ambulation and leave the patient much more reliant on trunk stability and upper-extremity ambulatory aids. Hip flexors are more critical than hip extensors, as they serve to advance the limb in reciprocal gait, whereas lack of hip extensors is compensated for by the strong hip ligaments, which tighten for stability in extension. A lack of ROM to at least neutral extension about the hip creates major challenges for the patient, even if the patient has excellent upper-extremity strength. This lack of ROM will not allow stability in standing once force is removed from the upper-extremity ambulatory aids. Creating hands-free standing balance is a highly desirable outcome of orthotic intervention. The patient is then able to use both upper extremities for ADL tasks.

ORTHOTIC INTERVENTION

Several factors play key roles in the success of orthotic intervention. To improve function without complication or patient risk, the clinician must be sure to address the patient's major complaint; the reason the patient and family came to see the therapist or orthotist must be clearly established to ensure compliance with orthotic intervention. It is important to establish a baseline of function so that results of intervention are measurable. In some situations the patient benefit is clear and immediate, whereas in others, concentrated instruction, orthotic modification, and time are required before improved function can be observed or measured. The process of donning and doffing the orthosis as independently as possible enhances the overall goal for the patient and family and must be well thought out by the experienced clinician. The clinician must be conservative in setting these expectations. It is important to remember that what happens in the clinical setting may not be easily reproducible in the home situation. The orthotic interventions must be kept as simple as possible: what is the least amount of orthotic intervention that will provide the expected goal? Although an obvious statement, the balance between too much and not enough can challenge the clinician's skill and experience. The use of trial orthoses can provide valuable information during the evaluation, and these are generally available commercially for short periods. Various types of heat-moldable plastics have been beneficial for many individuals. At times, however, their use adds risk and complication without improvement compared with traditional AFOs fabricated with metal and leather attached to the patient's shoe. For example, if the patient requires ankle and knee stability yet lacks sensation in the foot and ankle, the double-upright metal orthosis attached to the patient's shoe creates much less risk for possible skin breakdown than a rigid total contact plastic orthosis (see Table 34-1). With a plastic orthosis, the family must find a shoe big enough to easily fit the orthosis. Technological advancements have led to a number of additions to the arsenal of orthotists. Prefabricated orthoses with better sizing and materials have given the clinician additional tools for evaluation and for devising permanent orthoses. Preimpregnated graphite AFOs are now available in multiple sizes

and provide toe pickup during swing phase and some knee-stabilizing characteristics during stance phase. Although very lightweight, these orthoses provide dynamic stance phase control. Introduction of biomechanical forces to the extremities may cause unwanted movements or restrictions, and careful selection of components is essential to keep the focus on the orthotic plan. For example, a patient with a CVA may need more anterior lever force to provide knee stability, so one would plantar flex the orthotic ankle joint. However, this knee-stabilizing effect in stance phase would cause a toe drag during swing phase. A simple fix is to provide the opposite side with a 1/4-inch heel and sole lift for additional clearance during swing phase of the affected extremity (Table 34-2).

Clinicians need to set realistic, manageable patient-centered treatment goals. All too often, treatment plans are only in the minds of the clinicians and are either never or too poorly communicated with the patient and family. Clinicians should assume that the patient and family members will expect benefits of the intervention that will far exceed what the therapist knows are possible. The time to address those gaps is certainly before treatment, not when the patient and family realize that expectations regarding functional gains may not be realistic. If failure is the reason a patient recognizes that the intervention was wrong, the therapists have lost the patient's trust and the potential for future intervention guidance. Discussing realistic achievable goals of treatment, after assessing all factors, the home situation, and individual motivation, with the patient and family in language they understand is critical if successful orthotic intervention is to be achieved. The goal of orthotic care for a patient with CVA is to provide safe standing balance for transfer and minimal ambulation in the home. Patients and their families will realize the major benefit this will have on the home situation. However, without this identified as the goal before orthotic care, they may leave the therapeutic environment wondering why the patient cannot walk normally and participate in life activities that require longer distance ambulation skills.⁴ This clinical error is an all too frequent patient management mistake. Integrating orthoses with physical and occupational therapy motor relearning and neuroplasticity should help optimize functional recovery.

To provide a cost-effective orthosis in a timely manner with today's vast number of orthotic devices, the orthotist must stay abreast of the wide array of choices at his or her disposal to meet the needs of the patient. The reality of cost containment is not a recent event in the orthotic profession, as funding for these devices has always been challenged. This has necessitated the development of more cost-effective alternatives, such as the prefabricated orthosis. The introduction of heat-moldable plastics into orthotics in the late 1960s and early 1970s on a custom basis replaced, to a large extent, the need to mold leather and/or metal to fabricate an orthosis (see Table 34-1). This improved the total contact fit and dramatically reduced the time and skill level required for manufacturing. Today's orthotist has a multitude of devices from which to choose to meet the needs of the patient. Options range from custom-made devices using a patient mold to prefabricated custom-fit devices. A thorough understanding of the indications and contraindications for each of these devices is essential in order to meet patient needs. A lack of understanding of biomechanical principles, of the

TABLE 34-2 ■ INDICATIONS FOR COMMON ORTHOTIC MODIFICATIONS AND ADDITIONS

MODIFICATION OR ADDITION	DESCRIPTION
SACH modification	This modification is done by cutting out a triangular wedge in the heel of the shoe and inserting a softer material. The solid ankle cushion heel (SACH) modification is used to dampen the effect of the heel or posterior lever arm at heel strike. This force produces an anterior force to destabilize the knee, which may be undesirable.
Heel and sole buildup	Adding a ¼-inch heel and sole buildup to the unaffected side can create additional swing clearance needed on the affected side. This modification is indicated if additional dorsiflexion of the orthotic joint creates knee instability or if the patient lacks dorsiflexion range of motion.
Rocker-bottom heel and sole modifications	There are several different styles of rocker-bottom buildup. Although the roll built into this modification may differ, the basic results are the same—to add motion and translate the center of gravity forward when the ankle and/or knee joint is locked.
Long tongue stirrup, extended steel shanks	A stirrup is the metal attachment to the shoe. The use of a long tongue (a steel extension that goes distally between the bottom of the shoe and the heel and sole) is necessary to transfer the force created by restriction of ankle motion. Without this type of fabrication, the force produced at midstance will not be controlled. A steel shank produces the same control but is not part of the stirrup and may be used in combination with a rocker bottom.
Medial or valgus control T-strap; lateral or varus control T-strap	These straps, leather on traditional double-upright orthoses or plastic or padding control T-strap modifications on plastic AFOs, produce a force to reduce valgus (a medial T-strap) or varus (a lateral T-strap). A medial T-strap attaches to the shoe medially, and the beltlike strap goes around the lateral upright and is tightened. The lateral T-strap attaches to the lateral side of the shoe and applies a medially directed force by being tightened around the medial upright of the AFO.
Heel buildup	A heel buildup is used to accommodate heel cord tightness. The tibia must be at least 90 degrees to the floor for safe balance and ambulation. Common signs of the need to build up the heel are genu recurvatum and the heel slipping out of the shoe. The amount of heel buildup must be matched with the same heel and sole buildup on the opposite side for balance.
Instep or figure-of-8 straps	This orthotic modification is used to keep the heel seated in the shoe or plastic ankle-foot orthosis when a tight heel cord is present. These straps fit across the dorsum of the foot with a posterior attachment point.
Swedish knee orthosis	This prefabricated knee orthosis is an effective method to prevent genu recurvatum. It is typically indicated after a CVA for the patient who lacks proprioception and whose knee hyperextends, creating pain and slackening the knee ligaments. It can be used temporarily as a training orthosis or on a more definitive basis when persistent pain and instability are present.

limitations of prefabricated orthoses, and of custom fitting can lead to failure and increase the impairment problems existing within the patient environment. All orthoses produce a force field, some desirable and some undesirable. It requires an experienced clinician to make the most appropriate choices, as too often the failure of treatment is blamed on an orthosis. Usually such failure is the result of an inappropriate initial selection of orthotic components, lack of discernment between custom-made and custom-fit devices, or misidentification of the patient as an orthotic candidate. Prefabricated custom-fit orthoses are cost-effective only if they produce the desired goal over time. As a general rule, one should consider prefabricated custom-fit orthosis for patients who have an anatomically “normal” biomechanical structural environment and who will use the orthosis for only a short time. Custom-made orthoses for extremities or the spine are usually prescribed for patients who have deformity or unusual size or who must use the device indefinitely.

CLINICAL EXAMPLES

Paraplegia

Orthotic intervention for a patient with paraplegia is generally considered for the lower extremities at the T12 level in the complete lesion.⁵ Complete lesions higher in the cord leave the patient without enough trunk stability to use bilateral orthoses effectively. Although a thoracic extension can be added to bilateral KAFOs, this addition greatly increases the difficulty of donning the orthosis independently, and most patients will have great difficulty getting from sitting to standing.

The most appropriate orthoses for a T12 complete paraplegic are bilateral KAFOs. The patient generally uses a swing-to or swing-through gait, and successful use of orthoses requires excellent standing balance. There are three significant design requirements for these KAFOs: shallow thigh and calf bands, bail or French knee locks, and double-adjustable ankle joints.

Figure 34-6 ■ Double-adjustable ankle joint. The channels on the anterior and posterior sides allow for easy adjustment of dorsiflexion and plantarflexion range of motion. Springs can also be added to provide dynamic assistance to the movements.

A double-adjustable ankle joint has channels on the anterior and posterior sides of the joint. This allows the orthotist to easily adjust dorsiflexion and plantarflexion position and ROM, or even provide dynamic assistance via a spring added to the channel of the joint (Figure 34-6). The shallow bands force the center of gravity forward, inducing lordosis so the patient can rest on the iliofemoral or Y ligaments of the hip. The knee joint locks are automatic because the patient requires the upper extremities for standing. The bail or French

Figure 34-7 ■ Modifications necessary to control the ankle setting in a client with spinal cord injury (Scott-Craig shoe or stirrup modifications).

joint will lock as the patient stands and bends over the rigid ankle joint, forcing the knee joints into extension. The lock then can catch on the back of a wheelchair seat or other chair to release the lock and bend at the joint when the patient sits. The foot-ankle complex forms the basis for balance. A few degrees of adjustment at the double-adjustable ankle joint can make the difference between safe standing balance and limited standing balance. The long tongue stirrup extends at least to the heads of the metatarsals and farther if the patient is taller and heavier than normal (see Table 34-2). The use of a strutter bar from the upright of the stirrup extending to a transverse bar at the heads of the metatarsals with a long tongue stirrup (Scott-Craig design, Figure 34-7) ensures that the necessary rigidity is provided. A point between effective standing balance and ambulation is reached after training and ankle adjustment. Patients must have full ROM at the hips, knees, and ankles for use of these devices to be successful.

CASE STUDY 34-1 ■ A. M.

A. M. is a 21-year-old man with incomplete T12-level paraplegia secondary to a gunshot wound. A. M. has normal upper-extremity strength and ROM. He has had surgery for spinal fusion. Trunk strength is 4/5, left hip is 3/5, knee is 2/5, right hip is 1/5, and right knee is 0/5. ROM is full at hips, knees, and ankles. A. M. can transfer independently and has the goal of household ambulation, although he is aware that it “takes a lot of work.” A. M. was fitted with a right KAFO with shallow bands, drop lock knee joints, and

double-adjustable ankle joints locked in 5 degrees of dorsiflexion (Figure 34-8). Drop locks were used instead of bail locks because of the use of a unilateral KAFO. A. M. had balance, strength, and a foot orthosis on the left side. The left lower extremity was fitted with an AFO and double-upright and double-adjustable ankle joints adjusted to match the right orthosis. The distal attachment to the shoes was with long tongue stirrups and strutter bars. The patient was able to ambulate with forearm crutches.

Figure 34-8 ■ Patient standing wearing a right knee-ankle-foot orthosis. **A**, Lateral view; **B**, posterior view.

Hemiplegia

Patients who have had a CVA can vary widely in their need for orthotic intervention, from a simple AFO to assist toe clearance, to an AFO to stabilize both ankle and knee, to an orthosis used temporarily for training purposes.^{6,7} The use of a KAFO in the patient with hemiplegia is rarely indicated. Even though the more affected patient does not have knee stability, he or she rarely ambulates with a heel strike that would destabilize the knee and therefore can use an AFO with an anterior limited-range ankle joint. In addition, patients cannot don the KAFO with the use of only one upper extremity. With hip flexor weakness and knee instability on the affected side, the orthotic intervention may be to assist in transfers rather than to facilitate gait. As a general rule, orthotic intervention for the client with a CVA ranges from a static toe pickup orthosis to a double-adjustable ankle joint with the ankle locked. The use of dynamic components is not effective, because they will initiate spasticity. The lack of ROM into dorsiflexion or even to neutral causes the most significant problems for these patients. An ankle that lacks dorsiflexion ROM prevents advancement of the center of gravity and produces a lever arm that induces genu recurvatum and pain, and either the heel comes out of the shoe or the ankle rolls into varus. Because these patients lack

proprioception, this constant force directed posteriorly will, over time, be significant. The patient will develop pain in the knee and not ambulate, the heel cord will shorten more, and the cycle will continue. Heel cords rarely gain length after the patient has been discharged from the rehabilitation setting, and one must consider the family and home situation. Heel buildups on the affected side are used to bring the tibia into 90 degrees. Buildups of 1 to 1½ inches are not uncommon. Remember to balance the opposite shoe. When selecting between different orthotic components, it is best to choose the more stable orthosis. The use of trial orthoses during evaluation is invaluable and helpful initially. As the patient improves, he or she may require less orthotic management or no orthosis at all. A three-point pressure orthosis for the knee, such as a Swedish knee cage (Figure 34-9), is also a valuable training orthosis and, in the case of some post-CVA patients, is used daily when the degree of recurvatum exceeds the patient's ability to control the posteriorly directed force. The stirrup (the metal attachment to the patient's shoe) of the AFO must be firm and extend under the sole and heel to the heads of the metatarsals. Although this adds weight to the orthosis, it is necessary to transmit knee-stabilizing forces. Stirrups attached under the heel will only allow undesirable motion and will not provide the required stability.

Figure 34-9 ■ Prefabricated three-point pressure knee orthosis (Swedish knee cage) to control genu recurvatum.

CASE STUDY 34-2 ■ D. M.

D. M. is a 58-year-old woman who had a left CVA, resulting in a right hemiplegia, almost 2 years ago. She was evaluated at the request of her physician because of increased knee pain and poor standing balance. D. M. was fitted with a plastic AFO fixed at 90 degrees 14 months ago. She was wearing the orthosis, but the heel would not stay in her shoe. Evaluation showed that the patient lacked 15 degrees from getting the foot to neutral (the ankle was therefore in 15 degrees of plantarflexion), had 0/5 dorsiflexion or plantarflexion, and had 3-/5 knee extension and flexion. She also walked with the aid of a quad cane and had 10 degrees of genu recurvatum and slight genu varum

at midstance. Her goal was to walk with less pain and to be more stable. D. M. was fitted with bilateral upright, double-adjustable locked ankle joints with long tongue stirrups and a 1½-inch heel buildup (Figure 34-10). The left shoe was built up 1½ inches in the heel and sole to balance the right shoe (Figure 34-11). A Swedish knee orthosis also was used initially to help train the patient and to provide hyperextension control. Although the double-adjustable ankle joint does give total flexibility to change the angle, a 90-degree posterior stop also can be used. Patients who lack this much ROM provide an “anatomical” anterior stop.

Figure 34-10 ■ Shoe modification with double-adjustable ankle.

Figure 34-11 ■ Left double-upright, double-adjustable ankle-foot orthosis with balancing right buildup.

CASE STUDY 34-3 ■ M. H.

M. H. is a 59-year-old woman with a history of a CVA 1 year ago. She has left hemiplegia. She works as a facilities manager and walks through her office building several times per day. She underwent extensive therapy after the CVA and has good strength; ROM is within normal limits at her hip and knee. At her left ankle, M. H. has 3+/5 plantarflexion strength but 0/5 dorsiflexion or eversion strength, and she has extensor tone into plantarflexion and inversion. She ambulates very cautiously owing to her inability to dorsiflex and evert the foot during the swing phase of gait. She has a high risk of falling because of her ankle instability and has sustained multiple inversion sprains at the ankle.

M. H. was tested using an FES device and had an appropriate response to the stimulus. She was fitted with an FES device for foot drop. This unit consists of a cuff and control unit around her proximal calf, attached to electrodes on her skin near the fibular head. It allows her to ambulate barefoot and/or with various types of footwear, as it is programmed using the angle of her leg to determine the transition from stance to swing phase in gait. The unit is inconspicuous and lightweight. Her walking velocity, safety, and stability are significantly improved with the FES unit. She uses it throughout the day on a daily basis.

Paralytic Spine

Many neuropathic diagnoses affect the spinal column. Spinal muscle atrophy, tetraplegia, myelomeningocele, and Duchenne muscular dystrophy can all require orthotic intervention. Although materials, padding versus no padding, trim lines, length of time used, and optional area openings can vary with different conditions, most spinal stabilizing orthoses are TLSOs. Orthoses used for postsurgical stabilization tend to be of more rigid material to support the healing spine. The paralytic spine that is not surgically stabilized can have either a flexible or a rigid curvature. An orthosis for a patient with a rigid curvature is used to avoid further deformity and

differs from that used by the patient with a flexible curvature. If the curve is flexible, the orthosis will be used to hold some of the correction that can be obtained. Patients with paralytic spine deformity usually undergo casting for custom orthoses, and although non-weight-bearing supine casts can greatly reduce the curve, many patients will not tolerate the pressure once in the upright sitting position. Orthotic intervention usually has one or more of the following goals: (1) improved sitting balance, (2) support of surgical stabilization, (3) prevention of further spinal deformity, (4) use as an assistive positional device for better use of head and upper extremities, and (5) improved respiratory function.

Most TLSOs for these patients are total circumferential designs that use rigid materials (polypropylene) to less rigid materials (polyethylene) or a combination of padding with a rigid or semirigid frame internal to the heat-formable foam. Fabrication and fitting of these orthoses require an experienced orthotist and adherence to detail. Establishing the distal and proximal trim lines of the orthosis will require a fine balancing act between providing enough length to support the spine without breaking down the skin in accomplishing that goal. Several clinic visits are typically necessary to achieve the desired outcome.

Spastic Diplegic Cerebral Palsy

The goals of orthotic intervention in the patient with cerebral palsy are to control tone, prevent contractures, and provide a secondary support after a surgical procedure.⁸ Orthotic intervention for these individuals varies from region to region. As a general rule, the orthosis used to prevent contracture should be different from the orthosis used for ambulation. Some of the new designs incorporate modules

that can key into one another or be used separately. This feature allows flexibility, assists in donning (especially in a patient with spasticity), and meets several treatment objectives. Modular articulating joints with various settings and functions to use with thermoplastic orthoses greatly increase the options that are available today. With the goals of orthotic intervention stated earlier, total contact-type orthoses are generally the desired option. As with any total contact orthosis and hypersensitive or hyposensitive skin, a cautious balance between correction or holding and skin tolerance must be reached. The fitting of and follow-up for these types of orthoses require experience, knowledge, and patience. Combinations of padding, wedging, straps, and heat relief methods are often necessary to enable the patient to wear the orthosis for a significant amount of time on a daily basis. A patient with spastic diplegic cerebral palsy relies heavily on her or his orthosis and wears it out faster than most other orthotic patients. In the case of a child, she or he may grow out of the orthosis before it wears out. This should be considered in the design and fabrication.

CASE STUDY 34-4 ■ S. G.

S. G. is a 13-year-old girl with spastic cerebral palsy with involvement of all four extremities. She is nonambulatory with significant scoliosis. Her hip ROM is from -25 degrees to 135 degrees of flexion. S. G. is fully dependent and lacks upper-extremity use.

The goal of orthotic intervention was to prevent further deformity, maintain the thoracic and lumbar column height for internal organ function, and provide trunk stability for seating balance in her wheelchair. She was fitted with a custom TLSO

fabricated from a cast impression (Figure 34-12). It has $\frac{1}{4}$ inch of padding with a polypropylene outer layer, which has been modified over bony prominences for skin tolerance.

S. G. wears her TLSO not only while seated in her chair, but also in bed. Frequent checks of the skin were made during the first few weeks of use to establish trim lines and window type modifications. She continues to be checked periodically for comfort and control as she grows to ensure that the TLSO's fit and function are appropriate.

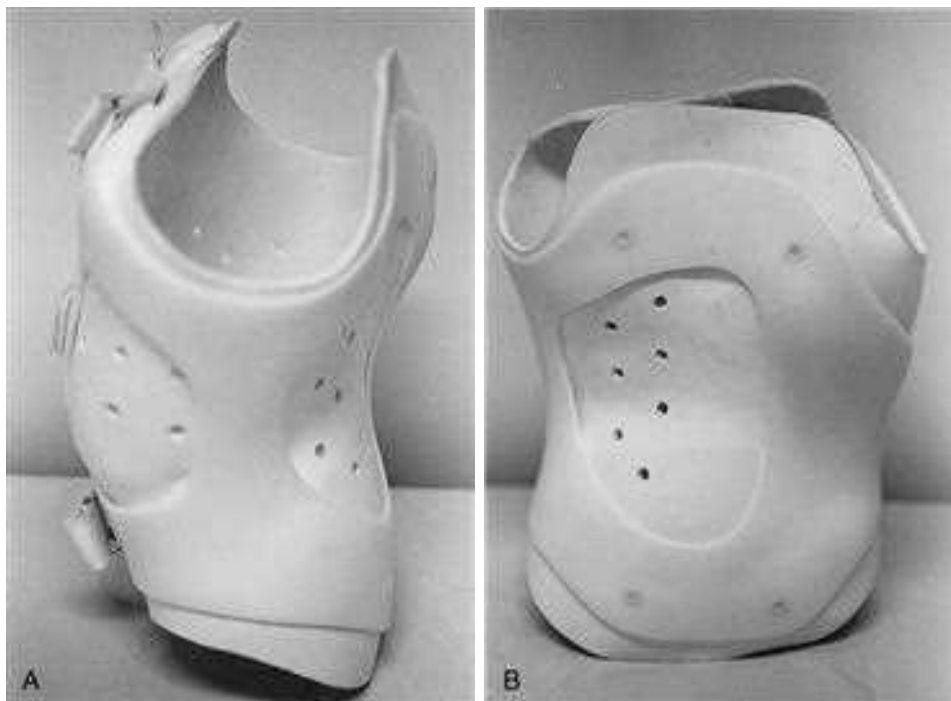

Figure 34-12 ■ Thoracolumbosacral orthosis with anterior opening. A, Lateral view. B, Posterior view. Cutouts in rigid plastic to inner soft foam are for expansion and comfort.

CASE STUDY 34-5 ■ R. B.

R. B. is a 41-year-old woman with spastic diplegic cerebral palsy. She has tight heel cords bilaterally, with -5 degrees from neutral ROM at the ankle. Plantarflexion strength is 3+/5, and dorsiflexion strength is 3/5 bilaterally. The patient has 5 to 7 degrees of varus in the calcaneus. The left lower extremity is asymptomatic. The right side has pain in the midfemur and at the knee. She has a bilateral genu valgum deformity of 5 to 7 degrees (Figure 34-13, A). ROM at the knees is full, and strength of the quadriceps and hamstrings is good. Her hips are normal except for some internal rotation; leg lengths are equal and sensation is good.

Because the right lower extremity was painful at the knee and ankle (Figure 34-13, B), the patient was fitted with an AFO that extended medially and proximally to the medial tibial condyle; ankle joints that had a posterior adjustment to limit plantarflexion; and a medial heel wedge and heel buildup of $\frac{3}{8}$ inch. The ankle was fitted with a submalleolar orthosis that fit inside the AFO (Figure 34-13, C and D). The submalleolar orthosis controlled enough pronation of the ankle along with the medial heel wedging and exerted a varus force at the knee (Figure 34-13, E). The heel buildup reduced the posteriorly directed force from midstance to toe off. The patient's symptoms were reduced, allowing her to be more active (see Table 34-1).

Figure 34-13 ■ A, Painful right genu valgus and pronation. B, Posterior view of right ankle. C and D, Client wearing submalleolar orthosis with pronation corrected. E, Patient in submalleolar ankle-foot orthosis extended to knee to control genu valgus.

Multiple Sclerosis

As MS progresses and further demyelination occurs, increased interruption of normal nerve impulses creates deficiencies in muscle control, vision, balance, sensation, and mental functions. Orthotic considerations for a patient with MS can vary as the patient's symptoms fade, recur, and change over the years with the disease. Clinical presentation may vary from month to month. Fatigue plays a major role in the symptoms, and the patient's expectations and willingness to use orthotic devices ebb accordingly. Typical patient reaction is reluctance to use any form of ambulatory aid or orthosis until safety is a major issue. Patients and family usually seek help when falls become more frequent. Lack of toe clearance during swing phase and poor knee stability and push off in stance phase are the most common problems that can benefit from orthotic intervention. Because of the nature of symptom fade and recurrence and the increase with fatigue, the weight and simplicity of orthotic intervention must be major considerations. In many instances the evaluation will indicate the need for a KAFO, but this will be rejected by the patient because of its weight and complexity.

The benefit of the KAFO for knee stability and foot and ankle control is counteracted by the patient's inability to advance the limb during swing phase and control the extremity, as well as a perception that he or she does not need that type of control. Most patients also will reject the use of a double-upright, double-adjustable metal orthosis for the same reason, and although their strength varies from day to day, they will judge need when they are at their strongest rather than their weakest. Traditionally, plastic AFOs are used to control foot drop and provide some medial and lateral ankle control. These orthoses also can provide some knee stability if the plastic is robust enough and if the medial and lateral trim lines are advanced anteriorly past the malleoli. This anterior force stops the center of gravity's forward progression at midstance, and, again, many patients reject this type of orthosis. The recent development of prefabricated AFOs made of graphite has met the needs of many of these patients (Figure 34-14). This ultralight orthosis fits inside the patient's shoe. It will provide toe clearance during swing phase and some dynamic knee stability and push off during stance phase.

CASE STUDY 34-6 ■ D. K.

D. K. is a 38-year-old mother of three young boys and works outside the home. She was diagnosed with MS at the age of 30. Until 4 years ago she was managing the symptoms with medication and having minimal ambulatory problems. With the birth of her son, she had to cease use of medication, and the symptoms recurred and weakness increased. At age 36 she was limiting her activity outside the home because of safety issues—she was falling and unstable in standing and walking. She was evaluated

at that point and was fitted with a right AFO, as she had foot drop and knee instability and lacked the ability to recover her balance if she caught her toe. A prefabricated graphite AFO was fitted to the patient (see Figure 34-14). D. K. now has toe clearance during swing phase and dynamic knee extension during stance phase. Shortly after beginning to use the orthosis, she was able to walk safely on uneven ground and walk down stairs step over step for the first time in 3 years.

Figure 34-14 ■ Example of an ankle-foot orthosis, which provides stance-phase advantages in addition to swing-phase assistance. (Courtesy of Otto Bock HealthCare.)

SUMMARY

All orthoses create a force system. It is important to understand and integrate the appropriate force to achieve the desired outcome of intervention. A thorough initial evaluation and knowledge of the multiple orthotic options available are vital to reaching treatment goals. There has been a dramatic improvement in material technology, along with far greater access to orthotics and a much wider range of indications for orthotic intervention. This should challenge the rehabilitation team to establish measurable goals and then to develop new goals leading from the treatment interventions with the most effective outcomes. This evidence-based practice will help provide better service for future patients.

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Analyze how the aging process may affect people with lifelong functional limitations and challenges in life participation.
2. Analyze the unique challenges faced by people with chronic motor impairments such as those associated with cerebral palsy, genetic malformations, developmental disabilities, postpolio syndrome, spinal cord injury, and traumatic or acquired head injury during the aging process.
3. Evaluate this population of patients/clients with sensitivity and skill, incorporating precautions and effectiveness of interventions.
4. Provide a framework for the examination process for individuals with chronic conditions.
5. Present holistic intervention considerations for individuals with chronic motor impairments.
6. Identify gaps in knowledge and research in the management of aging individuals with chronic neuromuscular conditions.
7. Appreciate the complexity of examination, evaluation, and management of the aging patient with chronic motor impairments.

Improvements in health care delivery, research, medicine, nutrition, and knowledge of health and physical activity have resulted in a new challenge for health care professionals—a growing population of individuals who have sustained and survived an initial injury to the central nervous system (CNS) with resulting secondary impairments and functional limitations and who are now experiencing the added effects of aging.

The aging process typically leads to gradual physiological changes in muscle strength, flexibility, and joint mobility and changes in balance and endurance. Physical activity and a healthy lifestyle have been shown to address age-related changes by delaying the decline and deterioration; however, age-related changes such as osteoarthritis and vascular changes are still likely to occur to varying degrees despite a healthy lifestyle. Healthy but sedentary older individuals report more problems in activities of daily living (ADLs) than do those who continue to be physically active and who previously had an active lifestyle.¹⁻³

In an individual with preexisting impairments and functional limitations, the aging process may present new or additional loss of components of functional activities and participation—a new challenge to the individual who may have had the opportunity to successfully participate in life activities in earlier adulthood. Individuals with existing disabilities undergo a similar aging process; however, the typical changes associated with aging are superimposed on the body system problems and functional limitations caused by the initial CNS injury.

In the realm of chronic problems in life participation, individuals who experienced the effects of polio in their younger years give clinicians an enlightening example of the chronic interaction among neurological and functional impairments, recovery, effects of aging, and health care. As a chronic condition, individuals who dealt with polio can teach therapists to reconsider and reevaluate their approach to individuals who are now experiencing activity limitations, impairments, and ineffective postures and movement. The challenges of aging with chronic body system problems or impairments are encountered by individuals who have postpolio syndrome (PPS); those who acquired CNS insult at birth (developmental disabilities including cerebral palsy [CP; see Chapter 12] and Down syndrome [see Chapter 13]); and those who acquired injury through disease or trauma sometime in the life span development process (traumatic brain injury [TBI; see Chapter 24], multiple sclerosis [MS; see Chapter 19], and spinal cord injury [SCI; see Chapter 16]).

The discussion of chronic impairments brings several questions to the forefront:

- What is the course of age-related medical conditions common in individuals with chronic impairments?
- Do age-related conditions vary among the developmental or genetic diseases or among conditions occurring at one point during the life span?
- What are the prevalence and/or incidence of secondary conditions in individuals with chronic impairments?

- Have specific treatment protocols for health provision for this population been identified?
- What is the state of dissemination of information related to aging and health to people affected by these conditions?
- How has the effect of aging with chronic body system problems changed the ability of these individuals to participate in life as well as their perceived quality of life?

As an emerging population, individuals with chronic impairments have not been on the receiving end of research. Much of what is known about nervous system disorders is in the pediatric realm and in the initial stages of care immediately after the initial injury or diagnosis. It is only recently that studies have begun to look at the health care implications of aging with chronic conditions. Therefore, definitive answers to the questions posed previously are still nonexistent or in the early stages of conception. Based on a review of existing literature, the consensus appears to be that there is a dearth of definitive information on the health status and effect of age-related processes among individuals with chronic conditions from developmental or genetic disorders or from injury sustained at one point in the life span such as TBI and MS. Moreover, there is agreement that further evidence-based research is needed in this emerging population.

This chapter aims to provide a holistic view of the management of the chronic problems of individuals with nervous system impairments, with consideration given to the effects of aging and compensation over time. Movement emerges from the interaction among the individual, task, and environment,⁴ with several variables and degrees of freedom. Therefore physical therapists (PTs) and occupational therapists (OTs) need to examine and address multisystem impairments and contributions to movement while appreciating the changing dynamics of a highly complex movement system.

DIAGNOSES WITH UNDERLYING CHRONIC CONSEQUENCES

Developmental Conditions

With increasing life expectancy, mainly as a result of innovations in health care, a unique group of individuals with chronic conditions are subject to age-related changes. Individuals with developmental disabilities constitute a growing segment of the aging society. This is a broad topic, in part because of the many conditions that are categorized as developmental disability. According to the Administration on Developmental Disabilities and the Administration for Children and Families,⁵ developmental disabilities are severe, chronic functional limitations attributable to mental or physical impairments or a combination of both, that manifest before age 22 years and that are likely to continue indefinitely. These result in substantial limitations in three or more of the following areas: self-care, receptive and expressive language, learning, mobility, self-direction, capacity for independent living, and economic self-sufficiency. These individuals also have a continuous need for individually planned and coordinated services.⁶ The definition envelops a wide range of conditions leading to significant and lifelong disabilities. This group includes those with genetic and

neurological conditions, two of the more common of which are CP (see Chapter 12) and Down syndrome (DS; see Chapter 13).

The question of whether unexpected changes among people with neurodevelopmental disabilities occur as they age and how these changes compromise functioning with progressive aging is of massive importance with the emergence of a population of individuals with developmental disabilities with increased life expectancy and concurrent increase in older-age-related diseases. According to Heller⁷ the number of adults with intellectual and developmental disabilities aged 60 years and older is projected to nearly double from 641,860 in 2000 to 1.2 million by 2030 owing to increasing life expectancy and the aging of the Baby Boomer generation. With the aging of adults with developmental and genetic disorders a new societal issue looms, as individuals with developmental disabilities have a lifelong need for external support. Much is unknown about the long-term effects of aging and maturation in adults with these conditions.

Adults with several types of developmental disabilities have life expectancies similar to those of the general population, excluding adults with particular neurological conditions and with more severe cognitive deficits. Recent studies show the mean age at death ranges from the mid-50s for adults with severe disabilities or DS, to the early 70s for those with mild to moderate intellectual disabilities.⁸⁻¹⁰

Concurrent with an increased life span, some evidence exists that certain individuals with developmental disabilities have experienced an increase in age-related diseases. Of the limited information available, research has shown that aging affects certain genetic and neurologically based intellectual and developmental disabilities that may increase the risk of age-related pathologies and lead to an increased occurrence of coincident conditions.¹¹ Of several developmental conditions, DS has been the subject of a substantial body of research. DS is known for resulting in advanced aging that includes a higher risk for Alzheimer disease and select organ dysfunctions.¹¹⁻¹³

Evidence exists that adults with CP, considered a life span disability, lose functional abilities earlier than individuals who are able-bodied.¹⁴ For CP, evidence is also increasingly pointing to specific age-related outcomes such as the effects of deconditioning, limitations with performance reserve, and possibly a shorter life span.¹¹ In adults with CP, secondary conditions commonly described in research primarily are related to the long-term effects on the musculoskeletal system, such as pain, degenerative joint disease, and osteoporosis.^{11,15,16} Secondary impairments in CP can progress subtly and may not appear until late adolescence or adulthood.¹⁵ Age-related health conditions are also seen in other genetic and neurological disorders as the affected individuals age. However, the nature of these risks lacks extensive substantiation in the literature.

Overall, knowledge of adult health issues for older people with developmental disabilities is limited.⁷ Several reasons contribute to the lack of knowledge. Limited health care programs exist for this population, likely because this is an emerging population. Most of the existing literature is in the pediatric domain rather than dealing with age-related issues. Although these individuals were likely seen by therapists for various functional limitations throughout their

lives, the professional training that health care providers have received regarding the care of these individuals has focused on early childhood and school-aged children. As a result, many adolescents and adults with developmental disabilities have difficulty accessing appropriate health care information regarding secondary conditions resulting from their specific disabilities. Moreover, in general, older individuals with developmental disabilities have more difficulty in finding, accessing, and paying for high-quality health care.⁷ Communication difficulties also limit the understanding of the experiences of aging adults with developmental disabilities. Evidence exists, however, showing that obesity and inactivity are more common in individuals with developmental disabilities than in the general population.¹⁷ Bazzano and colleagues¹⁷ identified several reasons for this health discrepancy, including individual and community factors, physical challenges, segregation from the community, lack of accessible fitness facilities and developmentally appropriate community programs, and cognitive deficits.

Given trends of increasing survival and longevity observed among individuals with developmental disabilities, it is sensible to consider a more in-depth look at the aging process among a variety of neurodevelopmental conditions and the need for a holistic approach. Although some literature exists regarding life span changes with these disorders, particularly DS and CP, there is lack of confirming evidence for most of these conditions. Horsman and colleagues¹⁴ advocate for research on the expectations regarding aging for adults with CP, including preventive measures to lessen the effects of secondary impairments. This recommendation applies to developmental life span conditions and other chronic conditions that are subject to age-related changes that may be magnified or made worse by existing impairments and limitations. Evidence-based research is necessary to better understand the long-term effects of aging on adults with developmental and chronic conditions. The challenge then is to provide a holistic examination that involves a multisystem approach and to provide appropriate referrals as necessary to address the multiple needs of individuals with developmental disabilities.

Neurological Conditions Acquired in the Life Span: Spinal Cord Injury, Traumatic Brain Injury, Postpolio Syndrome

In the realm of management of chronic movement dysfunction, PPS—the late effects of polio—becomes a model case for other chronic neuromuscular conditions. There is much to learn from the complex nature of the late effects of polio and the effects of aging on an already stressed system. The cause must be briefly discussed to further understand the possible effects of aging. PPS can affect polio survivors years after recovery from the initial polio infection and is characterized by multifaceted symptoms that lead to decline in physical functioning.¹⁸ PPS manifests with progressive or new muscle weakness or decreased muscle endurance in muscles that were initially affected by the polio infection and in muscles that were seemingly unaffected; generalized fatigue; and pain.¹⁸ The exact cause of PPS remains unknown on the basis of review of the literature. Although it is not clear what exactly causes the new symptoms, there appears to be a consensus that insufficient evidence implicates the reactivation of the

previous poliovirus.¹⁹ Underlying causes have been proposed in a variety of hypotheses from several authors, with aging playing a key role.²⁰⁻²⁴

The suggestion that aging contributes to PPS is supported in the literature.^{21,25,26} By the fifth decade of life, loss of anterior horn cells begins, and by age 60 years the loss of neurons may be as high as 50%.²⁷ Age-related changes superimposed on the already limited motor neuron pool after polio appear to be important factors in the development of PPS. With the effects of the normal aging process, the remaining anterior horn cells are further reduced to a point at which the deficits caused by the initial insult cannot be overcome. The loss of even a few neurons from a greatly exhausted neuronal pool potentially results in a disproportionate loss of muscle function.^{20,28} The loss of motor neurons from aging alone may not be a considerable factor in PPS because studies²⁰ have failed to link chronological age and the onset of new symptoms. Rather, it is the length of the interval between the onset of polio and the appearance of new symptoms that seems to be more critical.

Another plausible hypothesis alludes to overuse and fatigue of the already weakened muscles as a factor in the development of new muscle weakness.^{19,29,30} A study by Trojan and colleagues³⁰ provides support to this hypothesis. Their results suggest that length of time since acute polio, joint and muscle pain, physical activity, and weight gain are factors associated with PPS. Years of overuse after recovery from polio causes a metabolic failure leading to an inability to regenerate new axon sprouts. The exact cause of degeneration of axon sprouts is not known. Evidence to support this hypothesis can be inferred from muscle biopsies, electrodiagnostic tests, and clinical response to exercise.²⁰ McComas and colleagues³¹ suggested that neurons that demonstrated histological recovery from the initial virus were possibly not physiologically normal and were potentially vulnerable to premature aging and failure.

Other proposed hypotheses include persistence of dormant poliovirus that was reactivated by unknown mechanisms, an immune-mediated response, hormone deficiencies, and environmental contaminants.²⁰ Another hypothesis points to the loss of anterior horn cells during the initial polio as a factor.^{19,21} Findings from Trojan and colleagues³⁰ support the hypothesis that the severity of the initial motor unit involvement, seen as weakness in acute polio, is critical in predicting PPS. Individuals at greatest risk for PPS had severe attacks of paralytic polio, although individuals with milder cases also had symptoms.²⁰ These hypotheses have not been completely examined, and currently the evidence is not strong enough to support any one possible cause. Clinically it is difficult to assume that only one factor causes symptoms. The chronicity of the disease lends weight to the possibility that more than one factor contributes to the individual's symptoms.

Medical practitioners must take into account the effects of existing comorbidities and aging in the examination and management of PPS. The complexity and nonspecificity of symptoms warrant consideration of all possible contributors to the symptoms of PPS. Based on the recent literature, there appears to be some confusion regarding terminology pertaining to PPS. Compounding the general symptoms are the common problems in aging: decreasing muscle strength and endurance, joint problems, and myriad health deficits leading to functional losses. Physiological aging, overuse, and

comorbidities play contributory roles in disrupting the state of stability after the initial infection.

McNaughton and McPherson³² state that the simple descriptive labels “late problems after polio” and “of late deterioration after polio” are less limiting and do not imply a direct link with the previous polio diagnosis. Post-Polio Health International³³ uses the terminology “late effects of polio and polio sequelae” as the most inclusive category. *Late effects of polio* and *polio sequelae* pertain to health problems that are a result of chronic impairments from polio and may include degenerative arthritis from overuse, bursitis, or tendinitis. A subcategory under this heading is PPS leading to decreased endurance and decreased function.

Currently no definitive test exists in the literature to diagnose the late effects of polio or PPS. It remains a diagnosis of exclusion, and as such the diagnostic process for PPS is challenging and may be long. Halstead and Gawne³⁴ identified cardinal symptoms of PPS as new or increased muscle weakness, fatigue, and muscle and joint pain with neuropathic electromyographic changes in an individual with a definite diagnosis of polio. Diagnostic electromyography (EMG) may be required or used when the muscle pattern or history is atypical.

The criteria most commonly used for establishing a medical diagnosis of PPS were developed by Halstead³⁵ and are as follows:

1. A confirmed history of paralytic polio in childhood or adolescence
2. Partial to complete muscle strength and functional recovery
3. A period of at least 15 years of neurological and functional stability
4. Onset of two or more new health problems listed in Table 35-1
5. No other medical conditions to explain these new health problems

Modified from Halstead L, Wiechers D, editors: *Research and clinical aspects of the late effects of poliomyelitis*, White Plains, NY, 1987, March of Dimes, p 17.

ADL, Activity of daily living.

Dalakas³⁶ identified additional inclusion criteria in the diagnosis: residual asymmetrical muscle atrophy, with weakness, areflexia, and normal sensation in at least one limb and normal sphincteric function and deterioration of function after a period of functional stability unexplained by primary or secondary condition.

Several individuals who recovered from polio during the early epidemics were encouraged to exercise for years and to use heroic compensatory methods for function. An exhaustive regimen of daily stretching and strengthening, demanding compliance from individuals and their support systems, was strongly encouraged. Orthotics and assistive devices were promoted as a means toward independent mobility. The outcomes of rigorous training were individuals who adapted and compensated with their remaining capabilities. Compensations include use of muscles at high levels of their capacity, substitution of stronger muscles with increased energy expenditure for the task, use of ligaments for stability with resulting hypermobility, and malalignment of the trunk and limbs. With the late effects of polio or a diagnosis of PPS, many of these individuals may have extreme difficulty dealing with these new problems because of the attitude of “working hard” to reeducate weakened muscles and compensate for loss of function after the initial diagnosis.³⁷⁻⁴⁰ The new symptoms of PPS, which limits their motor function and likely impairs established personal and societal roles, require that they not work hard or overexert themselves. These two approaches are contradictory and can leave an individual frustrated and confused over therapeutic recommendations.

Spinal Cord Injury and Traumatic Brain Injury

For persons with SCI and TBI, a trend is seen toward increasing awareness on the effects of aging on the functional status of this group. Owing to medical advances, patients are now living 20 to 50 years past their time of injury. Numerous studies have been done describing quality-of-life issues for people with TBI; however, those studies seldom look specifically at changes in functional levels or what can be done to ameliorate the declines.⁴¹⁻⁴³

McColl and colleagues,⁴⁴ studying the impact of aging on people after SCI, have identified major categories of problems related to aging, such as musculoskeletal problems and joint, sensory, and connective tissue changes; chronic urinary tract infections; heart, respiratory, and other chronic diseases; secondary complications of the initial lesions, such as syringomyelia; and problems related to social and cultural acceptance and access or barriers. Evidence on specific age-related changes is presented in the section on examination.

Decreases in perceived health status and in functional abilities with increases in additional assistance for ADLs have been documented for aging individuals with SCI.⁴⁵⁻⁴⁹ In a study of 150 people aging with an SCI, nearly 25% reported decreases in the ability to perform functional activities that they had been able to handle after the acute rehabilitation phase. The subjects who reported decreases in functional ability were generally older (45 years compared with 36 years) and had longer postinjury periods (18 versus 11 years). The most common symptoms reported by the individuals with decreases in functional status were related to fatigue, pain, and muscle weakness. The ADLs reported

to be more difficult were transfers, bathing, and dressing. To maintain their functional levels, those with declines in functional ability reported needing additional equipment.⁴⁵

The need for further assistance with ADLs was echoed in a study by Gerhart and colleagues of individuals with SCI 20 years after the initial injury.⁴⁶ The study showed that 22% of the subjects reported an increased need for support with ADLs. Compared with a general group of nondisabled men and women aged 75 to 84 years in which 78% of the men and 64% of women did not need help with ADLs, the population of persons with SCI needed increasing support to remain independent, and the need for help occurred at a younger age. On average, those with quadriplegia required more help with ADLs around the age of 49 years, whereas those with paraplegia were able to maintain their functional level until age 54 years. The groups showing functional decreases reported greater fatigue, increased muscle weakness, pain, stiffness, and weight gain.⁴⁶ Other studies support the findings that 5, 10, and 15 years after the initial SCI, an association with the need for additional help with increasing age existed.⁴⁷

Liem and colleagues,⁴⁸ referencing an international data set of people with SCI, investigated a subset of 352 people at least 20 years after their injury. Thirty-two percent of the subjects reported needing increased help with transfers and housework compared with their functional abilities at acute hospital discharge. With increasing age, women had a higher incidence of reported musculoskeletal impairments, which may have been related to biomechanical differences between men and women (e.g., 40% lower upper body strength).

In addition to the need for ADL support, neurogenic bowel and bladder symptoms also worsen with age in some people with SCIs. With changes in general health status, polypharmacy, decreased activity, and poor nutritional patterns, bowel problems (particularly constipation) become more of an issue. Although constipation seems like a minor issue relative to paralysis, those with SCIs report significant abdominal distention and pain, an increased incidence of perineal and sacral skin breakdown, and in some cases autonomic dysreflexia. In addition to the discomfort of chronic bowel dysfunctions, the required bowel care programs may take more time, which can lead to increased psychosocial issues associated with anxiety about bowel accidents in social and work situations and may take time away from social activities for both the person with an SCI and the caregiver. For those with continuing bowel problems that interfere with life and work activities, a colostomy may be an option that increases independence from caregiver support during the bowel program.⁵⁰ Another complicating factor related to bowel dysfunction is the typical treatment for pain complaints. Because the origin of pain is often illusive, the most common treatment involves oral medications rather than referrals for therapeutic interventions. Pain medications, especially opioids, increase gastrointestinal difficulties in nondisabled populations,⁵¹ and the problem for patients with SCI is compounded.

Charlifue and colleagues,⁵² drawing on the National Spinal Cord Injury Database of 7981 individuals with SCIs that occurred from 1973 to 1998, found a slight decrease in perceived health status the longer one lived after SCI. Evidence was also found that those injured later in life had

a higher number of rehospitalizations after injury than those injured at a younger age. Despite palpable problems with the statistical issues within the sample, the study clearly indicated that the best predictor of a complication is a previous history of that complication. On the basis of their results, Charlifue and colleagues⁵² suggest that prevention of complications is the best approach to improve quality of health and quality of life for people aging with SCI.

Individuals with TBI are often neglected by professional health care and insurance providers after the acute rehabilitation period. According to Levin,⁵³ before 1980, individuals with brain injuries were considered “dead on arrival.” Persons who would have died from the TBI several decades ago are now living into old age and are coping with the changes caused by the aging process superimposed on their physical limitations and cognitive problems. Of great concern is the possible relationship between a history of brain injury and increased cognitive changes along the dementia continuum.⁵⁴ Cognitive decline in the nondisabled population is a problem, but the additive effect for a person with a previous TBI may seriously impair the person’s coping mechanisms when dealing with his or her own health and self-care needs.⁵⁵

Extensive work has been done on rehabilitation programs and quality-of-life issues related to head injury and, to a lesser extent, cerebral vascular accidents.⁵⁶ (See Chapters 23 and 24 for interventions for head injury and hemiplegia.) Unfortunately, the focus of rehabilitation after a TBI has been on the acute and rehabilitation stages of treatment and not the chronic problems that follow this group of patients into their older years. As with other chronic conditions, few patients see a therapist after they are discharged from rehabilitation unless they have new acute events such as musculoskeletal problems or a medical condition that causes a change in functional status.

Although TBI is a lifetime disability, little attention has been paid to the needs of aging persons with a TBI who may have recurring needs for physical and cognitive rehabilitation and retraining over the life span. Individuals who sustain a TBI in the older years will likely have different needs from those injured at a younger age. In a study on the effect of age on functional outcome in mild TBI, Mosenthal and colleagues⁵⁷ found that those injured later in life (after age 60) had longer inpatient rehabilitation periods and lagged behind younger patients in functional status at the point of discharge; however, similar to the younger individuals who sustained a head injury, the over-60 individuals showed measurable improvement during the 6-month study period. Therefore, aggressive management of older patients with TBI is recommended, and older patients may require continuing management owing to the overlying issues of the aging process.⁵⁷ This is echoed in the National Institutes of Health (NIH) consensus document on the treatment of people with TBI, which suggests that specialized interdisciplinary treatment programs need to be put in place to deal with the medical, rehabilitation, family, and social needs of people with TBIs who are over the age of 65 years. The document also concludes that access to and funding for long-term rehabilitation is necessary to meet long-term needs; however, it recognizes that changes in payment methods by private insurance and public programs may jeopardize the recommendations.⁵⁸

Although the authors of the NIH document recognize the need to deal with the aging processes associated with TBI, there continues to be a lack of services and trained professionals available, especially at the community level.⁵⁹ As with the SCI population, work is now being done to investigate the relationships among TBI, aging, and health. Breed and colleagues⁶⁰ found that older individuals with TBI were more likely than their age-matched nondisabled peers to report metabolic, endocrine, sleep, pain, muscular, or neurological and psychiatric problems. Their findings support those of Hibbard and colleagues⁶¹ and Beetar and colleagues,⁶² which suggest that medical personnel need to be prepared to treat a broad range of health issues in the aging TBI population. Fewer of the studies on long-term outcomes and issues in TBI extend to the 10- and 15-year postinjury periods that have been examined for patients with SCIs. In studies 5 years after the initial TBI, improvements in physical and social functions were noted in most areas for at least the first 2 years after injury, with the exception that those with a history of alcohol or drug abuse did less well. One could assume that continued abuse of alcohol or drugs would bode ill for individuals aging with a TBI.⁶³ In one study of 946 children and adolescents who sustained a TBI, Strauss and colleagues⁶⁴ found that patients with severe and permanent mobility and feeding deficits had higher mortality rates, with a 66% chance of surviving to age 50 years. In contrast, survivors with fair or good mobility had a life expectancy only 3 years shorter than that of the general population. However, because both severely and mildly injured individuals with a TBI can live well into and beyond their 50s, the impact of aging on the physical and cognitive deficits must be dealt with assertively to prevent superimposed disability.

Because aging individuals with an SCI or a TBI may have health problems similar to those of any aging population, primary impairments in muscle strength and endurance may be magnified. Therefore individuals with these chronic conditions who make repeat visits regarding medical problems such as musculoskeletal, cardiac, respiratory, and renal diseases should be referred for a comprehensive therapy examination and program that focuses on education, lifestyle changes, and health and wellness promotion interventions.

EXAMINATION OF INDIVIDUALS WITH CHRONIC IMPAIRMENTS

Estimates of the U.S. Department of Health and Human Services indicate that 40 to 54 million Americans have some type of chronic condition or disability.^{65,66} Conditions are diverse and may be related to trauma or chronic conditions such as MS.⁶⁶ Trends of increasing survival and longevity are now being observed among individuals with chronic conditions as they experience aging processes. It is timely to consider how to manage individuals with chronic impairments.

Examination of individuals with chronic impairments and disabilities is challenging to say the least. Not only are the impairments and functional limitations diverse, but the combinations of these impairments and limitations are many and unique to each individual owing to societal, personal health, environmental, and psychological

considerations. Moreover, the effects of aging will likely affect individuals differently depending on existing impairments, functional limitations, current health status, and each individual's attitude toward health and maintaining their functional status and lifestyle. This entails a more thorough, methodical, multisystem examination with a meticulous health interview and wellness model (see Chapter 2).

EXAMINATION: SYSTEMS MODEL

Aging with existing neuromuscular disorders, be it from a late-onset pathology or from a developmental condition, is a challenge for both the individual and the health care professional. There is a small body of literature on the later-life complications of early-onset acquired disabilities. Several problems may result from complex interactions among physical, medical, environmental, behavioral, and psychosocial factors.

Aging may confound late-onset symptoms or magnify the deficits from the initial CNS insult. With the trend of increasing longevity and survival rates from improvements in health care, it is necessary to look at how the health care provider approaches the examination of individuals with chronic impairments and activity limitations. As individuals with chronic neuromusculoskeletal impairments age, there will be an increasing number of comorbidities, and sorting out the cause of each new symptom will be increasingly complicated.

Bottomley⁶⁷ identifies essential components of a comprehensive geriatric assessment as psychosocial, functional, mental, and social health elements. These components are applicable to individuals with chronic neuromuscular impairments, who with aging are experiencing new symptoms or a magnification of preexisting impairments. [Box 35-1](#) shows a sample examination template for this population.

BOX 35-1 ■ EXAMINATION PROFILE FOR CHRONIC NEUROMUSCULAR IMPAIRMENTS

Examination: Systems Model

- Examination guidelines
- Health history
- Systems review
- Tests and measures
 - Musculoskeletal: strength, range of motion, and muscle length
 - Balance and coordination
 - Pain
 - Tone
 - Cardiovascular functioning
 - Integumentary
 - Mobility
 - Posture
 - Sensory deficits
 - Sleep
 - Temperature intolerance
 - Psychosocial considerations
 - Functional assessment

Challenges of Examination of Individuals with Chronic Conditions

Assessment of individuals with chronic nervous system conditions is challenging because of the diversity of impairments, the nonspecific nature of symptoms, and the complex interaction of several factors, including the heterogeneous effects of aging. Depending on their underlying health conditions, individuals with chronic conditions may have higher risks than others of developing preventable health problems.⁶⁶ In comparing nondisabled individuals with persons with disabilities, Iezzoni⁶⁸ found that the latter group is much more likely to have higher obesity and overweight rates and higher rates of depression, anxiety, and stress. Twenty-seven percent of adults with major physical and sensory impairments are obese, compared with 19% of those without major impairments.⁶⁸ Thirty-four percent of individuals with major difficulties in walking reported frequent depression or anxiety compared with 3% among those without disabilities.⁶⁸ Information on predisposition to conditions such as these is important for the health care provider during the health interview and examination process.

The examination of individuals with chronic impairments presents a different challenge than examining patients or clients with acute diagnoses. For both cohorts, the task of the health care provider is to determine the effect of the active pathology on the varied systems and function. However, for the individual with chronic impairments, an added challenge exists such that the impact of the active pathology is viewed with the underlying preexisting deficits in function and/or impairments that may leave the individual with a narrow margin for health.

Individuals with developmental and genetic disabilities and with conditions acquired through diseases or trauma sometime in the life span development have activity limitations and participation restrictions that are diverse and unique to each individual. Therefore some individuals may have higher risks than others of developing certain preventable health problems or may be more susceptible to developing secondary conditions owing to the long-term effects of the primary impairments from the original health condition.

The absence of specific medical diagnostic tests adds to the dilemma, as does the continuing uncertainty of the underlying cause and the lack of curative intervention. Health care professionals' limitations in knowledge of age-related medical disorders that are common in people with these conditions, including the prevalence and incidence of medical conditions with neurodevelopment disabilities also add to the complexity. [Box 35-2](#) provides several important pointers for examining this population of patients and clients.

The individual with chronic impairments who is currently facing an active pathology likely has adapted to his or her existing system impairments and activity limitations. Depending on their underlying health conditions, some individuals with chronic conditions may have higher risks than others of developing preventable health problems.⁶⁶ Thus, from an examination viewpoint, the critical task of the health care provider is determining what new changes to the individual's current abilities and disabilities have been brought on by the active pathology. These changes will likely affect the current functional abilities (e.g., mobility, ADLs), as will preexisting system impairments such as

BOX 35-2 ■ EXAMINATION POINTERS

- **Comprehensive:** A systems approach to address the number, complexity, and diversity of the deficits is a must. Essential components are physical, functional, mental, and social health.
- **Interdisciplinary:** Consideration for the functional, medical, vocational, and psychosocial issues warrants a coordinated evaluation of a team versed in addressing the unique needs of individuals with chronic neuromusculoskeletal conditions and disabilities.
- **Patient/client centered:** Factors that influence performance, such as fatigue, must be considered during the examination. Recognition of the individual's and family's values and goals is essential.
- **Thorough:** Assessment may take several hours and extend for two to four visits^{232,233} to better integrate the evaluation process and allow the patient to fully participate, contend with the recommendations, and engage in long-term management.

deficits in strength and endurance, pain, and so on. Regardless of the level of deficit, these individuals have some prior knowledge of deficits that affect function, which may help or may hinder their willingness to participate.

On the other hand, for the patient/client who has been otherwise healthy and functional and now has an acute diagnosis, active pathology may bring on impairments and limitations that are “new” experiences to the individual. The level of education should thus be adapted to the individual, and education performed on a case-by-case basis.

Moreover, the psychosocial aspect of a new pathology and its effect on function may be very different in an individual who has dealt with chronic impairments and limitations versus one who has been active up until the disease process. As with the level of education, the health care provider's approach to a patient/client should always be professional and respectful, with open lines of communication and active listening.

PTs may develop diagnostic focuses regarding functional limitations different from those of OTs. These variances depend on the functional activity limitations identified by the patient and the professional.^{69,70} An example of the physical therapy diagnostic process can be found in [Appendix 35-A](#).

It is critical for the clinician to examine all possible contributors to symptoms reported by the individual with chronic impairments. A thorough review of systems may identify symptoms that are related to the primary medical diagnoses, but equally important, it may identify symptoms that are associated with one or more existing comorbidities that have developed over time since the initial nervous system insult.

Health History

Therapists typically collect health history information as part of a comprehensive examination. The history information along with the symptom investigation and review of

systems and physical examination will provide guidance in the differential diagnosis process (see Chapters 7 and 8) and in the choice of examination and intervention techniques.

The information from the history will be useful in determining the possible cause of current difficulties or symptoms for which the patient/client is now seeking intervention (Box 35-3). Fatigue or pain may be present from unnecessary and inefficient movement strategies or from high levels of activity. Information on the habitual sleeping, sitting, standing, and walking postures along with ineffective use of devices may alert the clinician to possible factors contributing to the patient's current symptoms or difficulties.

Systems Review

A systems approach to the examination is essential because individuals with chronic conditions have a multitude of possible impairments with superimposed age-related conditions. This situation is best illustrated when examining individuals with PPS. The patient presentation in this condition is a complex interaction of all systems along with the effects of aging, previous interventions, and environmental, psychosocial, and medical aspects of care. The initial diagnosis of polio, which is critical in the diagnostic criteria, will need to be established. This may be difficult because approximately 10% to 15% of individuals who were believed to have or were diagnosed with polio did not have it, and some individuals with mild weakness were diagnosed as having nonparalytic polio.^{35,71}

Boissonnault⁷² discusses the review of systems as a vital component in the PT's role in medical screening and differential diagnosis (see Chapter 7). OTs are responsible for this same vital component. Possible multisystem involvement warrants review of all systems to determine if current problems are associated with existing comorbid conditions or occult disease or are indeed late manifestations of the initial disease process, as in the case of polio.

BOX 35-3 ■ COMPONENTS OF PATIENT/CLIENT HISTORY

- Demographics, include body mass index
- Growth and developmental history (particularly in those diagnosed with developmental disabilities and those with acquired diagnoses such as polio in childhood or spinal cord injury as an adolescent)
- Past medical-surgical history: include information on interventions and outcomes from initial diagnosis
- Family medical history: critical in ruling out possible contributors to symptoms such as pain from rheumatoid arthritis; critical for possible genetic contributor to original diagnoses
- Social and vocational history: include work status, modifications to work or home environment, and support system
- Living environment: include adaptive equipment, modifications done or necessary to home
- General current health status
- Current functional status, activity level, and perceived quality of life

Providing further substantiation for the need for a methodical and multisystem approach are findings of high rates of secondary conditions related to obesity and inactivity common in individuals with developmental disabilities. These secondary conditions include type 2 diabetes, cardiovascular disease, and metabolic syndrome, diagnoses that affect multiple systems.¹⁷ Individuals with developmental disabilities also have four to six times the preventable mortality of the general population.^{9,73} As therapists are entering into the decade of becoming primary care providers, anyone with a preexisting functional problem may walk into a PT or OT clinic searching for help. The importance of medical screening cannot be overemphasized.

The nonspecificity of symptoms seen in individuals with chronic movement dysfunction lends credibility to the need for review of all body systems. Fatigue, for example—a symptom frequently seen in individuals with chronic conditions of MS and PPS among others—is associated with several systems, such as endocrine, nervous, psychological, and cardiopulmonary involvement.

Tests and Measures

Through system assessment by the PT and/or OT, each individual with chronic movement problems should have an opportunity to participate in development of a unique clinical profile. This profile should reflect the strengths and limitations of that individual. Simultaneously these data should aid both the patient and the therapist in identifying realistic treatment goals and selecting the most appropriate intervention strategies. The choice of outcome measures will depend on the individual's current functional skills, the medical status, and the desires and expectations of the individual. Because the severity of symptoms is variable and nonspecific, the clinician is strongly urged to perform a thorough examination and take into consideration factors that may influence performance specific to that individual's functional impairment problems, such as fatigue and pain.

Critical to the examination process is the determination of secondary conditions. Secondary conditions have been defined as injuries, body system impairments, functional limitations, or disabilities that occur as a result of a primary condition or pathology^{15,74-78} as well as physical problems that were caused by small insults to one of the body systems not related to the primary condition. Musculoskeletal problems account for many of these secondary conditions; thus the musculoskeletal examination is of critical importance in individuals with developmental disabilities. Gajdosik and Cicerello⁷⁷ outlined numerous conditions that may affect the adult with CP; some can lead to significant loss in function and pain from complications such as fractures and osteoporosis. Other musculoskeletal conditions, including scoliosis, subluxations, dislocations, patella alta, foot deformities, pelvic obliquities, and contractures, further complicate the life progression of an adult with developmental disabilities.⁷⁷ Frequently these chronic conditions may have their origins in childhood, but because of the lack of sensory awareness may go undetected until later adolescence, adulthood, or well into advancing age when the body no longer has the ability to compensate for these abnormal biomechanical forces. Furthermore, as the aging process progresses, less regeneration of damaged tissue occurs, leading to greater cumulative trauma in joints and other

load-sensitive structures.⁷⁸ Again, these conditions need to be closely monitored over time to ensure appropriate intervention, optimizing an individual's function and minimizing damage to various tissues.

Fatigue

Fatigue is one of the most common symptoms reported by individuals with chronic conditions such as PPS⁷⁹ and MS.⁸⁰ Movement and performance of daily activities are more energy consuming for individuals with disabilities and may cause greater fatigue.⁸¹ Evidence also points to individuals with disabilities aging faster than those without disabilities; cardiovascular data from individuals with SCI indicate that persons with SCI may age faster than those without SCI.^{82,83} Cook and colleagues⁸¹ identified the lack of age-specific general population norms as an obstacle in the understanding and estimation of the influence of aging on the fatigue of individuals with neuromuscular conditions.

It is likely that that an earlier increase in fatigue with age might be observed in other chronic neuromuscular conditions; however, the effects of chronological age on fatigue in individuals with disabilities are not entirely clear.⁸¹ In a recent study, Cook and colleagues⁸¹ assessed fatigue and age in four clinical populations of individuals with PPS, SCI, MS, and muscular dystrophy (MD), comparing self-reported fatigue experience in different age cohorts with age-matched, U.S. population norms. A total of 1836 surveys were used in data analysis.

The authors concluded that individuals with disabilities reported higher levels of fatigue than the general U.S. population, regardless of age or disability type.⁸¹ Interestingly, the authors noted that the causes of fatigue likely vary by disability type—that is, MS, PPS, and MD are more likely to cause fatigue through a combination of central neurological processes, the effect of sleep disorders such as periodic limb movements (PLMs),⁸⁴ or increased physical effort, whereas in SCI fatigue may be a side effect of medications or result from sleep disorders.⁸¹

Results revealed not only that individuals with disabilities have a higher risk of experiencing fatigue than those without disabilities, but also that the risk for increased fatigue, compared with normative values, increases with age.⁸¹ The reported mean fatigue levels were the highest observed in older PPS age cohorts among the disability samples. In the MS group, fatigue was higher than in any other clinical group except PPS. The highest fatigue reported in the MS sample was in the 35- to 44-year-old age cohort, with lower fatigue in older cohorts except for those 75 years of age and older, but the older group had a small sample size. In the SCI group, peak reported fatigue was in the 55- to 64-year-old age cohort. The results for the SCI group younger than 55 years old were very similar to those for the general population.⁸¹

In the general population, very little change in fatigue levels for most adults was found moving from young (65 years) to middle (75 years) old age, whereas in the disability samples the authors saw a slight but consistent increase toward greater fatigue at this point in the life span.⁸¹ This increase in fatigue could be associated with current physical decline associated with disease progression.⁸¹ The authors concluded that more research is needed to determine the specific effects of fatigue on the functioning of persons

aging with disabilities and to further explore interventions that may shield against or reduce any negative effects that occur.⁸¹

Bruno and colleagues⁷⁹ state that fatigue has been identified as the most commonly reported, most debilitating, and least studied symptom in the postpolio sequelae. Generalized fatigue is typically described as overwhelming exhaustion or flulike aching accompanied by marked changes in level of energy, endurance, and mental alertness.²⁰ The lack of energy with minimal activity is often described as “hitting a wall,” thus the term “polio wall.” Polio survivors differentiated between the fatigue associated with weakness and a “central fatigue” that leads to attention and cognitive problems.⁷⁹ Severe fatigue affects not only physical function but mental function as well—hence the controversial suggestion that the fatigue associated with postpolio is caused by impaired brain function rather than the diffuse degeneration of motor units and motor junctions.⁷⁹

Descriptors for fatigue associated with PPS are significantly different.⁸⁵ The fatigue of PPS may not appear at the time of the activity, and recovery does not occur with typical rest periods. It has also been described as a sudden and total wipeout. In a few instances headaches and sweating appear, suggestive of autonomic nervous system overload.⁸⁶ Fatigue commonly occurs in the late afternoon or early evening. Fatigue that tends to last all day is atypical in PPS³⁵ and should alert the therapist to consider other possible diagnoses.

Similar to the fatigue of PPS, MS fatigue profoundly disrupts multiple aspects of general well-being.⁸⁰ Krupp⁸⁷ reported that 67% of individuals with MS reported fatigue as a major limiting factor in their social and occupational responsibilities compared with no reports in healthy adults. The fatigue of MS is unique in that it is exacerbated by heat, as are many MS symptoms. Fatigue may be acute, chronic, or intermittent or persistent, whether related to a specific diagnosis such as MS, CP, or polio or having no relation to the initial medical diagnosis. It is necessary to consider the role of other symptoms related to the specific medical diagnosis during the examination of fatigue.

The evaluation of fatigue includes the various factors that can induce or worsen fatigue. The history and examination also are used to assess for new medical diagnoses or the possibility of infection, an impending relapse, heat exposure (in the case of MS), and side effects from medications.

Differential diagnoses for fatigue are extensive and may include disorders of several systems, including psychological, cardiopulmonary, neurological, and endocrine disorders, and medication use. Specific conditions that may cause fatigue include depression, myasthenia gravis, hyperparathyroidism, congestive heart failure, sleep apnea, cancer, and infections. Numerous medications commonly used in symptom management can cause fatigue, including antispasticity agents, tricyclic antidepressants, and β -blockers. The challenge is to differentiate the fatigue caused by typical activities from the fatigue of chronic conditions.

Pain

Individuals with chronic diseases often have pain as a common symptom, most likely from long-term atypical biomechanical forces on joints and muscles or from long-standing

disease processes. Many developmental disabilities have a component of disordered movement, from hypomobility in the case of DS to hypermobility in the case of spastic CP. These abnormal joint stresses and strains cause long-term damage to the musculoskeletal system.^{77,88,89} The natural degradation of joint structures with aging coupled with weakness and atypical ground reaction forces leads to higher incidence of musculoskeletal pain.⁹⁰⁻⁹² Please refer to Chapter 32 for additional discussion of pain.

Pain that occurs with chronic conditions may be muscular or it may be joint related, or both. The source of pain needs to be considered because pain may limit the individual's functional abilities and lead to further decline. Muscle pain is often described as a deep, aching pain similar to the pain experienced during the initial infection. The pain is frequently aggravated by physical activity, stress, and cold temperature. Pain is unusual in that it does not occur at the time of activity but rather 1 to 2 days after a precipitating event.

Joint pain in itself usually results primarily from long-term microtrauma from abnormal biomechanical forces. An example might be the overuse of the shoulder girdle muscles and joint from a lifetime of use of Loftstrand crutches to compensate for lower-extremity impairments after polio. Joint pain is frequently associated with physical activity but is rarely associated with inflammation. Interventions are complicated by the presence of osteoporosis, lack of compensatory substitutions to rest the injured part, and, often, poor response to exercise. Failing joint fusions, uneven limb size, progressive scoliosis, poor posture, and abnormal mechanics may also contribute to pain.⁹³

Although pain is not a hallmark of many chronic conditions such as DS and MS, it may occur in some individuals with long-term impairments and thus should be part of a comprehensive examination. Pain frequently associated with MS is related to postural problems and inefficient use of muscles and joints to compensate for loss of function or spasticity.

More than 65% of individuals with PPS have reported neck, shoulder, and back pain radiating to the hip and leg.⁹⁴ This pain is expected because the incidence of major postural abnormalities and gait deviations is also high, as shown in Table 35-1.

Differential diagnosis for acute muscle and joint pain includes consideration of chronic musculoskeletal conditions leading to wear and tear and disorders with significant muscle or joint manifestations. The list is extensive and may include osteoarthritis, tendinitis, bursitis, fibromyalgia, rheumatoid arthritis, and polymyalgia rheumatica. The challenge is determining whether muscle or joint pain occurs from long-term wear and tear or from an acute or exacerbating occurrence.

Strength

Examination of strength is another critical component of the examination of individuals with chronic impairments. Long-standing weakness is an expected occurrence from decreased physical activity common in individuals with disabilities and chronic diseases. Strength deficits may result from several causes other than disuse such as upper motor neuron weakness, fatigue, compensatory movements, pain, or spasticity. It is likely, however, that aging

individuals with chronic conditions have adapted to the initial weakness associated with their diagnoses, as in the case of people with SCI or PPS who have led productive and functional lives since the initial diagnosis or acute onset.

Typical aging involves the losses of muscle strength, loss of power, and sarcopenia—processes that may intensify or build on the initial losses of strength. Delineation of weakness from age-related processes versus weakness as part of the disease process or that from lack of physical activity common in people with chronic impairments is difficult if not impractical from both research and clinical perspectives. Too many variables need to be controlled and accounted for unless specific muscle groups were examined initially and the findings well documented, which may have been the case for people with PPS. Many individuals with PPS have extreme difficulty dealing with these new problems because they were taught that hard work was the only way to correct physical problems that followed acute polio. These new problems, which also limit motor function, require that these individuals not work hard. These two concepts are contradictory and can leave an individual frustrated and confused over therapeutic recommendations.

Manual muscle testing of the entire body, although time-consuming, may be necessary to determine the muscular involvement. Muscle testing, however, may not always reveal the full extent of muscle involvement, and functional assessment may provide a better picture of individuals' potential and true difficulties. Performance and participation in daily activities will provide a better picture of a person's strengths and impairments. Therefore, current functional activities are critical in determining whether current mobility difficulties are related to the aging process, represent an exacerbation of initial disease processes such as in PPS, or are signs and symptoms of new medical concerns.

Weakness and Postpolio Syndrome. Weakness may occur in both previously affected and clinically unaffected muscles; however, it is primarily prominent in muscles most severely affected in the initial infection.³⁵ It is typically asymmetrical and may be proximal, distal, or patchy.⁹³ Weakness is primarily observed in repetitive and stabilizing contractions rather than with single maximum efforts. The decreased ability of the muscles to recover rapidly after contracting may be a factor. Recovery of quadriceps muscle strength after fatiguing exercise was significantly less in symptomatic PPS subjects compared with asymptomatic and control subjects.⁹⁵ Overuse of muscles in relation to their limited capacity has long been associated with these new problems.⁹⁶⁻⁹⁸ New weakness and atrophy have been attributed to metabolic overload of the giant motor units, with more pruning of muscle fibers than axon sprouting.^{99,100}

New muscle involvement may also cause signs and symptoms such as muscle fasciculations, cramps, atrophy, and elevation of muscle enzymes in the blood. Yet many of these physical signs and symptoms are also present in other neuromuscular problems such as amyotrophic lateral sclerosis (ALS; see Chapter 17). Fasciculations occur at rest and during contraction and tend to persist even when muscle pain and fatigue have been resolved. Muscle cramps are common in fatigued muscles and are alleviated by

decreased activity. The new weakness may or may not be accompanied by atrophy. New postpolio muscular atrophy of muscles is sometimes reported. It is very noticeable when it occurs in the gastrocnemius or the anterior tibialis owing to the effect on everyday ambulation. Elevation of muscle enzymes, indicative of muscle damage, has been found in individuals with PPS and has been related to the intensity of work.^{97,101,102}

Gross muscle testing may mask the true involvement because several muscles that were initially believed to be uninvolved were truly subclinically affected by polio. The pattern of definitive manual test findings (spotty, flaccid, and asymmetrical paresis or paralysis) is also used to confirm the initial polio diagnosis.

Several polio survivors are able to function at high levels of activity with few strong muscle groups as a result of the random, diffuse nature of the motor deficits and the body's ability to compensate with uncommon muscle and joint function. This delicate balance may be maintained for years, and a disruption from late-onset weakness of a significant muscle group can lead to disproportionate functional losses.

Superimposed pathological problems have been proposed as a possible cause of the later exhibition of new signs and symptoms in postpolio survivors. Several conditions may contribute to weakness, including arthritis, fibromyalgia, deconditioning from disuse, and coronary heart disease.¹⁰³

Range of Motion and Muscle Length

Limitations in joint motion from muscle contractures and from shortening of ligamentous joint structures are common in individuals with chronic disabilities. Likewise, hypermobile joints may also result from compensatory techniques forcing more mobility. An evaluation of the individual's activity levels and goals is vital before intervening with muscle and joint deficits. In some instances during the convalescent stage of the initial diagnoses, as in polio or SCI, selective tightness was allowed to give some stability to joints with paralyzed muscles. In addition, the body may develop useful contractures to maintain or regain function. The presence of spasticity, particularly in severe cases, may have also contributed to the development of contractures in older adults with CP, SCI, MS, or TBI. Before making attempts to stretch contractures, therapists should carefully evaluate the functions that may be lost if gains in range of motion (ROM) are achieved. Equally important is to evaluate what functions would be gained and what the cost would be. Consider that after 20 to 40 years these contractures resist any significant elongation, and aggressive intervention may cause more harm and loss of function.

Box 35-4 lists the secondary conditions that may develop in an individual with CP. These impairments not only cause pain but also limit mobility and interfere with performance of ADLs and leisure activities. Thus a thorough evaluation of musculoskeletal status and periodic monitoring are imperative to maintaining quality of life and social participation for these individuals.

Tone

Examination of tone is a focal component of the examination of individuals with chronic neuromuscular conditions. This group of individuals may demonstrate a wide range of

BOX 35-4 ■ SECONDARY CONDITIONS DEVELOPED BY INDIVIDUALS WITH CEREBRAL PALSY

PATHOLOGICAL CONDITIONS

- Fractures
- Osteoporosis
- Cardiovascular disorders
- Degenerative joint disease
- Spinal cord compression
- Dental problems
- Seizures
- Pulmonary dysfunction

IMPAIRMENTS

- Constipation
- Contractures
- Depression
- Emaciation
- Obesity
- Incontinence (bowel and bladder)
- Pain
- Ulcers
- Dysphagia
- Gastrointestinal problems
- Low self-esteem
- Nerve entrapments
- Overuse syndrome
- Balance problems

FUNCTIONAL LIMITATIONS OR ACTIVITY

RESTRICTIONS

- Inability to indicate toileting needs
- Dependence on others for activities of daily living
- Limitations in mobility
- Difficulties using public transportation

DISABILITIES OR LIMITATIONS IN LIFE

PARTICIPATION

- Difficulties living independently
- Limited recreational opportunities
- Problems with social relationships and intimacy
- Social isolation
- Difficulty with role as patient when medical professionals fail to make accommodations for treatment
- Underemployment

Modified from Gajdosik CG, Cicerello N: Secondary conditions of the musculoskeletal system in adolescents and adults with cerebral palsy, *Phys Occup Ther Pediatr* 21:49-68, 2001.

tone deficits from hypotonia seen with DS, to hypertonicity seen in persons with TBI, SCI, MS, or CP, to a mixed type with episodes of high and low tone.

Spasticity can interfere with mobility and may coexist with weakness. It may cause pain and atypical postures, predispose the individual to contractures (particularly those with severe spasticity), and interfere with hygiene and self-care. On the opposite end of the tone spectrum, persons with DS have hypotonia that may or may not limit mobility. Tone deficits in DS are not a primary limiting factor to mobility and physical activity, as the characteristic finding of marked hypotonia tends to gradually diminish with age.

Cognitive Function

Cognitive deficits may be a major disabling feature in genetic and developmental conditions such as DS and CP. Similarly, cognitive dysfunction may be a key symptom in chronic conditions such as MS, TBI, and SCI. The degree of cognitive deficits affects not only health management but also the long-term planning for aging processes in persons with chronic disabilities and conditions. The need for life-long external support is a considerable issue for those who are unable to independently care for themselves as they age. The degree of cognitive deficits in this population may range from memory deficits to mental retardation; the degree of cognitive and perceptual deficits determines participation in functional activities and self-care, mobility, compliance, and even health status.

Standardized outcome measures exist to measure cognitive impairments; the examiner is cautioned to consider the validity and reliability of outcome measures for specific populations before use. The reader is referred to chapters discussing specific diagnoses for detailed outcome measures. Because cognition is multidimensional, examination for deficits will need to be directed at different components of cognition. Screening may be as simple as a three-item recall or short questions determining the ability to follow commands, attention, level of consciousness, orientation, judgment, construction, and higher memory function.

Mobility and Posture

In individuals with chronic impairments, addressing inefficient alignments and postures is of critical importance, particularly if this area was not addressed early in their care. The dire effects of such malalignments and compensations described in the following paragraphs eventually affect functional abilities.

Asymmetrical or abnormal gait patterns, crutch walking, and propelling manual wheelchairs for several decades are frequently the major sources of the pain, weakness, and fatigue in people with chronic movement dysfunctions after a medical problem such as TBI, SCI, CP, PPS, or cerebrovascular accident (CVA). The incidence of pain in a group of 114 patients with confirmed PPS increased from 84% in those who were ambulatory without orthotics to 100% in those who used crutches or wheelchairs for locomotion.⁹⁴ A high prevalence of osteoarthritis in patients with PPS was documented in the hand and wrist by radiography.¹⁰⁴ More than twice the number of subjects with PPS had osteoarthritis of the wrist or hand than would be expected in a healthy population of the same age. The risk factor was significantly increased with lower-extremity muscle paralysis and use of assistive devices.

In an electromyographic study of walking in clients with PPS, Perry¹⁰⁵ demonstrated overuse and substitution activity of the vastus lateralis, biceps femoris, and gluteus maximus muscles when the soleus is nonfunctional. Such substitution and overcompensation in the long term, however, lead to microtrauma of ligaments and joint structures and exhaustion of neuromuscular units.

In addition to sitting in poorly supporting chairs, sofas, auto seats, and wheelchairs, the individual with chronic impairments may have trunk muscle paresis or asymmetries of the pelvic base and may spend up to 16 hours per day in the seated position. The typical posture is slumped, hanging on

posterior vertebral ligaments with loss of lumbar and cervical curves. Neck, shoulder, and back pain are therefore commonly reported.

Levels and types of mobility will be diverse in individuals with chronic neuromuscular impairments. Mobility may range from independent ambulation to gait with an assistive device all the way to wheelchair dependency, depending on existing impairments and cognitive function. Thorough examination should determine the current mobility levels and possible modification needs depending on new impairments or functional limitations. It may be necessary to include a seating examination in persons who are wheelchair dependent or sit for the majority of the awake hours.

Balance and Coordination

Deficits in balance and coordination in individuals with chronic conditions predispose these people to falls and limit safe mobility. As individuals with these conditions age, typical age-related changes in balance may add to the existing deficits and magnify functional limitations and impairments. Coordination and balance deficits need to be examined under functional conditions and in the context of the individual's daily activities. Standardized outcome measures are also available to objectively measure impairments; however, the reliability and validity of such measures in specific populations may be deficient. Use of outcome measures may provide a multidimensional look into deficits and provide objective baseline measures to track progress with intervention as well as progression of the movement dysfunction.

Environmental Temperature Intolerance

Consideration for the effects of heat and/or cold may be necessary when working with individuals with chronic diseases, and the examination must include a component of temperature intolerance. Two specific diagnoses embody this phenomenon: PPS for cold intolerance and MS for the negative effects of environmental heat.

Regulation of body temperature is often a problem for individuals with MS (see Chapter 19). Earlier, it was noted that a feature of fatigue unique to MS is that the fatigue is exacerbated by heat. Other MS symptoms may also be aggravated by heat. The Uthoff phenomenon¹⁰⁶ is an adverse response to external heat, causing fatigue or deterioration of symptoms; it often occurs with exercise. Specific recommendations for cooling during exercise intervention may be necessary to counteract the deleterious effects of heat. It is important that the examiner meticulously determine during the health interview the symptomatic effects, if any, of increased temperature in the aging individual with MS.

Sensory deficits per se are not hallmark features of polio; however, cold intolerance is a commonly reported late-onset symptom. Involved extremities in individuals with PPS are frequently abnormally cold as a result of sympathetic nerve cell involvement leading to decreased vasoconstriction and venoconstriction with heat loss to the environment.¹⁰⁷ The impairment may become worse with PPS. Environmental adaptation can create an easy solution to this problem as long as the individual with PPS is aware first of the problem and second of the adaptations necessary to avoid thermoinstability within the extremities.

Preventing versus responding to the inadequate vasore-sponse to cold empowers the individual to develop envi-ronmental control.

Sleep Disturbances

It is common knowledge that elderly individuals report and manifest sleep disorders.^{108,109} Thus, this body system problem certainly can be associated with aging individu-als with chronic movement dysfunction. Disturbances in sleep are a common symptom in persons with chronic neuromuscular diseases. Sleep deprivation is a contribut-ing factor to fatigue in individuals with MS. Similarly, more than 50% of individuals with PPS have been found to have sleep disturbances.¹¹⁰ These disturbances may be caused by pain, stress, hypoventilation, or obstructive apnea.¹¹¹⁻¹¹³ Bruno¹¹⁴ proposed a high incidence of abnor-mal movements in sleep in nearly two thirds of polio survivors, with 52% reporting sleep disturbance caused by these movements. All seven of subjects with PPS in the study demonstrated abnormal movements in sleep. The author points to the importance of eliminating sleep disor-ders as a cause of fatigue before the diagnosis of postpolio sequelae is made, particularly because it remains a diag-nosis of exclusion.¹¹⁴

In addition to the typical symptoms of muscular weak-ness, pain, and fatigue associated with PPS, some individuals also develop sleep disorders such as periodic limb move-ments (PLMs).⁸⁴ PLMs in sleep are repetitive episodes of muscular contractions with durations of 0.5 to 5 seconds; frequencies of five or more per sleep hour are deemed patho-logical. The association of PLMs with insomnia or daily sleepiness suggests the diagnosis of PLM disorder.⁸⁴ Whereas PLM has been related to the pathophysiology of PPS,¹¹⁴ the occurrence of PLM in PPS is not well known.⁸⁴ In a recent retrospective study of 99 patients with PPS, researchers assessed the frequency of PLMs during sleep, including other sleep-quality variables such as total sleep time, effi-ciency of sleep, apnea-hypopnea index, and awaking index.⁸⁴ Sixteen patients showed a PLM index that was considered pathological. The authors concluded that a close relationship between PLM and PPS exists; however, the prevalence of PPS with or without PLM and its combination with apnea-hypopnea is not clearly established, a finding in agreement with the conclusions of Jubelt and colleagues.^{84,115}

A thorough history and review of systems including a sleep history may reveal the potential causes and guide the therapist in the clinical decision-making process for referral and consultation. Sleep apnea, which occurs frequently in polio survivors, and other sleep disorders including abnor-mal movements in sleep, may be revealed with specific questioning, triggering the referral process. The therapist plays a role when the sleep disorder is associated with the area of pain management.

Life-Threatening Conditions

Limited knowledge exists of adult health issues for older individuals with developmental disabilities. Secondary med-ical conditions warrant further examination, particularly in aging adults with chronic conditions. Acute onset of new symptoms may suggest exacerbation of disease or decreased functional reserves or may arise from long-standing effects of impairments from the initial disease process.

In the case of PPS, bulbar muscle dysfunction⁹³ may also result from the new weakness. Life-threatening conditions such as hypoventilation, dysphagia, sleep apnea,¹¹⁶ and car-diopulmonary insufficiency require management by medical specialists.^{111,117,118} These problems occur in people with previous bulbar poliomyelitis who may or may not be using ventilatory assistance and in those with severe kyphosis or scoliosis. Respiratory failure may occur primarily in indi-viduals with residual respiratory insufficiency and minimal reserves.¹¹⁵

Functional Assessment

Performance in functional activities often provides a better picture of the losses stemming from chronic impair-ments. Decreases in strength are not usually revealed in a single-effort maximum contraction such as required in the manual muscle test. Resistive force during testing is a necessary element for two grades, 5 (normal, “N”) and 4 (good, “G”), whereas the other four grades are non-resistive and mostly nonfunctional, and few examiners are now tested for reliability.¹¹⁹ In a 1-year follow-up using quantitative muscle force testing, no differences were found in muscle strength, work capacity, endurance capacity, or recovery from fatigue of the quadriceps in either asymptomatic or symptomatic groups with PPS.¹²⁰ Nevertheless, there is at best a slow decline in functional ability, which clients may describe as loss of muscle strength. Clinically, individuals seeking therapy report functional loss or limitation more easily than a specific loss of muscle strength.

Functional assessment of individuals with chronic move-ment limitations provides a more practical and clearer picture of the abilities and limitations related to the initial condition or stemming from new impairments. Functional activities are visible and reportable performances of relevant tasks in the context of the individual’s culture.¹²¹ Functional tasks imply a specific goal and can range from simple to complex activities. In functional motor performance, the specific task and environmental context is as important as the individual functional movement (refer to Chapter 8). Consideration for these factors is necessary during examina-tion. Detailed functional assessment is outlined by Howle¹²² and Zabel.¹²³

Functional limitations are difficulties in performing spe-cific tasks. Difficulty in performing daily tasks including mobility and transfers may stem from overuse of muscles and joints that are already performing beyond their typical use, pain, fatigue, muscle weakness, weight gain, cognitive impairments, and decreases in functional endurance, among others. It can be logically inferred that individuals living with chronic movement impairments will reach a tipping point at which the performance of current activities will be hindered or the way activities are performed will require modification.

Decreases in functional activities over time for varied chronic conditions^{35,45-49,124} have been documented in the literature. As early as 5 years and up to 20 years after the initial SCI, individuals have reported decreases in func-tional activities and increased need for assistance with ADLs.⁴⁵⁻⁴⁸ An association with the need for increasing sup-port with advancing age in individuals with SCI is seen in the literature.⁴⁵⁻⁴⁷

TABLE 35-2 ■ MAJOR POSTURAL ABNORMALITIES IN SITTING, STANDING, AND WALKING IN 111 CONFIRMED POSTPOLIO CLINIC CLIENTS

POSTURE	ABNORMAL DEVIATION	NO.	%
Sitting (n = 111)	Absent lumbar curve	64	54
	Forward head (loss of cervical curves)	50	45
	Uneven pelvic base*	29	26
	Structural scoliosis	38	34
Standing (n = 76)	Absent lumbar curve	52	68
	Uneven pelvic base*	40	53
	Weight bearing on stronger leg	29	38
Walking (n = 76)	Abnormal gait deviations	76	100
	Major lateral trunk oscillations	33	43
	Obvious forward lean	40	53

*Pelvic asymmetry was ½ inch or more.

According to Agre and Rodriquez,¹²⁵ postpolio survivors with significant weakness perform daily activities at a different level of effort than other individuals; muscles of polio survivors may have to work near maximal effort during activities that individuals without polio can execute at relatively lower levels of effort. Individuals with PPS commonly report difficulty in walking, stair climbing,³⁵ and dressing (Table 35-2). Westbrook¹²⁴ described a 5-year follow-up study examining physical and functional abilities and health status of 176 individuals with PPS. During the course of the study, most subjects reported increases in muscle weakness, muscle and joint pain, and changes in walking. Notably, the participants reported more difficulty in four of the eight daily living activities (stair climbing, walking on level surfaces, transfers in and out of bed, and meeting the demands of home or work). Most of the participants (87%) also reported problems in meeting the demands of their job and completing household tasks. Clearly, the ability to perform motor tasks essential to completing one's goals and desires is multifactorial. Therefore, functional limitations are usually related to a combination of systems impairments.

In persons with PPS, to determine whether the cause of the new weakness is overuse or possibly disuse, a detailed assessment is required of home, work, recreational, and community activities.¹²⁶ This paradigm of multidimensional assessment is applicable to all individuals with chronic movement problems. If the client is merely asked what his or her activity level is, the response may lead to assumptions that weakness is from disuse. With specific questioning, one usually finds that the client is doing an extraordinary amount of physical activity. It is vital to establish a total picture of the client's activities in sitting, standing, walking, lifting, carrying, climbing stairs, using a telephone or a computer, and performing daily activities such as self-care and home management.

PSYCHOSOCIAL CONSIDERATIONS

The challenges of chronic diseases are ongoing as the individual ages. Despite new pharmacological interventions, several genetic, developmental, and neuromuscular conditions

remain incurable with uncertain courses as the person ages. Although individuals and their families cope effectively with the initial disease process, the incidence of depression is common in the presence of chronic disease and impairments. The impact of chronic conditions on family, marital life, and socioeconomic and financial functions is persistent. The clinician's attitudes, beliefs, support, and understanding will play a major role in the management of individuals with chronic impairments.

Most individuals living with chronic impairments and functional limitations have learned to adapt not only with their movement strategies, but also with the psychological and socioeconomic impact of the initial diagnoses. Not only have these individuals learned to live with the challenges of their initial diagnosis and its movement-related, functional, financial, and psychosocial impact, but their families and caregivers have likewise done so. It may not be surprising, then, that changes to once-established routines, either from acute medical conditions or from gradual but significant changes from the aging process, are resisted and negatively viewed. These individuals will possibly need more assistance, move slower, and need to cut back from activities once engaged in; the consequent changes in philosophy and lifestyle will not likely be welcomed by most individuals and their support systems.

Over the past years, several authors have addressed the prevalence of PPS, its causes, and the effects of aging on the development of PPS.* Some literature addresses the effects of aging on developmental and genetic disabilities, yet information on how aging affects individuals with existing impairments is still not conclusive. Because persons who are aging with chronic disabilities is an emerging population owing to improvement in health care delivery and nutrition, evidence on the consequences of the aging process remains uncertain. Similarly, the psychological effects are not as widely addressed in the literature. Not much is known about the quality of life of older adults with congenital or childhood-acquired

*References 19, 21, 25, 26, 31, 32, 35, 36, 71, 79, 93, 104, and 127-131.

disabilities. Psychological adjustment is difficult with any disease with an unpredictable course, and differentiating organic psychological problems from adjustment issues may complicate the management of individuals with chronic diseases.

As a chronic disease, PPS provides an informative example of the interaction among neurological and functional impairments, recovery, effects of aging, and health care. Much has been written about the psychological and psychosocial issues with PPS that is applicable to other chronic disabilities as well. A brief synopsis of the psychosocial considerations of PPS follows.

Postpolio Syndrome

Although the physical manifestations of and interventions for PPS are recognized, psychological symptoms become evident in polio survivors. Bruno and Frick³⁷ described psychological symptoms such as chronic stress, depression, anxiety, compulsiveness, and type A behavior in polio survivors; these symptoms not only cause distress but limit these individuals in making lifestyle changes to manage late-onset symptoms. Currie and colleagues¹⁰³ made generalizations about adults with childhood-onset or congenital disabilities spanning a range of disability types. Understanding the background of individuals with PPS and a few of the myths that helped to shape their lives is beneficial in their care. Fear of the disease was rampant during the early epidemics. Despite safety measures, children and adolescents contracted polio. Part of the coping strategy was encouraging the child to high levels of physical achievement; approval and rewards were gained by walking farther or faster and keeping up with or exceeding the performance of other children. The best treatment available for all polio victims at that time was from the March of Dimes, which entailed hospitalization for months at a time away from the individuals' families and communities. The situation led to feelings of abandonment, anxiety, and total dependence on strangers. The "polio patient" was expected to be a "good patient" and to "work hard." Indeed, these patients did work hard to reeducate weakened muscles and compensate for lost function.³⁷⁻⁴⁰ Courage, determination, and cheerfulness were attributes to be prized, self-pity was viewed unfavorably, and talking about the functional loss was not encouraged. Later in the recovery process, parents made decisions to have their children undergo multiple surgical procedures to allow removal of heavy braces so that they would "look normal" and "fit in." One can understand why clients react so negatively to the suggestion of orthotics.

Coping Strategies

The psychosocial issues confronting persons with PPS often are more disruptive than the physical problems.^{22,23,71,132-134} An increasing population of polio survivors is experiencing, with aging, an unanticipated late onset of new symptoms. Associated with loss of physical function and independence are social and psychological problems stemming from the inability to perform personal and societal roles. Previous research suggests that well-established, often compulsive behavior patterns may impair the ability to deal effectively with the new threats to functional independence. Bruno and Frick²⁴ confirmed the presence of psychological stress in survivors, noting that type A behavior and stress could

precipitate or exacerbate postpolio sequelae. In a later study in 1991³⁷ the same researchers suggested that the acute experience conditioned survivors into lifelong patterns of compulsive type A behavior, a behavior pattern that impairs the ability to cope with new late postpolio symptoms. Kuehn and Winters¹³⁵ also noted that symptom distress and intensity were less in individuals with greater coping resources. In this study¹³⁵ in Sweden of 113 patients with postpolio sequelae, results revealed that the prevalence of distress was highest in the physical dimensions of physical mobility, pain, and energy and lowest in social isolation. The high scores for the triad of dimensions were similar to the findings of previous studies.¹¹⁶

Individuals with PPS developed several styles to cope with their disability. Maynard and Roller¹³⁶ described coping styles according to severity of muscular involvement. Survivors with little or no obvious physical involvement were able to hide atrophy with clothing and avoided activities that revealed the weakness. Many individuals invested much energy in projecting normality and were so adept at denial that they disconnected themselves from the polio experience; often spouses do not know of the history of polio. This group can develop the most severe cases of PPS. The denial renders them detached from other individuals with PPS and thus difficult to assist.

Polio survivors with obvious physical involvement such as a limp or an atrophied extremity or who use an assistive device have usually pushed themselves to function at normal or supernormal levels. These individuals will tolerate high levels of pain before acknowledging the late effects of polio. The third group, the most severely impaired of the individuals with PPS, may have respiratory involvement or more mobility deficits. Several use or have used wheelchairs for mobility and required great effort and persistence to gain independence in self-care activities. The members of this group integrated their functional problems into their self-image and have led active, productive lives.

In a 5-year study of 176 individuals with PPS, it was unexpectedly found that participants' stress levels decreased over time.¹²⁴ The author hypothesized that eventually, lifestyle modifications and treatment contributed to the coping process. Kuehn and Winters¹³⁵ in their study found that more than half of their subjects of working age had gainful employment. Moreover, no difference in employment rate as a result of distribution of polio involvement was found, implying that this was not a deciding factor. The authors hypothesize that persons with severe polio involvement were either forced to choose or encouraged to take up an appropriate profession early in life, whereas those with less involvement had not needed such planning. Nevertheless, vocational issues encompassing satisfactory accessibility and equipment are an important part of management.

Response to New Diagnosis. The response to the diagnosis of PPS can range from relief to despair. Relief comes to polio survivors who have been told their symptoms were psychosomatic. Despair occurs when survivors are given a program of lifestyle changes and management suggestions that are opposed to the adage they followed during the initial infection. The proposed philosophy shift from "no pain, no gain" to energy conservation and rest may be viewed unfavorably or with disdain. Polio survivors who have led active lives may have significant

difficulty adjusting their lifestyle to new symptoms and decreasing abilities, and psychological support may be indicated.¹³⁷

The stresses of the diagnostic process also add to the challenges. Most health care professionals have limited understanding of the initial polio experience and the late effects of polio, and therefore the diagnostic process of PPS may take time and involve a series of physician consultations.^{37,38,138-140} Publicity from support groups has helped refer clients to PPS clinics or to specialists with knowledge of PPS.¹⁴⁰

Fear of the threat to independence, inadequate knowledge about the physiological changes, and the expectation of functional loss may contribute to the anxiety of polio survivors. Individuals with PPS will feel anxious about the prospects of changing roles with their families, friends, and co-workers.^{38,136,139} Defenses and coping strategies that have been successfully used for years have broken down, and the individual experiences overwhelming anxieties and conflicts.¹³⁹

Compliance. The patient-clinician relationship is an important determinant of compliance. Several authors^{24,37,141} have identified compliance as a significant problem in type A polio survivors. Although a few individuals with PPS readily accept suggestions for lifestyle changes, a few immediately make changes, and a few refuse to consider any changes at all, most will eventually make changes but will require support, patience, and time to process. Compliance is an issue encountered not only in individuals with PPS but in many individuals with chronic conditions. Clinicians' sensitivity, support, and respect will play a major role in the response of the patient/client to management suggestions. Acknowledging the individual's current activities, values, and goals is an important step in establishing a relationship with the patient/client. Allowing clients to express feelings about the new challenges, their prior high levels of physical achievement, and previous treatment is equally important.

A health care provider perceived to be knowledgeable, interested, and concerned significantly increases compliance with recommendations.¹⁴² Compliance of the client with PPS may be improved by the therapist's ability to suggest management strategies that are accepted as conventional and the ability to alleviate pain in the initial examination. Conservative management should be attempted first before more aggressive or life-changing interventions such as orthoses, mobility changes, or motorized carts, which they may have used in the past and eventually discarded. Therapists can also be a source of information about support groups.¹⁴⁰ Support groups offer information about every facet of living with chronic impairments, and these members may be positive role models to help not only the newly diagnosed individual in the transition process but also the aging individual with chronic disease and impairments deal with issues with maturation and advancing age.

HEALTH-RELATED DISPARITIES IN AGING ADULTS WITH CHRONIC DISABILITIES

Individuals aging with chronic impairments and conditions are exposed to the effects of aging and maturation differently than the general population. Persons with disabilities often start at the lower end of the health continuum owing to secondary conditions that overlap with the primary disability.¹⁴³

Few will argue that despite medical advances and public health initiatives, the reality is that health disparities, including decreased access to high-quality health care, health promotion, disease prevention, and health literacy, are still present and reflect areas that need to be addressed. Outlined here are some health disparities facing adults with chronic disabilities and conditions.

- Compared with the general population, higher rates of disability and obesity are seen among adults with developmental delay.^{66,144,145} Of adults with major physical and sensory impairments, 27% are obese, compared with 19% of those without major disability.⁶⁸
- Cardiovascular disease is one of the most common causes of death among aging adults with developmental delay.^{17,146,147}
- Evidence supports the earlier appearance of age-related health conditions in individuals with developmental delay. Conditions include cognitive decline, incontinence, and sensory losses.¹⁴⁸ Examples of health conditions that may be influenced by aging in persons with developmental delay were discussed earlier regarding individuals with CP¹⁴⁹ (who may have increased issues with musculoskeletal deformities, progressive cervical spine degeneration, dental problems, bladder or bowel dysfunction, or osteoporosis) and individuals with DS (who have a higher prevalence of early-onset Alzheimer disease compared with the general public).^{13,150}
- Generally, individuals with intellectual and developmental disabilities have poorer health and more difficulty in finding, accessing, and paying for higher-quality health care.⁷
- Adults with developmental disabilities also have limited access to medical care, which may result in lack of obesity screening, counseling, and management.¹⁵¹
- Higher rates of depression, anxiety, and strong fears and stress are seen in persons with chronic disabilities. Iezzoni⁶⁸ found that 34% of adults with major impairments in walking reported frequent depression or anxiety, compared with 3% in those without disabilities.

MANAGEMENT OF CHRONIC IMPAIRMENTS

Aging with Chronic Impairments

The management of individuals with chronic impairments is challenging, not only because of the possibility of multi-system involvement warranting a holistic approach, but also because much is unknown about effects of the aging process on chronic neuromuscular impairments.

Aging adults with chronic conditions may be more vulnerable to conditions that will make their old age potentially more difficult with an increased possibility for infirmity and dependence.⁷ Individuals with chronic and disabling impairments are often at an increased risk for the development of secondary conditions and further disability that can lead to further decline in independence and functional status and to mobility deficits. It has been suggested that people with chronic conditions such as living with developmental delay, may age differently based on the nature and severity of their disability, other coexisting health problems, and secondary chronic conditions. With increased life expectancy, health care professions will likely see an increase in the care of

those aging with chronic impairments. There is then a unique challenge for health care professionals to develop and implement programs for the management of aging adults with chronic impairments to effect optimal health status.

The heterogeneity of aging adults with chronic neuromuscular impairments lends to the need for individualized management programs. The aging process is unique for each individual, as is the recovery process in people with chronic conditions and the overall manifestation of late-onset or secondary symptoms. Therefore intervention will be dependent on the individual's current symptoms, functional needs, level of activity limitations, and values or goals.

Although evidence exists regarding interventions for individuals with chronic disease, overall, there is a dearth of information on specific treatment strategies if one considers the magnitude of associated diseases and the increasing population of individuals aging with chronic functional limitations and impairments. The reason for this is multifactorial; it may stem from the mismatch between the increase in number of individuals with chronic diseases that is resulting from longer life expectancies because of advancements in medicine and the gaps in our knowledge about the effects of aging in this population. The limitation on specific knowledge about interventions is echoed by Marks and colleagues, who state that there is a lack of framework for assessing health-related interventions for individuals aging with developmental delay.¹⁵²

A finite number of research and treatment centers have been established to deal with comprehensive care issues for individuals with disabilities.¹⁵³ The statement by Kailes¹⁵⁴ regarding the lack of helpful information related to exercising for those aging with a disability is troubling yet accurate. Considering the extensive evidence showing that many of the physical limitations that occur as part of aging in nondisabled people can be prevented or delayed by changing health habits, Kailes¹⁵⁴ suggests that individuals with disabilities need (1) appropriate fitness assessment measures that can be used with various types of disabilities, (2) exercise guidelines that are appropriate for age and types of limitations, (3) exercise facilities that are accessible, integrated, and not separate from those of nondisabled populations, and (4) exercise equipment that incorporates universal design features.

Unfortunately, in today's health care environment, many individuals with PPS, SCI, TBI, or developmental disabilities do not have access to specialists, including PTs, who understand their complex movement limitation-related needs and how these limitations affect participation in life. Care is fragmented, and physicians and therapists, if involved in the care at all, seldom have a comprehensive picture of the person's needs. Although one might assume that the managed-care system would provide coordination of care within the provider system, the reality is that there may be more restrictions in care, particularly for disability-related care that may require a period of continuing rehabilitation treatment and retraining. Even providers within the group seldom communicate because the group is composed of practitioners who accept the insurance contract rather than practitioners working together to improve health. In my experience, hardly any individuals aging with neurological conditions such as TBI, CVA, or SCI seek therapy

past their initial episode of care in the acute phase of the condition. This reality is confirmed in the literature; today persons with SCI or TBI are followed in comprehensive specialty centers or clinics as they age.^{155,156}

Multisystem Approach

Individuals with chronic neuromuscular conditions have multidimensional impairments across multiple systems. Chronicity of impairments in one system likely and eventually affects other systems. For example, an individual with limited physical mobility because of impairments in the neuromuscular system likely has decreased levels of physical activity, which in turn are correlated with lower muscle strength, which is associated with a greater degree of disability. Although the initial impairments may be in the neuromuscular system, over time the condition will affect the cardiovascular system from inactivity and potentially the integumentary system. An increased likelihood of multisystem effects in an individual with chronic impairments is a reality. Therefore a multisystem, holistic approach to management is warranted.

The rehabilitation clinician is in a unique position to provide holistic care to the client with chronic impairments. In the realm of management of chronic movement dysfunction, PPS becomes a model case for other chronic neuromuscular conditions—there is much to learn from the complex nature of the late effects of polio, and designing an intervention program may be as challenging as the evaluation because of the interactions of the systems and the influences of the environment, medical treatment, and aging. Before beginning physical or occupational therapy, it is necessary for the team to first identify and treat other medical and neurological conditions that may produce the reported symptoms.¹⁵⁷

The individual's values and goals are the most significant variables to take into consideration in designing the interventions. Improvement will largely depend on the patient's commitment and thus compliance. Relatively simple interventions may result in distinctive positive changes. Conservative management should be attempted first before major life-changing interventions. Psychological considerations play a major role in designing an acceptable and appropriate management plan that will encourage compliance. Lifestyle modifications may not be favorably viewed by some individuals who have "conquered" the disease and pushed themselves to be independent, as in the case of those with PPS or SCI in their younger years. Prescription of interventions that are perceived to be "radical" should be done with sensitivity and caution. The rationale for interventions should be carefully considered in light of the client's current functional status and goals. Introduction of orthoses, assistive devices, and mobility modifications is often difficult for the individual with chronic impairments to accept, given the long, arduous effort expended over years to avoid such devices and the movement adaptation achieved without such devices.

The long-term goals for individuals with chronic conditions center primarily on self-management of home exercise programs and appropriate lifestyle changes to reduce physical demands. No definitive, curative intervention currently exists for chronic neuromuscular conditions ranging from developmental delay (DS, CP) to those acquired through trauma or disease sometime in the life span

(SCI, TBI, PPS); therefore symptom management is a key element in both the short and long terms. Short-term goals focus on the symptoms present and may address the following areas:

- Modified strengthening and conditioning
- Postural correction
- Energy conservation
- Lifestyle modifications
- Mobility and locomotion
- Balance during functional activities
- Walking aids, mobility devices, orthoses
- Pain reduction
- Improved functional endurance
- Ability to transfer
- Respiratory care
- Weight control

The information is presented with an evidence-based approach and will specifically address the management of adults with PPS, SCI, and TBI. When possible, the intervention approaches first offered should focus on several problems at one time (Table 35-3). The importance of individualized programs that address the variability of symptoms cannot be overemphasized. The reader is referred to specific references for further details on management prescriptions.

Before discussion of specific intervention strategies, a shift in the philosophy of management of chronic disease and disability is presented. Within the past decade, in an effort to affect the trajectory of further decline from chronic conditions, there appears to have been a shift toward the promotion of health rather than the control of the disease itself.

HEALTH PROMOTION

Health Promotion with Chronic Conditions

Emerging in the public health arena is a call for attention to the growing population of aging adults with chronic disabilities and for reducing health disparities involving this aging population. There is consensus on a need to address issues related to the health and care of aging individuals with developmental and intellectual disabilities related to primary care, health promotion, health literacy, and health care providers.^{66,152}

Decreasing health disparities affecting aging adults with chronic impairments is an increasing area of focus, as evidenced by its inclusion in the national health goals for individuals with disabilities outlined in several documents such as the Healthy People 2020 initiative,¹⁵⁸ the New Freedom Initiative,⁶⁵ the U.S. Department of Health and Human Services document *Closing the Gap: A National Blueprint to Improve the Health of Persons with Mental Retardation*,¹⁵⁹ and the U.S. Surgeon General's Call to Action to Improve the Health and Wellness of Persons with Disabilities.¹⁶⁰ Healthy People 2010 cautioned that people with disabilities would be expected to experience disadvantages in health compared with the general population. Five years after the release of the U.S. Surgeon General's Call to Action, it was reported that some individuals with disabilities still lacked equal access to health care, and health promotion has been outlined as a goal to be achieved by people with disabilities.¹⁶⁰

TABLE 35-3 ■ EVIDENCE-BASED APPROACH TO THE MANAGEMENT OF POSTPOLIO SYNDROME

Generalized weakness	Lifestyle changes Therapeutic nonfatiguing strengthening exercises Aerobic exercise Orthoses Assistive devices Avoidance of overuse Weight loss
Pain	Therapeutic heating modalities* Cryotherapy* Activity reduction and lifestyle changes Pacing of activities Stretching Weight loss Assistive devices Orthoses Motorized mobility devices Nonsteroidal antiinflammatory drugs [†]
Dysphagia	Dietary changes or restrictions Breathing techniques Swallowing techniques Monitoring fatigue and timing eating when not fatigued
Fatigue	Lifestyle changes Energy conservation techniques Nonfatiguing exercise programs Lightweight orthoses and assistive devices Pacing of activities Frequent rest breaks Naps during the day Motorized mobility devices
Cardiopulmonary conditioning	Aquatic exercise training Endurance training Cycle or arm exercises
Psychosocial concerns	Postpolio support groups Interdisciplinary approach Counseling from psychologists, psychiatrists Vocational counseling Behavior modification
Pulmonary dysfunction	Preventive measures Noninvasive ventilatory assistance Pulmonary therapy Breathing exercises: glossopharyngeal breathing

Modified from Trojan D, Finch L: Management of post-polio syndrome. *NeuroRehabilitation* 8:93–105, 1997; Jubelt B, Agre J: Management of post-polio syndrome. *JAMA* 284:412–414, 2000.

*Effectiveness of heat and cold modalities are patient specific and must be used with caution.

[†]Antiinflammatory drugs have been shown to be effective in pain management in medical treatment of postpolio syndrome. The specific drug and dosage must be prescribed by the physician.

Health promotion is defined by Pender¹⁶¹ as activities motivated by the desire to increase well-being and actualize human potential. It includes self-initiated behaviors and stresses the need to enhance the responsibility and commitment of each person to achieve a healthy lifestyle. Health promotion was reflected in Healthy People 2010. Healthy People 2020 includes individuals with disabilities in all health promotion efforts as an emerging area in disability and health, reflecting a continuation of the initiative's prior goals for the well-being of persons with disabilities.¹⁵⁸

Shift to Health Promotion

In 1997, Patrick¹⁶² found that research on health promotion for individuals with health disabilities was almost nonexistent. Fast-forward to 2011: a shift from disability prevention to health promotion has emerged, and literature on health promotion efforts for persons with a variety of chronic diseases is emerging.

In contrast to health protection or disease-management behaviors, which are motivated by the desire to avoid illness or its effects, health promotion is not disease or injury specific.¹⁶¹ Whereas both wellness and disease-management interventions may focus on improving similar health behaviors, a critical difference between these approaches has been proposed by Stuijbergen and colleagues.¹⁶³ They assert that the significant difference is in how the individual is viewed with regard to the interaction between his or her chronic disability and the purpose or intention of the change in behavior—that is, control and management of disease versus maximizing quality of life and health. Furthermore, whereas wellness interventions have wellness or health in the forefront and the disease in the background,¹⁶⁴ wellness and health promotion interventions allow the individual to choose behaviors that improve and/or sustain the quality of life within the perspective of living with chronic conditions.¹⁶⁵

Part of the national initiative to improve the health of aging adults with developmental disabilities, the U.S. Surgeon General's Call to Action to Improve the Health and Wellness of Persons with Disabilities¹⁶⁰ stated that persons with disabilities can promote their own health through developing or maintaining healthy lifestyles. Embedded in this statement is the responsibility of the individual for his or her own health trajectory. This responsibility is shared with health care providers and support persons. A need to develop skills to improve health literacy related to health care issues is paramount to this responsibility¹⁵² and to encouragement of active participation. Health literacy is defined by Selden¹⁶⁶ as the degree to which individuals have the capacity to obtain, process, and understand basic health information and services necessary to make apt health decisions.

Early education combined with opportunities for lifelong learning can help individuals develop the skills and confidence needed to improve or manage healthy lifestyles with aging.¹⁵² Similarly, health care professionals need to improve, maintain, and use clear communication.

Health promotion and disease prevention activities should consist of specific health education programs and preventive or screening programs.¹⁵² In the paradigm shift to health promotion, some interventions have focused on a single behavior such as exercise or nutrition or a combination of interventions for a more inclusive lifestyle approach.^{163,165,167}

Community-Based Programs

With approximately 54 million persons with disabilities⁶⁵ targeted by public health initiatives, assistive technology advancements, and cultural changes, many barriers still exist to access to community-based programs.⁶⁵ Community-based interventions for health promotion are ideal for those with developmental disabilities because they address social inclusion, self-efficacy, and sustainability.¹⁶⁸ However, few community-based lifestyle interventions targeting those with developmental disabilities exist.¹⁷ Developing and implementing accessible programs in the community setting for adults with long-term disabilities remain challenging.¹⁵²

Today, adults with chronic movement dysfunction have more of an opportunity to participate in sporting events and recreational activities. Therapists need to be involved in the process to ensure optimum benefit of these activities for clients to be not only successful but also safe. As research supports fitness training for persons with chronic disabilities and impairments, more effort will be needed to maximize the availability of community-based facilities to meet the demand. Again, therapists can be instrumental not only in the design of equipment but also in advocacy efforts by educating governmental officials and third-party payers regarding the needs of those aging with chronic conditions. Therapists not only possess the knowledge of the physiological effects of exercise but also understand biomechanical principles critical to ensuring safety in fitness and recreational activities. Therapists can work with these individuals on maximizing strength, flexibility, body mass indices, and cardiorespiratory reserves. This focus will not only increase functional capacity and social participation of the adult with functional limitations but will lower the risk of medical comorbidities associated with the effects of physical inactivity.

Health Promotion Interventions: Evidence and Challenges

Iezzoni⁶⁶ identified several barriers faced by persons with disability to accessing health care and public health interventions. Physical access, communication, financial barriers, and discriminatory and stigmatizing attitudes were identified as externally imposed barriers.

Although there has been a shift in philosophy and growing interest in health promotion in individuals with chronic impairments, the supporting evidence on the effectiveness of these interventions has not been examined in depth. Although there are published studies on health promotion in people with chronic diseases, several challenges arise. Studies often involve varied chronic diseases such as cancer, heart failure, arthritis, or human immunodeficiency virus (HIV) infection, with few studies examining individuals with chronic neuromuscular conditions. The studies often involve small experimental interventional strategies, use small population samples, and have varied intervention delivery from individual, group, or community-based programs. Moreover, Stuijbergen and colleagues¹⁶³ found that despite the benefits of health promotion for improving or maintaining function and independence in older adults, very few studies had samples of older subjects. Iezzoni⁶⁶ asserts that improving access to health promotion and disease prevention should be a national public health priority.

A mounting body of evidence regarding the positive impact of health promotion and wellness interventions on individuals with chronic conditions is seen in the literature.¹⁶³ Although these studies report significant effects and used multiple outcome measures, they had small population samples that encompassed varied chronic conditions not specific to those with neuromuscular impairments alone. Moreover, types, lengths, and delivery of interventions varied greatly from community-based to independent settings. Therefore, generalization and comparison across studies are difficult to say the least. It is noteworthy that a review of the literature supports the benefits and positive effects of health promotion and wellness interventions; however, in agreement with the findings of Stuijbergen and colleagues,¹⁶³ minimal information exists about the long-term effects or efficacy of interventions.

INTERVENTION STRATEGIES

A paucity of evidence specifically addresses precise exercise or intervention plans in individuals with chronic impairments. This lack of data is evident in specific neurological populations: SCI and TBI, to name two. Although no published studies were found on exercise plans and aging in SCI, the interest in promoting exercise and lifestyle changes to prevent secondary medical problems has been identified. Similarly, most studies are conducted in the early years after TBI, and although TBI is a lifetime disability, little attention has been paid to the needs of aging people after a TBI who may have recurring needs for physical and cognitive rehabilitation and retraining over the life span. The information presented is directed more toward PPS, for which a body of evidence supports specific intervention strategies. In a recent review on the treatment of PPS through the Cochrane Collaboration, Koopman and colleagues¹⁸ found inadequate evidence from randomized controlled studies pointing to definitive conclusions on the effectiveness of different treatment options for individuals with PPS. Their results indicate that pharmacological intervention, specifically drugs such as lamotrigine and intravenous immunoglobulin (IVIG), and nonpharmacological interventions, specifically muscle strengthening and static magnetic fields, may be beneficial but need further research.¹⁸

As with other chronic neuromuscular conditions, there currently exists no curative treatment for PPS,¹⁸ and therefore rehabilitation management is regarded as the key intervention. The succeeding discussion presents strategies for the rehabilitation of chronic neuromuscular dysfunction with the goals of improving and/or maintaining functional capacities and decreasing secondary impairments magnified by aging or the chronicity of the condition.

Although primarily directed at PPS, most of, if not all, the intervention strategies are applicable to people with other chronic impairments; there are commonalities to all chronic neuromuscular conditions that need to be identified and analyzed from a long-term quality-of-life perspective. Individuals who are aging with these chronic functional limitations should be allowed to age with the dignity given to any other individual. The challenge to therapists will be to step out of the model of regaining functional skill through repetitive practice and into the model of maintaining function, energy conservation, and empowerment of that function to the individual needing service. The

client is and should be the individual who determines what aspect of functional activities are critical to quality of life and what compensations are acceptable and unacceptable as part of an adult life expectation. From that information and the analytical understanding of what is happening to the CNS of these individuals, clients and therapists together can establish realistic goals and intervention strategies that will optimize and maintain the potential motor function of those individuals.

Therapeutic Exercise

Strengthening and Conditioning

Evidence suggests that both physical activity and strength are significant factors in severity of disability.¹⁶⁹ It has been shown that muscle strength has a significant role in a spiraling model of decline. Specifically, lower muscle strength is correlated with a greater degree of disability. In terms of function, difficulties in motor activities are reported by those with poor strength. It is logical, then, that the management of chronic disabilities involves a strengthening program.

A mounting body of evidence supports strengthening exercises for individuals with PPS,^{93,170-174} contrary to the initial approach of no exercise because of fear of overuse or symptom exacerbation. Generally, survivors with PPS who exercised and avoided overuse demonstrated positive results without detrimental effects. Several types of nonfatiguing strengthening exercises, aerobic exercise, and the evidence supporting them have been examined. Willen¹⁷⁵ suggests that water exercise may be beneficial because it decreases the biomechanical stresses on the muscles and joints. Specific exercise prescription is dependent on several factors such as the current level of function, other presenting symptoms, and the client's interests.

Jubelt and Agre⁹³ note that the most important advance in the treatment of weakness in PPS involves the findings of several studies that mild to moderate weakness can be improved with nonfatiguing exercises. The benefits of nonfatiguing exercises using both submaximal and maximal contraction with limited number of repetitions are documented in the literature.^{93,170}

Isokinetic and isometric dynamometers have been used to record maximum muscle forces (or torques) in PPS subjects before and after resistive exercise programs designed to increase muscle strength. Two of the studies were of single cases,^{176,177} and two had 12 and 17 subjects.^{171,172} Both of the multisubject studies tested the quadriceps femoris. Einarsson¹⁷¹ investigated the effects of a standardized, 6-week, maximal effort and isometric strength training program on the quadriceps muscles of 12 individuals with postpolio muscles, nine of whom met the criteria for PPS. Einarsson¹⁷¹ reports an average gain of 29% in isometric strength and 24% in isokinetic strength over a period of 6 weeks; muscle biopsy specimens revealed no muscle damage. In addition to the feeling of well-being in most of the subjects during and after the training program, 10 of 12 subjects stated a feeling of increased strength in the trained muscle. In subsequent follow-ups 6 to 12 months after intervention, gains in strength did not decrease, and several subjects reported better performance in daily activities such as climbing stairs, walking, and standing from a chair.¹⁷¹

Fillyaw and colleagues¹⁷² reported a strength gain of 8% over a 2-year period. An isometric contraction was used for testing, and concentric-eccentric contractions were used for the exercise. These results do not compare with the strength gains of 100% and higher made by healthy subjects undergoing training but rather compare with serial testing when no exercise was done.^{173,174} For example, Munin and colleagues¹⁷³ measured the affected and unaffected quadriceps muscle every 6 months over 3 years to document muscle weakness in persons with PPS. They reported increases in muscle strength up to 25%. In older persons without polio, test performance gains of the quadriceps increased an average of 174% in 90-year-old subjects¹⁷⁸ and 107% in 60- to 72-year-old men.¹⁷⁹ In these two studies, thigh muscle area (as documented by computed tomography) increased by 9% and 11%, respectively, indicating an increase in muscle bulk.

The effects of nonfatiguing resistance exercises are well documented in the literature. Fillyaw and colleagues¹⁷² in a study of 17 subjects with PPS concluded that muscle strength may be increased in individuals with PPS and suggested supervision of exercise programs by PTs and quantitative muscle testing every 3 months to guard against overuse weakness. Agre and Rodriguez¹⁸⁰ suggested that a supervised exercise program could safely increase strength in subjects with PPS with at least a grade 3+ strength. Their program of a supervised 12-week nonfatiguing quadriceps strengthening program with rest intervals revealed no detrimental effects. Most of the participants reported improvements in quadriceps strength, endurance, and work capacity, and half noted increased strength recovery with rest periods after activity, walking, and stair climbing. A nonfatiguing weight lifting program for at least 24 weeks was examined in six subjects with PPS by Feldman and Soskolne.¹⁸¹ The results showed increased strength in 14 of the 32 muscle groups with maintained strength in 17 muscles.

Alternate-day, low-intensity, muscle-strengthening quadriceps exercises showed no adverse effects, with reported findings of increased endurance, strength, and work capacity. As a result of the low-intensity program, no increased muscle strength was found, although half of the participants sensed increased strength recovery after exercise.¹⁸² The same protocol but with a more vigorous program of 4 days per week revealed improvements in muscular work performance and endurance without unfavorable effects noted.¹⁸²

Because there are neural adaptations specific to the type of muscle contraction used for measurement and training, it is difficult to determine the differences in true increases in strength from the ability to improve performance on a specific test. Another term for this phenomenon or improvement in performance is *motor learning* (see Chapter 4). The theory states that the subject learns to perform the measurement or the exercise better without true gains in strength. This happens even with an apparently simple weekly maximum isometric contraction.¹⁸³ Evidence of this phenomenon can be seen when improvements are made in the opposite untrained muscle group (transfer of training), when the apparent strength gains are maintained for months after cessation of the training, and when there are no increases in the size of the muscle. The greatest improvements in test performance occur when the muscle contraction is the same for both the test and the training. Smaller increases are seen

when the measurement and training muscle contractions are different and when measures to decrease the effect of motor learning have been used.

The neural adaptation specific to the type of measurement or training is illustrated in the following study on older men.¹⁷⁹ Multiple tests to assess strength were performed. The training program required lifting and lowering 80% of the weight of one repetition maximum (1 RM), which was assessed weekly. After 12 weeks, there were average increases in quadriceps muscle strength of 104% for the 1 RM, 7% for maximum isometric, 8% for maximum isokinetic at 60 degrees per second, and 10% for isokinetic at 240 degrees per second. In addition, there was an increase in cross-sectional area of the quadriceps of 10%, and muscle biopsy showed approximately a 30% increase in muscle fiber size.¹⁸⁴ This study illustrates some of the complexities of designing or evaluating studies that attempt to measure changes in muscle strength.

In chronic movement dysfunction, high tone is a symptom that may be considered a deterrent to exercise. As therapeutic procedures became based on motor control, motor learning, and neuroplasticity theories, strengthening of spastic muscles may still be underused.^{185,186} In the past, placing resistance on a spastic muscle was thought to increase the spasticity. This tenet was interpreted to preclude anyone from advocating strength training in these individuals.^{185,187} Interestingly, the literature identified that one of the major problems of CP is weakness. Clinicians during the 1960s and 1970s believed that the answer to this weakness underlying spasticity was to increase proprioceptive and tactile stimulation.^{185,187} Current research would say that true strengthening would not occur through feedback alone and that resistance on muscle tissue is a necessary variable for strength training.^{90,188,189} Damiano and colleagues^{91,190-192} have shown that resistance training does not affect spasticity negatively and in fact improves many functional measures of gait. On the basis of these findings, clinicians should evaluate individual patients to determine whether the level of weakness is affecting functional performance or the attainment of personal goals. If indeed the individual's weakness is found to be clinically significant, then strength training is indicated. Strength training within functional patterns should lead to the greatest carryover.

Physical Activity

The literature clearly documents the benefits of physical activity, and in polio survivors with PPS, activity that falls within a safe range is beneficial to overall functional performance (Box 35-5). In a study involving women with disabilities in the Women's Health and Aging Study,¹⁶⁹ the authors found an inverse relationship between disability and physical activity, with the most disabled women being more inactive. In addition to diseases and musculoskeletal pain being directly associated with motor disability, lower levels of physical activity associated with poorer muscle strength contributed to a greater degree of motor disability.

Physical inactivity and obesity have been shown to be more common in individuals with developmental disabilities than in the general population.^{17,145} Specifically, Rimmer and Wang¹⁹³ in a study of 306 individuals with physical and mental disabilities found that the rate of obesity in those with intellectual disabilities was twice as high as in the

**BOX 35-5 ■ FUNCTIONAL EXERCISE:
KEY POINTS**

1. Consult with a health care team before starting an exercise program. A physical and occupational therapist can provide valuable insight and recommendations on activity type and intensity.
2. Avoid overuse of muscle groups.
3. Judicious exercise programs of low to high intensity can result in positive results. Include warmup and cool-down periods.
4. Short periods of activity are encouraged.
5. Allow for adequate rest between bouts of activity.
6. Alternate days may be necessary for full recovery (depending on activity type).
7. Individualized therapy program to address unique needs is critical.
8. Use energy conservation and joint protection techniques in regular routines.
9. Incorporate breathing, relaxation, mental imagery, and meditation exercises into daily activities.
10. Be cognizant of the body's alignment during exercise and functional activities.
11. Incorporate postural exercises and correction to address malalignments and unnecessary use of muscles and joints.
12. Compliance with clinical recommendations can significantly reduce symptoms and prevent further decline.
13. Listen to your body—pain is typically your body's way of alerting you to slow down or to stop.

general population. More alarming was the finding that the rate of extreme obesity (body mass index [BMI] equal to or greater than 40 kg/m²) was approximately four times higher among individuals with disabilities than in the general population. Moreover, individuals experience high rates of secondary conditions associated with obesity and inactivity, such as type 2 diabetes, cardiovascular disease, and metabolic syndrome.¹⁴⁶

Although few studies have been done on the impact of exercise or the best type of exercise for people aging with a TBI, Gordon and colleagues¹⁹⁴ studied 240 people living in the community with a TBI. They compared exercisers and nonexercisers with a TBI and exercisers and nonexercisers without a TBI. Typical exercise activities were swimming, jogging, biking, or sports that increased heart rate for more than 30 minutes at least three times per week for a 6-month period. Their findings suggest that although exercise did not decrease functional impairments related to the TBI, people who exercised reported fewer physical, emotional (less depression), or cognitive complaints (sleep problems, irritability, memory problems, and disorganization). Of interest was that the exercisers in the group with a TBI had more severe brain injuries than those who did not exercise. In their online TBI consumer report, Gordon and colleagues¹⁹⁵ recommend aerobic and nonaerobic exercises as beneficial. They also suggest that individuals with TBIs check out local exercise centers, independent living centers, or adult education classes and seek out videotapes that

might provide encouragement or support for engaging in exercise. There is no mention of referrals to PTs or OTs for guidance in setting up exercise or lifestyle change programs or locating resources within the community.

Cardiopulmonary Conditioning

Because cardiovascular disease is one of the most common causes of death among aging adults with developmental delay,^{17,146,147} and physical inactivity and obesity occur at higher rates in this population, cardiovascular conditioning is a critical part of the management of individuals with chronic impairments. The following information pertains to interventions for individuals with PPS, as the evidence is strong for this population. Although limited information exists for those with SCI or TBI, one can logically infer that some benefits are likely to occur with aerobic activities in these groups.

Aerobic testing using modified protocols to reduce fatigue has been used on the treadmill,¹⁹⁶ bicycle ergometer,¹⁹⁷ and arm ergometer¹⁹⁸ in individuals with PPS. There were no cardiorespiratory training effects in the first study, probably owing to the low intensity of the exercise, but the duration and distance of walking increased.¹⁷³ The two ergometry studies showed an increase in maximum oxygen consumption of 15% and 19%, which is a training effect comparable to normal values for age. There were, however, no changes in blood pressure or heart rate, particularly the expected decrease in resting heart rate that occurs with aerobic training. Although the intensity of the exercise protocols had to be reduced for some of the subjects, none had to terminate the exercise because of overuse symptoms, nor did these symptoms occur at the end of the studies. A problem in evaluating these studies is that it is not always clear whether the study subjects with PPS were asymptomatic, symptomatic (PPS), or mixed.

An endurance training program in subjects with PPS demonstrated beneficial cardiovascular and strength effects without adverse consequences.¹⁹⁹ Aerobic exercise such as using a bicycle ergometer, walking, or swimming may be useful, but the client must be interested in the activity to increase compliance.¹⁵⁷ Willen and colleagues¹⁷⁵ in a recent study of 28 individuals with late effects of polio found that a program of nonswimming dynamic exercise in warm water twice weekly resulted in decreased heart rate at submaximal work level, less pain, and positive functional impact. As with the previous studies on exercises, no adverse effects were noted. Their general fitness training, however, did not result in changes in muscle strength or endurance. Previous studies documenting improvements in muscle function and aerobic capacity were designed for three or more times per week; the authors hypothesize that a twice-a-week program was not enough to show improvements in the subjects' aerobic capacities or muscle strength.

The literature indicates that exercise within constraints can lead to several beneficial physiological and psychological adaptations in individuals with PPS.^{157,170} It appears that therapeutic exercise is beneficial when performed without causing undue pain and fatigue. As with any intervention, a comprehensive examination will assist in developing a well-rounded and individualized program tailored to the specific needs of the individual with PPS.

Pulmonary Status

Older individuals with neuromuscular diseases may have increased vulnerability to respiratory complications.¹⁰³ Respiratory insufficiency and sleep apnea may mandate intermittent or constant use of ventilatory devices. Nighttime noninvasive positive pressure ventilation may be beneficial.²⁰⁰ Pulmonary therapy and breathing exercises may help some individuals avoid tracheostomy.¹⁰³ In individuals with PPS who have respiratory impairments, respiratory muscle training may be beneficial in improving respiratory muscle endurance and general well-being.²⁰¹

The role of the therapist is to modify activities and teach glossopharyngeal breathing, manually assisted coughing, or bronchial drainage as indicated.^{202,203} If trunk supports are considered, vital capacity should be checked with and without an abdominal binder to determine the effect on breathing. The therapist's attention should also be directed toward prevention of problems that may occur from bed rest and maintaining as much function as can be permitted.

Fatigue Management

Use of muscles at high levels for extended periods will result in muscle overload. To perform the same activity with weak muscles, the muscles need to contract at a higher percentage of their capacity than is normally required. For example, in walking, clients with PPS contract their muscles at both higher intensities and for prolonged or even continuous periods in the gait cycle.⁹⁸ Energy expenditure for the task is increased, and the prolonged contractions keep the capillaries compressed to limit needed muscle nutrition. Clients with PPS are often observed using nearly maximum voluntary contractions to perform a daily activity. The muscles of individuals with PPS cannot maintain these high levels of activity indefinitely.

A general program addressing fatigue may include non-fatiguing daily activities and energy conservation techniques. Relaxation, breathing, and meditation exercises may also be useful. Lifestyle changes that incorporate methods that decrease physical demands and prevent further decline in function are the most efficacious way to target fatigue impairments. In a study by Agre and Rodriguez¹²⁰ symptomatic subjects with PPS demonstrated the ability to perceive muscular exertion. This is indicative of a mechanism to monitor local muscle fatigue that may be used to avoid exhaustion. Their study of pacing, defined as interspersed activity with rest, revealed less local fatigue and significantly greater strength recovery in subjects who paced their activities than when they worked at a constant rate to exhaustion. The Borg Rating of Perceived Exertion (RPE) is an outcome measure that may be used to judge effort (see Chapter 30). Finch and colleagues²⁰⁴ in a study of individuals with PPS found that after one training session subjects reliably used the RPE in an exercise test to monitor their effort and complete the test. Finch and colleagues²⁰⁵ have gone on to establish reliability and construct validity on an effort-limited treadmill test for individuals with PPS.

Peach and Olejnik²⁰⁶ on reevaluation found that compliance with recommendations affected fatigue; it was resolved or improved in a group of individuals who complied with recommendations and was unchanged or increased in the group of individuals who did not.

Sleep Disturbance

Sleep disturbance is a significant age-related change, with an estimated 50% of older adults reporting difficulty initiating or maintaining sleep.^{108,109} Several factors may contribute to reports of sleep disturbance, ranging from relatively apparent reasons to more medically complex reasons such as sleep apnea. Habitual sleeping patterns may provide important information. Sleep disturbances from medical or psychiatric conditions (e.g., chronic pain, dementia) or a primary sleep disorder that may be age related or a combination of these may further produce changes in sleep that may be reflective of typical normal developmental processes.¹⁰⁸ Loss of sleep with aging is often a result of the decreased ability to sleep in older adults.¹⁰⁹ According to Neikrug and Ancoli-Israel,¹⁰⁹ this diminished ability is less a function of age and more a function of other age-related factors such as medical and psychiatric diagnoses, increased medication use, and a higher frequency of specific sleep disorders.

A history of pain or numbness that is worse at night or on rising points to sleeping surfaces that are too firm or sleeping with joints in close-packed positions (usually the neck and shoulders). These problems are correctable with foam mattress covers or air pressure mattresses, cervical pillows, and modification of sleeping postures.

Given the frequency and significant number of older adults with sleep problems, health care professionals need to be more aware of sleep disturbances.¹⁰⁹ Changes in sleep quality and quantity in later life influence quality of life and level of function¹⁰⁸; thus it is critical to distinguish typical age-related changes in sleep from pathology-related sleep disturbances. More complex reasons for sleep disturbance such as sleep apnea may necessitate referral to specialists.

Decreasing the Workload of Muscles

Energy Conservation Techniques

Energy conservation techniques provide the easiest way to decrease the work of muscles without loss of function. Analysis of all activities by type, time, distance, and intensity is valuable in designing interventions. Such an inventory forms the basis for setting priorities and determining where and how individuals wish to use their limited neuromuscular capacity.¹²⁶

Questions addressed include the following:

1. Can one trip do for two or three?
2. Can the activity be performed in a less strenuous way, such as by sitting or using a rolling basket?
3. Can the activity be broken up into parts with change of activity or rest?
4. Are there easier ways to perform the activity with modern comforts and technology, including motorization and electronics?
5. Can someone else perform some of the physical aspects of the activity?

Particular attention should focus on activities that produce fatigue and pain. Specific suggestions may address breaking tasks into subtasks, making environmental adaptations such as to work height and locations, taking frequent rest breaks during activities, and using adaptive or ergonomic equipment.

Orthotics and Assistive Devices

Reduction of muscular overuse and fatigue may be accomplished with lightweight splints and braces, adaptive equipment, walkers, or crutches.^{93,103} The use of orthotics and/or assistive devices is individualized and specific to the patient, whose goals, along with the therapist's expertise, will ultimately determine the use of devices. For example, unlike most individuals with chronic mobility impairments, individuals with PPS may have strong and usually negative feelings about orthotics. The use of orthotics or assistive devices may be challenging for the individual newly diagnosed with PPS and facing a relatively "new disability." Polio survivors may have previously relied on devices or may have refused such devices earlier in life and consenting to using them again may symbolize defeat and acceptance of losses.

As with every intervention, a thorough explanation of the specific rationale and goals for the intervention not only will be helpful in gaining the client's trust but will also improve compliance. Rationale for orthotic use includes preventing falls and potential fractures, limiting joint motion and preventing pain, restoring weight bearing on the weaker extremity to decrease the work of the less affected leg in locomotion, improving posture and decreasing back pain, and decreasing energy expenditure.

Thoughtful consideration for the appropriateness of orthoses or assistive devices is critical; such devices should not be haphazardly prescribed or given as the only intervention of choice. They should be prescribed cautiously. Ineffective and inappropriate use of such devices will lead to malalignments, ineffective movement strategies, and postures that will cause more harm. Therapists should carefully evaluate the functions that may be lost or gained and the emotional and physical cost of the use of these devices.

Most individuals have long discarded braces and assistive devices and have relied on compensatory techniques for walking (Figure 35-1). If an orthosis has been used and is essential for walking, it often becomes a part of the individual's body image; thus the client may be resistant to changes in braces or devices. For other individuals, prior attempts to use plastic orthoses may have been painful or resulted in no functional use, and thus these patients may

Figure 35-1 ■ The functional compensations of a boy with paralysis of the right lower extremity show increased energy expenditure and progressive ligamentous laxity. (Adapted from Ducroquet R, Darroquet J, Darroquet P: *Walking and limping—a study of normal and pathological walking*, Philadelphia, 1968, JB Lippincott.)

previously have rejected the potential of such devices. Thus it may be difficult to persuade the long-term user to consider orthoses or an orthotic change. When given the appropriate orthosis or prescription, however, polio survivors may benefit significantly enough to improve their current symptoms. A retrospective study of lower-extremity orthotic management for ambulation in 104 postpolio clinic patients by Waring and colleagues²⁰⁷ revealed that 78% of patients noted that the appropriate orthotic prescription improved the ability to ambulate, increased apparent walking safety, and decreased pain.

In instances in which both the talocrural and subtalar ankle joints were fused surgically, the increased stresses on the posterior structures of the knee or the transverse tarsal joint for ambulation eventually lead to hypermobility and pain in these areas. Rocker bottom shoes may assist with restoring motion for walking. An ankle-foot orthosis (AFO) may address pain in the transverse tarsal joint, whereas a knee-ankle-foot orthosis (KAFO) may help with knee pain.

AFOs are recommended for dorsiflexor weakness resulting in dropfoot or slapfoot, for plantar flexor weakness with absent heel rise, and for mediolateral instability. Individuals with PPS have difficulty with solid AFOs because of the structural design; they are typically made with 5 to 10 degrees of dorsiflexion and are then placed in a shoe with a slight positive heel, thus increasing the angle of the posterior shell to the floor. In standing and walking, this causes a knee flexion torque, with potential buckling of the knee if the quadriceps muscle is weak. Clients may attempt to straighten the knee by pushing back against the posterior shell of the AFO, potentially causing pain. In such instances, AFOs should be made in slight plantarflexion so that the tibia is perpendicular to the floor in the usual shoes worn. This is the normal position of the ankle for toe and heel clearance.²⁰⁸ In cases of plantarflexion contracture, more plantarflexion is required in the AFO. Most jointed AFOs are of limited value because of the bulk and weight. Moreover, they require a larger shoe and do not provide much control for the ankle. Jointed AFOs allow adjustment to find the best angle in function.

A floor reaction AFO prohibits all ankle motion and can place forces to control the knee.²⁰⁹⁻²¹¹ The orthosis prevents dropfoot, promotes heel rise, provides an extension torque on the proximal tibia to supplement weak quadriceps muscles, and can limit hyperextension of the knee. It requires precision in fabrication for the knee extension torque to occur only when the tibia is perpendicular to the floor during gait. When used with rocker-bottom shoes, the client with a flail foot can walk with a more typical gait pattern. Subjects with ligamentous laxity of the knee, excessive tibial torsion, or paralysis of the quadriceps muscles are poor candidates for this type of AFO.

Shoe inserts, heel lifts, and molded foot orthoses can provide a number of inconspicuous corrections. Positive heel shoes with a broad base, such as cowboy boots, stacked or Cuban heels, or the Swedish clog,²¹² decrease the amount of dorsiflexion and plantarflexion motion and the work needed for ambulation. Rocker-bottom soles, which provide mechanical heel rise to assist the calf muscles, can be added to shoes and are commercially available. Work boots, dress boots, or basketball shoes may provide needed ankle stability.

Asymmetrical standing is typical in individuals with unilateral lower-extremity paralysis or pain. Standing is accomplished with more weight on the stronger limb, which must perform continuous, high-level isometric contractions (Figure 35-2). Unloading the stronger leg requires restoration of weight bearing on the more involved leg using a KAFO or in some instances an AFO that prevents advancement of the tibia in the stance phase (Figure 35-3).^{94,209-211}

An obvious forward-leaning posture is seen in some ambulatory individuals with PPS. This posture requires continuous contraction of the erector spinae muscles and leads to back pain, often radiating to the hip and leg. The forward-leaning posture is found in people with quadriceps muscle paresis and in those with ankle weakness. Those with quadriceps weakness must move the center of gravity of the body anterior to the knee axis to lock the knee and prevent knee flexion in stance. This posterior force also produces ligamentous instability and genu recurvatum (see Figure 35-1). In some instances, lightweight athletic knee braces allowing 10 to 15 degrees of hyperextension provide adequate control. More often, a KAFO with an offset knee joint allowing necessary hyperextension is required.²¹³⁻²¹⁵ People with dorsiflexor muscle paralysis or ankle instabilities walk in the forward-leaning posture to watch the floor and foot placement to avoid tripping and falling. Athletic ankle supports or boots may be sufficient to control some ankle instabilities. Molded and posted plastic AFOs with or without ankle joints are needed for more control. Flexible plastic AFOs and the dynamic spring dorsiflexion assists can correct simple dropfoot.⁹⁴ Once the forward-leaning posture is addressed, the individual can walk upright and back pain will lessen and may disappear within days.

Walking with lateral trunk shift in the stance phase (gluteus medius gait) produces abnormal forces and joint

Figure 35-2 ■ Lateral trunk shift in a postpolio individual to illustrate abnormal forces occurring in the back, knee, and ankle with resulting joint dysfunction and pain. Prevention of these abnormal forces and some correction can be provided by use of a cane or forearm crutch. (Adapted from Ducroquet R, Darroquet P: *Walking and limping—a study of normal and pathological walking*, Philadelphia, 1968, JB Lippincott.)

dysfunction from the spine to the foot. In addition to a strengthening program, these forces may be reduced with use of a forearm crutch or a cane (see Figure 35-2).

Long-term crutch walkers with or without orthoses and those with slow, precarious, or labored gait should be evaluated for appropriateness for use of motorized vehicles as their primary form of locomotion, whereas orthotic corrections or applications may be indicated to assist with transfers and short-distance walking.

Changes in Locomotion

In individuals with chronic neuromuscular impairments, the extent of impairment is influenced by the degree of neurological deficit in motor control, tone, and strength. In neurological disorders such as CP, deficits in tone may cause the individual to walk with a flexed-knee stance, which has higher biomechanical requirements and greater forces in the lower extremities.²¹⁶ Perry and Burnfield²¹⁶ stated that the most substantial increases occurred with knee flexion beyond 15 degrees. It is noteworthy that as the degree of knee flexion contracture increases, the amount of oxygen rate and oxygen cost progressively increase while comfortable walking speed decreases. Oxygen rate is the amount of oxygen consumed per minute and is related to the length of time that exercise can be performed.²¹⁶ Oxygen rate indicates the intensity of physical effort during exercise.²¹⁶ Oxygen cost pertains to the amount of energy used for walking; since it is typically greater than normal for a patient depending on the degree of disability, gait efficiency is less than 100%.²¹⁶ In children with spastic diplegia with

Figure 35-3 ■ This man has paralysis of the left lower extremity with severe fatigue, low back pain, pain and weakness in the right lower extremity, and decreased function. He can be seen to bear weight and stand on the right leg. Application of a left knee-ankle-foot orthosis (KAFO) with a free knee joint (with a drop lock for use in prolonged standing and walking on rough terrain) and a limited-motion ankle joint unloaded his right leg and permitted him to walk in an erect posture. His pain disappeared and he has regained function at work and in social activities.

moderate to severe disability with both lower extremities affected leading to a flexed hip and knee posture, the mean heart and oxygen rates were notably higher than normal and were consistently elevated even when upper-extremity assistive devices were not required.²¹⁷ The bilateral stance of flexed hip and knees requires considerable muscular effort from antigravity muscles even at slow speeds to prevent collapse in the child with spastic diplegia. Moreover, Perry and Burnfield²¹⁶ state that the elevated oxygen rate may be attributed to the limited motor control to perform the compensatory gait substitutions due to bilateral lower-extremities involvement. In contrast to typical children, the oxygen rate increases with age in children with spasticity. This is consistent with the increased size and body weight in older children and the difficulty with impaired motor control and spasticity. As the child ages, walking becomes more burdensome, and as Perry and Burnfield²¹⁶ state, the child may prefer to walk less and rely more on a wheelchair. This scenario illustrates the challenges associated with aging with chronic impairments and may very well be reflected in other neuromuscular diagnoses.

Despite severe difficulties with locomotion from overuse, asymmetrical gait patterns and movement, or ineffective use of assistive devices, changes or modifications are hard for many people with chronic mobility problems, such as many polio survivors, to consider. As locomotion becomes more arduous or painful, many begin to limit outside activities rather than modify individual methods of locomotion. Resistance to lifestyle changes is common in the PPS population and leads to needless suffering and functional decline.²⁰⁶

Prevention of this spiraling disability and restoration of lost function require a marked decrease in the amount of walking or propelling a chair and a change to methods of locomotion that do not cause pain, weakness, and fatigue. Independent ambulators or those with inadequate assistance may need to use a cane, forearm crutches, trunk support, shoe corrections, or new orthoses. Clients who have been walking for years with crutches with or without orthoses develop shoulder, elbow, and wrist injuries, as well as new muscle weakness, muscle pain, and fatigue. Use of personal mobility vehicles (motorized carts) for distance locomotion or as the primary form of locomotion may need to be explored, with walking reserved for transfers and short distances only. Lightweight manual wheelchairs only perpetuate the problems and eventually create new ones; use may lead to development of repetitive stress injuries of the shoulder, elbow, wrist, and hand. These people need to obtain electric wheelchairs or motorized carts if suitable. Manual wheelchairs at best only postpone problems. Use of motorized mobility devices will need to be explored to prevent fatigue, muscle overuse, and further damage to joints.

Use of motorized vehicles for locomotion should be considered and explored with sensitivity and caution. Specific rationales should be thoroughly understood by a seemingly resistant client, and perceptions regarding the use of such vehicles should be addressed. Changes in methods of locomotion may be justified to increase safety and prevent costly falls, to reduce energy expenditure and decrease fatigue, to prevent further repetitive injury and pain, and, most important, to increase function and quality of life. Those who do

make these difficult changes in their methods of locomotion seem to undergo a metamorphosis from pain and dysfunction to renewed activity and increased function.

Management of Postural Deviations

Altered biomechanics from atypical postures or faulty physiological neuromuscular processes over time may lead to deviations that may cause pain and further functional limitations. In polio survivors, common biomechanical deficits abound, including genu recurvatum, genu valgum, inadequate dorsiflexion in swing, mediolateral ankle instability, and dorsiflexion collapse during stance, as described by Clark and colleagues.²¹³ These deviations are very likely to be seen in persons with other neuromuscular diagnoses. Strengthening exercises may be used to correct these impairments initially, with orthoses as an alternative management.

Postural exercises incorporated with breathing and stretching exercises are a way to address ineffective postures identified in all positions. Mental imagery, which may avoid impairments from fatigue, may be used early in addressing postural correction. Mechanical restoration of the lumbar curve in all seating and all settings and activities can address the problem if contractures do not limit motion. Properly fitted clerical chairs, ergonomic chairs, anterior tilt seats, gluteal pads, and several types of lumbar rolls, back supports, and seating systems may be beneficial (Figure 35-4).

Figure 35-4 ■ Man with athetoid cerebral palsy working at his computer. His power chair has been modified with a back support and a seat cushion for proper positioning.

Individuals with abdominal muscle paralysis may benefit from custom-made thoracolumbar corsets, with the posterior rigid stays bent to produce a normal standing lumbar curve. Paretic or paralyzed neck muscles can be rested and supported by soft foam collars or supportive microcellular neck collars. People with severe trunk muscle paralysis or scoliosis with or without spinal fusion often support the trunk or relieve pain by pushing down with their hands or elbows on chairs, on tables, and on their hips. In time, such self-traction results in pain and weakness in their arms. Chair inserts and fixed supports as well as custom-made corsets, back braces, and molded body jackets should be considered. The rigid trunk supports, however, take away mobility used for function. Usually such supports can be worn for part of the day in activities in which trunk mobility is not essential.

For persons with abnormal biomechanical alignment resulting from spasticity, orthopedic deformation, or severe muscle imbalance, care must be taken to maintain proper alignment throughout the exercise. Additional positioning equipment may be required to assist the person in exercising independently. For example, persons with lower-extremity spasticity frequently exhibit medial rotation of their femurs and bilateral pronation. Combined with asymmetrical patterns of weakness and tightness, a squatting motion produces an excessive valgus angle at the knee. Ensuring satisfactory alignment throughout the arc of motion improves the efficacy of the exercise. Conversely, without this attention to biomechanical alignment, these imbalances and deformities can be exacerbated.

Limitations in Range of Motion

A thorough evaluation of muscle length and range of motion (ROM) is critical in the overall management of life activities in individuals with chronic mobility impairments. The clinician should consider that not all tightness or limitation in motion is detrimental. Selective tightness may have provided some stability to otherwise unstable joints with paralyzed muscles, and useful contractures may have been developed by the body to achieve function. An excellent example can be seen in individuals who contracted polio as children. Muscle involvement was primarily in one lower extremity with a decrease in growth of that extremity as a result of diminished weight-bearing forces. If the individual has at least a G- (4-) manual muscle test grade in the plantarflexors, the person will walk on the toes (in some plantarflexion) to decrease large drops in the center of gravity, resulting in increased energy expenditure for walking. Over the years, a plantarflexion contracture develops that can provide up to 3 to 4 inches for weight bearing on the shortened extremity. With a custom-made shoe, gait is similar to walking in a high-heeled shoe. This can be far more energy efficient than if motion were permitted to have dorsiflexion ROM.

Gentle myofascial release can also be beneficial for recent secondary impairments of muscles to decrease pain and muscle spasms, increase nutrition to the area, and slightly lengthen muscles.

Weight Management

Adults with chronic impairments, particularly those with developmental disabilities, are at high risk for obesity and its sequelae. Weight reduction, when appropriate, addresses

this health disparity and is an effective way to decrease the muscle workload, but it is one of the most difficult. Clinicians recommend a modest weight loss of 5% of body weight as an achievable and maintainable goal that may result in decreased hyperlipidemia, hypertension, and glucose intolerance.²¹⁸ Weight loss is slow without exercise, but it can be accomplished. Weight control needs to be incorporated as a permanent modification of nutritional habits rather than achieved in a short-term diet. Dietetic counseling and support groups are important components of this challenging lifestyle modification.

In a study of 431 community-dwelling individuals with developmental delay who participated in a community-based health promotion intervention, two thirds of participants maintained or lost weight (mean of 2.6 pounds, median 7 pounds, range 2 to 24 pounds) over a 7-month, twice-weekly program.¹⁷ The authors stated that even without the weight loss, the decreased abdominal girth achieved by participants may be predictive of a decrease in cardiovascular risk factors.²¹⁸

Pain Management

Pain management in the patient with chronic movement dysfunction is dependent on the cause of the muscle or joint pain. As an example of how pain management contributes to secondary health problems, patients with SCI who reported pain from musculoskeletal problems and overuse were seldom referred for therapeutic interventions but were treated primarily with prescription medications to treat painful conditions. This medical management often resulted in increased problems, such as constipation, fatigue, irritability, and frustration.²¹⁹ The cause of pain must be carefully determined to establish appropriate intervention and management strategies. Typical interventions for pain include activity reduction, therapeutic heating modalities, cryotherapy, stretching, or energy and joint conservation techniques.

If chronic overuse is the only or major underlying cause of the symptoms present, conservative measures can often slow or prevent further deterioration and may even lead to improved function. Conservative measures include reducing mechanical stress, pacing activities, supporting weak muscles, stabilizing abnormal joint movements, and improving biomechanics of the body. Interventions that address fatigue and weakness such as nonfatiguing functional activities, energy conservation,¹²⁶ more frequent rest periods, or change of activity²²⁰ are also useful in pain management. Antiinflammatory agents have been used to supplement conservative measures.

Joint conservation techniques may include use of ergonomic devices, elevated chairs, bathtub bench or shower stool, and weight control. Recommendations for the neck and upper extremities include seating and workstation corrections, telephone headsets, rolling carts for carrying items, newspaper support for reading, ergonomic computer screens, wrist rests, and keyboards.

Successful intervention for joint pain, however, requires identification and elimination of the cause of the pain. This is frequently difficult because the person with chronic movement dysfunction may not have the strength in other parts of the body to compensate and carry out an essential function, or the person may be unable or unwilling to make necessary lifestyle changes. Intervention techniques may include

inhibiting muscle spasm, stretching fascia and muscles, decreasing edema and increasing nutrition in joint structures, and mobilizing or stabilizing joints.²²¹ At some point, relaxation, meditation, modified tai chi (see Chapter 39), aquatic therapeutic exercise, or body awareness techniques such as Feldenkrais¹⁸³ may be beneficial.

Local pain and dysfunction can be treated as athletic injuries from overuse, but they require major modifications and careful monitoring of performance, pain, and fatigue. Many joint pain problems can be relieved and controlled by home program interventions such as rest for the injured part, mechanical postural corrections, cold packs, nonsteroidal anti-inflammatory drugs, orthotics, and pain-free ROM exercises.

With regard to McConnell taping, although no radiological evidence shows changes in actual alignment of bone, individuals without neurological diagnoses have experienced a 50% to 78% reduction in patellofemoral pain during activities.^{221,222} In the Postpolio Clinic of the Institute for Rehabilitation and Research in Houston, Texas, these taping techniques relieved anterior knee pain for several months at a time in all individuals with PPS who were selected to receive the taping. Relief occurred, although the ability to strengthen surrounding muscles was limited or impossible. The therapy program should also include assisting the client in carrying out the home program and lifestyle changes, along with the development of a continuing program of appropriate exercises.

As with the management of fatigue, compliance of the individual with chronic impairments with suggested recommendations plays a significant role in pain management. In those with PPS, Peach and Olejnik²⁰⁶ found that muscle pain was resolved in 28% and improved in 72% of people who complied with recommendations. In those who were non-compliant, muscle pain was improved in 14%, unchanged in 57%, and increased in 29%.

Alternative Pain Management

Pain sensitivity must be acknowledged by clinicians when providing therapy that may be perceived as painful, such as stretching, and in the treatment of acute pain.²²³ Persons with chronic movement dysfunction have undergone extensive orthopedic surgery in attempts to overcome their initial deficits, as in the case of some polio survivors, and some have pain or hypersensitivities at the surgical sites. Desensitization exercises may decrease the hypersensitivities if the client is willing to devote the necessary time. The most frequent old surgical sites of pain are in the trunk from surgery for scoliosis, the ankle near a subtalar arthrodesis, and the foot with hypermobility of the transverse tarsal joint. In most instances of foot pain, stabilization of the ankle and foot in a custom-made AFO and use of a rocker-bottom shoe has relieved the pain and permitted weight bearing and walking.²¹² Custom-made corsets and trunk supports in chairs may help with the pain at previous surgical sites in the trunk. Transcutaneous electrical nerve stimulation may be helpful for pain control (see Chapter 32). Most individuals, however, stop using these devices because masking the pain permits them to physically overdo, leading to further injury to their bodies.

Static magnetic fields have become a familiar alternative approach in the treatment of athletic injuries as well as in persons with PPS who have localized pain. In a double-blind randomized clinical trial, Vallbona and colleagues²²⁴ applied

active (300 to 500 Gauss) and placebo magnets in a group of 50 subjects with PPS and chronic pain. The magnets were applied to the palpable pain pressure point for 45 minutes. There was a significant ($P > .0001$) and prompt decrease in pain in the group receiving the active magnets compared with those who received the placebo.²²⁴

Cold and Heat Intolerance

Strumse and colleagues²²⁵ investigated the effect of climate on the outcomes of individuals with PPS. In a randomized controlled trial of 88 individuals diagnosed with PPS, subjects received one of three interventions: (1) warm climate rehabilitation (dry and sunny, temperature around 25 degrees Celsius or 77 degrees Fahrenheit) consisting of individual and group therapy with daily treatment in a swimming pool, physical therapy, and an individually adapted training program for 4 weeks, (2) cold climate rehabilitation consisting of indoor treatment as described for the first intervention in a rehabilitation center in Norway with rainy or snowy weather with temperatures around 0 degrees Celsius or 32 degrees Fahrenheit, or (3) the usual health care program (control). This study was included in the review by the Cochrane Collaboration, and the authors concluded that there is low-quality evidence of no beneficial effect of rehabilitation in warm and cold climates 3 months after intervention.¹⁸ The reviewers suggest that a more thorough description of the components of the program and outcome assessment for the usual control group would have clarified the short-term effects on both rehabilitation groups and the results of the study. The study could not demonstrate a positive effect of rehabilitation in warm or cold climate for PPS, and further studies are warranted.¹⁸

Most individuals with chronic conditions who have cold intolerance have learned to control heat loss as best as they can with clothing, massage, and local heat. For interventions, however, cold intolerance can pose a potential problem with the use of cold modalities in the treatment of injuries and pain. Most persons with PPS are hesitant to use local cold on any part of the body. They may typically use heating pads and hot water, which feel good at the time but may perpetuate or increase the edema, inflammation, and pain. Local cold is often more effective and is well tolerated by most people with PPS. Successful application of cold requires more client education about the use of cold and demonstration of the effects.

In persons with MS who are sensitive to environmental heat or an increase in body temperature, specific recommendations for cooling during exercises may be necessary to counteract the deleterious effects of heat. Aquatic exercises and swimming in a cool pool with temperatures at or below 82 degrees may be beneficial for cooling. Use of cooling vests, ice packs, air conditioning, and hydration during activities is also recommended.²²⁶⁻²²⁸ An example of a specific exercise recommendation is the use of a Schwinn Airdyne bicycle to help with cooling while cycling.²²⁶

Other Interventions

The reader is referred to specific pharmacological texts and specific chapters within this text for detailed pharmacological interventions for specific neuromuscular diagnoses. As emphasized earlier, the management of chronic conditions is individualized and dependent on the unique needs

of the individual based on the interaction of multisystem involvement. Thus the pharmacological management of persons with chronic conditions is also individualized and wide-ranging. Although there are classes of medications that are commonly used across varied neurological conditions (e.g. spasticity medications), the use of medication is still symptom and patient dependent. A literature review of pharmacological approaches for PPS revealed that controlled trials of pyridostigmine and prednisone have not been beneficial.^{25,229,230} Currently there is no specific pharmacological agent widely recommended to address the multiple symptoms of PPS.

As part of the evaluation, oral motor function is an important component in terms of sensation, speech, and swallowing. Because of their prevalence in persons with developmental delay, dysphagia and aspiration potential need to be carefully explored in the history. Owing to disturbances in muscle tone, these individuals often have difficulty with feeding, which may lead to serious medical complications and potential death. In general, intervention may consist of performing breathing exercises, using swallowing techniques, monitoring fatigue levels, avoiding eating when fatigued, and initiating dietary restrictions or changes. For those with dysphagia, specific management will warrant a thorough evaluation by a speech therapist. Recent advances in treatment including deep pharyngeal neuromuscular stimulation and neuromuscular electrical stimulation offer persons with poor motor control and weakness in pharyngeal musculature opportunities to improve safe oral feeding²³¹ (Figure 35-5).

CASE STUDY 35-1 ■ AGING WITH TRAUMATIC BRAIN INJURY

Mark was 19 years old when he was involved in a motor vehicle accident in which a drunk driver hit Mark's car while he was stopped at an intersection. He had severe injuries that included fractures of the left femur, both forearms and wrists, and right ankle; multiple internal injuries; "swelling" of the spinal cord; and increased intracranial pressure necessitating removal of part of his skull. He had sustained frontotemporal brain injury with no injuries to the spinal cord despite severe injuries from the accident. He had complicated postsurgical sequelae and was in a coma for 3 weeks. He stayed in the acute hospital for another 3 weeks and was sent to inpatient rehabilitation, where he stayed for 4 months. At discharge he was able to stand and walk short distances at home with minimal assistance, although primarily he used a power wheelchair as his main mode of mobility. Although his upper extremities were functional, he had to learn how to write and use his dominant extremity all over again. He had dysphagia and dysarthria, yet was able to communicate functionally. Mark reports he had difficulty with memory and other cognitive deficits, and those were as hard to deal with as the physical impairments from his injury. He continued outpatient physical, speech, and occupational therapy services for another 3 months and worked on the physical, cognitive, and psychological effects of his injury. He stayed

with his parents who at that time became his primary caregivers as he transitioned to a new lifestyle.

In the 20 years after his injury, Mark learned to live with the chronicity of his injury and its secondary effects. He learned to walk with a walker then a cane and eventually walked without an assistive device with a slow, ataxic gait. He learned to use public transportation and navigate his way in the community by using landmarks for spatial orientation. He was involved with support and volunteer groups for several years that provided him the socialization and support he needed, particularly in the early stages of his injury. He married in his mid-20s, and his wife assists him with daily activities as needed, although Mark says he is independent with "everything" except with instrumental ADLs, specifically balancing the checkbook, grocery shopping, and cooking. They live in a one-level home with steps at the front and side entries and have done "some modifications" with bars and a shower chair installation in the bathrooms and wider doors in the bedrooms. Mark says he has seen a PT "maybe once or twice" in the subsequent years for back pain or walking but has not received continued care since his long episodes of therapy after the initial injury. He candidly states that he gets by with all physical abilities although it is "hard at times" and does not currently engage in a specific health or

Continued

CASE STUDY 35-1 ■ AGING WITH TRAUMATIC BRAIN INJURY—cont'd

exercise program. He says he has “learned to live with it” and shares some sadness at being unable to finish his education and care for his parents, who are now in their early 80s.

Now at 48 years old, Mark reports he is starting to feel more fatigued with walking and has noticed the need for more frequent rests. He continues to walk without an assistive device for indoors and short distances but uses a single-tip cane for long distances in the community and outdoors. He and his wife are saving to renovate the front and side entries of the home, which currently have five steps and handrails. Although Mark is able to navigate the steps on his own, he has noticed more difficulty over the years. In the previous year, he fell once on the steps and once in the community as he stepped off a curb. He now uses a “memory” notebook more frequently. He volunteers at the local library three times a week and continues to use public transportation as his primary mode of transportation. “I’m slower, but I get there,” he states. He “feels” the secondary impairments from his initial injuries—for example, contractures of the hamstrings, decreased ROM of the ankles and shoulders, postural impairments, gait deficits, and memory deficits—“more now that I’m getting old.” He has more frequent bouts of back and hip pain from a combination of biomechanical changes from chronic impairments and

possible contributions from aging. He has not sought physical therapy services despite the symptoms, difficulties, and changes in the past couple of years. Although he is interested in seeking physical therapy services, he has not done so, thinking that he will not qualify for services because of the chronicity of his condition. He volunteers at a local physical program where he is provided pro bono services at least twice a year.

Points for discussion (suggested answers can be found online) include the following:

- What further secondary impairments and functional limitations do you anticipate?
- What recommendations regarding lifestyle changes would you give Mark?
- If he decides to seek physical therapy services, what recommendations would you give for a holistic program?
- What specific systems need to be examined and addressed in the intervention?
- What services are available for individuals with chronic conditions? Community and hospital or outpatient-based services?
- What health care and community services *should* be available to individuals with chronic conditions?

CASE STUDY 35-2 ■ PERSONAL REPORT: POSTPOLIO SYNDROME*

Today my life is filled with optimism and hope. This was not the case long ago. I am 58 years old and have been diagnosed with PPS. I contracted polio at the age of 2 years, but for the first time in my life I feel disabled.

It is difficult for me to determine when the symptoms began. My life has been filled with caregiving, of first my mother-in-law, who was ill for the last year of her life, and then my parents, who had special needs. I had a vague awareness that I was slowing down, not able to do some of the things that I had always done. But at that point in my life, the focus was not on me. It seems like when I was able to take a deep breath again, I was in a lot of pain.

I was able to see a doctor who specializes in PPS. She recommended a new leg brace and she also recommended physical therapy. The new brace, while better for my body, is asking it to do different things. I basically am trying to learn how to walk all over again. My pain stems from weakness and tight muscles in my unaffected limb. My unaffected leg has been stressed by many years of overuse. The pain I experience is mainly in my hip and occasionally in my knee. Because of the stress of this pain, my stamina is less than it once was; my balance is not good, and just the task of moving from point A to B is a challenge. I found that I needed to use crutches to help take weight off of my leg. The pain that I felt a little over a year ago became the focus of my life. It affected everything I did. My day was reduced to struggle to even shower and dress, let alone do anything else. I had to depend on my husband to do more and more.

During this period I would allow myself, if I was having a really bad day, to just do nothing. Some days I wouldn’t even get

out of bed until 11:00 AM. This didn’t happen too often, but if it did, I allowed myself to not feel guilty. I think that this helped with my mental state. Yes, some days I would get frustrated and impatient and other days depressed, but it never lasted for too long. I have seen, on a personal level, what positive thinking can do. My parents were told that I would never walk again. I walked.

Having had polio, I learned at an early age how to “figure things out.” If I couldn’t do things one way, I perhaps could another. I think that this mindset has helped with my newest challenge. After meeting with my PT, she helped to map out a plan to achieve my goals. My goals are simple; I want to walk without pain and without crutches. I want to cross my left leg over my right knee to tie my shoe. I want to build up my stamina so that I can go shopping. I want to be in the best health that I can be in. I want to remain independent.

I am learning that achieving my goals may be a long process. It has been a little over a year and I still have a long way to go. I have gained some strength, my stamina has increased, and I am a bit more flexible, but more important, the pain level some days is just an afterthought. I am starting to regain my life.

I have learned in the past year how important it is to listen to your body. I have learned how to manage my work, rest, and exercise time. I understand that to achieve my goals it has and will take a lot of hard, sometimes painful, work. I also understand the importance of working toward my goal and achieving it. I consider myself to still be a relatively young woman who has a lot left to do in my life. Life is a gift, and that is what I want to do—live mine fully.

*Orva Klopfer, as relayed to Holly Klopfer Holton, PT, DPT.

CASE STUDY 35-2 ■ PERSONAL REPORT: POSTPOLIO SYNDROME—cont'd

Points for discussion (suggested answers can be found online):

- If this individual were to seek physical therapy consultation, what history information should the therapist ask?
- What screening questions should the therapist ask?
- What specific systems should the therapist screen?
- What specific tests and measures are appropriate for this case?
- What possible interventions are possible for this individual?
- What considerations should be taken into account when planning for intervention?

APPENDIX 35-A ■ Movement Diagnosis Process Used by Physical Therapists

The *Guide to Physical Therapy Practice*⁶⁹ outlines specific examination guidelines based on a diagnostic classification using preferred practice patterns. In the process of determining the appropriate physical therapy diagnosis, the pathophysiological features of poliomyelitis, current functional status, and impairments are invaluable. As an acquired viral disease that primarily affected the central nervous system (CNS), polio infected a broad age range, with the initial infection lasting a finite time. Individuals with postpolio syndrome (PPS) are then classified according to the Neuromuscular Pattern and fall into two categories:

Pattern C: Impaired Motor Function and Sensory Integrity

Associated with Nonprogressive Disorders of the Central Nervous System—Congenital Origin or Acquired in Infancy or Childhood, Adolescence

Pattern D: Impaired Motor Function and Sensory Integrity

Associated with Acquired Nonprogressive Disorders of the Central Nervous System Acquired in Adolescence or Adulthood

Individuals for whom the specific patterns are used may not have all of the symptoms listed as commonly reported. As Weiss²³³ notes, although impaired sensory integrity is not a common deficit after polio, these patterns should still be more appropriate than any of the identified patterns that clearly apply to individuals without polio or patterns that specifically include polio in their exclusion criteria.

The examination element of the patient/client management model distinctly identifies three components: history, systems review, and test and measures (see Chapters 7 and 8). The application of these components in the management of individuals who have had polio can be found in this chapter beginning with the section on health history.

KEY TERMS

adverse drug reactions
disease
drug interactions
drug therapy
impairment
pharmacist

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify how drugs may positively or negatively affect the behavior of individuals within a neurological rehabilitation setting.
2. For a given disease state, comprehend how drugs may affect that disease state and the implications on an individual's potential for neurological rehabilitation.
3. When considering one or more impairments, recognize the influence of drug therapy on these impairments and on an individual's potential for neurological rehabilitation.
4. Recognize the importance of a collaborative approach in resolving drug-related issues and how those issues affect an individual's potential for neurological rehabilitation.

Drug therapy is one of the most rapidly expanding therapeutic interventions in the health care system. Whereas monotherapy (the use of one drug for treatment of a single disease state) is preferred, complex pathologies and comorbid conditions usually render this goal impossible. In addition, most of the problems associated with multidrug therapy at one time were generally isolated to geriatric patients, but such problems have expanded because of more aggressive drug treatment in all age groups. Only rarely will an occupational or physical therapist manage a client who is not receiving drug therapy for conditions either related or unrelated to the therapist's scope of practice. Drugs used for the management of a wide variety of disease states may have unintended or undesirable effects on a therapeutic plan for a client undergoing neurological rehabilitation. Although the occupational or physical therapist may not be responsible for monitoring all aspects of a client's therapeutic plan, the scope of drug-related complications must be recognized. A client's pharmacist, who is acutely aware of the prescribing practices of the client's physician(s), may be instrumental in resolving the drug-related impact of any medication on a therapeutic plan. The client will benefit greatly from an effective collaboration that includes the therapist and a pharmacist. Focusing on drug effects, diseases, and impairments, this chapter addresses these interactions from three perspectives. First, the chapter discusses what the body does to a drug (pharmacokinetics) followed by what a drug does to the body (pharmacodynamics). Second, the chapter covers a disease- or pathology-driven model that focuses on the pharmacological approaches used in drug therapy of major diseases that are often concurrent with rehabilitation. Finally, the chapter presents an impairment, activity, or functional limitation-driven model that focuses on the effects of drugs on the impairment and resulting functional deficit and the impact on the therapeutic plan. Although defining every problem associated with a

class of drugs or among patients with a particular impairment is not possible within the scope of this chapter, highlighting common difficulties is important.

CLINICAL PHARMACOLOGY

Medications do not affect all clients in the same way, and rehabilitation specialists should be concerned whether a drug achieves or falls short of achieving its therapeutic response. Many situations may alter a drug's response, including drug dose, drug interactions, and a client's comorbidities, and the effect on functional recovery can be positive or negative. In order to understand the impact of prescriptions, the pharmacology of medications used by clients will be discussed. Pharmacology—or the science of drug origin, nature, chemistry, effects, and uses—is commonly divided into two important areas: pharmacokinetics and pharmacodynamics.¹ *Pharmacokinetics* refers to how drugs are absorbed, distributed, biotransformed (metabolized), and eliminated in the body, whereas *pharmacodynamics* can be defined as the study of the biochemical and physiological effects of drugs and their mechanism of action.¹ Many clients in the rehabilitation population will be undergoing pharmacotherapy, and clinicians need to understand how drugs work in the body and how drugs work differently in different populations to optimally manage clients.

In looking at pharmacokinetics, how the drug is absorbed into the body from its site of administration must be considered. Drugs may cross many membranes before reaching their target and can be affected by factors such as drug size, physical state, and dispensing temperature.² The absence or presence of food in the digestive tract, characteristics of the membrane, and the drug's ability to bind to plasma proteins can also play a role in the rate of absorption and distribution. Some medications such as Sinemet for Parkinson disease can be absorbed more slowly with a high-protein meal, thus decreasing their availability and potentially affecting function.

When a drug binds to a plasma protein such as albumin, the drug is held in the bloodstream and thus is unable to reach its target cells.¹ The term *bioavailability* is often used to describe how much of a drug will be available to produce a biological effect after administration.

Metabolism is the next step in pharmacokinetics, involving the biochemical pathways and reactions that affect drugs, nutrients, vitamins, and minerals. The first-pass effect is an important phenomenon because many drugs absorbed across the gastrointestinal (GI) membrane are routed directly to the liver.¹ The liver is then the primary site of metabolism before distribution to target organs. Variations in drug response and metabolism may be caused by genetic factors, the presence of disease, drug interactions, age, diet, and gender.² Drug doses in the elderly and young are often reduced to compensate for their physiological differences. Any drug or disease that affects metabolism has the potential to affect drug activity. Excretion is the last step in pharmacokinetics and removes drugs from the body. Most substances that enter the body are removed by urination, exhalation, defecation, and/or sweating.¹ The main organ involved with excretion is the kidney. *Elimination* is another term for excretion and is often measured so that dosages of drugs can be determined more accurately. The rate of elimination is helpful in determining how long a particular drug will remain in the bloodstream and thus indicates for how long the drug will produce its effect.

Pharmacodynamics focuses on how the body responds to drugs; it deals with the mechanism of a drug's action or how drugs exert their effects. Successful pharmacotherapy is based on the principle that in order to treat a disorder, a drug must interact with specific receptors in its target tissue. Drugs activate specific receptors and produce a therapeutic response. Optimal treatment with medications will result only when the physician is aware of the sources of variation in responses to drugs and when the dosage regimen is designed on the basis of the best available data about the diagnosis, severity, and stage of the disease; presence of concurrent diseases or drug treatment; and predefined goals of acceptable efficacy and limits of acceptable toxicity.¹ Rehabilitation professionals are poised to assist the other members of the medical team with the data needed to assist in determining the effectiveness of a pharmacotherapeutic plan.

DISEASE PERSPECTIVE

A number of diseases and their treatment regimens may be concurrently managed while a client is in a neurological rehabilitation environment. The pharmacological interventions for these conditions and their implications from both a physiological and a disease or pathology model are addressed. Although not a comprehensive list, these include Parkinson disease, cancer, seizure disorders (epilepsy), cardiovascular disorders, disorders of mood, autoimmune disorders, diabetes, infectious diseases, pulmonary diseases, and GI disorders.

Parkinson Disease

Parkinson disease is a degenerative disorder involving a progressive loss of dopaminergic neurons in the substantia nigra. This deficit in dopaminergic function results in resting tremor and difficulty in the control of voluntary movement. Cardiovascular function, bowel motility, and cognitive function are

often compromised. Although not directly associated with the motor system pathology, the functional deficits are emotionally devastating to the patient, resulting in depression and other mood disorders. The predominant pharmacological approach in the management of Parkinson disease is the enhancement of dopaminergic function in the affected brain regions. Among the earliest successful approaches was the use of levodopa (L-dopa), a precursor of dopamine in the central nervous system (CNS). The use of this agent (and all agents to date) only enhances the dopaminergic function in remaining neurons. This approach has no effect on the progressive loss of neurons. In addition to central conversion of L-dopa to dopamine in the substantia nigra, a similar conversion occurs in the limbic system, a brain center associated with the regulation of behavior. Excessive dopaminergic influence in the limbic system has been associated with aberrant behaviors, including paranoia, delusions, hallucinations, and related psychiatric disturbances that may influence sleep and mood. These behavioral changes are obviously antagonistic to any therapeutic plan. In addition to L-dopa, a dopamine precursor, agents that inhibit the breakdown of dopamine, enhance the release of dopamine, or have dopaminergic agonist activity will have similar behavioral effects (Box 36-1). Dopaminergic agents may produce postural hypotension and syncope by virtue of their ability to produce vasodilation on the basis of CNS and peripheral actions.^{3,4} If clients are unable to take their medication, an increasing danger exists (with extended therapy) that movement may be impossible and the normal chest wall expansion and contraction may be compromised (see Chapter 30).

BOX 36-1 ■ AGENTS FACILITATING DOPAMINERGIC ACTIVITY IN THE MANAGEMENT OF PARKINSON DISEASE*

AGENTS CONVERTED TO DOPAMINE

L-dopa (in Sinemet)

AGENTS THAT STIMULATE RELEASE OF DOPAMINE

amantadine (Symmetrel)

AGENTS THAT REDUCE BREAKDOWN OF DOPAMINE

carbidopa (in Sinemet)

entacapone (Comtan)

rasagiline (Azilect)

selegiline (Eldepryl)

tolcapone (Tasmar)

AGENTS THAT ARE DOPAMINERGIC AGONISTS

apomorphine (Apokyn)

bromocriptine (Parlodel)

pergolide (Permax)

pramipexole (Mirapex)

ropinirole (Requip)

ANTICHOLINERGIC AGENTS

benztropine (Cogentin)

diphenhydramine (Benadryl)

trihexyphenidyl (Artane)

*The effects of these agents on muscle tone are complex and dose dependent.

Because Parkinson disease is progressive in nature, clients may have different presentations depending on the stage of the disease and the presence of pharmacological interventions. In the early months of the disease, the motor signs may be particularly subtle, and patients may report only slowness, stiffness, and trouble with handwriting. Particular attention to the history of tremor, slowness of fine motor control, a hunched and slightly flexed posture, and micrographia may lead the physician to diagnose Parkinson disease in its early phases.⁵ As Parkinson disease advances, patients have increasing difficulty in activities of daily living and gait as well as bradykinesia and distal tremor.

Once a definitive diagnosis has been made, controlling symptoms of the disease and the side effects of medications is balanced with the level of functional involvement. The physician and client may discuss the option of a number of medications (see **Box 36-1**) but must determine the best approach on the basis of the clinical presentation. One limitation is the side effect of involuntary movements (dyskinesias). These dyskinesias can be difficult to control and are different from the involuntary movements caused by the disease itself. As mentioned earlier, dopamine agonist regimens that do not cause dyskinesias can also be prescribed, but their effect on symptoms is not as potent.⁶ Often physicians may begin treatment with a dopamine agonist and continue with the agonist as long as symptoms are satisfactorily controlled. Later the physician can initiate treatment with L-dopa when the disease is in the advanced stages. With the elderly client who has cognitive deficits, combination therapy may be the initial choice. Once a medication regimen has been initiated, the client and therapist may notice improvement in Parkinson disease symptoms and therefore functional abilities. After taking a medication over time, clients may find that the effect of the medication begins to wear off before the next dose is scheduled. At this point consultation with the rehabilitation team is recommended to potentially change the medication timing or release ability or combine the treatment with other antiparkinsonian medications.

Great emphasis is placed on treating the motor features of Parkinson disease, but clients may have nonmotor manifestations, including depression, anxiety, cognitive impairment, and dementia. Often the client does not mention these difficulties because he or she does not link them to Parkinson disease. Clients may demonstrate some of these difficulties, and the therapist should recognize the symptoms and refer the client for further follow-up.

The major problems that patients have after 5 years of treatment for Parkinson disease are fluctuations (both motor and nonmotor), dyskinesias, and behavioral or cognitive changes.⁷ The mechanisms behind these complications relate both to the underlying Parkinson disease and to the effects of medications. Motor fluctuations take several forms. Most commonly, a predictable decline in motor performance occurs near the end of each medication dose (“wearing off”). Patients change gradually from “on” with a good medication response into an “off” period 30 minutes to 1 hour before the next medication dose is due. Often patients have involuntary movements (dyskinesias) as a peak-dose complication, and sometimes similar movements occur at the end of the dose. Sudden and severe cataclysms of motor fluctuation occur rarely, with ambulatory patients

becoming immobilized over a period of seconds (“sudden on-off”).⁸ Because these fluctuations occur throughout the day, accurate detection requires the cooperation of the patient, who must be trained to complete diaries of function.⁹ These journals generally divide the 24-hour day into 30-minute segments to detect good medication response (“on”), poor medication response (“off”), disabling dyskinesias, and sleep.

In general, therapists working with clients taking antiparkinsonian medication must be aware of both the positive and the negative side effects of medications to meet functional goals and outcomes effectively. Learning the difference between tremor and dyskinesia is crucial. The therapist must coordinate therapy sessions during good medication response times to assist optimal outcomes. In addition, clients should be monitored for postural hypotension, dizziness, and cognitive changes. Therapists have the unique opportunity to determine the best timing, frequency, and duration of the treatment, and understanding the impact of a client’s drug regimen will only enhance the outcome. Therapists must also be aware that exercise increases metabolism. Increased metabolism may use up the medication faster; thus an individual who generally remains symptom free (no off times between doses) will again exhibit signs of the disease (distal tremors and axial or proximal rigidity). These increases in symptoms may be a drug dosage problem, not signs of further degeneration of the basal ganglia. All changes in symptoms should be discussed with both the pharmacist and the physician.

Cancer

Cancer is a general term for classifying disorders associated with abnormal and uncontrolled cell growth. Virtually any organ system in the body can be affected, either as the primary site of the disorder or as a secondary site associated with metastasis. Cancer may interfere with neurological rehabilitation in various ways. Tumors within the brain may interfere with cognitive and motor function as well as autonomic and metabolic control (see Chapter 25). Peripherally, tumors may interfere with peripheral nerve function and associated motor control or may produce pain. In addition, drugs that reduce cancer pain may interfere with cognitive and motor function.¹⁰ Among these, morphine and related opiate derivatives are notable (**Box 36-2**). A significant degree of tolerance to the CNS depressant effects of these agents will develop with long-term administration. In cancer chemotherapeutic regimens, many antiemetic agents are used. These include dopaminergic antagonists (which may produce motor deficits similar to Parkinson disease), dronabinol (a chemical component of marijuana, which can affect cognitive function), as well as high-dose corticosteroids (which affect mood). Some antitumor agents may be neurotoxic; a reduction in deep tendon reflex, paresthesias, and demyelination is associated with vincristine (Oncovin).¹¹ Naturally, any change in drugs that involves a cancer treatment regimen (directly or indirectly) requires the approval of the client’s oncologist.

The main role of rehabilitation specialists is to help patients with cancer recover from the physical changes that accompany their illness, promote function in activities of daily living, and help provide adaptations to activities within the limits of each patient’s function and the illness. Clinicians

BOX 36-2 ■ EXAMPLES OF NARCOTIC ANALGESICS, MORPHINE, AND RELATED AGENTS*

alfentanil (Alfenta)
 buprenorphine (Buprenex)
 butorphanol (Stadol)
 codeine
 fentanyl (Duragesic)
 hydrocodone (Vicodin)

 levorphanol (Levo-Dromoran)
 meperidine (Demerol)
 methadone (Dolophine)
 morphine (MS-Contin)
 nalbuphine (Nubain)
 oxycodone (Roxicodone)
 oxymorphone (Numorphan)
 pentazocine (Talwin)
 propoxyphene (Darvon)
 remifentanil (Ultiva)
 sufentanil (Sufenta)
 tapentadol (Nucynta)
 tramadol (Ultram)

*Effects on motor systems are systemic or indirect.

should be aware of chemotherapy side effects and the side effects of medications given to treat the toxic effects of chemotherapy.

A number of chemotherapeutic and nonchemotherapeutic medications are used to fight cancer. Most therapies against cancer operate on the simple principle that because cells in tumors are actively dividing, agents that kill dividing cells will kill tumor cells.¹² Tissues that rapidly divide in the body are therefore at risk, including hair, mucosal lining, bone marrow, immune cells, and skin epithelial cells. Nonchemotherapy medications called *biological response modifiers* (BRMs) are naturally made by the body but delivered in large quantities and at higher doses than what the body is capable of producing.¹³ Interferon and interleukin are two of the most commonly used medications. Monoclonal antibodies are also used as chemotherapy to suppress the immune system.

Chemotherapy often has side effects that affect the integumentary, GI, hematological, and neurological systems. Each type of therapy has potential side effects as well as more general side effects of the treatment regimen. As a result of chemotherapeutic treatment of cancer, patients often have muscular weakness, fatigue, pain, immobility, and reduced flexibility. Often the therapist will have to be supportive and flexible with treatment plans to accommodate for changing physiological, psychological, and social factors during treatment.

GI symptoms such as nausea and vomiting may occur, and medications such as Compazine and Reglan may be given to help control these episodes. Symptoms of diarrhea may be addressed through prescriptions or the use of over-the-counter (OTC) medications including milk of magnesia and magnesium citrate. The development of mucositis or esophagitis is also possible. A prescription solution of three

medications (Benadryl, nystatin, viscous lidocaine) can help relieve the pain, inflammation, and potential associated fungal infections. Bone marrow suppression from chemotherapeutic regimens may lead to increased risk of infections, increased risk of bleeding, and increased fatigue and lack of exercise capacity resulting in musculoskeletal weakness. Patients undergoing chemotherapy may receive one or more medications to signal the bone marrow to increase output of white blood cells (Neupogen), stimulate the production of red blood cells (Epogen), and stimulate increased production of platelets (Neumega). These therapies may be instituted to help the patient more quickly reverse suppression of bone marrow and allow the chemotherapy to continue without interruption.¹⁴ Generalized symptoms include fever, body aches and pains, and feelings of ill health and fatigue. No specific medications are used to improve these symptoms. In general, taking medications such as acetaminophen, ibuprofen, or narcotics for fever and pain may help. The use of exercise as an adjunct therapy for cancer treatment–related symptoms has gained favor in oncology rehabilitation as a promising intervention.^{15,16} Exercise is thought to help improve endurance and functional abilities.¹⁵ The major side effects associated with BRMs and monoclonal antibodies are generalized as well and include fever and flu-like symptoms with associated arthralgia and myalgia. Other side effects include lymphedema characterized by fluid retention caused by disruption of lymphatic drainage or removal of lymph nodes. As mentioned earlier, neurological changes may occur, with the development of neurological signs as well as forgetfulness, suicidal ideation, and depression. The rehabilitation professional is an important team member in oncology because he or she potentially affects quality of life.

Seizure Disorders (Epilepsy)

Epilepsy is associated with a diverse group of neurological disorders resulting in motor, psychic, and autonomic manifestations. Many antiseizure medications may produce drowsiness, ataxia, and vertigo (Box 36-3). Some may produce cognitive disorders in children and adults.^{17,18} Although these adverse effects may be exhibited throughout therapy, they are most troublesome during initiation of drug therapy, addition of a drug, and dosage escalation. Sudden discontinuation of antiseizure medications may result in status epilepticus, which may be fatal. Many antiseizure medications are finding successful applications outside epilepsy, especially in the area of pain management.

The practicing clinician working with clients who have a history of seizure disorders must be prepared for the onset of a seizure and be aware of any adverse side effects of medications. Adverse side effects are typically determined on a clinical basis, signifying the importance of recognition by the health care provider. Many of the common side effects can also have negative implications for motor learning, especially while the client is getting used to the medication or the dosage is being elevated or tapered.

The treatment of seizure disorders with pharmacotherapy is typically intended to control the seizure activity completely without producing unwanted side effects. Pharmacological intervention usually begins with one medication (monotherapy); if this drug is unsuccessful a second is added while dosage of the first is tapered. Or a combination may be

BOX 36-3 ■ ANTICONVULSANTS*

acetazolamide (various brand names)
 carbamazepine (Tegretol)
 clonazepam (Klonopin)
 diazepam (Valium)
 ethosuximide (Zarontin)
 felbamate (Felbatol)
 fosphenytoin (Cerebyx)
 gabapentin (Neurontin)
 lacosamide (Vimpat)
 lamotrigine (Lamictal)
 levetiracetam (Keppra)
 lorazepam (Ativan)
 oxcarbazepine (Trileptal)
 phenobarbital (various brand names)
 phenytoin (Dilantin)
 pregabalin (Lyrica)
 primidone (Mysoline)
 rufinamide (Banzel)
 tiagabine (Gabitril)
 topiramate (Topamax)
 valproic acid (Depakene)
 vigabatrin (Sabril)
 zonisamide (Zonagran)

*Effects on motor systems are direct and may decrease tone at higher doses. Direct effects on muscle are minimal. This list includes benzodiazepines that have antiseizure applications.

needed. The effects of the medications vary and may include enhancing the inhibitory effects of γ -aminobutyric acid (GABA) (benzodiazepines); reducing posttetanic potentiation, thereby reducing seizure spread (iminostilbenes); or modulating neuronal voltage-dependent sodium and calcium channels (hydantoin).¹⁹ The overall result is a reduction in abnormal electrical impulses in the brain. The choice of antiseizure drugs primarily depends on the seizure type and, if possible, the diagnosis of a specific syndrome. If seizures are recurrent and occur during critical periods of childhood, adolescence, and early adulthood, they may result in significant impairments in function and increased disability.

Some side effects may be slow to develop and difficult to diagnose because seizures can often be mistaken for sedation or cognitive dysfunction, especially in children, who may not report drug side effects. Practitioners can also mistakenly accept reversible drug toxicity as a necessary consequence of a seizure disorder. The number of seizures occurring during physical or occupational therapy should be tracked to assist in determining appropriate pharmacotherapy.

One common antiseizure medication, valproic acid (Depakene), may cause nausea, vomiting, hair loss, tremor, tiredness, dizziness, and headache. Valproic acid has also been reported to aggravate absence seizure in clients with absence epilepsy.²⁰ Metabolic side effects may include an increase in glucose-stimulated pancreatic insulin secretion, which may be followed by an increase in body weight.²¹ Long-term valproic acid use is known to increase bone resorption in adult epileptic patients and lead to a decreased bone mineral density.²²

Another seizure medication, carbamazepine (Tegretol), is considered a safe drug but has a long list of adverse events, most commonly ataxia and nystagmus.²³ Other systems frequently involved are the skin, the hematopoietic system, and the cardiovascular system. Gabapentin (Neurontin) is another well-tolerated antiseizure medication with proven clinical efficacy and a low incidence of adverse events in clinical trials. Common side effects include dizziness, fatigue, and headache. Phenytoin (Dilantin) has adverse reactions including ataxia, nystagmus, slurred speech, confusion, dizziness, and, at high doses, peripheral neuropathy.

Benzodiazepines (e.g., diazepam) are useful in managing status epilepticus, but their effects are not long lasting so they are often used along with a primary anticonvulsant. The most frequent side effects are dose-related sedation, difficulty with concentration, dizziness, and difficulty walking.

Pharmacological adverse events that occur under the influence of seizure medications must be recognized by the rehabilitation specialist to participate in a team approach to patient care. Therapists can assist in determination of effectiveness of a specific treatment regimen, appropriate timing of rehabilitation interventions, and the overall progress of the client during rehabilitation.

Stroke, Hypertension, and Related Disorders

Stroke, by virtue of the interference with blood flow and oxygenation, produces both reversible and irreversible neurological deficits (see Chapter 23). The loss of function associated with stroke has at least two major causes. The first involves loss of oxygenation to a critical brain region, followed by glutaminergic rebound and excessive calcium influx with apoptosis (programmed cell death). Current drugs and those under development are aimed at restoring blood flow and inhibiting glutaminergic hyperexcitability and intracellular apoptotic mechanisms.²⁴ The second pathogenic issue is related to reperfusion injury associated with oxygen radicals and associated cellular damage. In this case, free radical scavengers have shown some promise in animal models of stroke.²⁵ To reduce the damage associated with thromboembolism in such cases, tissue plasminogen activator has been recommended. However, this agent is most effective when given within an hour after the vascular insult. Drugs with other mechanisms used to improve the prognosis of stroke are under development. However, drugs used for concurrent conditions (atherosclerosis and hypertension) before and after a stroke are complicating factors for optimal outcomes from rehabilitation. These drugs include β -adrenergic antagonists, which reduce heart rate and correspondingly reduce exercise tolerance. Occasionally, calcium channel blockers, α -adrenergic blockers, and related agents may cause similar effects, including weakness, dizziness, syncope, and cognitive disorders. Changes in serum electrolytes induced by diuretics and the angiotensin-converting enzyme inhibitors may affect the heart, the vasculature, and skeletal muscle and ultimately cause impairments in areas such as strength of contraction.²⁶ Box 36-4 lists many of these drugs. Many of the cholesterol synthesis inhibitors (agents used to reduce serum cholesterol) may induce muscle weakness (Box 36-5).^{27,28} Abrupt discontinuation of antihypertensive medications may result in a hypertensive crisis, dramatically increasing the risk of stroke and related disorders.

BOX 36-4 ■ COMMONLY USED ANTIHYPERTENSIVE AND CARDIOVASCULAR DRUGS***β-ADRENERGIC BLOCKING DRUGS**

acebutolol (Sectral)
 atenolol (Tenormin)
 betaxolol (Kerlone)
 bisoprolol (Zebeta)
 carteolol (Cartrol)

 losartan (Cozaar)
 olmesartan (Benicar)
 telmisartan (Micardis)
 valsartan (Diovan)

*Effects on motor systems are predominantly systemic or indirect.

Clinicians caring for patients with stroke, hypertension, and cardiac disorders will benefit from understanding the impact of any medication on the therapeutic plan. These clients may be taking any number of medications to manage the acute and subacute complications of cardiovascular impairments and their resulting sequelae. Other complications after stroke that may require pharmacological intervention include urinary tract infections, musculoskeletal pain, deep vein thrombosis, pressure sores, shoulder subluxation, and

depression. All these medications have their own issues, and health care providers must be aware of adverse events and any alteration in function of the heart that may occur in relation to exercise.

Anticoagulants such as heparin, warfarin, and aspirin (so-called *blood thinners*) are used to prevent another stroke after the first one has occurred. Side effects may include bleeding, allergic reactions, thrombocytopenia, and, in the case of aspirin, stomach irritation.²⁹ Blood thinners make the client more susceptible to bruising; therefore care must be taken in client handling and choice of activity. Antiarrhythmics are used to restore normal conduction patterns of the heart. Antiarrhythmic drugs may make some clients experience lightheadedness, dizziness, or faintness when they get up after sitting or lying down (orthostatic hypotension).³⁰ Antiarrhythmic drugs may also cause low blood sugar or changes in thermoregulation.³¹ The most common side effects are dry mouth and throat, diarrhea, and loss of appetite.³² These problems usually go away as the body adjusts to the drug and do not require medical treatment. Therapists must be prepared for hypotensive events and the need to educate clients on positions that will reduce the effects of orthostatic hypotension.

BOX 36-5 ■ HYPOLIPIDEMIC DRUGS (HMG-CoA REDUCTASE INHIBITORS)*

atorvastatin (Lipitor)
 fluvastatin (Lescol)
 lovastatin (Mevacor)
 pitavastatin (Livalo)
 pravastatin (Pravachol)
 rosuvastatin (Crestor)
 simvastatin (Zocor)

*May rarely produce muscle damage through a direct effect on the muscle.

Hypertension is a common disorder that is frequently encountered when treating patients in the rehabilitation environment. Antihypertensive medications are used to lower blood pressure (see [Box 36-4](#)) by limiting plasma volume expansion, decreasing peripheral resistance, and decreasing plasma volume. Often clients under medical management will undergo changes in dose and additions or deletions of medication, which may lead to problems during rehabilitation. Side effects of these medications may include increased frequency of urination, increased urinary excretion of potassium, orthostatic hypotension, hypotension, dehydration, tiredness, fatigue, cold hands and feet, and dizziness.³³ When working with a client taking antihypertensive medications, health care providers should monitor for side effects, clinical signs, and the client's perceived exertion. Generally, people on antihypertensive medications require careful cardiovascular monitoring during any physical activity.

Many clients may become depressed after a neurological disorder such as stroke or a cardiac event.³⁴ It may be attributable to a natural loss of physical function or a neurochemical response to changes in brain chemistry. Clients with signs and symptoms of depression (sadness, anxiousness, hopelessness, suicidal ideation) should be referred for further follow-up by the physician. Many antidepressant medications take at least 2 weeks to achieve a therapeutic level. Antidepressants may cause temporary side effects (sometimes referred to as *adverse effects*) in some people. These side effects are generally mild. Any unusual reactions, side effects, or behaviors that interfere with functioning should be reported to the doctor immediately. The most common side effects of tricyclic antidepressants (TCAs) are dry mouth, constipation, bladder problems, sexual problems, blurred vision, dizziness, and drowsiness.³⁵ The newer antidepressants have different types of side effects, including headache, nausea, nervousness, insomnia, agitation, and sexual problems.³⁶ Therapists working with clients who are depressed may need to delay rehabilitation until the depression is well managed.

Hyperlipidemia is considered a modifiable risk factor for heart disease and stroke. Many clients may be receiving pharmacological treatment to reduce their cardiovascular risk. Several types of drugs are available for cholesterol lowering, including statins, bile acid sequestrants, nicotinic acid, and fibric acids.³⁷ The statins are considered first-line drugs and are generally well tolerated but can produce myopathy under some circumstances.³⁷ An elevation of creatine kinase level is the best indicator of statin-induced myopathy and should be checked for when clients report leg pain. Bile acid sequestrants also produce moderate reductions in cholesterol. Sequestrant therapy can produce a variety of GI symptoms, including constipation, abdominal pain, bloating, fullness, nausea, and flatulence. Nicotinic acid (niacin) therapy can be accompanied by a number of side effects. Flushing of the skin is common with the crystalline form and is intolerable for some persons. However, most persons have tolerance to the flushing after more prolonged use of the drug. The fibrates have the ability to lower serum triglycerides and are generally well tolerated in most persons. GI symptoms are the most common reports, and fibrates appear to increase the likelihood of cholesterol gallstones.³⁷

Overall, clients taking cardiovascular medications need careful monitoring for any drug impact on cardiorespiratory

or metabolic responses in relation to rehabilitation activities. Thus the effects of drugs must be considered in developing the rehabilitation plan (see [Chapter 30](#)).

Anxiety and Depression

Agents used in the management of anxiety, whether from acute or chronic disease, must be carefully titrated. Among these agents are the benzodiazepines, whose anxiolytic (anxiety-reducing) dosage range immediately precedes a dose that may affect motor skills and cognitive function ([Box 36-6](#)). In subjects of all ages, but especially the geriatric population, administration of benzodiazepines may produce paradoxical excitement, confusion, and behavioral changes.³⁸ Geriatric subjects also have an increased incidence of injury from falls concurrent with use of benzodiazepines and other sedative-hypnotic drugs. Although benzodiazepines may have variable effects on learning and declarative memory, these effects may differ among the benzodiazepines, displaying considerable variation among individuals. If producing sleep alone is desired, zolpidem (Ambien) and zaleplon (Sonata) are attractive alternatives because these agents do not have anxiolytic effects. Although the anxiolytic agent buspirone (Buspar) is relatively free of benzodiazepine-like effects, the onset time for the desired anxiolytic effect is characteristically delayed.³⁹ Lack of compliance with anxiolytic agents may increase panic attacks and reduce effective interactions with a therapist.

The emergence of the selective serotonin reuptake inhibitors (SSRIs) has revolutionized the treatment of depression. The older agents, such as the TCAs, are just as effective in the management of several forms of depression; however, their adverse effect profile is somewhat different. TCAs often produce drowsiness and orthostatic hypotension, effects that complicate any rehabilitation regimen.⁴⁰ Although these effects may be produced by SSRIs, their incidence is much reduced. Certain TCAs, by virtue of their ability to inhibit the reuptake of norepinephrine in adrenergic nerve terminals, may be used at lower doses for neuralgia. Although these low-dose regimens are usually not associated with the side effects previously mentioned, some patients may be more sensitive to these effects than others. This requires increased vigilance for the care team in determining iatrogenic versus pathological sources of somnolence and syncope. A partial list of antidepressants is presented in [Box 36-7](#). Noncompliance with antidepressant therapy may result in lack of interest in any therapeutic regimen.

BOX 36-6 ■ ANXIOLYTIC BENZODIAZEPINES*

alprazolam (Xanax)
 clordiazepoxide (Librium)
 clorazepate (Tranxene)
 diazepam (Valium)
 halazepam (Paxipam)
 lorazepam (Ativan)
 oxazepam (Serax)

*Note that benzodiazepines indicated for sleep induction are not included in this list. The above agents reduce muscle tone through a direct effect on motor systems at higher doses.

BOX 36-7 ■ ANTIDEPRESSANTS: EXAMPLES OF TRICYCLIC ANTIDEPRESSANTS (TCAs) AND SELECTIVE SEROTONIN REUPTAKE INHIBITORS (SSRIs)*

TCAs

amitriptyline (Elavil)
amoxapine (various trade names)
clomipramine (Anafranil)
desipramine (Norpramin)
doxepin (Adapin)
imipramine (Tofranil)
nortriptyline (Pamelor)
protriptyline (Vivactil)

SSRIs

citalopram (Celexa)
escitalopram (Lexapro)
fluoxetine (Prozac)
fluvoxamine (Luvox)
paroxetine (Paxil)
sertraline (Zoloft)

*These agents may produce complex direct and indirect effects on motor systems with minimal effects directly on muscle.

Patients with stroke and other neurological diagnoses often have depression, which reduces motivation and decreases compliance with a therapeutic regimen. Although obviously linked, the degree of functional restoration after a stroke does not always correlate with resolution of depression.

Many patients with neurological disorders are diagnosed with or experience anxiety and depression. The cause of affective symptomatology can be the result of cognitive and emotional deficits or impairment of brain function from the existing pathology.³⁴ In the rehabilitation environment many patients may show signs and symptoms of anxiety or depression that can make the process of recovery more difficult. The rehabilitation professional must recognize the manifestations of both anxiety and depression such as fear of dying or “going crazy,” heart palpitations, shortness of breath, difficulty concentrating, depressed mood, diminished interest or pleasure in activities, sleep disturbance, changes in appetite, psychomotor retardation and agitation, and suicidal ideation.⁴¹ Anxiety and depression may limit the client’s full participation in recovery of function and are associated with poorer outcomes.^{36,42}

Anxiety and depression can be managed well when treated with the medications discussed previously, but some drugs—including centrally acting hypotensives (methyldopa), lipid-soluble β -blockers (propranolol), benzodiazepines, and other CNS depressants—may cause a depressed mood.¹ Therefore review of the medication regimen in someone with depression is useful in case one of the medications may be implicated.

Pharmacological treatments for anxiety and depression should be administered at a dosage and time that ensure the best patient response during rehabilitation treatments. Anti-anxiety medications (see Box 36-6) act within a short time after ingestion, producing their effects of sedation and relaxation and thereby reducing anxiety. Higher levels may cause drowsiness, sleep, and anesthesia and are associated with

falls, which may not be ideal when trying to promote recovery of function. Antidepressant medications (see Box 36-7) typically take weeks for therapeutic levels to be achieved in the brain and an improvement in mood to be demonstrated. Rehabilitation may be appropriate for a client taking these medications when they have improved the client’s mood and outlook. Side effects of antidepressants can also cause some difficulties, including lightheadedness, drowsiness, short-term memory loss, disturbed sleep, clumsiness, sedation, and low blood pressure.

Some evidence has shown that recovery from brain injury may be positively influenced by antidepressants^{43,44} and that antidepressants can play a role in brain plasticity.⁴⁵ These studies suggest that recovery of function after brain injury can be influenced by experience and pharmacological intervention. Rehabilitation specialists need to be prepared to assess responses to pharmacotherapy, recognize adverse effects, manage minor side effects, and seek appropriate assistance for adverse events.

Arthritis and Autoimmune Disorders

In rheumatoid arthritis (RA), autoimmune mechanisms play an important role in the inflammatory process and progressive joint destruction. Because of the constant pain associated with movement, clients will seek nonprescription drugs (including dietary supplements) that often escape prescription drug monitoring programs in pharmacies. It is important for all health professionals to recognize this issue, particularly with RA. In the management of RA, the therapeutic approach may influence the progress of rehabilitation. Aggressive treatment with glucocorticoids may reduce joint pain and facilitate movement, but it may produce changes in mood and muscle wasting.⁴⁶ Although this is reversible and limited to systemic administration of high-dose corticosteroids, its impact cannot be overlooked and certainly affects physical or occupational therapy prognosis. Prednisone and related glucocorticoids may often produce a false sense of well-being that may exceed the ability of the patients to engage safely in certain exercise regimens. From the patient’s perspective, this pharmacological effect is perceived as a “cure” and does not provide the motivation to continue with exercise therapy. The same problems may exist with the use of corticosteroids in other autoimmune disorders.⁴⁷

Nonsteroidal antiinflammatory agents (NSAIDs) (Box 36-8) have long been used for the relief of pain with arthritis; however, depletion of prostaglandins in the gastric mucosa produces bleeding, which has limited their usefulness.⁴⁸ The development of newer agents that are more selective for isoforms of cyclooxygenase (COX-2 inhibitors) that are involved in joint inflammation is a major advance. An example is celecoxib. Although bleeding disorders are dramatically reduced, the incidence of ataxia with these agents may be increased.⁴⁹ Unfortunately, cardiovascular toxicity risk has led to the withdrawal of most of the COX-2 inhibitors from the market. Clients with neurological diseases or pathological processes with problems requiring antiinflammatory medications may develop side effects that interact with and complicate existing motor deficits. Failure to comply with the arthritis medication regimen will likewise reduce effective movement.

Clinically, clients with the onset of RA may have a number of systemic manifestations, including fatigue, anorexia,

BOX 36-8 ■ COMMONLY USED NONSTEROIDAL ANTIINFLAMMATORY AGENTS (NSAIDs) AND SALICYLATES*

aspirin or acetylsalicylic acid
 celecoxib (Celebrex)
 diclofenac (Voltaren)
 diflunisal (Dolobid)
 etodolac (Lodine)

 flurbiprofen (Ansaid)
 ibuprofen (Advil, Motrin, Nuprin)
 indomethacin (Indocin)
 ketoprofen (Orudis KT, Oruvail)
 ketorolac (Toradol)
 meclofenamate (various trade names)
 mefenamic acid (Ponstel)
 meloxicam (Mobic)
 nabumetone (Relafen)
 naproxen (Aleve, Naprosyn)
 oxaprozin (Daypro)
 piroxicam (Feldene)
 sulindac (Clinoril)
 tolmetin (Tolectin)

*Only at higher doses will these agents affect motor systems directly. Most problems are through systemic or indirect effects.

generalized weakness, and musculoskeletal symptoms followed by synovitis. These forewarning symptoms may continue over weeks or months before more specific symptoms occur. The initial evaluation of the patient with RA should document symptoms of active disease (e.g., presence of joint pain, duration of morning stiffness, degree of fatigue), functional status, objective evidence of disease activity (e.g., synovitis, as assessed by tender and swollen joint counts, and the erythrocyte sedimentation rate), mechanical joint problems (e.g., loss of motion, crepitus, instability, malalignment, or deformity), the presence of extraarticular disease, and damage detected radiographically.⁵⁰ Neurological complications of RA may occur in the CNS (cerebral vasculitis), the peripheral nervous system (nerve compression), the neuromuscular junction (myasthenic syndrome), and muscle (myopathy).⁵¹ Depending on the stage of involvement, the client may be undergoing nonpharmacological modalities (education, weight loss, range-of-motion exercises) and pharmacological therapy including analgesics, NSAIDs, steroids, disease-modifying antirheumatic drugs (DMARDs), and BRMs.

The goals of pharmacological treatment of RA are to prevent or control joint damage, prevent loss of function, decrease pain, and improve joint function.⁵⁰ NSAIDs assist in analgesia and decrease inflammation, thus allowing the therapist to work on range of motion and strengthening, but they do not alter the disease process. Because NSAIDs regulate the production of chemicals (prostaglandins) in the body that help trigger inflammation by inhibition of an enzyme (COX), they sometimes lead to unwanted side effects previously discussed. Data suggest that although selective COX-2 inhibitors have a significantly lower risk of serious adverse GI effects than do nonselective NSAIDs, they are no more effective than nonselective NSAIDs, are related to

cardiovascular events, and may cost as much as 15 to 20 times more per month of treatment than generic NSAIDs.^{52,53}

Steroids are synthetic forms of naturally occurring hormones produced by the adrenal glands and are typically administered orally or by injection. They provide rapid and powerful reduction of pain and inflammation, thus resulting in improved function. Recent evidence suggests that low-dose glucocorticoids slow the rate of joint damage and therefore appear to have disease-modifying potential.⁵⁴ Side effects include blood sugar elevations, cataracts, hypertension, increased susceptibility to infection and bruising, osteoporosis, and weight gain, depending on the dosage and length of treatment. They are often used at disease onset or with disease flares as a temporary aid in obtaining control. Disabling synovitis frequently recurs when glucocorticoids are discontinued, even in patients who are receiving combination therapy with one or more DMARDs. Therefore many patients with RA are functionally dependent while taking glucocorticoids and continue them long term.⁵⁰

An important foundation in the treatment of RA is the use of DMARDs, which are medications that reduce signs and symptoms, reduce or prevent joint damage, and preserve the structure and function of the joints. Their use alone or in combination has been reported to allow patients to remain active and productive.⁵⁵ The most common DMARDs in current use include methotrexate, sulfasalazine, hydroxychloroquine, leflunomide, and cyclosporine. Others include gold salts, azathioprine, and D-penicillamine. Side effects may include diarrhea, eye damage, liver damage, nausea, and vomiting and depend on the DMARD taken.

Finally, BRMs are a newly developed class of medicines that restore or stimulate the immune system to fight disease. BRMs target specific parts of the immune system that destroy joints. Some do so by blocking the effects of tumor necrosis factor (TNF), a protein involved in RA through the inflammatory cascade, and are credited with improving signs, symptoms, and function in patients with RA.⁵⁶

Rehabilitation therapy is important in maintaining physical function in clients with RA. With combinations of medications, health care providers can reach goals of increasing or maintaining joint mobility; decreasing pain; improving functional abilities; improving cardiovascular fitness; and educating clients on the use of assistive devices, joint protection, and energy conservation.

Infectious Diseases

Both bacterial and viral diseases may produce neurological disorders (see Chapter 26). The neurological impact of treatments and prophylactic measures must be understood. Although this may be readily apparent for drugs, vaccines have also been implicated in causing similar problems. The association of a hypotonic-hyporesponsive episode with the pertussis vaccine is such an example.⁵⁷

In the course of treating bacterial diseases, many antibiotics and anti-infective agents may compromise sensory, motor, and cognitive function. These functions may be compromised temporarily or permanently and may be patient specific. First, in the critically ill patient, aminoglycosides (gentamicin, tobramycin, and amikacin) and vancomycin may produce ototoxicity, such as hearing loss (reversible and irreversible) and vestibular damage (dizziness, vertigo, and ataxia). Minocycline is also associated with vestibular

toxicity.⁵⁸ Extra precautions may be necessary to prevent falls during and after therapeutic exercise sessions. Fall-prevention programs must be developed in these cases as well as with the use of sedative-hypnotics, as previously noted.

A wide variety of viral diseases interfere with neurological function. Polio is historically the most widely recognized (see Chapter 35). Acquired immunodeficiency syndrome (AIDS) may manifest as a wide variety of neurological disorders (see Chapter 31). A recent finding is that protease inhibitors, which reduce the assembly of viral particles, may dramatically reduce and possibly reverse the neurological manifestations of AIDS.⁵⁹ Although adverse effects associated with antiviral and antibiotic agents may be intolerable, noncompliance may result in increased resistance of the virus or microorganism to retreatment.

The guiding principle of chemotherapy for infection is selective toxicity, in which the agent must cause more harm to the pathogen than to the host. Problems associated with antimicrobial therapy include resistance to drugs, side effects, allergies, and suppression of normal flora. Clinicians ask clients to exercise under conditions in which they may potentially have a compromised immune response because of trauma, a pathological condition, or surgery. These conditions may make clients more susceptible to infection, slow healing, and slow recovery.⁶⁰

An increasing number of strains of antibiotic-resistant bacteria are now emerging, in large part because of the overuse and misuse of antimicrobial drugs by health care providers.⁶¹ Overuse of antimicrobial drugs exerts a selective pressure among bacteria, encouraging the emergence of antibiotic-resistant strains by eliminating antibiotic-sensitive strains, promoting the establishment of bacteria with rare mutations of resistance, and permitting the spread of resistant strains from infected individuals.⁶² One example is the use of antibiotics for upper respiratory tract infections caused by viruses. This has been shown to have no beneficial impact on the course of the disease.⁶³ Infection control in the rehabilitation environment is essential to stop the spread of disease. Therapists must be diligent with infection control procedures such as handwashing, updating vaccinations, and cleaning all equipment. Educating clients to use antibiotics only when needed and complete the entire course of medication can potentially slow the proliferation.

Common adverse effects from the use of antimicrobials and antiviral drugs include nephrotoxicity and ototoxicity (aminoglycosides), GI complications (cephalosporins, clindamycin), thrombophlebitis and vertigo (tetracyclines), jaundice (erythromycin), photophobia (vidarabine), neurotoxicity (metronidazole), and allergic reactions (β -lactam antibiotics). The therapist must be aware of adverse side effects to assist with early recognition and referral to the physician.

Antibiotics kill various normal commensal bacteria in the gut, altering the balance and allowing overgrowth of pathogens.⁶⁴ This change of bacterial flora is believed to result in increased toxins from pathogens and can cause infection with resistant microbes.⁶⁴ When clients are taking drugs to fight infection or undergoing procedures or surgeries that place them at risk for infection (indwelling catheters), they can be more susceptible to infectious agents. Abscesses or contamination as a result of the normal flora into a normally

sterile body site is often the reason for perioperative antimicrobial prophylaxis.⁶⁵ Rehabilitation specialists will most likely see many clients who are undergoing chemotherapy with anti-infective medications and play a crucial role in preventing and controlling infectious disease in the health care setting. Therapists need to update their knowledge foundation with evidence-based protocols for specific diagnoses and treatments as well as understand when infections may or may not need antimicrobial medications. In addition, education of patients about why antimicrobial agents are not indicated in specific situations, how to alleviate symptoms, and what signs indicate further follow-up may help them understand the growing problem of antibiotic resistance.

Diabetes

Diabetes, as a disorder of insulin production and sensitivity, has two major forms. Type 1 has an autoimmune component based on destruction of pancreatic islets, but success in modulating this pathogenic feature has been limited. As a result, clients with type 1 diabetes are necessarily insulin dependent. The pathogenic features of insulin insensitivity characteristic of type 2 are not well understood, but a wide array of therapeutic agents have been developed for management of this condition. Although the metabolic states of type 1 and 2 pathologies may differ somewhat, the chronic pathologies associated with poorly controlled hyperglycemia are remarkably similar. The development of peripheral neuropathy (see Chapter 18) is a progressive problem in patients with diabetes. This neuropathy compromises sensory and motor control. In addition to long-term management of diabetes from a glucohomeostatic perspective, other agents show promise. Treatment of diabetic neuropathy with trazodone or mexiletine is an example.^{66,67}

A more acute problem is swings in blood glucose level from inappropriate diet, exercise, insulin, and oral hypoglycemic drug administration. The balance of these factors is important, and monitoring of blood glucose level is essential. Swings in blood glucose level are often associated with changes in behavior and sensorium. This may pose a safety concern because cognitive and motor function may be impaired as a result. An increase in exercise will decrease the blood glucose concentration, thereby reducing insulin requirements. These factors should be carefully considered in any exercise regimen for the client with diabetes.⁶⁸ A list of oral hypoglycemic agents is presented in [Box 36-9](#). Lack of glucose control because of noncompliance with medications that are useful in controlling diabetes will only return the client to an accelerated course to peripheral neuropathies and related sequelae.

In the clinical setting the health care practitioner must remember that the main goal of diabetes management is to prevent both the small-vessel complications (e.g., retinopathy and neuropathy) and large-vessel complications (e.g., heart disease and amputation) of the disease linked with elevated blood glucose levels. Diabetes is therefore often controlled through intensive, tailored treatment regimens of diet and physical activity, oral agents, and insulin.⁶⁹ Each of these regimens is designed to potentially reduce hyperglycemia and can result in hypoglycemia if not monitored.

Initially, the physician and client with diabetes can work together on a treatment plan to manage the disease. An important first step includes diet, physical activity, and a

program to reduce body weight by 5% to 10%.⁷⁰ The effects of exercise as a cause of hypoglycemia deserve particular consideration because physical activity represents the most variable factor in the routine of many clients, especially those in rehabilitation.⁷¹ With vigorous exercise, glucose use can increase severalfold, and this increase can persist long after the completion of the exercise, resulting in a fall in blood glucose long afterward. Although diet and activity are important cornerstones for diabetes care, oral agents and/or insulin may eventually be required to achieve glycemic control.

Five classes of oral agents are available to help or make the body use its own insulin, including sulfonylureas (chlorpropamide), meglitinides (repaglinide), biguanides (metformin), glitazones (rosiglitazone), and α -glucosidase inhibitors (acarbose). These classes of medications have specific regimens and may be prescribed as monotherapy or taken in combinations that may include insulin. Side effects vary from weight gain to GI symptoms to hypoglycemia. Hypoglycemia as a side effect of pharmacotherapy is of concern in the rehabilitation setting because abnormally low glucose levels can cause alterations in cognition, cardiovascular hemodynamic changes, and an increased risk of physical injury.⁷² The signs and symptoms of hypoglycemia can vary from person to person and may depend on how fast the blood sugar drops. Early signs include shaking, sweating, fatigue, and weakness. Later signs may include confusion, combativeness, and exhaustion that inhibits eating, which may lead to loss of consciousness.

Insulin is a primary therapy in type 1 diabetes, in which the body has no ability to produce its own insulin. When oral antidiabetic agents no longer assist in maintaining glycemic targets, insulin is usually instituted in the diabetic with low production or resistance to insulin (type 2 diabetes).⁷³ Many forms of insulin are available, and administration is typically through subcutaneous injection or insulin pumps. Insulin can be long acting or short acting and is often used in combinations to maintain the optimal level of glycemic control. Hypoglycemia is the primary problem associated with insulin use because of its ability to lower blood sugar.⁷³

Health professionals working with clients who have diabetes should consider a number of strategies for prevention of hypoglycemia and be able to analyze the risk and benefits

of exercise. Because glycemic control is individualized, each client must be addressed uniquely, and as a member of the health care team the rehabilitation specialist can potentially assist in education of all those involved in the care of the client. The following are guidelines published by the American Diabetes Association (ADA) and should be implemented in clients with known type 2 diabetes.⁷⁴ Medical evaluation of the client before exercise begins is important to determine the extent of involvement and complications present. Prepare the client for exercise by monitoring glycemic control before, during, and after exercise. Exercise is contraindicated if fasting glucose levels are more than 250 mg/dL and ketosis is present; use caution if glucose levels are greater than 300 mg/dL and no ketosis is present. The patient should ingest added carbohydrate if glucose levels are less than 100 mg/dL. Document when changes in insulin or food intake are necessary, and learn the glycemic response to different exercise conditions (e.g., light, moderate, heavy). Food intake should include consumption of carbohydrates as needed to avoid hypoglycemia. Carbohydrate-based foods should be readily available during and after exercise.

Clinicians need to have an understanding of what causes diabetes, the effects of medications and exercise on the regulation of blood sugar levels, signs and symptoms of hypoglycemia, and what should be done in a diabetic emergency.

Pulmonary Diseases

Many clients with neurological problems have pulmonary disease as well (see Chapter 30). The treatment of pulmonary diseases presents an unusual challenge. Many drugs used for treatment of asthma, emphysema, and chronic obstructive pulmonary disease (COPD) are intended to have direct effects on the lung, yet systemic effects are often unavoidable. Adrenergic bronchodilators, such as albuterol, epinephrine, and metaproterenol, may increase heart rate and tremor.⁷⁵ If tremor first manifests because of a neurological insult, then these drugs may exaggerate the motor impairment. Although ipratropium is an anticholinergic with bronchodilating properties, the associated systemic anticholinergic effects (such as urinary retention with prostatic hypertrophy) are not well tolerated in geriatric men.⁷⁶ Prednisone and related corticosteroids may dramatically reduce the degree of pulmonary hyperresponsiveness but often produce systemic effects as previously noted. These are often reduced (but not necessarily eliminated) with the use of inhaled corticosteroids such as beclomethasone, budesonide, flunisolide, and triamcinolone. Although the use of xanthines in asthma is declining, theophylline in asthma and obstructive pulmonary diseases can produce changes in cognitive function, including delusions and hallucinations with higher doses. General CNS stimulation, including nervousness, insomnia, and seizures, is well recognized.⁷⁷ Tremor and nausea are often produced with theophylline, even with clinical dosage regimens commonly accepted. Finally, the increase in diuresis caused by theophylline in patients with prostatic hypertrophy is certainly troublesome. The metabolism of this drug is often changed by other medications, which complicates therapy. These changes in drug metabolism may increase toxicity or decrease efficacy.⁷⁸ Newer classes of disease-modifying agents known as *leukotriene modifiers* (montelukast and zafirlukast) are

being favored in many regimens for the management of asthma. Although cardiovascular and neurological side effects of these drugs appear to be dramatically reduced when compared with other agents, they have been implicated in several important drug interactions.⁷⁸ Lack of compliance with these medications decreases pulmonary gas exchange, ultimately decreasing motor performance.

Clients may have signs and symptoms of lung dysfunction during exercise, including nonproductive cough, dyspnea, alterations in breathing rate and chest expansion, changes in skin color, as well as changes in auscultation and percussion findings. Symptomatic pharmacotherapy may be required to reduce disease-related symptoms such as shortness of breath and improve exercise tolerance.⁷⁹ The client should begin exercise after medications to improve exercise tolerance. Often with chronic lung disease, exacerbations may be caused by an infection; therefore antibiotics may be prescribed.⁸⁰ In addition, thinning and mobilization of secretions in airways with mucolytics and chest therapy may be necessary.⁸¹ Oxygen therapy is a secondary therapy that may be necessary for hypoxemic patients.⁸⁰ This therapy reduces the hematocrit level to more normal levels, moderately improves neuropsychological factors, and ameliorates pulmonary hemodynamic abnormalities.⁸² Oxygen therapy may be indicated during exercise for patients whose levels become desaturated during low-level activity.⁸³ Understanding the use of pharmacological treatments for pulmonary dysfunction can assist the rehabilitation professional in promoting improved strength, exercise tolerance, and functional abilities in clients with pulmonary dysfunction.

Gastrointestinal Disorders

Among the wide variety of agents used in the treatment of GI disorders, problems with agents affecting GI motility are among the most frequently encountered. Antiemetics that are dopaminergic antagonists, such as prochlorperazine (Compazine), chlorpromazine (Thorazine), and promethazine (Phenergan), may produce extrapyramidal side effects resembling Parkinson disease through the drug's actions on the basal ganglia.⁸⁴ Dronabinol (Marinol), a cannabinoid derivative from marijuana, is an effective antiemetic but may produce cognitive and sensory disturbances, including drowsiness, dizziness, ataxia, disorientation, orthostatic hypotension, and euphoria.⁸⁵ The selective serotonin antagonists dolasetron (Anzemet), granisetron (Kytril), and ondansetron (Zofran) are effective and valuable antiemetics, especially in cancer chemotherapy. The most common adverse effect is severe headache.⁸⁶ The benzodiazepine lorazepam is an effective adjunct for control of emesis. Problems associated with benzodiazepines have been previously discussed. Corticosteroids such as dexamethasone should be included among the antiemetic agents; their adverse effects have also been previously discussed.

In producing normal motility, metoclopramide (Reglan), domperidone (Motilium), and cisapride (Propulsid) are often used. The adverse effects of metoclopramide are primarily through dopaminergic antagonism. Domperidone was developed to reduce these CNS effects and has been used to treat diabetic gastroparesis with some success.⁸⁷ Cisapride, a restricted-use prokinetic agent, may have a wide variety of CNS effects, including dizziness, mood disorders, vision changes, hallucinations, and amnesia, although with low

incidence compared with concerns of arrhythmias induced by this drug.⁸⁸ Compliance with medications that reduce problems with the GI system may have little direct effect on motor performance but may prove troublesome to the client's quality of life.

In the rehabilitation setting, GI signs and symptoms are common problems for many clients. The side effects of drugs reported in formularies show that almost all oral preparations are the potential cause of some form of GI disturbance.⁸⁹ Signs and symptoms include upper GI effects such as nausea, vomiting, indigestion, gastric reflux, and stomach pain or lower GI effects such as diarrhea, constipation, colonic pain, and blood in stools. These symptoms may be caused by an underlying GI condition (gallstones and acid reflux) or side effects from medications (nausea and vomiting). Because GI problems can be prevalent and challenging, cause poor compliance, and be a signal for a more serious condition, the causes and potential approaches used to ameliorate the symptoms must be understood.

Medications can modify GI absorption, cause dysmotility, damage the mucosal lining, or change the bioavailability and resulting effectiveness of drugs. Some drugs modify the absorption or activity of nutrients, ions, and drugs. Drugs such as metformin (used in the treatment of diabetes) may reduce the absorption of vitamin B₁₂, with the potential development of megaloblastic anemia, necessitating exercise precautions.⁹⁰ Other drugs that damage the mucosal lining (methotrexate, allopurinol, neomycin, colchicine, methyl-dopa) may reduce nutrient absorption, leading to deficiencies.⁶⁴ One class of agents, NSAIDs, is estimated to be regularly used by 5% to 10% of the U.S. population, with more than 70 million prescriptions filled annually and more than 30 billion OTC tablets sold.⁹¹ These drugs are implicated in patients reporting gastric dyspepsia (pain or discomfort in the upper abdomen), and concomitant administration of proton pump inhibitors (which block production of stomach acid) and prostaglandin analogs (which protect the stomach lining) may often reduce mucosal erosion.⁶⁴

Drugs that cause dysmotility of the small intestine such as TCAs (for depression), anticholinergics (for asthma), calcium channel blockers (for heart failure), and opiates (for pain) may be commonly administered to patients within the rehabilitation population.⁶⁴ The large intestine is more likely to have reduced motility, with abdominal pain, constipation, nausea, vomiting, and abdominal distention present. Many patients require increased activity, change of dietary habits, or laxatives to improve motility.⁹² Precautions must be taken because of the potential for chronic use of laxatives, fluid and electrolyte imbalance, steatorrhea, protein-losing gastroenteropathy, osteomalacia, and vitamin and mineral deficiencies.⁶⁴

It is important to note that some supplements and fluids (e.g., grapefruit juice) taken with medications can potentially cause changes in the bioavailability of drugs. Concurrent ingestion of iron causes a marked decrease in the bioavailability of a number of drugs such as tetracycline (an antibiotic), methyl-dopa (an antihypertensive agent), levodopa (for Parkinson disease), and ciprofloxacin (an antimicrobial).⁹³ Grapefruit juice is also known to change the bioavailability of some medications, leading to an elevation of their serum concentrations; these drugs include cyclosporine (an immunosuppressive agent), calcium antagonists

(for hypertension), and coenzyme A reductase inhibitors (statins).⁹⁴

Most medications have the potential to cause some form of GI difficulties, whether taken systemically, topically applied, or given by the parenteral route.⁶⁴ Most adverse effects can be reduced with identification of the causal relation, proper administration of the drug, and administration according to all the guidelines on the label. Therapists may suggest specific timing of medication administration to relieve symptoms and increase participation in therapy. The role of physical and occupational therapists should be recognized in observing adverse drug events to warn patients of early signs of potential problems, provide education, and refer for further follow-up by the pharmacist or physician.

AN IMPAIRMENT PERSPECTIVE

In this section of the chapter, different forms of neurological impairments are discussed and appropriate drugs are identified that either reduce or increase the degree of impairment. Although not a comprehensive list, these impairments include sensory impairments, motor problems, cognitive deficits, problems with balance and coordination, cardiovascular impairments, and problems with muscle tone; a brief overview of neuroplasticity is included. Remember that pharmacists have been educated and work closely with physicians who have been educated in a disease or pathology model. A large portion of physicians' practice is related to drug therapy as it is related to disease and pathology. Looking at drugs from an impairment, functional activity, life participation model is not the role of either the physician or the pharmacist. Thus movement specialists, whose model for care is based on function and quality of life, need to bridge the gap between these concepts because the outcome of the interactions dramatically affects the potential of the individual after any CNS dysfunction.

Sensory Impairment

Drugs that affect hearing, vision, and touch may influence any type of sensory, cognitive, and motor impairment. In any impairment, the processing of accurate sensory information is crucial to modify and adjust procedural programming during movement. A subject must be able, through visual, manual, or auditory cues (even through olfactory means), to relate to or recognize the relevance of the external environment, engage the specific motor programming centers that reach consensus regarding the specific motor response, and produce the series of signals that may progress uninterrupted through spinal mechanisms and the motor endplate to a regional muscle group for an appropriate response. Any impairment or drug that affects any component within these systems, whether early or late in this sequence, will affect the motor performance. Clients with sensory integrative problems are often given medications such as those for attention-deficit disorder, anxiety, seizure, and depression.⁹⁵ As previously discussed, certain drugs may influence hearing (as previously indicated regarding infectious diseases) or produce tinnitus (e.g., aspirin), which may be distracting and thus ultimately affect motor performance.⁵⁸ Changes in the visual field (e.g., with ethambutol and anticonvulsants) are likewise important. Analgesics and topical anesthetics may dangerously affect surface heat or cold discomfort and undermine avoidance cues. However, elimination of excessive

pain (peripheral and central) may enhance cognitive focus and learning as well as allow an individual to move as part of daily living, which will help maintain power, range, balance, and thus quality of life. The CNS functions with the consensus of multiple interactions. Because the branched as well as sequential nature of systems links sensory and motor functions, the peripheral effects of drugs commonly modify the function of central systems. This is a relatively unappreciated reason why drug therapy can modify rehabilitation techniques both positively and negatively (see Chapter 9). Therapists must be aware of medications when working with clients who have sensory impairments. Medications can increase or alleviate signs and symptoms, as well as produce unwanted side effects. Clients may benefit from alterations in the environment to limit sensory sensitivities, timing of treatment to coincide with the most effective dose of medications, and monitoring for unwanted side effects.

Cognitive and Central Motor Control Impairment

Disorders of mood (anxiety and depression) reduce initiative in the rehabilitation process. In this context, anxiolytics and antidepressants may have a positive impact. However, if the dose is not carefully titrated, drowsiness and anterograde amnesia will cloud effective response and learning. Both antidepressants and many of the benzodiazepines may cause these effects, as previously discussed. Behavioral disorders, especially those associated with untreated psychoses or dementia, impede cognitive function. Although antipsychotics may correct these disorders, the dopaminergic antagonism associated with these may interfere with the function of the basal ganglia and facilitation of movement. Many newer antipsychotic agents (also known as the *atypical antipsychotics*) have, in addition to dopaminergic antagonism, serotonin antagonist activity, which may reduce the extrapyramidal side effects of the earlier agents when analyzed as movement dysfunction (Box 36-10) (see Chapter 20). The therapist should be monitoring for signs of depression, which is common in clients who have had loss of function. Effective management of depression is dependent on finding an appropriate formulation and therapeutic dose, which may take weeks, and clients will need education and support. Extrapyramidal motor signs should be monitored and reported to the health care team.

Vertigo, Dizziness, Balance, and Coordination

Many agents with histamine antagonist and anticholinergic activity have been used for treatment of vertigo and dizziness. Meclizine and related antihistamines are primary examples. Occasionally, sinus congestion can result in impaired vestibular function and dizziness. In the absence of hypertension or related autonomic dysfunction, an indirect-acting adrenergic agonist such as ephedrine or pseudoephedrine can reduce this congestion and improve this condition (see Chapter 22).⁹⁶ Dizziness is a common clinical problem, affecting at least a third of the population in one form or another at some point during their lives.⁹⁷ Medications should be reviewed in all patients with dizziness, as numerous medications can be associated with this effect, including alcohol and other CNS depressants, aminoglycoside antibiotics, anticonvulsants, antidepressants, antihypertensives, chemotherapeutics, loop diuretics, and

salicylates.⁹⁸ Clients should be monitored for orthostatic hypotension and hyperventilation. Depending on the cause of dizziness, clients with dizziness may benefit from canolith repositioning procedures,⁹⁹ vestibular exercises,¹⁰⁰ instrumental rehabilitation training on a moving platform,¹⁰¹ positional education (sitting at bedside before standing), use of compression garments, dietary changes (salt and fluid intake), and use of simple physical counter-maneuvers such as squatting to temporarily but rapidly raise blood pressure.¹⁰² Symptoms of dizziness and balance dysfunction should be reported to the health care team for determination of the underlying cause and best management strategies.

Cardiovascular Impairment

In the management of hypercholesterolemia, the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (see Box 36-5) may produce myopathies to various degrees. Changes in hemodynamics caused by antihypertensive regimens must be monitored because these agents can produce syncope and lower exercise tolerance. Weakness from intermittent claudication is a challenge that can be managed in part with cilostazol.¹⁰³ Any drug that is used to decrease spasticity as a consequence of stroke and related cerebrovascular disorders may impair motor control and thus affect motor learning. A discussion of these drugs is outlined in the next section (see also Chapters 23 and 30). Cardiovascular impairments are common in the rehabilitation setting. Knowing the pharmacological management for and side effects of medications related to the cardiovascular system will assist the therapist in providing high-quality care. Clients will benefit from education on modifiable and nonmodifiable risk factors, monitoring blood pressure and heart rate, signs of heart failure, vascular effects of modalities, and responses to exercise and positional changes.

Spasticity and Muscle Tone

Muscle spasms may be controlled with centrally acting and peripherally acting agents, all of which produce drowsiness, dizziness, and muscle weakness to various degrees.¹⁰⁴ Commonly used agents are listed in Box 36-11. Pharmacological management of muscle tone, spasticity, and coordination of movement is of primary importance in neurological rehabilitation.

With regard to spasticity, several additional options are available. Tizanidine (Zanaflex) is the newest of the α -adrenergic agonists available to reduce spasticity, primarily through activation of descending noradrenergic inhibitory pathways.¹⁰⁵ Clonidine (Catapres) has similar actions. Intrathecal administration of baclofen (Lioresal) produces an antispasmodic effect through enhancement of GABAergic function, both central and spinal.¹⁰⁶ Likewise, enhancement of GABAergic function and reduced spasticity can be realized through the antiseizure drug gabapentin.¹⁰⁷ Selective motor neurons can be inactivated through local injection of botulinum toxins.¹⁰⁸ These agents inhibit the release of acetylcholine at the neuromuscular junction. The investigational agent 4-aminopyridine has been shown to reduce spasticity in patients with spinal cord injury.¹⁰⁹

The involvement of serotonin in maintenance of muscle tone and spasticity is complex and controversial. Cyproheptadine, a relatively nonselective serotonergic antagonist, can reduce spasticity and maintain muscle tone.¹¹⁰ However, SSRIs used as antidepressants may occasionally increase spasticity,¹¹¹ and clozapine (Clozaril), a selective serotonin antagonist, may produce muscle weakness.¹¹²

In addition to spinal cord injuries, multiple sclerosis (MS) may cause spasticity as a complication. Although several interferons have been used in the management of MS, interferon beta-1b has been shown to increase spasticity (see Chapters 19 and 24).¹¹³ Therapists often work closely with clients who are undergoing treatment with antispasticity medications. Knowing the underlying cause of the spasticity in the client with neurological impairments (disruptions of inhibitory control) and using concomitant rehabilitation therapy may assist with decreasing pain and improving range of motion and functional ability. Therapists should have an understanding of the desired effects of agents and the adverse effects, including sedation and addictive properties.

Neuroplasticity

The effects of drugs on plasticity are highly controversial. In Alzheimer disease a loss of plasticity may occur through deficits in hippocampal and cortical function, leading to memory loss (see Chapters 4, 5, and 27). Many anticholinesterase agents improve memory, which may provide evidence that they enhance neuroplasticity.¹¹⁴ At the time of this publication, the primary agents used in the management of Alzheimer disease are anticholinesterase agents. Within the past few years, agents affecting the glutaminergic system have shown promise.¹¹⁵ Based on the putative molecular mechanisms of the pathology, inhibitors of β -amyloid formation and related modulators may hold additional promise.¹¹⁶ This rapidly evolving area of research may provide interesting avenues for treatment of Alzheimer disease. Neuroprotective agents that aim to prevent neuronal death by inhibiting one or more pathophysiological steps in the process that follows brain injury or ischemia are currently under development for neurological disorders including stroke, spinal cord injury, traumatic brain injury, and Parkinson disease. In addition, studies on enriched environments are providing knowledge related to neuronal capacity for regeneration and repair in the adult and ageing brain and spinal cord.¹¹⁷ The future of neuroplasticity in rehabilitation may be enriched when medications that protect or promote neurological recovery can be paired with techniques to improve function.

RESEARCH AND DEVELOPMENT PROSPECTS

The prediction of which areas of pharmacological research will have the most valuable impact on the management of neurological disorders and the resulting residual impairments is difficult. Drug development is a continuous process, although this text must have a definitive end point. Many drugs with outstanding promise for treating neurological diseases will have adverse effects that may be less acceptable than the neurological problem (or in fact may be lethal in rare cases) and may require removal from the market. In spite of these disappointments, many reasons for optimism exist.

Among the burgeoning areas of biotechnology that will have an influence on neurology will be the discovery, characterization, and application of neuronal growth factors, related growth modifiers, and cellular implants, which may have the long-term promise of either partially or completely restoring nerve function. Among these are stem cell implants, whose function and development have been tested in a limited number of patients.¹¹⁸ It is also likely that drugs will continue to play an important role as adjuncts in disorders partially treated with stem cell therapies. Although these developments are unlikely to have extensive application within the next few years, over a period of decades these and related developments will take root and revolutionize our understanding and treatment of a wide variety of neurological disorders.

The pharmacist stands as a valuable resource for physical and occupational therapists today and will continue to do so in the future. Pharmacists must participate in the management of drug therapies that may be related to each area discussed in this chapter. Therapists should consult the pharmacist about new drug developments and discuss potential problems that these new drugs may have on neurological rehabilitation. This is especially true when new drugs not mentioned in this text are being administered to clients. These discussions can illuminate intended and adverse effects that may affect interventions and

change patient outcomes. These drugs may cause improvements as well as exacerbations in movement function. Some of those changes are disease or pathology related. Other changes are attributable to spontaneous return, new learning, and neuroplasticity within the CNS. Changes can also occur because of drug therapy. Those changes, as stated, can be both positive and negative. The scope of practice for occupational and physical therapists does not involve differentiating which change is caused by which process, but these professionals certainly can recognize functional changes. When changes are positive, the team needs to be made aware, and most likely everyone will take credit for the changes. When the changes take away function, families and therapists are often the first to identify those changes. The pharmacist and physician will need to determine why the system is deteriorating. The therapist is responsible for sharing those negative behavior changes with the team and monitoring for future changes when drug regimens have been altered.

SUMMARY

The vast array of drugs, along with their intended and unintended consequences, can pose significant challenges to all clinicians. An awareness of the client's perspective in dealing with diseases and impairments can yield valuable information to prevent and/or manage the adverse impact of drugs on rehabilitation. One component of this perspective is the client's desire to self-medicate in addition to undergoing clinician-prescribed therapy. The pharmacist can often provide guidance that can be effectively relayed to a client's therapist(s). This degree of vigilance can yield greater rewards for the client in terms of effective management of multiple diseases and reduced interference with rehabilitation. Resolving problems with therapies requires a team approach. When drugs are involved with management of these problems, the client's physician, pharmacist, therapist, nurse, and caregiver must be aware that drugs pose a certain degree of risk with every positive step. The team must work closely to address adequately inquiries into possible drug problems and opportunities for therapeutic success.

CASE STUDIES

In a previous edition of this text, two patients in case studies were pharmacologically managed for cognitive decline with donepezil (Aricept) 10 mg (1 tablet) daily. This information was shared with their physical therapists, and their therapy was successfully maintained until the patients' deaths. Important lessons have been learned since the last edition from the management of these two cases and have also changed the way one author (H. R.) now writes referrals for physical or occupational therapy for any patient identified with a cognitive problem. This recommendation should be applied to any patient who is treated for memory loss or is suspected of having a cognitive loss. The plan for physical or occupational therapy intervention must also consider the mental-cognitive abilities of those who will care for the patient at home—the spouse, other family members, or an outside care provider. Sometimes home programs are not always completed because the patient does not understand or the family member in charge forgets the instructions or does not remember to have the patient do activities that help regain functional movement and thus activities of daily living. The primary care provider may also be in the early stages of dementia. The plan should include

illustrations and clear and easy-to-follow pictorial instructions of the exercises or functional activities. These must be given and discussed with the care provider for more effective reference and follow-up. If during the course of a scheduled medical and occupational or physical therapy visit the care provider does not come with the patient, request that the care provider accompany the patient on subsequent visits.

Other drugs related to donepezil are available for dementia. These need closer attention to titration to acceptable dosage levels (e.g., rivastigmine [Exelon] 1.5 mg, 3 mg, 4.5 mg, and 6 mg, administered twice daily; galantamine [Razadyne] 4 mg, 8 mg, and 12 mg, administered twice daily; and memantine [Namenda] 5 mg and 10 mg, administered twice daily). The combination of Aricept and Namenda is well accepted for extending cognitive function. Regardless of the drug used, the impact of progressive dementia will exceed drug efficacy and adversely affect occupational and physical therapy. This reinforces the necessity for family and care provider involvement in all phases of therapy.

The two case studies presented in this section illustrate the importance of obtaining a complete medical history before initiating therapy. Unfortunately, and all too often, physical and occupational therapists are asked by the referring physician to look only at a specific problem, for example, “improve upper limb mobility,” and are not given background medical history other than perhaps a one-word descriptor such as “stroke” or a short note such as “weakness in upper and lower extremities.” Unless the therapist has access to a full medical history, including prescription and OTC drugs, the therapy requested may be less than fully successful because many drugs have adverse side effects that may alter cognitive function or the patient’s ability to learn and redevelop impaired motor functions.

Therapists must know and understand the underlying pathophysiology of the referred patient’s diagnosis to evaluate the impairment that is causing motor dysfunction. In addition, therapists need to understand how drugs affect the specific physical impairment that is altering the quality of life through day-to-day activity—in some cases hour by hour—functioning. For example, drugs given to patients can either alter or promote their depression and can interfere

with intellectual, cognitive, and pain levels, all of which can alter their ability to fully participate in physical and occupational therapy. Often patients’ cognitive abilities are modified by either their organic problem or the medical drug therapy. If a cognitive impairment is present, the therapist needs to assess how severe it is to adjust instructions and plan of therapy to a level at which the patient can succeed. The cognitive level, along with the primary medical diagnosis, shapes the physical and occupational therapy prognosis.

Knowledge of the drugs currently being used by the patient provides guidance in structuring therapy and may determine whether the plan of care will be effective. For example, will a patient taking pain medicine have a cognitive level that permits a full understanding of what is being asked during therapy? Will drug therapy provide adequate pain management to enable physical manipulation by either the therapist or the patient in response to the commands? When is the pain medication administered, and is the time in relation to the appointment appropriate? How long does the drug work, and does it have negative effects on cognition?

These are only a few examples of the kind of questions that therapists need to ask to design and implement therapy programs that enhance patients’ abilities to recover motor functions, prevent physical regression, and perhaps even retard or stop some aspects of mental regression caused by either drug therapy or endogenous depression. Clinicians must keep in mind the potential for both positive and negative drug-induced changes and ways that these can alter or improve the overall physical and mental status of the patient. The following case studies further illustrate the interactions among the disease, pharmacological management, and physical or occupational therapy interventions.

CASE STUDY 36-1 ■ MULTIPLE SCLEROSIS

C. G. is a 42-year-old white man with relapsing remitting MS who had an Extended Disability Status Score (EDSS) of 1 when first seen. He now has an EDSS score of 3.1. C. G. is no longer able to work. He had been a building contractor, and for a short period after his MS diagnosis he continued working until he lost the use of his legs. He is currently confined to a wheelchair, is incontinent for both bowel and bladder, has lost the ability to stand, and is unable to dress or transfer from any seated position, such as to toilet himself or shower independently. In addition, he is no longer able to prepare his own meals during the 8 to 10 hours per day he spends alone from his family.

HISTORY

C. G. had been treated unsuccessfully with two of the interferon drugs (interferon beta-1a and beta-1b [Avonex and Betaseron]) used to retard MS progression. He is now taking

glatiramer (Copaxone), a third MS-suppressive drug, and his condition is currently stabilized. Unfortunately, he has sustained considerable damage to both his brain and spinal cord.

Although MS is a crippling disease of motor and cognitive functions, C. G. remains cognitively intact but has slowed thinking. He also has lapses in immediate recall and occasional indiscretions of judgment that result in inappropriate conversation with outside family members. He expressed suicidal ideation and was treated effectively with paroxetine (Paxil) for his depression. Paxil, an SSRI, was specifically chosen because of its minimal cognitive blunting effects.

All of C. G.’s identified disabilities occurred gradually, but with a sudden progression of his disease his motor impairments progressed from poor lower extremity ambulation and postural control to involvement of his upper extremities and dependence on a wheelchair. He needed therapy initially for ambulation

CASE STUDY 36-1 ■ MULTIPLE SCLEROSIS—cont'd

and more recently for wheelchair use and transfer techniques. As his MS status deteriorated, control of his upper extremities began to decline. Again therapy was ordered to teach him alternate ways to accommodate to these new losses in upper motor control and strength. He was retaught how to get dressed, use the toilet, shower, and feed himself.

Drugs used in the management of MS patients must be considered in any therapy plan, but most clinicians do not share this information or list it only as a part of the patient's chart. At the initial referral of C. G. for gait training, he was taking baclofen (Lioresal) for management of muscular spasms and associated pain. This drug, however, has the potential to increase weakness and fatigue as well as introduce some CNS depression. This is important information because C. G.'s MS was already responsible for motor weakness, but the need to reduce painful muscle spasticity outweighed the loss of muscle strength. If the therapist had not known that C. G. was taking baclofen, the physical therapy plans would have been significantly jeopardized because the therapist would have assessed C. G. as being weak simply because he had MS. The therapy plan needs to include exercises and maneuvers that compensate for the drug-induced motor weakness. C. G. was also taking oxybutynin (Ditropan) for bladder control, a drug that has a potential side effect of drowsiness; in C. G.'s case the Ditropan dose was minimal and was not a cognitive concern. As noted, he had been placed on paroxetine, which also can contribute to

muscle weakness, but in his case this did not increase his upper extremity weakness.

C. G. was referred to therapy for functional training, such as transferring from his wheelchair to a bed, shower stool, or toilet; dressing; and eating. Understanding the patient's environmental status, which includes his family situation, is also important in creating a therapy plan. C. G.'s therapy was through home health and incorporated a plan appropriate to C. G.'s environment. C. G. is married and has two children. His wife must work to support the family. The children are not yet in high school and are gone much of the day. Thus C. G. must manage self-care while the family is away during the day. Understanding how drug therapy enhances or interferes with physical or occupational therapy interventions is the only way to optimize the interaction of both and enhance the quality of life for C. G.

POSTSCRIPT

Unfortunately, with MS the demyelinating of neurons is relentless and progressive. At this writing, C. G. has begun to lose additional upper extremity mobility after an MS exacerbation 6 months after his last occupational therapy treatments. He has recently been taught to use assistive tools to grasp and pull items to him, such as books, utensils, and doorknobs. The assistive tools were introduced by the therapist treating C. G., thus extending C. G.'s self-reliance and security during time alone.

CASE STUDY 36-2 ■ PARKINSON PLUS SYNDROME

Mrs. N. is a 72-year-old married woman with Parkinson plus syndrome whose disease status has progressed over the past 5 years, resulting in impaired gait, periods of severe rigidity, dystonia, occasional oculomotor dysfunction, significant behavioral and cognitive changes, and some speech impairment. She is a highly educated woman who had been a speech and special education therapist and administrator. In addition to the aforementioned problems, she now has attention span difficulty, is emotionally labile, and tends to ramble on tangentially to questions posed or simply on her own. Mrs. N. is still oriented to time and place, but to a large extent she is now housebound.

Mrs. N. is currently wheelchair dependent and has had extensive therapy over the past 5 years to keep her mobile and reduce muscle atrophy. She has been given hydrotherapy to facilitate both limb motion and flexibility. Her right hand and both arms are frequently immobilized for short periods of time by rigidity as a result of levodopa blood level peaks. These have been recently modulated by the addition of ropinirole (Requip, a dopamine agonist), and this drug, along with therapy to decrease upper extremity impairments, has improved her ability to carry out voluntary hand and arm movements. Mrs. N.'s limb movements are characteristically slow and deliberate as a result of the pathological features of Parkinson disorders. She does not have any cogwheeling of the biceps, hands, or head frequently seen in Parkinson patients. Her muscle mass is reduced as a result of disuse atrophy and noncompliance with home-instructed daily exercise. She continues, with poverty of

motion, to feed herself but depends on her husband for assistance in dressing and transferring from her wheelchair to the toilet, bed, and shower despite the fact she could do these maneuvers on her own if she chose to do so.

She remains in a long-term stable relationship with a highly supportive husband, who is slowly being driven to exhaustion by her constant demands for attention. She scores well on mental status examinations and does not yet demonstrate marked signs of dementia but frequently has appeared slightly groggy. Mrs. N.'s chief complaint has been one of poor motor control and strength in both her upper and lower extremities. She is still able to stand but now requires assistance during walking. She is unable to sleep normally, finds rolling over or changing position in bed to be difficult, and wakes her husband to rotate her frequently throughout the night.

Her Parkinson disease is being less than successfully treated with standard antiparkinsonian therapy, that is, levodopa and carbidopa. With the addition of Requip, she has improved somewhat. One of the telltale characteristics of a Parkinson plus syndrome is that patients do not respond as well to levodopa therapy as do persons with pure Parkinson disease. Thus the importance of adjunctive physical and occupational therapy to assist Mrs. N. in maintaining mobility cannot be overstated.

Mrs. N. has several other problems that affect her quality of life and her therapy. She, like many other patients with a parkinsonian syndrome, has significant joint pain for which she uses OTC drugs (NSAIDs) in addition to gabapentin

CASE STUDY 36-2 ■ PARKINSON PLUS SYNDROME—cont'd

(Neurontin, an anticonvulsant drug with neuropathic pain-relieving properties). Mrs. N. has painful muscle spasms that have been moderately well managed with baclofen. She has a nocturnal sleep problem that is lessened by using zolpidem tartrate (Ambien), which helps her get 3 to 4 hours of quality sleep. However, her daytime inactivity has resulted in significant nighttime sleep disturbance that even zolpidem does not always cover.

Unfortunately, Mrs. N., like so many patients with chronic problems, has sought secondary sources for relief of pain and fractured sleep without informing her medical and physical-occupational therapy team until she began to experience a new set of problems caused by polypharmacy or prescriptive or OTC agents. She has been reluctant in the past to disclose her use of these additional agents, several of which have clouded assessment of her therapy. This is not an uncommon occurrence with patients who have progressively degenerative conditions.

Clinicians must routinely ask about patients' drug use and specifically about the use of OTC drugs at each visit. For example, Mrs. N. reported at one recent visit that she was having a hard time following her therapist's instructions and participating in the sessions. She was sure the therapist was "not paying proper attention to my needs." This not being the case, the therapist asked, "So, Mrs. N., refresh my mind and save me some time from looking it up. What medicines are you now taking?" She responded, "Sinemet, as you told me to; Requip; Ambien at bedtime; Synthroid; Klonopin; and a new pill I got at the health food store for sleep." She was taking two drugs—

Klonopin and the OTC drug melatonin—both of which would account for the therapist's response that Mrs. N. appeared groggy and was not able to follow directions. The Klonopin she got from a psychiatrist friend of the family. She had put herself on these three sleep drugs, one long acting and the other two short acting, but in combination additive. In addition to this, the drug gabapentin, which was managing her neuropathic pain at a dose of 1200 mg/day, contributed to her level of drowsiness—a known side effect of gabapentin. Mrs. N. was already taking the short-acting non-sensorium-clouding zolpidem, which had been given to her for her sleep disorder. Zolpidem does not cause daytime hangover drowsiness. The key to her new daytime lethargy was found in the Klonopin and melatonin.

The offending drugs were discontinued with an explanation of why she should not add drugs. Mrs. N. subsequently returned to therapy, and her therapist found her once more able to participate in the therapy plans that had been worked out for her. Asking patients to review the drugs they are taking is vital to the entire health care team and to their ultimate success.

With the recently confirmed diagnosis of Mrs. N.'s Parkinson plus syndrome, all that can now be offered to her is supportive therapy, both medical and physical. She is in a class of Parkinson patients who do not respond well to the antiparkinsonian drugs. Her medical management now depends on her participation in physical and occupational therapy and her resisting the temptation to add other drugs that will only cloud her senses and not improve the underlying pathology. Mrs. N. and her husband have now accepted this, and she is doing better.

KEY TERMS

Computed tomography (CT)
Imaging
Magnetic resonance image (MRI)
Radiograph

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Recognize the various ways the brain can be labeled according to the slice and what differences in the types of cuts help identify the slice or image.
2. Transition from viewing a subject in various spatial positions to seeing the skeletal frame in that position to visually recognizing the entire nervous system when the subject is placed in the same position.
3. Recognize various slices of the central nervous system; what nuclear masses are visible in that slice; how the ventricles change from one slice to another; and how sagittal, horizontal, and coronal slices present those nuclear masses and/or ventricles differently.
4. Recognize the difference in diagnostic capabilities of radiography, computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine scans.
5. Identify neuroradiological descriptive terminology.
6. Recognize normal and abnormal neuroanatomy on radiographs, CT scans, and MRI images.
7. Analyze information obtained from imaging of the central nervous system and integrate this information into the neurological clinical presentation and the patient's intervention.
8. Recognize and analyze how a medical diagnosis using imaging may and may not be reflected in the movement diagnosis made by a physical or occupational therapist.

The increasingly complex role of physical and occupational therapy practitioners in health care delivery has increased the need for these clinicians to acquire knowledge and skills that will further enhance their ability to make appropriate decisions involving patient/client management. The recognition of direct access practice in many states and the increasing role of physical and occupational professionals as primary care providers have heightened the need for these clinicians to recognize and analyze how different medical tests and procedures affect movement and function. This differential analysis is critical in order for these professionals to know when to refer a client to another health care practitioner, when to refer and treat, when to merely treat, and when to neither refer nor treat (see Chapter 7).

Indeed, with the advent of doctoral education in physical and occupational therapy, entry-level knowledge of content such as pharmacology, radiology, and medical screening has become an accreditation requirement. Therapists are recognizing the value of information obtained from medical imaging studies in the appropriate delivery of physical and occupational therapy services. Orthopedic radiology is now a common part of curricula; however, content on neuroradiology, more specifically the application of neuroradiology in practice, is lacking. In a study by Little and Lazaro,¹ it was found that many of the physical therapy practitioners in California use medical imaging in their practice. When looking at the types of imaging, the majority of respondents

felt comfortable using results (and radiology reports) from radiographs obtained because of a musculoskeletal problem. This study showed the lack of access to and confidence in using medical images of the central nervous system (CNS).

In certain instances it may be easier for therapists to recognize musculoskeletal problems when viewing medical images because the abnormality in the structure directly correlates with what is manifesting as a movement problem. When images of the CNS are viewed, these correlations may be much more complex owing to the relationship of nuclei, tract systems, ventricular balance, and basic neurochemistry. For example, when looking at a bone fracture (Figure 37-1, A) versus a vascular insult (Figure 37-1, B), it is clear that the fracture and its effects on the bone, muscle, or skin can easily be visualized and interpreted. The second image of the CNS has many surrounding structures that must be identified in relation to the vascular insult.

In 2007 the journal *Physical Therapy* produced a special issue on neuroradiology in physical therapy practice. It is encouraging to note that this issue offered physical therapy clinicians an opportunity to understand the modalities used in the imaging of the brain and the spinal cord (for details, see the article by Kimberley and Lewis²). However, the rest of the articles presented the application of neuroradiology in physical therapy research,^{3,4} and although these articles provided valuable information for the practicing clinician, the articles did not specifically give insights as to how clinicians

Figure 37-1 ■ **A**, Radiograph showing a fractured olecranon. **B**, Computed tomography scan showing an infarct of the middle cerebral artery. (**B** from Wikipedia. <http://en.wikipedia.org/wiki/File:INFARCT.jpg>.)

can use knowledge of neuroradiology in their actual patient/client management.

VISUALIZING THE CENTRAL NERVOUS SYSTEM

Before jumping into viewing images of the nervous system, the reader needs to be very familiar with the position and type of slices presented in those images. **Figure 37-2** illustrates the three types of slices common to the nervous system. The horizontal slices shown in **Figure 37-3** are cuts made horizontally through the brain beginning with a superior slice at the level of the beginning of the lateral ventricles. This individual would be lying supine if the brain were cut as shown. If a person were standing, the horizontal slice would be horizontal to the ground with the frontal lobes facing forward (toward the nose) and the occipital lobe in the back. The slices cut horizontally are always perpendicular to the brain stem and spinal cord or perpendicular to the upright position of the brain regardless of the position of the head in space. All right and left slices will look exactly the same as long as the nervous system has not sustained any insult. **Figure 37-4** shows the position of an upright human and what the skeleton would look like in the same position. Can you visualize what the horizontal slices would look like? The horizontal section would be perpendicular to this upright position. When viewing radiological slices in horizontal, the slices will often be on a slight angle with the lower portion slightly forward. Most of these films are taken when individuals are supine, which places the brain off vertical so a correction is made. The film usually slices horizontally through the brain as if the

head were slightly tucked, similar to the image of the adult in **Figure 37-4, A**. Also, some radiologists want a slightly different angle to the slice because they are looking for specific orientations. When viewing these films, try to look at the radiological slice pattern (scanogram), if shown. **Figure 37-3** shows a progression of horizontal slices as if the individual were supine and the slices began anteriorly with emphasis on ventricular changes as part of the progression. Many of the medical images of the brain are viewed as horizontal (or axial) slices or views. The person is lying supine when undergoing computed tomography (CT), magnetic resonance imaging (MRI), or positron emission tomography (PET). Therefore the imaging process cuts 90 degrees off the horizontal plane of earth in order to achieve horizontal slices of the brain. Remember to look at the scanogram, if available, to identify the position of the head in relation to the cuts.

Coronal slices in the right hemisphere look similar to those in the left hemisphere except that the top of the slice will not look like the bottom on either side (see **Figure 37-2**). The two sides will reflect each other, with the tops being alike as well as the bottoms. Depending on where the cut is made, the result will be cortex on the outside, tracts (white matter) projecting downward, and gray matter again inferior and medial within the slices as the thalamus, basal ganglia, caudate, hippocampus, and so on are viewed. These slices begin at the top and cut down through both sides of the brain, with the slice ending on the inferior section. The progression of the slides can go from front (frontal lobe) to back (occipital lobe) or back to front. If visualized in a standing subject, the slice would begin in the superior frontal area and slice

Figure 37-4 ■ A, Photograph of a human standing. B, A skeleton standing.

downward through the brain toward the feet, thus cutting equally on both sides. These slices can proceed in the posterior (backward) direction of the brain but always cutting from the top toward the bottom with equal distribution on each side. Figure 37-5 progresses from the front of the brain toward the back using the ventricles as a point of reference.

For sagittal cuts (see Figure 37-2), most cuts start by slicing down through the central fissure separating both sides of the brain. This cut is called a *midsagittal section*. Each sagittal slice proceeds outward toward the lateral aspect of the brain on each side respectively, depending on which side is being sliced. Anatomically, you begin as if you were slicing down through the middle of the face and the back of the head when a person is standing. Each sagittal slice moves from the inside outward toward the ear or laterally away from the midsagittal slice. Each slice cuts through the front and back of the brain from top to bottom and proceeds from medial to lateral. Sagittal images usually begin on either the right or the left side and continue slicing toward the middle to the midsagittal section separating the two sides of the brain, and then proceed toward the outside on the opposite side of the brain from the beginning slice.

Another way to conceptualize the nervous system is by visually sequencing from a view of a human in a specific position to the skeleton of a human in that position to an intact plastinated nervous system in that same position. The reader is encouraged to try to visualize what the horizontal, coronal, and sagittal slices might look like given the spatial position of the individual. Once you can easily recognize the various types of slices and where the slice was made when viewing the nervous system, you are ready to begin viewing radiological images.

IMAGING OF THE CENTRAL NERVOUS SYSTEM

It is beyond the scope of this chapter to discuss the physics behind the more common imaging modalities (see article by Kimberley and Lewis² for background). The purpose of this chapter is to provide the clinician a method of systematically evaluating medical images of the CNS, and, more important, to provide examples of how clinicians can use these images to guide practice.

CT and MRI remain the two most common modalities for imaging the CNS. CT scans of the brain are widely used in acute neurological injuries in which the speed of the examination is of primary importance. A common application of this is in acute traumatic brain injuries, when rapid assessment of information about hematoma formation and brain swelling is imperative to make appropriate decisions regarding medical management. Although there is less anatomic detail in CT than in MRI, the level of detail being generated by a CT is generally sufficient for the appropriate management of the patient with an acute injury. Because CT also administers the highest dose of radiation (as it is a series of x-ray exposures), it causes a higher risk of development of conditions associated with increased levels of radiation exposure.

Owing to its increasing availability, MRI can also be an ideal choice for imaging the brain and the spinal cord. MRI provides excellent resolution and can also be performed with contrast to enhance the detail even more. MRI, however, generally takes longer than CT to perform, and it requires the subject to avoid excessive movement while the machine is actively scanning. Also, because MRI uses powerful magnets, the use of this modality in patients with metal implants is contraindicated. With regard to cost, MRI is still more costly than CT, but this expense is rapidly coming down as more hospitals and clinics are investing in this technology.

As mentioned earlier, contrast media can also be used in both CT and MRI to enhance the image, although that will increase the scanning time. There are also additional risks associated with contrast, such as possible allergic reactions to the medium being used to enhance the image.

Clinical Decisions Regarding the Need for Imaging Studies

Obviously, patients with acute neurological symptoms should be seen by a medical practitioner, but individuals with chronic neurological problems should have imaging films that reflect those anatomical lesions as well as the movement dysfunction associated with those medical diagnoses. When the movement dysfunction changes in the direction of increased impairments, then new images may need to be obtained. A therapist may be in a situation in which recommending that new images be taken is appropriate. After the radiologist has read and interpreted the new films, decisions can be made as to whether the patient needs to be referred to another practitioner such as a neurologist. From the standpoint of the therapist, it is critical that a therapist analyze how his or her evaluation matches or does not match the movement diagnoses seen in the clinic and reported by the patient, the family, or the advocate for the individual. If there is a mismatch, it is the therapist's responsibility to bring the information and the question to the attention of the physician of record who is treating the

patient and then to the team. For example, if the radiological report clearly states a cerebellar problem but the movement dysfunction more closely represents basal ganglia involvement, there is a mismatch. Thus, further exploration by those health care providers needs to be pursued in order to more accurately develop treatments from all individuals involved in the care of that person. However, it is *never* the responsibility of a therapist to correct a physician's medical diagnosis or any other diagnosis outside the scope of a therapist's practice. It is the responsibility of the physical or occupational therapist to report the inconsistencies between the imaging report or medical diagnosis and the specific movement dysfunction seen and reported in the therapy situation.

GENERAL GUIDELINES FOR REVIEWING MEDICAL IMAGES

Radiodensity

Because CT scans, like conventional radiographs, are images formed by the absorption of x-rays by the body at different densities, evaluation of CT images is the same as evaluation of conventional radiographs. Structures in the body that absorb a lot of x-ray energy are *radiopaque* and will be white on the image. Structures that absorb less x-ray energy will be different shades of gray. Air does not absorb any x-rays and will be black on the film, and is said to be *radiolucent*. Bone is an example of a radiopaque structure and will be white on the image. Because the skull is composed of bones of varying thickness, portions of this structure that have more bone will be whiter than those with less bone. Contrast media can be positive (white; heavy metals such as gadolinium) or negative (black; air, however, is not used as a contrast medium in the CNS). Brain matter and spinal cord will be varying shades of gray. The sinuses are normally filled with air and will therefore show as black, whereas the ventricles are filled with cerebrospinal fluid and will be a shade of gray on a CT image.

There are a few steps to follow when evaluating neuro-radiological images. These steps are presented in the following sections.

Step 1

Gather All Pertinent Information Regarding the Patient's Neuroimaging Studies

As mentioned earlier, because of the complexity of the structure and function of the CNS, it would be appropriate to have a radiologist and a neurologist or neurosurgeon to read the images first and make a report before the physical or occupational therapist reviews the images. Previous neuroimaging scans and reports will also provide additional information regarding the progression or improvement of the conditions, or the involvement of other structures that may have implications for the patient's care. Review the report thoroughly, making note of the structures that were reported to be normal as well as the ones that were reported to be pathological. This will provide insight as to the patient's potential movement disorders, as well as functions that may be normal for the patient. This review can also reveal a mismatch between the report and the presented movement diagnosis.

Step 2**Be Familiar with Background Information, and Orient Yourself Correctly to the Image**

After reviewing the imaging report, the clinician then examines the actual images. The clinician must be familiar with the basic background information presented on the image. Normally the film will contain information such as the patient's name, age, and medical record number; the date of the scan; and the name of the hospital or facility that performed the procedure (Figure 37-6). The date of the scan is particularly important when attempting to establish relationships between what can be seen on the image and the patient's presentation. There might be a mismatch between what is shown on the image and what the patient is doing because of either resolution of the condition or worsening of the pathology. Comparing scans taken at different intervals will also assist the clinician in arriving at some general impressions on

Figure 37-6 ■ Computed tomography scan of the brain with identifying information. (Courtesy Dr. John Wells. How to Read a CT Scan of the Brain. www.neurosurgical.ca/ComputerAssistedLearning/readingCTs/scanogram.htm.)

the rate or recovery (or lack thereof) or prognoses following physical rehabilitation.

Markers may also be available. The use of markers significantly simplifies analysis by allowing the examiner to easily orient the film correctly. Common markers include *R* and *L* for right and left, respectively, and *A* and *P* for anterior and posterior.

Often a scale is provided for the clinician to relate the size of the structures on the image to actual size.

Next, the clinician should be familiar with some of the basic technical detail. CT and MRI can provide multiple “slices” of the brain, much like slices in a loaf of bread. Often a single large film containing all the images arranged in order can be found. Usually, the first image on the left top most corner is the “scout view” or scanogram and serves to illustrate the orientation and thickness of each slice. Depending on the suspected pathology, the slice orientation could be frontal, coronal, or sagittal, based on the specific structure in question.

Certain views of the CT image can also be produced by the radiology team by manipulating certain image parameters. These “windows” are presented in Figure 37-7. A bone window shows bone the best and is helpful when a skull fracture is suspected. A brain window shows brain matter the best and is used when the suspected pathology is caused by or affects the brain matter (tumors, atrophy of the nuclear masses, or general atrophy of the brain itself). A subdural window is beneficial when suspecting the presence of subdural hematoma or swelling of the brain. With MRI, the images can also be “weighted” (for example, T1 versus T2). T1-weighted images show better gray matter–white matter contrast, whereas T2-weighted images might show edema better. As mentioned earlier, contrast may be used with either CT or MRI to improve visualization of the structures in question.

Step 3**Do a Quick Scan-through, Then Examine Thoroughly**

After getting familiar with the basic information, the clinician should then make a “quick scan” of the image, noting the pathology that quickly stands out. After doing so, a more thorough analysis of each film in the series must be done. Multiple windows and/or successive slices are often helpful in visualizing the extent of the pathology. The

Figure 37-7 ■ Computed tomography scan of the brain showing three different windows. **A**, Bone window. **B**, Subdural window. **C**, Brain window. (Images courtesy Dr. John Wells. How to Read a CT Scan of the Brain. www.neurosurgical.ca/ComputerAssistedLearning/readingCTs/windows.htm.)

clinician mentally constructs a three-dimensional image of the brain from the two-dimensional scan. In a CT scan, knowledge of radiodensity is helpful in making this accurate representation, as is knowledge of normal structure and function of the CNS.

Several resources recommend slightly different methods of analyzing an image. The following are suggestions to make the process more organized and efficient.

1. Examine the symmetry.⁵ Compare both sides of the brain as represented on the image. In orienting the images, the right side of the brain is usually shown on the left. Look for a midline shift by drawing an imaginary line from the anterior falx cerebri to the posterior falx cerebri. Identify the side of the greatest shift and measure it (in centimeters or millimeters). It would also be helpful to look for signs of mass effect (when structures on one side are “pushed” to the other side, or a possible atrophy on the structures on one side that pushes the structures on the other side across the midline). Additional structures to inspect for symmetry include the basal ganglia, thalamus, and corpus callosum.
2. Examine the size and shape of the structures.⁵ This is particularly helpful when looking at the integrity of the ventricles and cisterns. When filled with excessive fluid as in hydrocephalus, the ventricles enlarge disproportionately. This enlargement is seen in babies as a result of a variety of pathologies (see Chapter 15) and in children and adults after brain trauma (see Chapters 23 and 24). Likewise, in atrophy of the brain tissue the ventricles may also become enlarged; this is often seen in elderly adults as the brain loses gray matter and the ventricles enlarge to fill in the extra space (see Chapter 27). Examining the size and shape of the sulci may also be beneficial when looking at atrophy of the specific structure, thereby accounting for the abnormalities of movement being observed.
3. Look for lesions in the brain. Space-occupying lesions such as brain tumors or hematoma can be visualized (Figure 37-8). Because the brain has such a finite size to fit snugly within the cranial vault, any lesion in the brain has the potential to push brain structures to the midline or to displace the structure and create more serious pathology. Plaque formations secondary to multiple sclerosis can also be visualized as bright white spots in the gray matter (Figure 37-9).
4. Examine densities.⁵ As mentioned previously, different tissues will have different densities, and these differences are what forms the generated images. Hyperdensities may include blood, tumors, or enhancing lesions, whereas common hypodensities include air, non-enhancing tumors, and chronic hematoma.

Step 4

Establish Relationships between the Structures Involved and the Presenting Impairments, Movement Dysfunctions, and Activity Limitations

There are two possible clinical scenarios in which the medical imaging information is reviewed. First, the therapist may be reviewing the medical imaging information before seeing the patient for the initial examination or evaluation. If this is the case, the therapist is expected to

Figure 37-8 ■ T1-weighted magnetic resonance image with intravenous contrast showing a brain tumor. (From Wikipedia. http://en.wikipedia.org/wiki/File:Hirismetastase_MRT-T1_KM.jpg.)

Figure 37-9 ■ Magnetic resonance image showing plaque formation caused by multiple sclerosis. (From Wikipedia. <http://en.wikipedia.org/wiki/File:Dawsonsfingers.jpg>.)

use this information in relation to other medical information in the chart (from physician’s history and physical examination, nursing notes, and so on) to get an initial sense of what the patient may be able or unable to do. This will allow the therapist to plan for the appropriate tests and measures to perform during the examination (Case Study 37-1).

CASE STUDY 37-1 ■ A PATIENT WITH A BRAIN TUMOR*

The patient was a 71-year-old woman with history of glioblastoma multiforme, the most aggressive form of brain tumor (refer to Chapter 25). It has been reported that a second recurrence of this condition is associated with a less favorable prognosis.⁶ The patient had previously undergone tumor resection, chemotherapy, and radiation. She had then been found to have another recurrence of the left frontal glioblastoma multiforme of 4 cm (Figure 37-10), for which she had undergone a stereotactic resection (Figure 37-11) of the tumor. After this surgery she underwent intensive inpatient rehabilitation.

Her past medical history included history of radiation therapy, seizure disorder, diabetes mellitus, hypertension, anemia, and leukopenia. Medications include Dilantin, Lipitor, dexamethasone, fosinopril, and metformin.

The patient's primary caregiver was her husband. They were both retired, living in a single-story home with two steps to enter. She had two supportive daughters who lived nearby and were available for support as needed. Before the most recent hospitalization, the patient had been at a supervised level of assistance with ambulation outdoors and independence for household ambulation, with no assistive device required.

The medical images revealed a resected parietal lobe tumor in the left side of her brain. In the imaging report it was noted that there was significant edema in the surrounding area and that mainly white matter tracts were affected. However, no midline shift or mass effect was noted. In addition, the tumor was reported to be located near the Broca and Wernicke areas but superficial to the ventricles.

Based on the information provided by the imaging reports and the associated medical images, the clinician developed several initial impressions about the patient's presentation and care. First, the note about significant edema indicated more diffuse, global effects on movement and function; associated structural impairments rather than only dysfunctions specific to parietal lobe damage would be expected. The lack of midline shift or mass effect indicated a more favorable prognosis for survival for the patient. The information about the tumor being located near the speech areas indicated the possibility of deficits in expressive and receptive communication. Finally, damage to

the parietal lobe indicated the potential for agraphia, aphasia, and agnosia. Because the parietal lobe is also largely important for perception and interpretation of somatosensory information, the formation of the idea of a complex purposeful motor act may also have been impaired.

The initial examination confirmed and supported all the expected movement deficits and clinical presentation of the patient. She underwent intensive occupational, physical, and speech therapy to improve her functional mobility and ambulation, self-care and activities of daily living, and also speech, swallowing, and communication. There was a concerted effort among the rehabilitation team and the patient's family to optimize communication strategies while minimizing patient frustration. For example, more complex tasks such as transfers were broken down into smaller components and then practiced extensively as components and as whole functions. The transfer task was broken down into three steps: (1) locking the brakes, (2) removing the legrests, and (3) standing and turning to sit on the destination surface. These step-by-step instructions were written on the patient's whiteboard; practiced during speech, physical, and occupational therapy; and communicated to the family and rehab team. Hand-over-hand guidance and facilitation were also included during instruction, as was use of mental rehearsal to remediate executive and visuomotor deficits to improve motor sequencing and problem solving while decreasing perseveration and frustration.⁷ The rehabilitation team worked closely together to standardize treatment techniques, increase opportunity for task carryover, and decrease the patient's frustration with learning. Speech therapy started to integrate pictures and words representing tasks learned in physical and occupational therapies. In addition, therapy became more focused on repeated task training of three or four essential skills versus multiple activities, games, and skills.

This case example demonstrated how medical imaging information not only confirmed the expected presenting deficits in movement, function, communication, and learning of the patient but also included information that guided the rehabilitation team in selecting interventions that optimized function for this patient.

*Case adapted from Parikh M: *The use of medical imaging in neuromuscular physical therapy practice: a case report*. Samuel Merritt College Physical Therapy Case Report Presentations, May 2007.

The second clinical scenario involves the use of medical imaging information to guide clinical decisions during the actual occupational or physical therapy session. One of the major goals of this step is to make sure that the movement dysfunctions presented by the patient match the information obtained from the medical images. The therapist is expected to act accordingly and to demonstrate sound judgment, especially when the mismatch indicates a possible life-threatening situation. For example, if the imaging results indicate a small focal area involvement but the patient demonstrates significant

impairment in movement and function, the mismatch may be indicative of a worsening and potentially life-threatening condition that must be communicated to the physician and other members of the medical team.

As mentioned earlier, the complexity of the structure and function of the nervous system makes interpretation of imaging information very challenging. There may be situations in which images may not fully explain what the patient or client is able to do in terms of function and movement (as illustrated in [Case Study 37-2](#)).

Figure 37-10 ■ A, Axial view showing tumor. B, Coronal view showing tumor.

Figure 37-11 ■ Images after surgery for tumor resection. A, Lateral view. B, Axial view.

CASE STUDY 37-2 ■ A PEDIATRIC PATIENT WITH DEVELOPMENTAL PROBLEMS AT 18 MONTHS

The patient was a full-term baby. The doctors identified through ultrasound that the child had an unusually large head and were expecting problems. At birth, they had placed the child in the neonatal intensive care unit (NICU) and obtained CT scans of his head. It had been identified that he did not have closure of his lateral and third ventricles. Their prognosis had been that the child would die within days after birth. They had encouraged the family to take him home and spend as much time with him as they had before his death.

One author of this chapter was called in to help colleagues establish realistic expectations and treatment protocols for this child. The child was 18 months of age at the time of this therapist's first visit. The child's motor development was very delayed owing to the large size of his head (hydrocephaly). He was also nonverbal, and the doctors had concluded that he had an extremely low level of intelligence. He had loving parents who played with him, fed him, bathed him, and interacted with him all day. They felt he had more ability than the pediatrician had stated.

This video case study illustrates a situation in which there is a mismatch between the medical diagnosis/medical imaging

results and what the client presents in terms of function and movement. This case will engage and guide the therapist in a clinical decision-making process of analyzing the client's movement and functional capabilities and relating those to the integrity of the specific areas of the nervous system that are responsible for the movement or behavior. It is recommended that the reader first look at and analyze the motor function of this child at 18 months and then 6 months later, looking specifically for increased motor function and potential. During the interim, the child did receive weekly therapy, but most of the practice was done at home with the parents interacting with the child. Analyze the movement from a motor learning and neuroplasticity perspective as you determine the potential for motor control. Then look at the MRI images that lead the doctors to diagnosis the medical problem and the prognosis of death. Then ask yourself what could be happening to cause such a mismatch between a movement and a medical diagnosis?

Note: The continuation of the case, including the video clips and imaging results, can be found on the companion website.

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will,

when available, provide a link for the reader to a Medline abstract for the article cited. There are 7 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Summarize the need, demand and principles for integrating advanced robotic technology in neurological rehabilitation.
2. Define common terminology used in the field of rehabilitation robotics and technology.
3. Classify the different types of advanced technology used in neurorehabilitation.
 - a. Rehabilitation robots and assistive technology including:
 - i. Service robots for movement
 - ii. Service robots for physical assistance and indoor and outdoor navigation
 - iii. Nonwearable robotic assistive device for mobility, unweighting, and object manipulation
 - iv. Wearable robotic assistive device for upper-limb object manipulation
 - v. Wearable robotic assistive device for lower-limb mobility and gait training
 - vi. Communication robotics to enable interpersonal interaction
 - vii. Interactive entertainment robotics for companionship and emotional support
 - b. Advanced clinical technology including:
 - i. Virtual reality training systems for improved neural recovery of upper- and lower-limb function
 - ii. Computerized learning-based gaming systems for home training of individuals with physical disabilities and memory impairments
 - iii. Computerized patient simulators for teaching clinical diagnoses and intervention strategies to medical professionals
 - iv. Computer technology for teaching home exercise programs to patients
4. Use the guidelines for integrating robotics and assistive technology into a patient's rehabilitation program.
5. Summarize the challenges and basic engineering principles involved in creating rehabilitation robotics and interfacing with advanced technology to help individuals to design:
 - a. Robots that operate independently
 - b. Controllers, actuators, and sensors required for service and assistive rehabilitation robots
 - c. Human interfaces (physical, sensory physical, cognitive, and brain machine)
 - d. User-friendly interfaces and controllers to maximize kinematics (e.g., force, velocity, timing)
 - e. Rehabilitation robotics based on the materials and control technology currently available
 - f. Safe robotics for rehabilitation
6. Discuss the benefits of performing a cost-effectiveness analysis when considering the application of robotic technology in rehabilitation.
7. Describe the challenges of commercializing robotic devices.
8. Discuss the future of advanced technology and rehabilitation.

*The authors would like to thank Susan L. Whitney, PT, PhD, DPT, NCS, ATC, FAPTA, for her contribution of the case study on virtual reality training for a patient with unilateral vestibular hypofunction. Dr. Whitney is a professor at the University of Pittsburgh, Departments of Physical Therapy and Otolaryngology.

This chapter presents and discusses the integration of computer-assisted technology as one approach to maximize independence and quality of life in older adults and people with moderate to severe physical impairments. Rehabilitation robotics and computer-assisted technology use brain interfaces, sensorimotor interfaces, virtual reality (VR) environments, and learning-based gaming programs to remediate sensory, motor, and cognitive impairments and improve memory skills and physical abilities required for independent mobility and self-care at home, in the community, at work, and during the performance of recreational activities.

INTRODUCTION TO THE APPLICATION OF ROBOTICS AND TECHNOLOGY IN REHABILITATION

General Overview

The purpose of this chapter is to excite rehabilitation professionals about the integration of technology in rehabilitation and the potential to expand possibilities for healing, adaptation, compensation, and recovery for individuals with neurological impairments. Robotics and technology are considered supplemental to “one-on-one rehabilitative therapy,” not a replacement for individual therapy. This chapter will provide an overview of technology and rehabilitation robotics appropriate for consideration within neurological rehabilitation. The chapter will not provide a detailed analysis of all of the technology that is available or an exhaustive bibliography referencing all of the studies that have been carried out in the area of rehabilitation robotics.

The objective of rehabilitation technology is to empower clinicians and individuals to take responsibility and control of the environment, facilitate physical and cognitive recovery, and comply with learning-based practice to drive neural adaptation and neural reorganization. The principles underlying technology and rehabilitation are summarized in [Box 38-1](#). Since the early 1990s, medical science has been able to minimize damage to the nervous system postinjury. It is known that the central nervous system (CNS) possesses the potential for spontaneous healing and recovery. Learning-based sensory and motor training can be used to drive recovery of function. Rehabilitation robotics are a logical addition to supervised, one-on-one therapeutic interventions.¹⁻⁹

Robotic technology can provide service, unweighting, passive assistance, active assistance, variable and on-demand assistance, or a combination of service and assistance.¹⁰ Computerized and robotic technology provides the foundation for patients to practice and attend to purposeful, goal-oriented, progressive tasks spaced over time. This technology can also minimize the risk of injury during retraining. Robotic interfaces, actuators, and controllers can convert sensory, physical, and cognitive signals to control robots, permit perception of spatial relationships, mobilize individuals in space, assist in object manipulation, provide emotional support, and allow individuals to call for help and communicate with others. In addition, through creative virtual training environments and gaming technology, patients can improve memory, motor skills, and movement quality. In addition, patient simulators can help medical professionals learn diagnostic processes, treatment interventions, and manual techniques. Computer-assisted technology can also improve our

ability to teach home exercise programs to patients. Over the next 10 years, robotic technology will expand the opportunities for clinicians to assist patients to achieve maximum independence and quality of life with less dependence on others.

History Supporting the Use of Technology in Neurological Rehabilitation

The idea of interfacing technology with rehabilitation was introduced into practice by George J. Kelin in the 1940s. Kelin was a productive inventor from Canada who invented the power wheelchair for patients with quadriplegia, the microsurgical staple gun, and a wide range of industrial gearing systems. He also contributed to internationally important innovations in aviation and space technology. During the early 1970s, a new field emerged known as *mechatronics*, which combines mechanical, electrical, and control engineering design principles to produce a diverse range of useful practical devices.^{11,12} The science of biomechatronics then developed as a unique engineering discipline responsible for integrating neuromusculoskeletal appliances with biological systems to control and facilitate human-machine interactions as well as developing interfaces, sensors, actuators, and energy supplies to create functional devices for human use.¹³

The first conference on rehabilitation robotics was held in 1990. There are now multiple conferences each year on rehabilitation robotics. In 1999 the Robotics and Automation Society created the Rehabilitation Robotics Technical Committee to improve definitions and understanding about rehabilitation and assistive robotics.¹⁴ The scope of this technical committee has been recently specified as rehabilitation and assistive robotics. This modification is the direct outcome of the scientific progress and maturity reached in this broad research area. The goal of rehabilitation robotics is to investigate the application of robotics to therapeutic procedures for achieving the best possible motor, cognitive, and functional recovery for persons with impairments associated with aging, disease, or trauma (e.g., stroke, neuromotor disorders, brain trauma, orthopedic trauma, cognitive disease).

In particular, service robotics include aids for supporting independent living of persons who have chronic or degenerative limitations in motor and/or cognitive abilities, such as the severely disabled and the elderly. Such robotic devices are typically key components of more general assistive and supportive systems. These service robots usually integrate telematic, mechatronic, and other technological devices such as smart house designs and advanced human-machine interfaces. On the other hand, innovative, passive assistive, and active and dynamic assistive robotic devices are being integrated into rehabilitation programs to maximize recovery and functional independence skills.

Some clinicians have been skeptical of robotics in rehabilitation. Some health care providers worry that robots will replace therapists; others worry that robots are unsafe.⁸ However, researchers have persisted in developing innovative hardware, new control strategies, improved compliance, and feed-forward and adaptive control systems, as well as computerized modeling. In addition, new assistive, wearable robotic arm devices have been developed (e.g., MIT-Manus, the MIME, the ARM, and the iARM) to more carefully outline

BOX 38-1 ■ PRINCIPLES SUPPORTING ADVANCED TECHNOLOGY AND REHABILITATION ROBOTICS IN NEUROREHABILITATION**PRINCIPLE I**

Goals for advanced technology and rehabilitation robotics include the following:

- A. *Indirectly augmenting* functional independence of individuals with impairments by:
 1. performing mobility tasks for individuals at the home (e.g., using automatic motorized wheelchairs to move individuals from room to room; transitioning individuals from bed to chair and from chair to standing; moving patients who are standing; smart houses; calling for help)
 2. minimizing the need for assistance from another individual
 3. performing functional activities of daily living (ADLs; e.g., getting objects, cooking food, doing dishes, bathing, transferring)
 4. helping perform difficult or repetitive tasks at work (e.g., assembly line tasks; lifting and moving heavy objects)
- B. *Directly improving* human motor skill capabilities of individuals with impairments to enable them to:
 1. perform functional tasks independently
 2. improve voluntary control
 3. perfect quality of movement
 4. learn new skills

PRINCIPLE II

Advanced technology and rehabilitation robotics should maximize neural adaptation and reorganization through the creation of practice opportunities that:

- A. are attended, repetitive, purposeful, goal oriented, progressive, and spaced over time
- B. are fun, interesting, and practical
- C. are task oriented
- D. provide feedback on accuracy of task completion
- E. can be matched to patient abilities

PRINCIPLE III

The objectives of assistive rehabilitation robotic devices need to be clearly defined in terms of:

- A. unweighting a limb to reduce patient effort required for movement
- B. actively canceling mechanical limitations on movement of the patient and robot arm dynamics (e.g., friction, inertia, and weight under gravity)
- C. gently and progressively moving a limb to assist patient effort to perform a task
- D. stabilizing a joint to enable a patient to produce a controlled movement
- E. assisting the patient to improve the accuracy and quality of a movement
- F. assisting the sequencing of movements
- G. providing resistance to strengthen movements

PRINCIPLE IV

Robotic technology must be:

- A. safe for training
- B. reliable in performance

- C. able to reduce risks of injury (e.g., falls)
- D. able to minimize injury during use

PRINCIPLE V

Robotic technology should be:

- A. adaptable (across patient needs, side, type of actuation)
- B. able to integrate interfaces, actuators, and controllers sensitive to the ability of the individual

PRINCIPLE VI

Robotic devices need to be:

- A. reasonably priced and cost-effective
- B. versatile
- C. durable
- D. repairable
- E. easy to use

PRINCIPLE VII

Wearable robotic devices must be:

- A. lightweight
- B. easy to get on and off
- C. portable
- D. cosmetically acceptable
- E. interfaced to patient ability (sensory, motor, cognitive, brain)
- F. minimally harmful to the skin
- G. dynamically adaptable to performance capabilities

PRINCIPLE VIII

Robotic technology for rehabilitation needs to be defined by:

- A. location of the control system relative to the patient (controlled at a distance from the user [e.g., Web, Skype]), controlled in proximity to the user [e.g., by a therapist or engineer], or controlled by the user [e.g., wearable device or interface])
- B. environmental connection of the device and the patient (fixed to a nonmobile surface [e.g., wall], attached to a mobile platform [e.g., wheelchair], freely mobile with the patient [wearable])
- C. type of control system (e.g., joystick, sensor, breath)
- D. type of interface (physical, sensory, cognitive, brain)
- E. type of anatomical connection (e.g., by end effector only, end effector and multiple points of attachments with serial links or temporal links)

PRINCIPLE IX

Brain controlled interface rehabilitation robotics must be:

- A. considered after all other alternatives have been unsuccessful
- B. minimally intrusive despite surgery
- C. physically accessible via remote control outside the brain
- D. controlled with minimal patient risk and with safety
- E. potentially controlled by cognition or the patient's mental effort
- F. able to extend patient's independent task performance

and address the engineering challenges related to what the robot can do, the logical physical targets for active assistance, and the joints and the types of movements that can safely be assisted.

There is no question that the demand for rehabilitation robotics is currently increasing, particularly with soldiers with traumatic injuries returning from war zones and with aging baby boomers. With the proliferation of innovative hardware, new control strategies, improved compliance systems, error amplification strategies, adaptive controls, and optimization of neurocomputational modeling, robotics and technology can provide assistance within virtual environments to speed up learning and recovery.

To endure, rehabilitation technology and robotic devices need to be reasonably priced, versatile, safe, reliable, durable, repairable, and easy to use. If devices are wearable, they also need to be lightweight, easy to don and doff, portable, and cosmetically acceptable. Robotic devices must also be adaptable across a variety of users and environments. Depending on their purpose, rehabilitation devices can operate at a distance from the user, be in proximity to the user, or be attached to the user. The device may be controlled through a motor, sensory, or brain interface. The device can perform tasks for individuals, passively move an individual, stabilize movement, assist and direct a movement, resist a movement, and even be “intelligent.” The primary technological challenge that remains is the complexity of controlling the accuracy, direction, balance, and force of robotic devices across the multiple body segments to successfully accomplish a task. This is a particular challenge when creating wearable robotics for human use.

The field of rehabilitation robotics is still considered to be in its infancy. However, with the increasing demand for effective rehabilitative strategies, many new and exciting innovations are being developed. There are many robotic systems in various stages of research and development, but only a few are commercially available. Improvements in engineering, materials, human physical interfaces, software, and robotic designs will require constant analysis and adjustment in the future. It is projected that the market for personal robotic devices will be worth \$15 billion by the year 2015.^{15,16} The challenges of robotic engineering are broad. Clinicians will need to participate in research to help document cost-effective outcomes as well as to develop efficient screening criteria to match patient needs with available robotic devices. One of these challenges will be to bridge the gap between the mechanical attributes of robotic sensors, actuators, controls, microprocessors, force, velocity, friction, unweighting, pressure tolerance, software design, and flexibility with the human limb, brain, and nervous system. Important issues related to safety, materials, technology, and the quality of matching machine and human movements must constantly be considered. These engineering issues are discussed later in this chapter.

CLASSIFICATION OF REHABILITATION ROBOTS

General Principles

There is a variety of ways to classify computerized technology for rehabilitation. For this chapter, we will group robotic technology first in terms of how robotics are used

with or by the client relative to rehabilitation. This classification system is summarized in [Figure 38-1](#) and [Box 38-2](#). Rehabilitation technology can be further classified by a variety of variables summarized in [Box 38-3](#). Rehabilitation robotics can also be classified by type of interface used. Some classification systems classify technology by multiple parameters.

Service robots usually focus on task performance, movement assistance, and stability. These devices can be fixed, can be movable, or can be attached to a wheelchair ([Box 38-4](#)). Assistive robotic devices help patients perform a task with direct or indirect assistance. Some of the assistive robotics are nonwearable but assist through unweighting or movement assistance ([Box 38-5](#)). Wearable robotics are specifically designed to be worn by patients to assist movements. These are designed for the upper or lower limb ([Box 38-6](#)). There are some new assistive training devices for the spine such as the Valedo Shape, Valedo Motion, and Hocoma devices ([Figure 38-2](#)). Prosthetic devices help patients maintain function despite the loss of a limb. Vocational robotics can enhance performance at work either in terms of repetitive motions or high-force task production that would otherwise be dangerous to humans. Communication robotic devices are designed to improve communication potential for subjects who cannot adequately speak or hear. Emotional support robotics are designed to provide emotional support for isolated individuals at home.

VR training technology (with and without robotics) provides the opportunity to simulate simple and complex environmental and clinical situations to facilitate learning ([Box 38-7](#)). Game-oriented computerized learning systems are currently popular for fun and recreation, but they can also facilitate memory as well as sensory and motor skill development. Finally, computerized technology can also enhance teaching home exercises to patients.

In this chapter, we will not address prosthetics for amputees, vocational robotics, communication robotics, emotional support robotics, or socially assistive devices,^{17,18} as these areas are considered specialty oriented and may or may not be included in traditional neurorehabilitation programs coordinated by physical or occupational therapists. However, information about the impact of the sound of the robot voice on patient motivation and compliance may be relevant to effectiveness. It is also important to acknowledge there are a number of motorized chairs, lifts, and walkers available that can be used to transition a patient from sitting to standing, or provide unweighting while walking or working on balance. Examples can be found in [Box 38-8](#). Many of these systems are electromechanical systems controlled by the patient or the therapist. These devices are not usually programmable and are not classified as “rehabilitation robotics” or “advanced technology.” However, these types of devices are very beneficial for helping patients maintain walking and training to improve safety and quality of gait at home and with supervision. It is important for therapists to be sure these types of assistive devices have been integrated into a patient’s rehabilitation program and at home before recommending more sophisticated technology.

Classification of Rehabilitation Robotic Technology

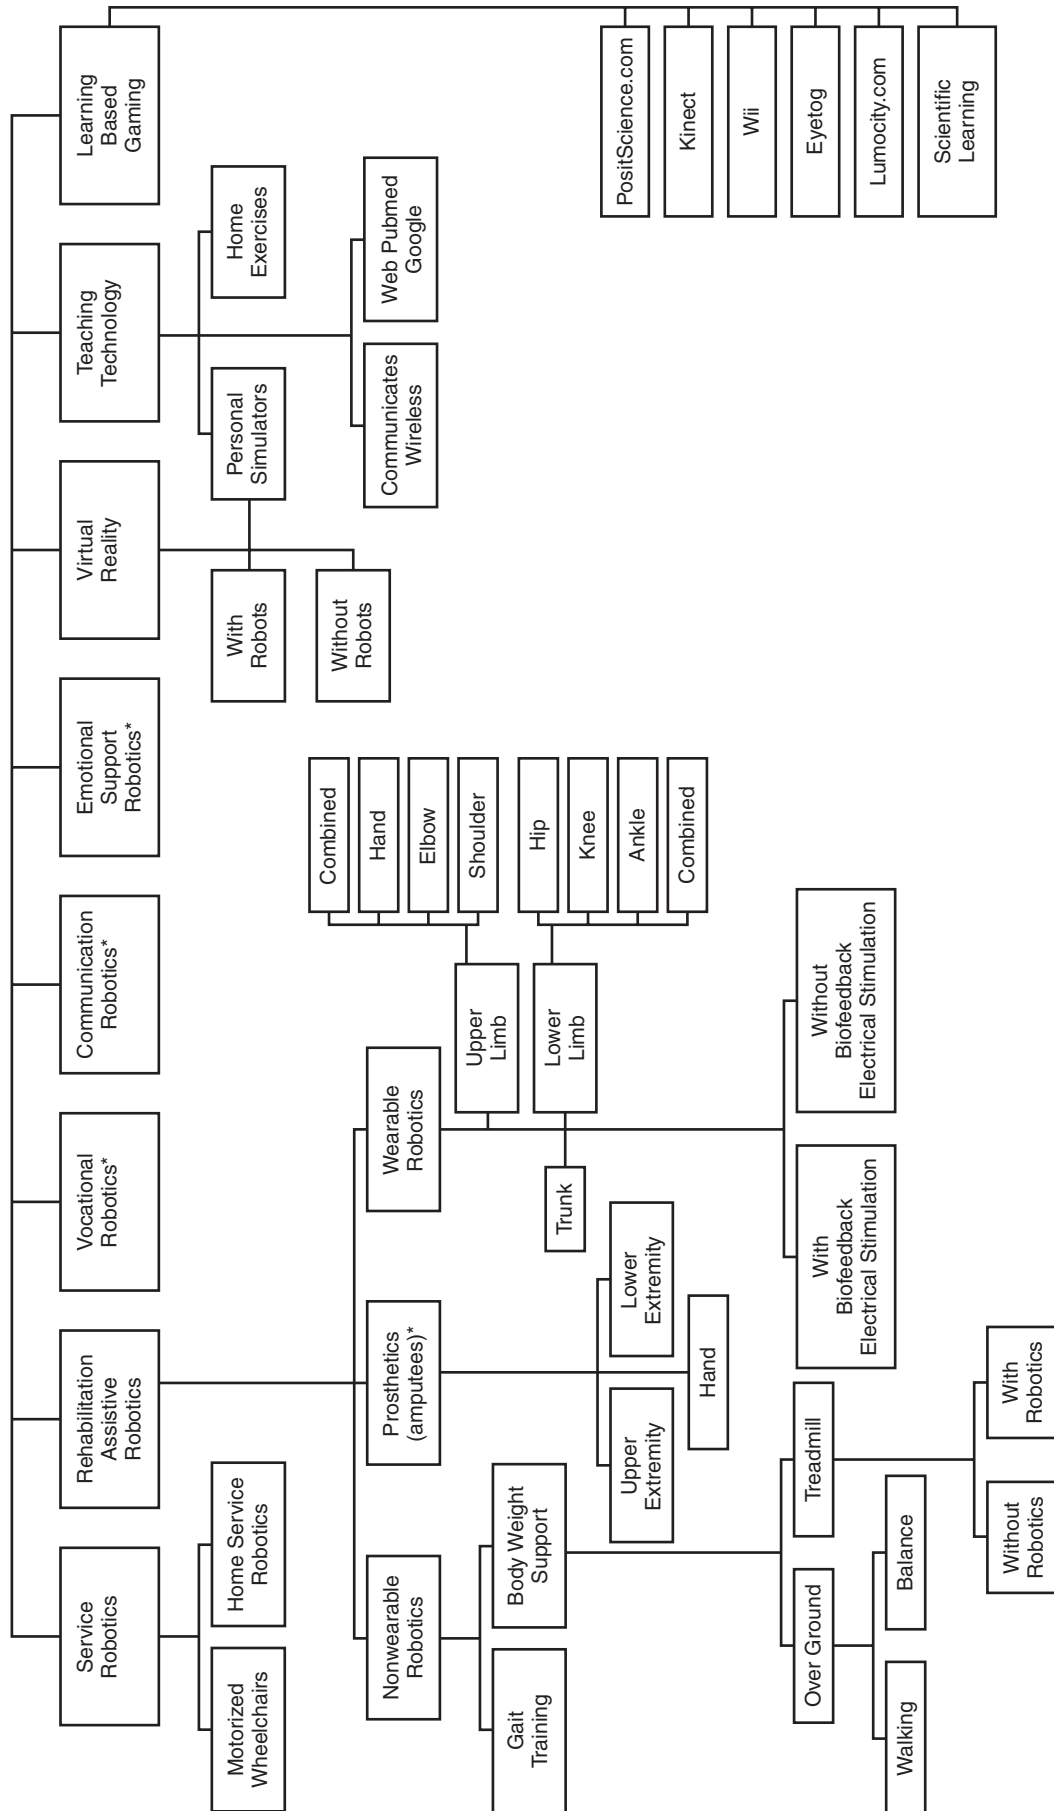

Figure 38-1 ■ Classification of Rehabilitation Technology. * Topic not discussed in this chapter.

BOX 38-2 ■ CLASSIFICATION ACCORDING TO HOW THE ROBOTICS ARE USED

- Service robotics
- Assistive robotics
- Vocational robotics
- Prosthetic robotics
- Emotional robotics
- Communication robotics
- Virtual reality technology and robotics (including personal simulators)
- Learning-based gaming technology
- Technology for teaching

BOX 38-3 ■ REHABILITATION TECHNOLOGY CLASSIFICATION

- Purpose
- Anatomical part serviced (upper or lower limb)
- Wearability
- Attachment: fixed and stationary, attached to wheelchair, or freely movable
- Interface used to operate

BOX 38-4 ■ TYPES OF SERVICE ROBOTIC DEVICES

- Fixed—preprogrammed task performance
- Mobile service—mechanical slaves
- Wheelchair-mounted—upper-limb manipulators
- Automatically guided wheelchairs (AGWs)
- “Smart houses”—designed for independence

BOX 38-5 ■ TYPES OF NONWEARABLE ASSISTIVE ROBOTIC DEVICES

- Body-weight-supported mobile walking aids
- Robotic devices for physical support (indoors, outdoors)
- Robotic devices for physical support, unweighting, and mechanical stepping in place
- Robotic devices for unweighting and controlled destabilization
- Robotic devices for unweighting and gait training
- Robotic devices for unweighting and robotic stepping on a treadmill

BOX 38-6 ■ CHARACTERISTICS OF WEARABLE ASSISTIVE ROBOTIC DEVICES

- Fixed or wheelchair mounted (upper limb)
- Freely movable
- Assist in virtual task or actual task practice (single or multiple tasks)
- Interface sensory, physical, cognitive, or brain
- Unilateral or bilateral
- Assist single joint or multiple joints
- Can integrate neuromuscular stimulation for muscle activation (skin or implanted electrodes)
- May use biofeedback to encourage muscle recruitment

Figure 38-2 ■ ValedoShape and ValedoMotion—new spine robotic training devices for movement and stability with neuromuscular stimulation. (Courtesy Hocoma, Volketswil, Switzerland.)

BOX 38-7 ■ EXAMPLES OF HOW VIRTUAL REALITY CAN ASSIST LEARNING

- Creating simulated environments for teaching patients how to perform different tasks, such as driving
- Using patient simulators to teach health professionals how to diagnose and treat patients
- Using gaming computerized technology to facilitate neural reorganization
- Using computer technology to teach how to do home exercises

BOX 38-8 ■ EXAMPLES OF ASSISTIVE DEVICES NOT CONSIDERED ADVANCED TECHNOLOGY OR REHABILITATION ROBOTICS TO ENHANCE MOBILITY

- Up n' Go walker
- New Up n' Go walker
- Mobility Research walker
- Guldman harness system

Description of Robotic Systems by Type

Service Robotic Systems that Provide Movement Assistance

Service robotics assist individuals with severe disabilities. Most commonly, the robot performs everyday activities (e.g., assisting with eating, drinking, object replacing, ambulating). There are three main types of schemes: desktop-mounted robots, wheelchair-mounted robots, and mobile autonomous robots. In general, these robots are used in the home, are interconnected to a variety of control systems, and are programmed to the environment and consequently are not very portable.¹⁹⁻²¹

These types of robotic devices are generally used by patients with severe physical impairments and are generally preprogrammed to perform certain tasks. There are also

some autonomous robots in which the cognitive interface between the user and the robot is used to tell the robot to perform a new task or to help the patient perform the task. These robotic systems are successful if the robot, the user, and the manipulated objects remain in the same initial set position every time a concrete task is performed. With the wheelchair-mounted manipulator, the relative position of the user with respect to the manipulator needs to remain the same. Although there are a variety of simple service-based robotic devices, most are complex, and setting them up at home generally requires a computer or engineering specialist.

Several examples of service robotics are described in Box 38-9.²²⁻³⁰ A major issue is patient control options for service robotic devices. For example, through the use of

BOX 38-9 ■ SUMMARY OF SERVICE ROBOTICS

I. FIXED UPPER-EXTREMITY SERVICE ROBOTIC DEVICES

- A. The earliest robots were fixed-site robots.
- B. Fixed robotics were located in a *nonmovable* workstation.
 1. The arm was preprogrammed to carry out selected routines which the user selected by pressing appropriate buttons (e.g., Seamone and Schmeisser at Johns Hopkins University, 1974).
 2. These workstations led to early Desktop Vocational Assistive Robots
 3. These units were good for selective, predictable tasks.
- C. Stanford University researchers, Boeing, and researchers responsible for several advances in France made significant improvements, particularly in integrating existing robotic systems.
- D. Later, special manipulators were constructed to better fit the environment and the task.
- E. The most well known systems for feeding were the Handy 1, My Spoon, and Neater Eater.²²
- F. Today, these devices have been advanced with powered programmable devices (devices can provide maximum control for those with minimal voluntary ability and assistance for individuals who are trying to retrain the arm to work in a functional task).

II. MOBILE SERVICE UPPER-LIMB ROBOTS

- A. Mobile service upper-limb robots are actually mechanical slaves. They are instructed to perform tasks.
- B. The technology must be adequate to operate autonomously.
- C. These units are expensive both in development and maintenance and usually require an engineer to set them up in the house and maintain their function over time.
 1. The best known was developed in California at Stanford (the MoVAR system).²³
 2. This has a mobile base and a console to give feedback to the user to improve control.

3. The HelpMate robot is another mobile service robot that a disabled person can use to carry things from one place to another. If there is a cluttered environment within the home, that external environment negates the practical use of this robot.
4. The KARES II robot system²⁴ uses a visual server to help provide assistance with movement (e.g., an eye mouse and a haptic suit with the arm mounted on a remote-controlled mobile base).
5. The Wessex robot allows different tasks to be performed in different rooms.

III. WHEELCHAIR-MOUNTED UPPER-EXTREMITY MANIPULATORS

- A. Wheelchair-mounted manipulators were first designed at the VA Prosthetics Center in New York (1984).
 1. This sophisticated wheelchair-mounted manipulator is able to reach from the floor to the ceiling.
 2. It has 7 degrees of freedom and a gripper hand.
 3. This device may be sold to a rehabilitation facility to enable training of multiple users at that site. It is also sold to individual users. It is relatively expensive.
- B. The Raptor²⁵ was produced at a lower cost (only 4 degrees of freedom).
- C. Exact Dynamics has also created a robotic manipulator (iARM) that is designed to help provide independence to people with severe disabilities.
- D. Exact Dynamics also produces the Dynamic Arm Support (DAS), which compensates for the forces of gravity, making the arm practically weightless. These devices are currently being used in rehabilitation settings for training and for research.

IV. AUTOMATICALLY GUIDED WHEELCHAIRS (AGWs)

- A. Powered wheelchairs can have autonomous intelligence systems attached.
- B. AGWs are service rehabilitation robots intended to move the individual with severe disability.

Continued

BOX 38-9 ■ SUMMARY OF SERVICE ROBOTICS—cont'd

- C. Computer sensing devices can be set up to handle emergencies and assist with task performance.
- D. The robot must receive instruction about the destination point.
 1. These work best in a fixed, predictable environment and operate on an information decoding system whereby sensors identify the position and compare that position to the destination.
 2. The algorithm must create a collision-free path from the starting point to a target.
 3. Some robotic devices detect location and perform object avoidance behaviors through the use of ceiling-mounted or doorframe-mounted cameras.
 4. In some cases the user may be able to modify the environmental situation by programming in new obstacles.

V. REHABILITATION SERVICE ROBOTS: SMART HOUSE DESIGN

- A. For individuals with physical disabilities and older individuals, these smart devices allow residents to live independently with minimal or no human assistance.
- B. There are a number of smart devices that can be installed in the house that are linked to one another to process information from the inhabitant to make decisions and take actions in case of emergency.
- C. Smart house designs continue to be an area of development, particularly with the increasing number of aged individuals who are no longer able to manage independently.
 1. One example is the Robotic Room developed at the Sato Laboratory of the Research Center for Advanced Science and Technology in the University of Tokyo.²⁶
 2. The Robotic Room consists of a ceiling-mounted robot arm (long-reach manipulator) and an intelligent bed with pressure sensors for monitoring the person's posture.
 - a. Modules monitor respiration without attachments.
 - b. Cameras detect positions of the ends of the quilt on the bed.
 - c. There is a second robot that is mobile to perform transportation tasks. The cameras on the ceiling detect robot positions.
 - d. The interface of the robot consists of three ceiling-mounted video cameras to detect orientation of the user's hand. When the user points at the robot, the television, curtains, and so on will be controlled.

VI. FUNCTIONAL INTEGRATION OF MULTIPLE ROBOTS IN THE INTELLIGENT HOME ENVIRONMENT

- A. In the intelligent home environment, there are additional rehabilitation robotics designed to work with home-installed devices.
- B. Placed in the correct arrangement, these robotic devices are controlled in a coordinated manner.
 1. The M3S (multiple master–multiple slave) is a communication robot installed in the home.
 2. This robotic system started with the TIDE Project²⁷⁻²⁹ and has set the standard for this type of robots.
 3. Users can assemble a specific complete modular system.
 4. In case of emergency, the user can halt the operation of the whole system (“dead man switch”).
 5. The ICAN Project (Integrated Control for All Needs) developed the functional integration aspects of the system.²³
 6. The main objective is to propose an optimal control over all home-installed devices by a single interface device (e.g., joystick or switch input).
 7. ICAN is a collaborative project in Europe and continues to receive government support.³⁰

headpieces on robotic devices, information can be detected from flexion and extension, rotation, and side bending of the head to operate wheelchairs, TV sets, telephones, doors, and security systems. There are also some new interfaces that are sensitive to facial movements and optoelectronic detection of light-reflective head movements.³¹ Other interfaces are sensitive to eye movements or use voice recognition, brain control,^{32,33} and gesture recognition.³⁴ These interfaces not only may allow control of the robot but also may be applied to move a limb or perform a task.

Service robotics are recommended when patients have achieved their maximum potential and still need assistance to live independently. A therapist may continue to work with a patient at home in order to maintain range of motion, minimize skin problems, and review whether the robotic technology is still providing the necessary assistance. However, an engineer will usually assume the primary responsibility for maintaining and adjusting the robotic equipment.

Assistive Robotics

Nonwearable Assistive Robotic Devices. Nonwearable assistive robotic technology can be programmed for unweighting, facilitating compliance, providing assistance to perform a task (at home or at work), manipulating the environment, communicating (general interaction or calling for help), or improving memory and learning. Nonwearable assistive robotic technology includes devices that can sense the user's force and velocity of reactions and facilitate assistance. These robotic devices may also be programmed to implement different movement exercises to fit the needs of the user.

A variety of parameters such as range of motion, sequential motions, force, and speed can be adjusted. A few of these devices have become commercially available, but many continue to be used for testing in the laboratory. At present and in the foreseeable future, the emphasis is on enabling devices that encourage dynamic patient

movements for training or for enabling independence. These types of devices do not include electromechanical devices such as motorized bicycles in which different speeds can be set (see the discussion of screening patients for service robotics).

Types of Nonwearable Assistive Robotic Devices. There is a variety of nonwearable assistive robotic devices. Some of

these nonwearable assistive robotic devices are summarized in **Box 38-10**.³⁵⁻⁴³ This group of robotic devices primarily includes powered wheelchairs with autonomous intelligence, body-weight–supported mobile walking aids, robots for body support with indoor and outdoor navigation, hands-off service robotic devices, and body-weight–supported treadmill systems (BWSTs) with and without robotics.^{37,41-45}

BOX 38-10 ■ NONWEARABLE ASSISTIVE ROBOTIC DEVICES FOR GAIT TRAINING

I. BODY-WEIGHT–SUPPORTED MOBILE WALKING AIDS

- A. Newly designed rehabilitation robotic systems can function as walking aids to help those who cannot walk independently.
- B. Some mobile walking aids can walk the client, but others can also be used for training the patient to walk.
 1. There are several electric motor-based gait rehabilitation systems.
 2. Generally, gait rehabilitation systems include a robotic manipulator, a mobile platform, and a sensor system.
 3. The robotic manipulator controls the amount of body-weight support.
 4. The robot is mounted on a mobile platform that not only can support the user's weight but can be adjusted to the height of the subject and provide stability when walking.
 5. The robot has sensors to detect the status of the user (direction and velocity).
 6. The mobile platform moves the whole system according to the subject's motion with objects in the way of the moving platform detected by ultrasonic sensors on the front of the system.⁴³
 - a. The mobile platform can vary from having a carlike design to having a mobile base with driving and steering wheels and differential driving mobile bases.
 - b. The front-wheel-drive carlike model has a complex mechanical design and can be very expensive.
 - c. The synchronous driving and steering mechanisms are complex but can approximate human walking, especially when the path is not linear.
 - d. Differential driving mechanisms require two independent driving wheels.
 - e. The mechanical architecture is simple and practical to implement but may require more maintenance.
 - f. There are training and following modes.
 - g. The challenge is to have sensors that can control stop and go of the user.
 - h. The supervisor can push an emergency stop button, but if the user is generally weak and does not have adequate balance reaction, the patient could fall when the mobile unit stops suddenly.
 - i. Example: the gait rehabilitation system:
 - (a) Used to study the impact of unweighting on gait parameters and patient exertion and heart rate.³⁷

- (b) Researchers have demonstrated that with increasing amounts of unweighting, there is an increase in single leg support and a decrease in double leg support, in terms of the percentage of time a given leg contacts the ground during steady-state walking.
 - (1) At 0% unweighting, single leg stance was 34.5%.
 - (2) At 20% unweighting, single leg stance was 38%, with 23% on both limbs.
 - (3) At 40% body unweighting, single leg stance was 42.5%, and 17.5% of time included bilateral support.
- (c) With increased unweighting and comfortable walking speed, there is a decrease in heart rate.
 - (1) Heart rate was 97 at 0% unweighting.
 - (2) Heart rate was 90 at 20% unweighting.
 - (3) Heart rate was 85 at 40% unweighting.
 - (4) Heart rate would vary to some extent by speed of walking and treadmill slope.³⁷

- C. If the device is primarily used to facilitate standing to prevent contractures and skin ulcers, it may be classified as a stander rather than a walking aide.

II. ROBOTS FOR PHYSICAL SUPPORT

- A. Indoor navigation
 1. These devices assist users with limb and trunk weakness and visual impairments; usually the patients are older.
 2. These machines usually have a motorized base to give physical support to the user.
 3. The robot control system identifies its specific location and puts out voice synthesized navigation instructions or warnings about obstacles on the intended routes.
 4. The robot automatically detects the user intention regarding walking speed and direction of movement.
 5. Examples include the HITOMI,³⁸ the PAM-AID,³⁹ and the WHERE (walking and moving helper robot system).³⁷
- B. Indoor and outdoor navigation
 1. These devices provide physical support for unweighting, harness or robotically controlled protection from falling, and the ability to step.
 2. The robot protects against falling when the end-range body sway has been exceeded.
 3. These devices are best for improving postural righting reactions without falling.

BOX 38-10 ■ NONWEARABLE ASSISTIVE ROBOTIC DEVICES FOR GAIT TRAINING—cont'd

- C. Unweighting with robotic-controlled stepping
 1. These devices can include harness support and unweighting while the user stands on an electro-mechanical platform system.
 2. The feet are attached to assistive computerized devices that force stepping of the feet.
 3. Training is done on the device (e.g., electromechanical gait trainer developed by Hesse).
 4. With practice in stepping, the goal is to improve efficiency and effectiveness of walking.
 5. Studies with this device confirm it is safe and there are improved outcomes as measured by increased walking speed and endurance.
- D. Unweighting with robotic-controlled destabilization
 1. One device that has been tested at the University of Chicago is the KineAssist (IMAGE).⁴⁰ (See Figure 38-6.)
 2. The KineAssist is a robotic gait training device that emphasizes balance recovery training during gait training.
 3. The goal is to provide partial body-weight support and postural control on the torso while the patient walks over ground.
 - a. This device is on a mobile, multidirectional base that allows the patient to walk over ground, indoors or outdoors.
 - b. The trunk and pelvis are free to move, the legs are accessible, and the arms are free.
 - c. A servomotor follows the patient in forward, rotation, and sideways walking.
 - d. It has a robotic arm that is linked to the patient's trunk.
 - e. The robotic arm can be set to allow the patient to move easily and even exceed the limit of stability.
 - f. The robot can also be programmed to specifically interfere with stability.
 - g. The patient can lose balance and "fall," but the robotic arm will stop the fall after a defined range.
 - h. The patient can experience what is needed to keep from falling when the limit of stability has been reached.
 - i. With practice the patient can improve postural righting and balance.

III. HANDS-OFF SERVICE ROBOTS

- A. These are devices that can be placed on the less affected side to restrict motion of a limb.
- B. The objective is to force the patient to use the affected limb (similar to constraint-induced therapy in which the least-affected limb is constrained with a mitt or a cast; see Chapter 9).
- C. Usually the robot is programmed to perform specific tasks with the patient assisting.
- D. The robot could give feedback by nodding, talking in a synthesized voice, or using a prerecorded friendly human voice with humor and engagement that could be matched to some extent to the patient's personality.
- E. Patients appear to perform better when they receive a robot voice for feedback and the robot personality is matched to the patient.

IV. BODY-WEIGHT-SUPPORTED GAIT TRAINING SYSTEMS

- A. Without computerized assistance for stepping
 1. Body-weight-supported gait training systems are designed to unweight the body to enable the patient to walk more easily.
 2. The purpose of unweighting is to decrease ground reaction forces, protect against falling, improve balance, and improve walking speed over ground (see Table 38-4).
 3. Most of these devices integrate self-regulated stepping by stimulating the automatic stretch stimulus to activate the pattern generator for stepping at the spinal cord level.
 4. With unweighting, it is possible to maintain physical activity while undergoing healing and recovery.
 5. Progressive unweighting and reweighting may also be important for maintaining bone mineralization during healing.
 6. Unweighting may also make it possible for patients to perform more complex tasks such as one-footed balance, end range reaching without falling, and coordinated movement patterns such as skipping, dancing, ice skating, and roller skating without the risk of falling.
 7. With unweighting:
 - a. Patients can slowly build up endurance and strength as well as perform tasks that are difficult when fully weighted (e.g., rising on toes, squatting, jumping, skipping).
 - b. When unweighting is used over the treadmill, it is possible to increase the treadmill speed so the individual who is training can achieve higher speeds of walking or running.
 8. A variety of unweighting systems are available for gait training. Most use a harness system; however, in 2011 new unweighting systems that use a harness and a leg system, air, or a bike seat were introduced.
 - a. Some emphasize walking over a treadmill and some over ground.
 - b. Some emphasize balance training and some emphasize gait training.
 - c. Most unweighting systems are comfortable at up to 20% to 30% of unweighting.
 - d. Some body-weight-support systems can comfortably unweight the body up to 80% (AlterG), and some 100% (e.g., GlideTrak, Gait Trainer).
 - i. In 2008, the AlterG air-distributed unweighting treadmill systems were approved by the U.S. Food and Drug Administration (FDA) for physical rehabilitation and gait training.
 - (a) The patient stands on the treadmill in an enclosed waist-high pressurized bag air-chamber.
 - (b) During use, pressure inside the chamber is increased until the pressure difference across the waist seal generates

BOX 38-10 ■ NONWEARABLE ASSISTIVE ROBOTIC DEVICES FOR GAIT TRAINING—cont'd

- an upward “lifting” force, evenly distributed to the lower body to counter gravitational body weight.
- (c) As pressure within the chamber is increased, a greater proportion of the patient’s body weight is supported (a range of 0% to 80% for patients weighing 140 to 300 pounds).¹⁴
 - (d) The unit can be ordered with port-holes to allow the therapist to reach into the bag to assist the patient.
- ii. In 2010 the concept of a bicycle was used for unweighting.
 - (a) The GlideCycle unweights the patient by supporting the patient through the pelvis on a posted seat similar to a bicycle with anterior bar support against the ilium.
 - (b) The patient is essentially standing in a cone of support to stride with the legs.
 - (c) This system can be used on a treadmill or over ground. The legs are free to move in a stride-type fashion.
 - (d) When the patient swings the arms, an increased demand is placed on balance.
 - (e) Stepping the legs can be easily facilitated by a therapist.
 - (f) When the unweighting is performed over ground on a two-wheel or four-wheel bicycle, the individual can be outside and enjoy the terrain, still unweighted.
- B. Body-unweighting treadmill systems with computer assistance for stepping and walking**
1. Some body unweighting systems include a robot to assist with stepping.
 - a. The Lokomat (Hocoma) is a body-unweighting treadmill system that uses a harness for unweighting, suspending the patient over a treadmill.
 - i. An exoskeleton, robotic manipulator is attached to the patient’s legs with many sensors to detect the status of the user and step the legs.
 - ii. With linear potentiometers attached, the user’s walking direction and velocity are analyzed, and then parameters are computer generated to assist the patient in walking.
 - (a) Walking is facilitated by setting the speed of the treadmill and setting the parameters of leg movement.
 - (b) Use of the device is referred to as “robot-assisted walking therapy” and involves passive movement.
 - (c) At the early stage of spinal cord injury, the goal is to stimulate neural adaptation and recovery.
 - (d) In the late stage of healing after spinal cord injury, the objective is to facilitate good metabolism, prevent contractures, decrease bone demineralization, and facilitate well-being.
 2. Other laboratory model robotic gait trainers use a system of cuffs and straps to help walk the legs.^{41,42}
 - a. One system is a simple strap system (ARTHUR).
 - b. Another system includes a combination of straps and computerized control systems (PAM and POGO).
 - c. The KNEXO is a bilateral lower-limb robot-assisted exoskeleton developed by Pieter Beyl in Brussels.
 - i. This includes an evaluation platform and a gait training device.
 - ii. It has a high-force pleated pneumatic artificial muscle (PPAM) system to enable full knee support during treadmill walking.
 - iii. It has a zero torque mode for unassisted walking and reference knee pattern recording.
 - iv. It has a tunable assistive mode with safe interaction with human movement. Stepping is facilitated over a treadmill.
 - d. STRING-MAN⁴²
 - i. Novel system for gait rehabilitation
 - ii. Developed in Berlin
 - iii. Purpose is to restore posture and gait functions
 - iv. Provides partial body-weight support
 - v. Supports patient to autonomously perform gait training
 - vi. Assesses and supports patient initiative
 - vii. Quantifies measurement of motor function
 - e. Passive gravity balancing leg orthosis (University of Delaware)^{35,36}
 - i. Boom to support hip motor.
 - ii. Has a hip linear actuator.
 - iii. Spring-loaded winch to support device weight.
 - iv. Walker used to support the device.
 - v. Used over the treadmill but will be used over ground.
 - vi. Load cell on hip linear-actuator.
 - vii. Knee linear actuator.
 - viii. The orthosis is connected to a walker, and its trunk has four degrees of freedom with respect to the walker (vertical and lateral translation, rotation about vertical axis and horizontal axis perpendicular to sagittal plane).
 - ix. Hip joint has two degrees of freedom with respect to the trunk, one in the sagittal plane and the other for abduction-adduction motion.
 - x. Knee has one degree of freedom with respect to the thigh segment.

Purpose of Nonwearable Assistive Robotic Devices.

Nonwearable assistive robotic devices were designed primarily to facilitate mobility and gait training. More specifically, body-weight–supported gait training systems were initially designed to unweight the body, decrease ground reaction forces (GRFs), and protect against falling (Figure 38-3). Under these assisted conditions, it is easier for patients to achieve intense levels of exercise such as walking, skipping, and running with less pain and less trauma to the joints.⁴⁶ These systems also allow runners to exceed the speed of overground running while being protected from falling.⁴⁷ Unweighting also allows patients to increase their heart rate more slowly while running or jogging at a higher speed.⁴⁷ For patients with spinal cord injuries, body unweighting over a treadmill was a translation of basic science findings to clinical practice. In animal studies, walking ability could be restored after induced spinal cord injury by facilitating the spinal generator for stepping through movement of the treadmill belt.⁴⁸⁻⁵⁰ Through unweighting, it is also possible to maintain metabolic activity while allowing healing and recovery after joint inflammation, muscle injuries, degenerative joint conditions, bone fractures, surgical repairs, joint replacements, osteoporosis, stroke, or head trauma. Most of the research on bone density is based on studies involving patients with spinal cord injuries. In these studies, walking on a BWSTS does not significantly increase bone density. However, those who walk on the BWSTS lose less bone density than those who do not exercise on the treadmill.^{51,52} On the other hand, although body-weight–supported treadmill training (BWSTT) may not necessarily increase bone density, particularly in patients with spinal cord injuries, exercise (with or without BWSTT) can increase muscle mass and/or prevent atrophy. On the other hand, in one study the use of shorter, frequent mechanical loading sessions was correlated with enhanced bone mass.⁵³ More research is needed to determine the time and frequency of standing and walking exercises and their beneficial effects on bone density.⁵⁴

Key Features of Unweighting. A key feature of BWSTT is the degree, comfort, and convenience of adjustable support.⁵⁵ Whereas harness systems are the most commonly used for unweighting, when high levels of body support are needed or patients are jogging, these harnesses can be uncomfortable

Figure 38-3 ■ Body-weight–support trainer or body-weight–supported treadmill trainer: Lokomat robotic system. (Courtesy Hocoma, Volketswil, Switzerland.)

and cause pressure chaffing. This has led to the development of new body-weight–support systems such as the AlterG trainer (Figure 38-4), which uses a lower-body air distribution system, or the GlideTrak and Glide Cycle, which use a suspended bicycle seat–type unweighting system (Figure 38-5). The movement of the treadmill support surface provides an automatic stretch stimulus for the individual to step. In addition, the speed can be modified to stimulate faster or slower lower-extremity movements, which is very beneficial for individuals who need to vary the rate and responsiveness of their motor movements, such as clients with Parkinson disease, aging adults, or individuals with balance impairments. See Table 38-1 for a summary of the characteristics of some of the current unweighting systems.

Effectiveness of Body-Unweighting Treadmill Training.

Various biomechanical studies have been done to confirm the parameters of unweighting. After use of early lower-body positive pressure support (LBPPS) prototypes, Grabowski^{46,47} reported that GRFs were reduced while metabolic power demands were maintained during running. Individuals could achieve faster running speeds when under conditions of unweighting. With slow-speed running on the LBPPS (1.0 to 1.5 mph), it is possible to reduce GRFs by 50% when the body is unweighted to 27% to 48% of normal body weight. At faster speeds (3 to 5 m/s; 6.6 to 11 mph), individuals must be unweighted to 25% of their body weight to maintain a GRF similar to that during walking over ground.

During progressive levels of unweighting, Ruckstuhl⁵⁵ compared cardiorespiratory performance, gait parameters, and comfort between a laboratory prototype device similar to the LBPPS AlterG trainer and a traditional harness BWSTS. Subjects reported significantly greater comfort using the AlterG trainer and greater tolerance for high unloading. Subjects had significantly lower heart rates when training on the LBPPS versus the harness-based body

Figure 38-4 ■ Body-weight–supported treadmill trainer: AlterG. (Courtesy AlterG, Fremont, Calif.)

support system. Other clinical studies have been carried out to confirm the benefits of body unweighting for patients with neurological problems (Box 38-11).

The outcomes studies on BWSTT (in patients after stroke, after spinal cord injury, and with Parkinson disease) have generally positive findings. BWSTT enhances gait speed, endurance, and potentially quality.⁵⁶⁻⁵⁸ It is important to force patients to walk at community-level velocities of at least 0.8 m/s (faster than 2.0 mph).⁵⁹⁻⁶³ With forced intensity, patients are more likely to achieve physiological and possibly neuroprotective benefits.^{64,65} For those who make the greatest gains, the improvement has been noted as increased single-limb support, particularly on the most affected limb of individuals after stroke.⁶⁶ Although there are positive mobility benefits of BWSTT for patients with spinal cord injuries,^{58,59,67-73} guidelines still have not been generated regarding the best parameters for training (e.g., speed, amount of unweighting, time of intervention). Furthermore, one randomized clinical trial found that intense task-specific gait training over ground was equally as effective as intense body-weight-supported gait training for patients after stroke and after spinal cord injury.⁷⁴ In another study, BWSTT produced similar gains in mobility compared with locomotor training at home.⁵⁶ However, there were more falls in those patients who were started on locomotor training early rather than late. In addition, although the outcomes of improved gait performance are similar for BWSTT and aggressive bracing-assisted walking over ground for patients post-stroke, the patients with the most severe impairments made the greatest gains with BWSTT.⁷⁵ Other researchers have reported statistically significant gains in balance, balance confidence, and quality of life after chronic poststroke patients were trained on a BWSTS. However, over the long term the gains were not necessarily considered to meet the criteria for minimal detectable change.⁷⁶ It appears that the gains in speed after BWSTT should be 0.16 m/s to

achieve a *minimal clinically important difference*.⁷⁷ Furthermore, there may be additional training activities that can be done to increase the effectiveness of BWSTT, such as VR training,⁷⁸ electrical stimulation,⁷⁹ constraint-induced therapy and/or robotics,⁷⁰ or dual-task learning-based training.⁸⁰

One BWSTS device allows the individual to walk over-ground while having one arm attached to the apparatus. The KineAssist gait trainer–destabilizer is an example of this type of body-supported gait trainer (Figure 38-6). Its primary function is to retrain balance to prevent falling. It is considered a BWSTS because the attached arm perturbs the individual while walking and can also provide some support. It perturbs the individual to fall and then catches the individual before he or she falls to the ground.⁴⁰

Wearable Assistive Robotics

General Issues of Wearable Robots. Wearable assistive robots are person oriented. The distinctive aspect of the wearable robot is that the exoskeleton is mapped onto the body or limb(s) with touch, pressure, visual, auditory, or movement sensors. The exoskeleton is worn by the individual, but the internal or external interface must be mapped to the anatomy, a cognitive control mechanism, or the brain. Wearable assistive robotic technology extends, complements, empowers, replaces, or enhances the function or capability of the individual. Ideally, the wearable orthotic moves with the individual in open space. However, some of these devices are in the developmental phase and are temporarily tethered to electronic systems or workstations.

Key Elements of Wearable Assistive Robotic Devices. Two major issues in wearable robotic devices are safety and dependability. A third major issue is the quality of the interface with the patient and the control of the assistive robotic device. In designing a wearable robotic device, biological principles must be followed. It is important for the robot to be adaptable with minimal weight, muscle fatigue, and energy consumption. In addition, there should be minimal

TABLE 38-1 ■ NONWEARABLE ASSISTIVE UNWEIGHTING GAIT TRAINING SYSTEMS

NAME	TYPE OF UNWEIGHTING			ROBOT ASSISTED	SURFACE FOR TRAINING			ENVIRONMENT		FREEDOM OF TRUNK	CHALLENGE TO BALANCE

BOX 38-11 ■ BRIEF SUMMARY OF TRENDS FROM RESEARCH ON EFFECTIVENESS OF NONWEARABLE BODY-WEIGHT-ASSISTED GAIT SYSTEMS**CHRONIC POSTSTROKE PATIENTS**

Body-weight–supported treadmill training (BWSTT) (10% to 30% unweighted, two to five times per week for 3 to 12 weeks, with or without one-on-one gait training with a physical therapist or gait-assisted treatment including neuromuscular stimulation or ankle-foot orthosis) is associated with increased gait speed, increased time on the affected limb, and increased endurance during training when the speed of the treadmill is increased to speeds faster than the patient would normally walk.

Patients who make the greater gains in gait speed after BWSTT (e.g., 0.08 m/s) also have greater increases in terminal stance hip extension angle and hip flexion power (product of net joint moment and angular velocity) and higher intensity of muscle firing of the soleus.⁷⁷

PATIENTS WITH PARKINSON DISEASE

Walking with BWSTT guarding on a circular treadmill with and without unweighting has been shown to decrease freezing. However, the exact parameters for training (frequency and intensity) to produce long-term effects for unweighting are yet unknown. This area of research is in its infancy.

Patients with mild to moderate Parkinson disease exercising at moderate to high intensity using BWSTT (two to three times per week for 8 to 12 weeks) have increased endurance, enhanced quality of gait, improved balance, and reduction in falls.⁸⁰

Figure 38-6 ■ KineAssist gait trainer–destabilizer. (Courtesy Kinea Design, Evanston, Ill.)

damage imposed on the tissues while the biological systems have high functionality. The extremities can be used to perform multiple tasks, and the redundancy of the joints and degrees of freedom (shoulder, elbow, and wrist) allow human subjects to perform tasks in a variety of ways, creating high functionality. The robot must be adaptable, have minimal weight, be slim, create minimal muscle fatigue, conserve

energy, and be easy to control. In addition, there should be minimal damage imposed on the tissues while the biological systems have high functionality. Consistent with biomechanical function of the upper limb, the upper limb must be able to perform multiple tasks with redundancy of the joints and degrees of freedom from the shoulder to the elbow to the wrist. This redundancy, integrated within different environments,

provides the opportunity for variation in movement, high functionality, and minimum energy costs.⁸¹

With the nervous system as a model responsible for processing sensory (afferent) information (e.g., tactile and kinesthetic [muscle length, joint compression]) to generate a movement (efferent), the system is based on an internal model of processing, with action potentials generated after excitation. This action potential triggers muscle contractions at the motor end plate. Three types of muscle fibers can be facilitated: skeletal, smooth, and heart muscles. The heart muscle is controlled by the autonomic nervous system. When excited, the muscles change shape (especially length) owing to the sarcomeres' contractile elements producing a force that is dependent on the volume of the muscle and its innervation. A little force recruits the slow fibers first. With increased force, faster fibers are excited. The excitability of the muscle fiber is not linear; however, passive length-tension relationships are linear.

The sensorimotor mechanisms are essential to this model. The muscles are actuators with built-in sensors that measure length, rate of change of length, and force. These muscle receptors are part of the proprioceptive sensory system. With muscle movement leading to joint movement, the Golgi tendon organs (GTOs) are activated. When the GTO is compressed, it is excited and limits firing to avoid muscle tearing and joint damage. The intrafusal muscle spindles sense the length of the muscle fibers, and the extrafusal fibers sense the length of the muscles. These fibers control the stretch reflex and the inhibitory reflex caused by the GTOs.

The biomechanics of the human limbs must also be considered part of the model. The limbs move in a three-dimensional space. The concavity and convexity of the joint surface control limb movement. This movement can be altered by using the limb in an open or closed chain condition.

In addition to the neural, muscle, and sensory components, there are other issues that modify patient responses. First is the strength of the stimulus. Second is the consequence of the action. Third is the tendency to minimize complexity of movement. Fourth is the imitation of movements and actions of others (e.g., following someone). Then there is the replication of the movements and the ability to accomplish the task in the same way more than once. However, it is not easy to model the biological system owing to

the many redundancies and complexities. Engineering models tend to try to simplify the systems.

Assistive robotic devices for rehabilitation need to be slim, lightweight, and easy to control mechanically. If the device is mounted on a wheelchair, it needs to be mechanically integrated with the control of the wheelchair and consume minimal power.

Walking efficiency is one area that has been studied for many years. Walking, for example, is a translation of the center of mass over the base of support, with progressing, controlled falls, prevented by having the swing leg come through and quickly plant the heel or foot to catch the fall. Usually a certain speed (cadence and step length) is selected to minimize metabolic energy.

Classification of Wearable Assistive Robotic Devices.

Wearable assistive robots can be classified in a number of ways. Most simply, they can be classified by body part, such as the upper limb, lower limb, or trunk. They can also be classified by how they are powered (e.g., static orthotics for stability, prosthetic robots, or empowered exoskeletons for task performance or mobility for gait training). Empowered exoskeletons, called *extenders*, are controlled by the individual and are usually designed to enhance the performance of the subject beyond natural ability. This is a type of master slave. These robotic devices usually require an external force. Most often, these master slave robotics are used in space and certain types of research rather than rehabilitation and will not be elaborated on in this chapter.

In designing a wearable robotic device, biological principles must be followed. The wearable robot must be adaptable with minimal weight, muscle fatigue, and energy consumption. It should be compact, miniaturized, portable, and energy efficient. In addition, there should be minimal damage imposed on the tissues. Redundancy of the joints and degrees of freedom allow a variety of ways patients can perform a task. However, these redundancies may be hard to control. Wearable robotic devices will vary by type of human interface system incorporated (e.g., brain neurons, cognitive, sensory [tactile, pressure], physical [movement], or breath). At a minimum, the physical interface of a wearable robot requires an actuator and a rigid structure to transmit forces to the neuromusculoskeletal system.

Some common types of wearable assistive devices are summarized in [Box 38-12](#)^{10,11,82-114} for the upper extremities

BOX 38-12 ■ WEARABLE ASSISTIVE ROBOTICS FOR THE UPPER LIMB

I. WEARABLE ASSISTIVE ROBOTIC DEVICES: FIXED, ATTACHED TO WHEELCHAIR, OR MOBILE⁸³

A. Workstation assistive robots (fixed site)

1. Manipulator fixed to a wall or a surface.
2. Manipulator may be able to move in different paths.
3. Control system has information about the objects in the immediate environment.
4. Usually unilateral.

5. Some are preprogrammed to perform functions for the user.

- a. DeVAR (Desktop Vocational Assistive Robot).
- b. RTX, Tim Jones, United Kingdom, 1985; paved the way for rehabilitation robotics
- c. RAID, Stanford University Telematics for the Integration of Disabled and Elderly people (TIDE)
- d. Handy 1 (Rehab Robotics) feeding aid-based robot
- e. My Spoon (Secom, Tokyo, Japan)
- f. Neater Eater (Buxton, United Kingdom)

BOX 38-12 ■ WEARABLE ASSISTIVE ROBOTICS FOR THE UPPER LIMB—cont'd

- B. Wheelchair-mounted robots for training
1. Usually unilateral.
 2. First arm robot developed by Neville Hogan and his research group at Massachusetts Institute of Technology (MIT).^{86,87}
 3. The primary commercially available model for this is the Manus.
 - a. Currently manufactured by Exact Dynamics as iARM, ARM, and MIT-Manus.
 - b. Supports the shoulder and arm and assists movement of the arm.
 - c. Has a handpiece that can be used to help manipulate objects.
 - d. Upper-limb robot goes anywhere end-user takes the chair.
 - e. Can be switched for right and left.
 - f. See task practice for more information.
 4. Raptor Rehabilitation Technologies, Division of the Applied Resources Corporation
 - a. Lower cost than Manus
 - b. Four degrees of freedom
 5. Spitting Image (Jim Hennequin in United Kingdom)
 6. Armeo (Hocoma) attached to chair and workstation (see virtual task practice)
 7. WREX—Wilmington Robotic Exoskeleton (new model WREX II)
 - a. Can be attached to most common wheelchairs and seating systems (three different mounts and forearm support).
 - b. Exoskeleton approximates normal human anatomy.
 - c. Linear elastic bands are used for balance, provide antigravity lift, and assist movements.
 - d. Can be switched for right and left.
 - e. WREX II has a motor to assist the rubber bands to lift heavier things.
- C. Temporarily mounted but freely moving upper-limb robot: Jacob Rosen, University of California, Santa Cruz
1. Mounted to wall during development stage.
 2. Can be used for unilateral or bilateral training.
 3. See description under virtual task practice.
- D. Freely moving wearable assistive upper-limb exoskeleton
1. MoVAR, Stanford University (the DeVAR on wheels)
 2. KARES II robot system, developed at KAIST in Korea, with arm mounted on mobile base
 3. Wessex robot (Bath Institute of Medical Engineering)
 4. Myomo mPower 1000 for the elbow (see under biofeedback-assisted devices)
 5. Armeo (see virtual practice)
 6. Bioness L200 for the wrist (see under neuromuscular stimulation-assisted upper-limb robotics)
- II. WEARABLE ASSISTIVE ROBOTIC DEVICES FOR TASK PRACTICE**
- A. Virtual reality task practice
1. Armeo—Hocoma
 - a. Robot fixed to chair.
 - b. Used to perform virtual tasks at a workstation.
 - c. Supports affected arm and hand.
 - d. Facilitates self-initiated and intensive, repetitive movements within a three-dimensional environment.
 - e. Games are fun and provide feedback to facilitate motivation.
 2. University of California, Santa Cruz upper-limb exoskeleton
 - a. Robot includes two arms; patients can train with one or both arms.
 - b. Exoskeleton has six degrees of freedom at the shoulder and four at the elbow and wrist.
 - c. Does not include a robotic hand.
 - d. Exoskeleton hooked to wall frame.
 - e. Patient performs virtual tasks.
 - f. Robot unweights the arm, decreases joint friction of the device, and on some games assists the patient in performance.
 - g. Robot measures kinematic data associated with the task performance.
 - h. Subject works in open space, but the exoskeleton is fixed to a support stand on the wall.
 - i. Has potential to be connected to a brain interface.
 3. L-Exos system (University of Pisa, Italy)
 - a. Five degrees of freedom and force feedback.
 - b. Used to study the benefits of robotic-assisted virtual reality-based rehabilitation for chronic poststroke patients.
 - c. Patient sits with the right forearm (not left) in the exoskeleton.
 - d. Video projector displays a virtual scenario: a reaching task.
 - e. A motion task constrained to a circular trajectory and an object manipulation task are practiced.
 - f. Designed to be used in a fixed workspace.
 - g. On some tasks, the robot provides assistance; on other tasks, no guided assistance is provided, but the therapist can elect to unweight the arm.
 - h. Device is controlled by two concurrent impedance controls.
 - i. Reaching and following accuracy are calculated.
 - j. Patient cannot use the device to move around and perform a variety of daily activities.
- B. Real task practice
1. Single task robots—The single-task robots carry out predefined tasks (e.g., eating) activated by simple input devices. The most successful example is the Handy 1.⁸³
 2. Multitask robots
 - a. Manus Assistive Robotic Manipulator (iARM, ARM, MIT-Manus, Exact Dynamics)⁸⁴
 - i. Wearable orthotic is activated and monitored based on myoelectric and visual signals.
 - ii. Robot is attached to the wheelchair; is available where the wheelchair is located.

BOX 38-12 ■ WEARABLE ASSISTIVE ROBOTICS FOR THE UPPER LIMB—cont'd

- iii. Patient puts on the exoskeleton and is able to use a gripper end-effector to perform tasks.
- iv. Manus-HAND includes fingers with three joints.
- v. Crossed tendon mechanism is used to control the amount of flexion and extension movements.
- vi. Movement of the wrist is separate from movement of the hand.
- vii. Dexterous nature of the hand is limited by the current actuation technology.
- viii. Force sensors are present on the thumb and two fingers.
- ix. There is real-time identification of electromyographic commands and computation of control loops and force biofeedback.⁹⁹
- x. Has a two-fingered gripper end-effector.
- xi. Has six plus two degrees of freedom.
- xii. User can control the Manus ARM by accessing menus on standard devices (e.g., keypad, joystick, or switch).
- xiii. Patient can move each joint individually.
- xiv. Vision system has two cameras mounted with the camera at the shoulder providing the perspective of the occupant and a camera within the gripper to provide a closer view of computer control.
- xv. Task includes a gross reaching movement to the target and then fine motor control of the end effector to manipulate the object.
- b. Mirror Image Mobilization Enabler (MIME) System (Department of Veterans Affairs Research and Development, Palo Alto, Calif).
 - i. Bimanual robotic device
 - ii. Uses an industrial available robot (PUMA) to apply forces to the paretic limb during three-dimensional movements to perform actual tasks
- c. In Japan, two exoskeleton-based systems were developed at Saga University.
 - i. One-degree-of-freedom interface was designed for the elbow using a robot to interpret human subject intention.
 - ii. A newer two-degrees-of-freedom interface is used to assist human shoulder joint movement.
- d. In Switzerland, the ARM was also developed with three degrees of freedom for shoulder and one degree of freedom for elbow actuation.
 - i. Patient performs task-oriented repetitive movements.
 - ii. Receives visual, auditory, and haptic feedback.
- e. The Salford Exoskeleton is based on a pneumatic muscle actuator system (pMA) and provides power over weight ratios.
- f. Gentle/S robotic assistance (Europe)—integrates haptic technologies with high-quality virtual environments to drive practice in patients with upper-limb impairments.⁸⁵

III. BIOFEEDBACK AND UPPER-LIMB ROBOTIC DEVICES: ACTUAL TASK PRACTICE

- A. Myomo mPower 1000 exoskeleton for the elbow
 - 1. It is a wearable assistive robotic device for facilitating control of the elbow.
 - 2. It is programmed to sense patient effort (muscle firing) with elbow flexion and extension before providing assistance to the patient.
 - 3. mPower 1000 is approved by the U.S. Food and Drug Administration (FDA) for use in the home or in the clinical setting.
 - 4. Designed to pick up patient effort and then assist with elbow movement for patients after stroke, spinal cord injury, multiple sclerosis, cerebral palsy, muscular dystrophy, or traumatic brain injury.
 - 5. Based on MIT-developed technology.
 - 6. Fits like a sleeve on the arm.
 - 7. Has sensors that are in contact with the skin and the muscles to detect even faint muscle signals.
 - 8. When the person tries to move and the muscle fires, the robot will engage to assist in completing the desired movement.
 - 9. Unit can be programmed to assist with elbow flexion, elbow extension, or both elbow flexion and extension.
 - 10. Sensor electrodes are placed over the biceps and triceps.
 - 11. Therapist selects the desired mode, and the patient practices object manipulation and task activities with assistance of one or both muscles.
 - 12. Device is battery powered and allows the patient to move around when practicing.
 - 13. The patient and the therapist create the tasks.
 - 14. Robotic device does not include an end effector such as a hand or a claw.
- B. Hand Mentor (Kinetic Muscles)—another upper-extremity assistive robotic device that assists patients with repetitive practice of hand and wrist movements
 - 1. Electrodes are applied to the forearm within a wearable exoskeleton to sense muscle contraction.
 - 2. The patient is asked to participate in recruiting the muscles with some biofeedback regarding success.
 - 3. With or without voluntary muscle contractions, the assistive device helps the patient move the wrist.
 - 4. Device is used while the patient sits in a fixed place or position.
 - 5. Functional task activities are not performed.
 - 6. There is no end effector for the hand.
 - 7. Patient focuses on extension or flexion of the wrist.
 - 8. Unit must be plugged into the wall.
 - 9. Designed primarily to train patients poststroke, but could be used for patients with other neurological diagnoses.
- C. AMES—assisted movement with enhanced sensation (upper limb)
 - 1. Developed by Paul Cordo (Oregon).
 - 2. Uses biofeedback regarding voluntary joint torque.

BOX 38-12 ■ WEARABLE ASSISTIVE ROBOTICS FOR THE UPPER LIMB—cont'd

3. Sensation of motion enhanced by tendon vibration.
4. Initial trials with acute poststroke patients with severe impairments.
5. Effective at restoring functional movement in upper extremity in profoundly disabled acute poststroke patients.
6. Does not restore functional movement at fingers or wrist joints.
7. Product moving into the commercial market.
8. Some further development underway to try to convert electromyographic signals from voluntary muscle contractions into useful biofeedback on a graphic display.
9. Unit has a lower-limb robotic device attached.

IV. NEUROMUSCULAR STIMULATION AND WEARABLE UPPER-LIMB ROBOTICS TO ASSIST TASK PRACTICE

A. Neuromuscular stimulation to facilitate upper-limb movements with assistive robotic devices

1. Surface electrodes
 - a. Bioness L200
 - i. Surface electrodes on wrist muscles
 - ii. Assistive robotic device for stimulation of wrist flexors and extensors of the wrist
 - iii. Programmable
 - (a) Patient must have an intact peripheral nervous system.
 - (b) Operates on a battery, and the hand can be used as part of training.
 - (c) Muscles are stimulated, and the patient is instructed to move in the direction of the stimulation.
 - (d) One challenge is contractures of the finger flexors. When wrist extension is stimulated, the fingers go into flexion.

- (e) Another challenge is excessive spasticity in the finger flexors making it difficult to open the hand even with stimulation of the extensors of the wrist and fingers.
- b. Handmaster system (NESS, Ra'anana, Israel)⁸²
2. Muscle-implanted electrodes for neuromuscular stimulation with assistive robotic devices (no commercial products in 2011).
3. Subdural implanted electrodes in brain to provide electrical stimulation to control limbs for patients after spinal cord injury. Current area of research in 2012 with promise for functional use in the clinic.

V. BRAIN-CONNECTED WEARABLE UPPER-LIMB ROBOTICS

A. Brain interfaces are being developed.

1. Control is by direct brain connections (surface electrodes).
2. When there are no other options to help patients control a limb or an exoskeleton using usual interfaces, the brain may become the primary connection.

B. Brain-machine interfaces.

1. Involve the control of a robot through a direct implantation of an electrode in the brain.
2. The patient only has to “think” about performing a task and the exoskeleton can move the limb with an end effector to perform the task.
3. Is the newest form of advanced technology and is currently directed toward the upper limb.
4. Research in this area is being completed at a variety of neuroscience and neurorehabilitation research laboratories.
5. Collaborations developing to use existing robotic devices and develop a brain interface.
6. Challenges regarding how long the electrode can remain in the brain (implanted in cortex or basal ganglia or embedded in subdural space).

(Figure 38-7) and Box 38-13^{10,11,35,42,115-121} for the lower extremities (Figure 38-8). In general, they are divided into three categories of wearable robots: single-task robots, workstation robots, and wheelchair-mounted manipulators (see Figure 38-7). They can also be classified by whether they use neuromuscular stimulation or biofeedback to assist the movement (Figure 38-9). Some patients use these wearable assistive robotics for training and recovery. Those who have reached a plateau in recovery may continue to use these assistive robotic devices for ongoing functional assistance and safety.

In 2012, there were a variety of wearable upper-limb robotic devices on the market, and most were unilateral (see Box 38-12). At the same time, there were fewer lower-limb wearable robotic devices on the market; however, a variety of lower-limb exoskeletons are under development^{10,11,35,94} (see Box 38-13).

Wearable Assistive Robotic Devices with Neuromuscular Stimulators. Wearable assistive robotics with neuromuscular stimulation are available for both the upper and

lower limbs. Ideally, both muscle stimulation and active voluntary muscle contractions are used to increase functional use. These robotic devices may facilitate muscle contractions in one or more directions around one joint such as the elbow, wrist, or ankle.

The primary impairment that can be addressed with neuromuscular stimulation is muscle weakness, but the patient may also have neuromotor control problems or abnormal synergies of movement. These devices work only when peripheral nervous system function is preserved. However, in the case of patients with spinal cord injuries, multiple electrodes may need to be used to sequentially activate a series of muscle contractions to enable walking. Similar robotic devices are available for patients poststroke. The electrodes are placed on the skin within the wearable robotic device and programmed for stimulation during specific movements.

Effectiveness of Wearable Assistive Robotic Devices. The effectiveness of wearable assistive robotic devices is promising. Assistive robotic devices for the lower limb have

Figure 38-7 ■ Wearable upper-limb assistive robotic exoskeleton devices. **A**, Myomo upper-limb robotic assistive device. **B**, Bioness L200 arm and wrist trainer. **C**, Shoulder, elbow, and wrist upper-limb assistive robotic bilateral device. **D**, Armeo robotic arm. BOX 38-13 ■ GAIT TRAINING WEARABLE ASSISTIVE ROBOTIC DEVICES FOR THE LOWER LIMB**I. LOWER-EXTREMITY GAIT TRAINING WEARABLE ASSISTIVE ROBOT****A. Unilateral exoskeleton****1. Tibion Bionic Leg**

- a. A wearable, unilateral, assistive robotic device, commercially available in 2009.
- b. Exoskeleton is noninvasive: rigid and soft material.
- c. Exoskeleton can fit right or left leg.
- d. Uses sensors, a microprocessor, an actuator, and customized software to automatically detect a user's action (e.g., walking or climbing stairs).
 - i. Actuator provides power assistance and resistance at knee.
 - ii. Sensory interface: responds to pressure (weight) in shoe insert to signal microprocessor to provide appropriate assistance:
 - (a) Extends knee when sensor is loaded.
 - (1) Heel strike: loads sensor and extends knee
 - (2) Load on sensor: extends knee when rising to standing
 - (b) Releases knee extension when sensor is unloaded during heel off in swing phase of gait.
 - (c) Provides resistance (eccentric flexion) when sensor loaded and patient moving from standing to sitting or descending a stair.
 - iii. Combines a drive force system with an external support system.
- e. Programmable to the individual patient in terms of:
 - i. Patient weight
 - ii. Amount of loading (threshold to activate) robotic device
 - iii. Amount of assistance in knee extension
 - iv. Amount of resistance (eccentric control of knee flexion)
- f. Battery operated.
- g. Weighs approximately 5 pounds.
- h. Effective¹¹⁵
 - i. Helps with teaching patients to put weight on affected limb (especially those with neglect).
 - ii. Provides assistance with transitional movements.
 - iii. Enhances walking speed, endurance, and quality of gait.
 - iv. Seems to have carryover to assist ankle dorsiflexion.
 - v. Can also be used with an ankle-foot orthosis (AFO).
 - vi. Patients can practice walking indoors and outdoors independently.

B. Bilateral robotic-assisted lower-extremity exoskeletons**1. REX (robotic exoskeleton)**

- a. Bilateral robotic exoskeleton for walking.
- b. "Step-in" exoskeleton.
- c. Device supports an upright posture and robotic-assisted walking.

- d. Does not require a backpack or crutches.
- e. Two large legs support and lift the user.
- f. User controls the system with joysticks at his or her side on the exoskeletons.
- g. Can be used by individuals who can self-transfer and operate hand controls.
- h. Used mostly with patients with spinal cord injuries.
- i. Suitable for patients with other orthopedic and neurological conditions.
- j. Uses a rechargeable battery (runs for 2 hours; takes 3 to 4 hours to recharge).
- k. Costs approximately \$150,000 and is available only in New Zealand and England.
- l. Programmable; provides assistance for both legs through sensors, microprocessors, and actuators controlled by a joystick.¹¹⁶

2. Ekso—Berkeley, California

- a. Initially referred to as eLEGS in Home Rehabilitation System; designed by Homayoon Kazerooni, University of California, Berkeley; manufactured by Berkeley Bionics)
- b. Original step-in bilateral exoskeleton was used in war to assist a soldier to carry people and objects
- c. Ekso Bionics (formerly Berkeley Bionics)
 - i. Integrates sensors in the crutches and the feet with computer-generated stepping of the legs, including flexion of the knee.
 - ii. Enables paraplegic patients to walk with a four-point gait.
 - iii. Model for gait training is being designed for patients poststroke.
 - iv. Patient has to have enough strength to rise from the chair or a wheelchair.
 - v. Easy to step into exoskeleton.
 - vi. Computer and battery carried in backpack.
 - vii. Primary advantages are that this exoskeleton:
 - (a) Can be used indoors and outdoors
 - (b) Allows individuals to take their first steps after five to ten sessions of training
 - (c) Can be worn over regular clothes
 - (d) Has a battery that lasts about 6 hours
 - (e) Allows users to attain a speed of 3 km/hr, which is close to the speed of a community ambulator
 - viii. Currently available to institutions for clinical use and for research.
 - ix. Scheduled to become commercially available for personal use and training in 2012.
 - (a) Price range: \$90,000 to \$100,000.
 - (b) Clinical tests are underway for patients with spinal cord injuries and stroke.¹¹⁷

3. ReWalk

- a. Bilateral robotic exoskeleton.
- b. Motorized gears move the legs.
- c. Computer-equipped backpack with battery to power the device for 3 to 4 hours.
- d. Motion sensors and onboard processing monitor the upper-body movements and center of gravity.

BOX 38-13 ■ GAIT TRAINING WEARABLE ASSISTIVE ROBOTIC DEVICES FOR THE LOWER LIMB—cont'd

- e. When user shifts the body, the device steps in the proper direction.
 - f. Patient uses stabilizing crutches.
 - g. Developed by Argo Medical Technologies.
 - h. Available for institutional training.
 - i. ReWalk for personal use will be available by the end of 2012.¹¹⁸
4. Cadence Biomedical
- a. Cadence Biomedical walking system developed by Brian Glaister (Seattle, Washington) to assist with gait training in patients with weakness or loss of control of the lower limbs
 - b. Bilateral exoskeleton using springs to activate assistance at the hip and the ankle
 - c. Can be used unilaterally
 - d. Approved by the U.S. Food and Drug Administration for gait training.
 - e. Requires casting to fit the spring system into an exoskeleton.
5. STRING-MAN—wire robotic gait system
- a. Integrates robotic technology with control algorithm.
 - b. Developed at Fraunhofer IPK, Berlin.⁴²
 - c. Combines body-weight support with controlled weight suspension and postural control.
 - d. Provides automatic, comfortable, efficient, and adjustable preparation of the patient.
 - e. Has programmable system for controlling biomechanical patterns of gait.
 - f. Facilitates patient's own initiatives and effort (assistive).
 - g. Initial studies have been small but positive trends.
- C. Lower-limb assistive robotic devices with neuromuscular stimulation
1. Surface electrodes
- a. WalkAide
 - i. Facilitates dorsiflexion and eversion through electrical stimulation.
 - ii. Activates firing via the peroneal nerve when tibia moves anteriorly just after roll off and through swing phase.
 - iii. Commercially available for rent or purchase.
 - iv. Programmable: amplitude, frequency, timing.
 - v. Unit includes electrodes in a cuff; can be worn on left or right.
 - (a) Has a walking mode and an exercise mode
 - (b) Adjust amplitude to encourage joint effort of patient activation and electrical stimulation
 - (c) With time and improved dorsiflexion and eversion, may no longer be needed.
 - b. Bioness L300
 - i. Facilitates dorsiflexion and eversion through electrical stimulation.
 - ii. Activates firing via the peroneal nerve when heel lifted off ground at push off.
 - iii. Commercially available for rent or purchase.
 - iv. Programmable: amplitude, frequency, timing.
 - v. Unit includes electrodes in a cuff with controller around neck or in pocket.
 - vi. Can be worn on left or right, but best if patient has a left cuff and a right cuff.
 - vii. Has a walking mode and an exercise mode.
 - viii. Adjust amplitude to encourage joint effort of patient activation and electrical stimulation.
 - ix. With training, there has been improvement in dorsiflexion and eversion; sometimes device is no longer needed.
- c. Bioness L300 Plus for foot drop and thigh weakness
- i. Stimulates the quadriceps for knee extension
 - ii. Can be worn with the Bioness L300 for the ankle (usually they are sold together)
 - iii. Triggered with heel strike
2. Implanted neuromuscular stimulation
- a. Implant electrodes for single or multiple muscle groups.
 - b. For the ankle, implant electrodes for peroneal stimulation.
 - c. For sequential gait in patients with spinal cord injuries, implant a series of multiple electrodes for walking.
 - d. Facilitates sequential gait in patients with spinal cord injuries.
 - e. Eight- to 12-channel units have been implanted in several research studies for patients with partial cervical spinal cord injuries.
 - f. System has been well tolerated and reliable.
 - g. Has been associated with increased endurance and walking speed after 12 weeks of training.
 - h. Improves efficiency with practice.
 - i. Advantages: decreases skin irritation, can decrease amplitude necessary for activation.
 - j. Disadvantages: needles may be uncomfortable; can get infected.
 - k. Expensive and not necessarily user friendly for patient to use alone.
- D. Biofeedback-facilitated assistive robotic devices
1. Foot Mentor (Kinetic Muscles)
- a. Uses the same Mentor Pro device as the Hand Mentor.
 - b. Has different programs to facilitate foot dorsiflexion and extension exercises.
 - c. Picks up biofeedback cues from patient when asked to engage the muscles.
 - d. Assists the patient into the desired movements.
 - e. Practice at a fixed workstation.
 - f. Unit must be plugged in.
2. AMES—assisted ankle movement with enhanced sensation
- a. Uses biofeedback of voluntary joint torque.
 - b. Sensation of motion enhanced by tendon vibration.
 - c. Effective at restoring functional movement in lower extremity in profoundly disabled chronic stroke patients.
 - d. Did not restore functional movement at the ankle joint.
 - e. Continued development to try to convert electromyographic signals into useful biofeedback on a graphic display.

B

Figure 38-8 ■ Lower-limb robotic assistive devices (with and without NES). **A**, Tibion Bionic Leg. **B**, Ekso Bionics bilateral wearable lower-limb assistive device. (A, courtesy Tibion, Sunnyvale, Calif; B, courtesy Ekso Bionics, Richmond, Calif.)

Figure 38-9 ■ Lower-limb assistive robotics with neuromuscular stimulation. Bioness wearable lower-limb assistive robotic device with neuromuscular stimulation. **A**, Foot drop system. **B**, Knee extension system. (Courtesy Bioness, Valencia, Calif.)

been positively associated with short- and long-term gains in gait speed, quality of gait, endurance, time in single leg stance, toe clearance, and balance.^{35,115,119,120} There is also positive evidence supporting the effectiveness of training with a neuroprosthetic ankle-foot gait trainer, with short- and long-term gains reported in gait speed, endurance, safety, and quality.¹²²⁻¹²⁶

For upper-limb assistive robotic training, there are positive trends for improving motor control, particularly in patients poststroke.^{84,96,105,106,127-143} Unfortunately, based on

a systematic review of upper-limb robotics,^{132,133} improved function in task performance and object manipulation was not necessarily correlated with improved motor control. The gains in motor control appear to be greatest when one-on-one care is supplemented with robotic training.

Research studies also report improved motor control with the integration of a neuroprosthesis in functional arm training (e.g., includes neuromuscular stimulation or biofeedback).^{82,144-146} However, although there are greater gains in motor control, these gains are not necessarily associated with improved function.¹⁴⁶

For both upper- and lower-limb neuroprostheses, greater gains are made by patients with the most spontaneous recovery before robotic training. In addition, earlier training appears to be associated with greater gains in motor control. Training needs to be repetitive and intense (several hours a week) for a period of time (e.g., 2 to 8 weeks). Unfortunately, some of the robotic devices for the upper limb do not have an end effector, limiting the gains in object manipulation.

For both upper- and lower-limb assistive wearable robotics, more research is needed in a variety of areas: comparing the effectiveness of unilateral versus bilateral training; functional benefits of wearable exoskeletons for the upper limb that have an end effector to allow better object manipulation; the benefits of one-on-one therapy supplemented with robotic training compared with one-on-one therapy or robotic training alone; timing of the robotic intervention; and intensity of training. It will also be necessary to determine whether a device should be leased for temporary use or purchased for long-term use.

Vocational Rehabilitation Robotics. Vocational rehabilitation robots are primarily designed to perform everyday activities. The user is significantly impaired and unable to independently perform everyday work activities without assistance. These robots help individuals perform occupational activities including the operation of equipment. These devices should be considered by the broader physical rehabilitation clinical team including social workers, employers, and psychologists.

Communication Devices. Most communication devices include communication aids (e.g., hearing aids, voice amplification systems, computer keyboards). However, there are some assistive robotic devices that are currently being used that are appropriate for patients who are deaf or blind. For example, the Dexter hand can act as a finger-spelling hand for patients who are deaf or blind. Because finger spelling is not understood by the general population, the Dexter also enables a person to input normal text and the Dexter converts it to finger spelling.

Another important element for communication is the ability to read a book. Designing a robot to turn pages has been very challenging. Although there are page-turning robotic devices on the market, they are expensive, bulky, and not reliable. New computerized book reading devices serve as an alternative for those with limited physical capacity to turn pages.

Emotional Interactive Entertainment and Friendly Robots. Emotional interactive entertainment robots (EIARs) are similar to VR systems. EIAR systems are designed for communication and emotional support.¹⁴⁷ EIAR devices can increase emotional comfort and give emotional relief to people who live alone.

Entertainment robots are mechatronic devices that exhibit animal-like behaviors.

For example, within the project Home Information Infrastructure House (HII) house, National Panasonic introduced a user-friendly home interface for older people as a memory jogger (e.g., cuddly toys). The speech synthesis can reproduce phrases and can be programmed to remind users to take their medications at a particular time. Failure to respond can activate a direct call to a caregiving staff member who can then check on the user. BECKY,¹⁴⁸ a friendly robot from Korea, demonstrates different behaviors according to the emotional status of the user. The seal robot and the cat robots from Japan^{149,150} provide interactions between hospitalized human patients and the pet robots. The Autonomous Robotic Remedial Activity (AuRoRA) Project^{151,152} applied robots to education and therapy for children with autism.

SCREENING PATIENTS FOR THE INTEGRATION OF ROBOTIC TECHNOLOGY

General Screening

The criteria used to determine which patients might benefit from rehabilitative technology will change over time. Screening is partly an art that includes sensitivity to the individual and the family, as well as a science. Before screening a patient for robotic technology, clinicians need to be certain that all standard assistive devices have already been integrated into the individual's rehabilitation program. Ultimately, guidelines should be developed to match the potential of the individual with the prognosis for independence, with and without dependable, user-friendly technology.

An objective evaluation is needed to match a patient with a commercially available robotic device. This evaluation must include a thorough assessment of anatomical, physiological, cognitive, and sensory impairments. Whenever possible, standardized tests should be used to document strength, flexibility, endurance, balance, coordination, synergistic responses, hypertonicity, gait, balance, posture, and postural righting skills. These impairments need to be integrated into functional and task-specific assessments of motor learning, motor control, activities of daily living (ADLs), work requirements, and recreational needs. Then each patient should be screened by defined objectives relative to outcomes in terms of quality of life and independence. Subjective and emotional issues such as attention, motivation, history of positive health behaviors, durability, depression, desire for independence, and commitment to learning must also be considered. Many of these assessment tools are described in Chapter 8. The challenge is to determine if achieving rehabilitation goals requires integration of advanced technology and whether the patient has the potential to be trained to benefit from the prescribed technology.

Specific Screening by Type of Robotic Device

Table 38-2 summarizes some screening criteria that could be used by the therapist to determine if a patient can include rehabilitation technology into the plan of care in order to maximize function. This table also summarizes the level of function required by the patient to be able to effectively use robotic technology to improve independence and quality of life. The criteria to assess patient needs and abilities are classified by type of robotic technology. The criteria are

neither all-inclusive nor exclusive but serve as a starting point for a therapist to make a recommendation for this type of technology to be considered.

Screening Patients for a Service Robotic Device (e.g., Motorized Wheelchair)

Motorized wheelchairs are the most common type of "service" technology used in rehabilitation. Motorized wheelchairs are designed for patients who have extreme weakness of the legs, upper limbs, and trunk and who cannot use a manual wheelchair to achieve an element of independence. One of the most important issues to consider is how the individual patient will control the wheelchair. Frequently this is a team decision including the patient, the family, the therapist, and the supplier.

When a patient is going to use a motorized wheelchair outdoors, consideration must also be given to car accessibility and public transportation. Many individuals will use a motorized wheelchair at home and around the neighborhood and use a manual wheelchair when traveling out in the community. For community integration with the motorized wheelchair, some special adaptations will be needed for the car. A drive-in ramp or a lift plus a seat belt for the person and the chair are minimum requirements. It may be possible to install driving controls for the hands instead of the feet and create a wheelchair-accessible van if the person has sufficient cognitive ability but has minimum control of the legs but good control of the hands and arms. This control system requires the ability to grasp and release the steering wheel, turn a key in both directions or push a start button, and turn the steering wheel to the right and left with sufficient control of the head to look to the side and back to control the van in order to back up.

For those with limited ability to control a motorized wheelchair, automatically guided wheelchairs (AGWs) can facilitate transportation in the indoor environment. The AGW relies on verbal commands from the user and/or programmed responses. The programs are usually goal oriented. With these "go to goal" wheelchairs, the patient gives the command through a sound, a word, or pressure, and the navigational system automatically manipulates the chair to the goal. The AGW will work best in a structured or semistructured environment in which the locations of objects in the environment are fixed. These devices usually have passive sensitivity, with sensors programmed for object location. Often the actuating and force sensors as well as the relays are mounted on the ceiling of the room. The sophistication of the sensors creates a variance in the cost of these chairs. The chair also needs to be integrated with other home service robots. Therefore a team including patient, family, therapist, and representative from the company providing the service robots should be involved in determining what is needed.

There are also new power assist wheelchairs (PAWs) for patients with acceptable upper-limb function. Shoulder strain is often an issue in patients who are very active in a manual chair. Thus the new PAWs are designed to minimize shoulder strain. They have been adapted specifically for patients with paraplegia after spinal cord injury.

If a patient also requires a home service robotic system to perform all ADLs and instrumental activities of daily living (IADLs) for the patient, a team would also be necessary to screen the patient to determine all the patient's needs as well

TABLE 38-2 ■ SCREENING PATIENTS FOR INTEGRATING ADVANCED TECHNOLOGY OR REHABILITATION ROBOTICS INTO NEUROREHABILITATION

SCREENING CRITERIA	SERVICE ROBOTIC DEVICES	ASSISTIVE ROBOTIC DEVICES	
		NONWEARABLE— MOBILITY AND UNWEIGHTING	WEARABLE—MOBILITY AND OBJECT MANIPULATION
Criteria for determining potential benefit for patient to integrate advanced or robotic technology	<p><i>Patient with severe physical impairments challenged to be independent without personal assistance:</i></p> <ol style="list-style-type: none"> 1. Has significant weakness of trunk and limbs (0, trace, poor) 2. Has minimal voluntary control of trunk and limbs 3. Cannot use a manual chair independently 4. Requires personal assistance to transfer to and from chair 5. Cannot step without maximum assistance 6. Unable to walk or stand independently 7. Unable to meet ADL needs without personal assistant 8. Is cognitively alert and aware 	<p><i>Patient with mobility impairments compromising safety, full independence, and quality of life:</i></p> <ol style="list-style-type: none"> 1. Has impaired ability to walk 2. Has poor or slow balance responses 3. Demonstrates unstable single-limb support (unilateral or bilateral) 4. Is at risk of falling 5. Could benefit from fall protection when standing 6. Is weak (has poor strength) 7. Has difficulty initiating stepping 8. Lacks high-quality voluntary control for walking 9. Has involuntary synergistic movements 10. Has reduced flexibility 11. Uses an assistive mobility device 12. Needs to reduce ground reaction forces when walking or during intense exercise owing to pain, inflammation, osteoporosis, joint replacement, incoordination, and so on 13. Walks very slowly (household ambulatory but limited community ambulation) 14. Must maintain cardiopulmonary and metabolic health 15. Could benefit from stimulation of neurotransmitters and endorphins 	<p><i>Patient with impairments compromising mobility and/or independent task performance at home, at work, or during recreation:</i></p> <ol style="list-style-type: none"> 1. Is unable to perform common daily tasks for independence without an assistive device or personal assistance 2. Needs assistance at one or more joints 3. Needs assistance to complete a task 4. Takes excessive time to complete task 5. Needs assistive device to ensure stability to walk 6. Has experienced a fall or an injury when performing a daily task (e.g., toileting) 7. Cannot live safely alone without personal assistance 8. Cannot cross the street in time 9. Needs more controlled forced task practice 10. Needs assistance to improve quality 11. Is not afraid of computerized or electromechanical devices 12. Is learning “abnormal” movements 13. Lives alone, but safety is in question 14. Drives but needs some assistance with transfers and/or arm or leg movements

Screening criteria to determine if patient has the **ability** to use advanced or robotic technology

Patient has potential to achieve independent wheelchair mobility and ADLs at home with reduced human assistance:

1. Has cognitive ability to control motorized and robotic devices
2. Has the sensory, physical, and cognitive abilities to control a motorized chair (e.g., via joystick, head movement, button press, breath, piezoelectricity, voice) without human assistance
3. Can activate an automated harness system to transfer into a wheelchair
4. Can sit in a chair with or without positional assistance
5. Has sufficient understanding and ability to activate robotic service and emergency devices to be independent without human assistance (smart house designs)

Patient has the potential to improve walking quality and speed, endurance, and independence with progressive practice or training:

1. Has cognitive ability to participate in training
2. Has sufficient attention and understanding to cooperate in gait training
3. Has adequate head and trunk control to maintain postural uprightness when legs moving
4. Has sufficient strength in legs to stand up when unloaded or protected from falling
5. Has some sensation in lower limbs or can see legs
6. Has partial movement in major muscle groups in lower limb (hip, knee, ankle)
7. Has sufficient range of motion to get into standing or walking position
8. Can transfer onto the treadmill or transfer from chair to standing
9. Tone does not prevent the feet from staying on the ground or stepping when unloaded
10. Has ability to step when standing over ground or over treadmill
11. Steps after perturbation of the treadmill
12. Can swing leg through clearing floor or treadmill (with or without AFO).
13. Stepping speed can be changed with treadmill speed
14. Can tolerate training several hours a week

Patient has the sensory, physical, and cognitive ability to control a wearable device to achieve independence in mobility and/or object manipulation:

1. Has intellectual ability to understand how to use the wearable assistive orthotic device
2. Has the ability to don the wearable assistive device (or has someone at home to help)
3. Is motivated to use a wearable assistive robotic device to improve independence
4. Has basic stability of the head and trunk to move the limb(s) (even if positioning device is required)
5. Involuntary movements do not interfere with robotic assistance
6. Has adequate standing balance (with or without cane or walker) to work with a wearable assistive orthotic gait training exoskeleton
7. Has the range of motion to allow full or partial task function
8. Has adequate sensation to sense rubbing and chaffing of orthotic device
9. If inadequate sensation, has sufficient vision, audition, touch, or cognition to monitor wear and control of interface
10. Has adequate strength to lift the weight of the exoskeleton
11. Has sufficient voluntary control to assist the exoskeleton
12. Able to use the robotic assistive device several hours per day
13. Has the physical, sensory, sensorimotor, and/or cognitive skills to control the interface of the assistive robotic device
14. If unable to meet 13, may be eligible for advanced technology using a brain interface

TABLE 38-2 ■ SCREENING PATIENTS FOR INTEGRATING ADVANCED TECHNOLOGY OR REHABILITATION ROBOTICS INTO NEUROREHABILITATION—cont'd

SCREENING CRITERIA	SERVICE ROBOTIC DEVICES	ASSISTIVE ROBOTIC DEVICES	
		NONWEARABLE— MOBILITY AND UNWEIGHTING	WEARABLE—MOBILITY AND OBJECT MANIPULATION
Screening criteria to determine temporary versus permanent need for technology	<p><i>Patient has:</i></p> <ol style="list-style-type: none"> Goals and objectives to be functionally independent without personal assistance Predictable disease- or impairment-specific issues that are not going to change or may get worse A support system (family or community) to check on status at home Home that can be modified to accommodate robotic equipment 	<p><i>Patient has:</i></p> <ol style="list-style-type: none"> Goals and objectives to be functionally independent without personal assistance Predictable disease- or impairment-specific issues that necessitate regular exercise to maintain independence A progressive neurodegenerative condition that could be slowed with regular exercise A support system (family or community) to check on status at home Access to public transportation to access resources The ability to drive (e.g., take driver's training or simulation; car modification) to maintain independent access to needed resources 	<p><i>Patient has:</i></p> <ol style="list-style-type: none"> Goals and objectives to be functionally independent without personal assistance Predictable disease- or impairment-specific issues that require regular exercise to maintain and maximize independence despite injury or disease Ability to maintain if not maximize independence despite injury Ability to use robotic technology to improve functional recovery Ability to put on and remove the assistive devices Ability to slow down progression or maintain or improve function despite neurodegenerative condition that could be slowed with protected, guarded, stress-reduced intense exercise A support system (family or community) to check on status at home Access to public transportation to achieve community independence Ability to maintain independent community driving with regular training, simulation, car modification
Screening criteria to determine safety	<p><i>Patient has:</i></p> <ol style="list-style-type: none"> Ability to call for emergency help if devices do not work Secondary harness systems to prevent falling with robot-assisted transfers Ability to manipulate control devices to stop or encourage function of the robot Ability to turn off the robot when inappropriate movements develop 	<p><i>Patient can:</i></p> <ol style="list-style-type: none"> Safely step on and off the treadmill Tolerate the tension of the harness or unweighting system Spontaneously step as triggered by the moving treadmill Express concern if exercising beyond his or her limits Manipulate the parameters of the treadmill Tolerate the end range parameters for performance (e.g., high speed) 	<p><i>Patient has:</i></p> <ol style="list-style-type: none"> Adequate sensation to notice increased pressure or chaffing or skin sensitivity to electrodes Ability to decrease the hypertonicity that interferes with function or causes pain Sufficient cognitive awareness to recognize abnormal robotic behaviors (e.g., forced movement in abnormal directions) Ability to stop excessive, abnormal movements Ability to initiate self-directed movements with robotic assistance

Screening criteria to determine **accessibility** of advanced or robotic technology

Patient has:

1. Access to financial resources to afford advanced technology
2. Access to technology that is currently commercially available
3. Access to technology that is currently accessible in his or her geographical area
4. Opportunity to arrange for technical help to maintain equipment
5. Evidence available in terms of cost-effectiveness
6. Insurance that will help cover costs

Screening criteria to determine **cost-effectiveness** of advanced technology or rehabilitation robotics

There are clinical research trials reporting:

1. Objective outcomes as measured by decreased personal assistance, which can be documented in terms of hourly costs saved
2. That resource investment costs can be amortized across 5 years
3. That patients could gain 5-10 years of independent function at home
4. That the patient would be able to sustain independence at home (versus in skilled living environment) in the last few months of life

Patent has:

1. Resources to purchase needed equipment for home use
2. Resources to pay to use equipment in the community
3. Equipment that is commercially available in his or her community
4. Equipment available in the community
5. Evidence on cost-effectiveness of the technology
6. Insurance that will help pay for lease or purchase

1. Objective outcomes focused on maintaining independence at home in lieu of an extended care facility
2. Patient can minimize falls and decrease risks for inpatient stay resulting from fall injuries
3. Patient able to sustain safe, independent indoor navigation without personal assistance
4. Patient able to get out of house and move in community independently or with public transportation

Patient has:

1. Resources to obtain assistive robotic devices
2. Access to commercially assistive robotic devices in his or her area
3. Ability to have equipment brought to his or her residence
4. Access to someone to fit, maintain, and repair the device
5. Evidence on cost-effectiveness
6. Insurance to assist with payment

1. Objective outcomes focused on maintaining independence at home
2. Patient can perform ADLs and community activities safely
3. Patient uses assistive devices to minimize risk of falls
4. Patient remains committed to brain and physical fitness
5. Patient maintains safe, independent indoor and outdoor navigation without personal assistance
6. Patient able to get out of house and move in community independently or with public transportation

ADL, Activities of daily living; *AFO*, ankle-foot orthosis.

as to assess the availability and accessibility of resources. The team needs to include a representative from the company that would be creating the “smart house” to enable the patient to be independent with minimal personal assistance. Refer to [Appendix 38-A](#) for potential Web addresses for various companies offering this type of service.

Specific Screening of Patients for Assistive Nonwearable Robotic Technology: Example of Body-Weight–Supported Gait Training Technology Systems

The patient needs to go through general and specific screenings to determine the appropriateness of integrating a nonwearable assistive robotic device into the rehabilitation program (see [Table 38-2](#)). The patient who is most likely to benefit from body-weight–supported gait training is the patient who has the prognosis for functional independence but needs to train to improve quality, endurance, speed, and stability of gait. Thus many patients with problems described within this text might benefit from this type of training. Those who do not have the potential for independent ambulation could still benefit from training on a BWSTS. In these cases, the training would be directed toward enhancing metabolic health, providing a sense of well-being, increasing circulation, and minimizing secondary impairments associated with excessive sitting such as decubitus ulcers and bone demineralization. These patients may need robotic, human, or harness assistance to achieve standing or stepping as well as bracing of the neck and trunk when upright. Patients with joint pain in the back or knee may also benefit from wearing supports when standing or exercising.

If a patient does not demonstrate the ability to bear weight on a single limb, then robotic control of the lower limbs may be the preferred mechanism to facilitate secondary benefits. When all the movements are passive, however, there will be minimal gains in terms of neural adaptation and reorganization. On the other hand, it may counter the secondary problems of bone demineralization and decubitus ulcers and be of value as a maintenance strategy.

In spite of advancements in rehabilitation robotic technology, some patients may still have difficulty taking advantage of this type of therapeutic assistance ([Box 38-14](#)). In patients with challenging impairments, for safety the use of an overhead harness to access the treadmill may be required, in addition to close supervision by one or more therapists.

Specific Screening of Patients for Wearable Assistive Devices

Most patients with temporary or permanent sensory, motor, or structural impairments can benefit from training with a dynamic wearable assistive device. However, there are currently no guidelines that can be applied to assist a clinician with objective screening. Some screening criteria have been developed to try and match patients to devices, with a focus on safety.^{10,11,86,94,153-157}

Screening must be sensitive to the characteristics of the individual and consistent with factors in [Table 38-2](#). After identifying the parameters of performance and the potential benefits of assistive wearable technology, the patient, the family, the therapist, and sometimes the orthotist should determine what assistive robotic devices or advanced technological equipment are available to meet the patient’s needs. The team

BOX 38-14 ■ MATCHING PATIENTS TO EFFECTIVE WEARABLE ROBOTIC DEVICES

In attempting to match a patient to an effective wearable assistive robotic device, several questions must also be asked about the dynamics of the robot providing assistance:

1. How much force can the robot safely exert to overcome resistance from hypertonicity?
2. How strong does the patient need to be to overcome the weight of the wearable assistive robotic device?
3. Does the robot need to be programmed across multiple joints to move with high-quality movements?
4. Does the robot need to stop if the individual does not initiate movement in the exact pattern of the programmed assistance?
5. Is there negative learning when there is a mismatch between the patient’s movements and the robotic assistance?
6. Can the amount of assistance provided be dynamically controlled by the robot while being based on the patient’s need for task performance?
7. Can the therapist or the patient easily modify the assistance given by the wearable robotic device?

also has to assess where the devices are located, whether they are accessible, whether the device should be rented or purchased, and whether the insurance company will help pay for the rental or purchase of the device.

Ideally patients will use a wearable robotic assistive device to try to drive neural adaptation to recover function. Thus some patients may “train out” of the robotic device as they recover more function. Obviously, it would be better for these patients to rent rather than purchase the orthotic. Other patients would benefit from purchasing the assistive device because the robotic device improves function and independence despite ongoing impairments. Long-term use is also common when a patient has a degenerative condition, when the impairments are likely to get worse rather than better, and when with assistance independence can be prolonged.

In addition to the general and specific screening criteria, it is important to note that some assistive robotic devices may target control of one specific joint. However, given the biomechanical links, flexibility and sensory and motor characteristics must be assessed at each major joint above and below the primary assisted joint. For example, the Tibion Bionic Leg (see [Figure 38-8, A](#)) focuses on assisting the knee, but the patient’s hip and ankle also should be assessed. The less affected side also needs to be evaluated. To maximize the benefit of a wearable assistive device, patients should ideally have some ability to voluntarily initiate movement and a grade of poor or greater strength to be able to assist in the movement.

Wearable robotics must be programmed to assist patient function but also to stop to avoid harm. This requires a balance between the dynamic nature of the wearable assistive device and a patient’s weakness, lack of voluntary motor control, and the presence of involuntary muscle activity including hypertonicity (e.g., spasticity, dystonia, rigidity, tremor) ([Box 38-14](#)). For example, how much force would the assistive device need to provide to overcome involuntary tone? Other relevant questions must then be asked: If a

robotic device is programmed to assist with flexion and the patient initiates movement into extension or abduction, will the robot have to stop assisting the limb to prevent harm? If the robot stops assisting, is there a negative effect caused by the mismatch of force between the patient and the robot? Does the patient need consistent assistance or variable assistance? How will the therapist, the robot, or the patient determine how much assistance is needed? In one case a patient may need unweighting of only a limb, and in another case both unweighting and assistance may be needed. In theory, the amount of assistance needed should decrease with recovery of function. Thus it is helpful if the wearable assistive device can easily be adjusted by the therapist or the patient.

Despite the advancements in rehabilitation robotics, some patients will still have difficulty wearing an assistive orthotic. For example, wearable assistive orthotic devices may not work well for patients with severe sensory impairments, severe balance problems, a fear of falling, or inadequate assets to control the device or for elderly patients who are afraid of computerized technology (see [Box 38-15](#)). Sophisticated rehabilitation robotic devices may also not be recommended for patients who are disoriented, who have severe pain or neural hypersensitivity, or who cannot don the apparatus independently ([Box 38-16](#)).

It may be appropriate and helpful for patients with severe sensory and motor impairments to train using VR technology with or without assistive technology. Patients may begin with mental imagery and practice before engaging in physical practice, without and then with the integration of wearable robotic devices. It is also possible to begin the training with the assistive technology while in a harness system to protect from falling. In addition, depending on the severity of balance and voluntary abilities, it may be necessary for patients to train with technology under careful direct supervision. In cases in which balance and motor control are good but can be improved, it may be possible for patients to train at home with wireless telemetry-type supervision.

BOX 38-15 ■ IMPAIRMENTS THAT INTERFERE WITH UNWEIGHTED GAIT TRAINING

Individuals with the following impairments may not be good candidates for use of body-unweighted gait training:

1. Severe cardiopulmonary disease
2. Severely high blood pressure
3. Unstable blood pressure when standing or walking
4. Uncontrollable seizures
5. Uncontrolled diabetes
6. Complete loss of sensation
7. Unhealed incisions
8. Pressure sores
9. Severe and fragile osteoporosis
10. Unexplained swelling or lymphedema of the lower limbs
11. Severe contractures of the legs
12. Vegetative state
13. Inability to communicate
14. Uncooperativeness
15. Lack of head control

BOX 38-16 ■ INTERFERENCE WITH COMPLIANCE WITH WEARABLE ASSISTIVE ROBOTIC DEVICES

Specific cognitive or emotional impairments might interfere with compliance with and benefits of retraining with a wearable assistive robotic device. Patients with such impairments include the following:

1. Patients who are afraid of computerized or advanced technology
2. Patients who are confused, hallucinating, or unable to understand how to don the device or how the robotic device works
3. Patients with excessive hypersensitivity of the skin, severe pain, or complete loss of sensation to touch

If the patient does not meet the cognitive screening criteria for using either physical or cognitive sensors to control a wearable robotic, then a more sophisticated psychocognitive screening may be necessary. In these cases, biomagnetic imaging may be appropriate to determine if the individual could benefit from a wearable exoskeleton that has been mapped directly to the brain. Brain-mapped wearable robotic exoskeletons are available for patients with severe motor impairments. This brain-mapped wearable robotic allows the individual to use specific brain signals to help the individual achieve control of the limbs and the trunk to complete tasks. These brain-mapped wearable exoskeletons are still in the developmental stage. Most are not yet available on the commercial market.

OTHER ADVANCED TECHNOLOGY: CONTRIBUTION TO NEUROREHABILITATION

Virtual Reality Technology

Definitions and Benefits of Virtual Reality Technology

One of the most important issues in neurorehabilitation is creating the most effective training environment. To achieve maximum neural adaptation, training must be specific, task oriented, repetitious, spaced in time, progressed in difficulty, and salient to the outcomes targeted. VR technology allows the creation of the most applicable practice environment in which novelty, complexity, obstacles, task appropriateness, and progressive changes can be manipulated. With some virtual training, a therapist can conveniently immerse a patient into computer-generated multisensory, task-appropriate environments. This environmental variety can be stimulating, engaging, and fun, while enhancing compliance in practice. VR training can be not only adapted to the impairment or the acuity or chronicity of recovery but also directly related to the type of functional outcome desired. In addition, VR can be programmed for intensity and duration of training. Furthermore, VR training can be supplemented with traditional or robotic therapy. One additional attribute, and equally important, is that changes can be made efficiently in the virtual world while the patient and the therapist are in the same location.

VR is becoming increasingly popular as a way to enrich the environment for retraining the brain. It can be used as an

assessment measure, a training tool, an outcome tool, or a combination of all three. One of the greatest aspects of virtual environmental manipulation is that it can be done safely and rapidly without changing the venue of the patient or the therapist. Real-world situations surrounding task performance can be re-created while precisely and systematically manipulating environmental obstacles and constraints. Without danger to the individual, task difficulty can be increased. Sensory parameters can be changed, adapted, and scaled to the user's changing abilities. Object properties can also be changed easily, along with reliable changes in object location and orientation. In these VR environments, it is possible to study how individuals interact with objects and situations, particularly when changes are made in conditions within the virtual world. For example, for walking, it is possible to re-create real-work obstacles to develop adaptive responses—for instance, a perceived rock that needs to be stepped over. A variety of patient populations can be integrated in VR retraining paradigms; however, it cannot be assumed that VR training will be equally effective with patients with different types of movement impairments or medical diagnoses. VR can be designed to target regional neural reorganization or improve task functions.^{94,157-166}

A variety of VR paradigms were available at the time this chapter was prepared. These paradigms can be defined for an individual for supervised training, for multiple users, or for practice at home.¹⁶⁷ The types of VR training will continue to expand. In order to be able to compare outcomes with different approaches to VR training, there needs to be a way to categorize the paradigms. One way may be to organize the training according to the type of learning paradigm facilitated. Refer to [Box 38-17](#) for examples of some of these learning paradigms. Ultimately guidelines need to be developed to match the training paradigm with the patient impairments. A therapist will need to assess not only motor impairments but also emotional, cognitive, and perceptual impairments, especially when working with individuals who have sustained some CNS insult. This will not be a simple process. In addition to variability in patient impairments, the match needs to consider patient personality and age; user friendliness, costs, availability, accessibility, and location of equipment; ease of use; and supervision needed.

Does Virtual Reality Simulate Reality in the Physical Environment?

One important question is whether movement kinematics produced in virtual environments are associated with the same

kinematics in the real physical environment for healthy subjects and those with impairments (e.g., poststroke).^{157,159,160,168} In a VR study of reaching, grasping, transporting and releasing a ball, with one exception both healthy subjects and subjects with a hemiparesis used similar movement strategies in the VR environment as they did in the real environment. Both healthy controls and patients with hemiparesis used less wrist extension in the VR tasks, but healthy subjects reduced wrist extension more than subjects with a hemiparesis. In a three-dimensional VR environment, subjects had to place targets in different places with different combinations of arm joint movement. The task was to point quickly and accurately to each of six targets in a random sequence. Very few movement kinematic differences were reported in the different environments for healthy subjects and for poststroke subjects. Healthy subjects made faster movements, pointing more accurately with straighter endpoint paths than poststroke patients. The poststroke patients demonstrated less accurate movements and a curved path to the target with less trunk displacement. In another research study, there was an increase in movement time, and the movement endpoint trajectories were more curved in the virtual environment than in the physical environment for both healthy subjects and poststroke patients.

One criticism has been that VR environments lack real-life haptics, defined as the sensory interface of the patient and the object being manipulated. Some of the new virtual training systems now integrate haptic assistance, adaptive antigravity support, or even robotic technology to enhance motor outcomes. In one laboratory, traditional dynamic posturography was adapted to VR.¹⁶⁹ The objective of this study was to test and train postural righting behaviors in different virtual environments to simulate real-work conditions. It was hypothesized that shifts in spatial perception, visual inputs, and force perturbations would elicit normal positive postural reactions to right the body. Keshner and Kenyon¹⁶⁹ reported measurable gains in postural orientation with this type of training in the virtual environment.

Mental imagery is another way to manipulate the environment. This manipulation can be considered a variant of VR training. In this case, the patient mentally imagines performing tasks such as object manipulation or walking. This mental imagery can be guided or spontaneous. It can also include progressive and repetitive practice. It can also be combined with VR training and actual task practice.^{146,157,170-175}

Effectiveness of Virtual Reality Training

The major question regarding the interface of VR and the real world is whether task practice in a progressive, strategically manipulated environment is associated with a greater return of function compared to task practice alone. Is it possible that a virtual training environment would help patients specifically recover more recalcitrant skills—for example, could it drive greater neural adaptation to achieve higher levels of arm function in patients poststroke? Large research studies on the effectiveness of the different VR paradigms are still in their infancy. There has been some quantification of the physiological mechanisms of VR and the effectiveness of VR rehabilitation technologies based on laboratory testing, case studies, and small controlled trials, and large randomized clinical trials are needed to examine the benefits of different types of VR training in different types of VR paradigms.¹⁶⁰ If the evidence suggests that VR training

BOX 38-17 ■ EXAMPLES OF LEARNING PARADIGMS THAT COULD BE FACILITATED WITH VIRTUAL REALITY

- Movement initiation
- Action execution
- Feedback reinforcement
- Haptic feedback
- Augmented repetitive practice videocapture virtual reality
- Exoskeleton robotics integrated with simultaneous virtual reality
- Mental practice and virtual reality

significantly enhances the recovery of function beyond task practice alone, then studies on cost-effectiveness are needed. VR systems can be expensive. The incremental gains in performance must make a clinically significant difference in patient function in the community. If this can be documented, then guidelines for neurorehabilitation may need to integrate VR technology as a standard aspect of rehabilitation, particularly in the early stages of retraining.

Small randomized clinical trials have been carried out using VR training with and without robotics. The findings are positive in support of improved motor control. The results are less clear with regard to improved function.^{158,161-163,176-178}

One study of effectiveness has been reported by researchers using the commercially available Rehabilitation Gaming System (RGS) VR system.¹⁷⁹ This system specifically targets functional training to maximize plasticity after a neural insult. It is a noninvasive multimodal system of stimulation. It has been tested primarily for rehabilitation of the upper extremity of patients after stroke. RGS provides VR tasks in which the movements of two virtual arms are controlled by the subject's own arm movements. The RGS system incorporates a variety of tasks, graded in complexity and difficulty. The games can be adapted to the capability of the individual. RGS VR tries to model gaming in order to heighten arousal and performance as well as potentially being entertaining. The user is asked to reconstruct different elements of a variety of IADLs. The hypothesis is that action execution combined with observation of correlated movements in a virtual environment may activate undamaged primary or secondary motor areas, which will facilitate improved function.

The behavior in the virtual environment appears to be consistent with the behavior in the real world.^{158,160} Furthermore, effectiveness of the RGS VR was enhanced when the observation of hand movements was consistent with the orientation of the observer. For example, first-person perspective appeared to be more effective than third-person perspective in terms of driving cortical activation during performance of virtual tasks. Also, the first-person perspective appeared to recruit the motor system to a greater extent, allowing for integration of kinematic information. The integration of kinematic information in motor learning appeared

to result in a higher degree of representation and more effective functional reorganization. The researchers also observed that the behavior in the virtual environment was consistent with the behavior in the real world.^{158,160} The differences between paretic and nonparetic limbs were preserved. Each training task included 300 repetitions. Three hundred repetitions produced robust and accurate data. Given these data, it was possible to calculate the error distribution for the paretic and nonparetic arm. For both limbs, there was measurable arousal before a missed event. This finding suggests that this type of training or therapeutic environment could be another way to provide feedback. For example, just before the patient is likely to fail, the patient would be made aware of that potential rather than being given feedback about failure on the task itself. The physiological effects on heart rate were not consistently related to the stress of completing a task. On objective and functional tasks, the RGS VR group showed similar absolute improvement from baseline to week 5 compared with individuals in the control groups, who did not interface with a VR environment. However, in the second 6 weeks, the patients in the RGS VR group showed a higher mean increase in all of their outcome scores on functional measures, whereas the control subjects tended to plateau after 5 weeks.

Small randomized clinical trials have also been conducted on the effectiveness of mental imagery and improved motor control and task function.^{170,171,173,175,180} Usual therapy enriched with mental locomotor, kinesthetic, visual, or auditory practice was associated with greater gains in mobility for healthy patients and those with impairments. Specifically, elderly patients and poststroke patients made greater gains with a combination of auditory step rhythm imagery in addition to locomotor imagery. Other researchers have reported that poststroke patients had greater reductions in measured impairments and improvement in task-specific function in the upper limb after regular physical therapy and mental practice than after regular physical therapy alone.¹⁷⁵ However, although motor control improved with robotic-assisted virtual training using the WREX upper-limb robot, there was no correlation between these reported motor benefits and performance improvements.¹⁵⁹

CASE STUDY 38-1 ■ BEFORE AND AFTER VESTIBULAR REHABILITATION TRAINING USING A VIRTUAL REALITY ENVIRONMENT

Mrs. S. was a 52-year-old woman who came to the clinic with a diagnosis of unilateral vestibular hypofunction and a chief complaint of being unable to go into large crowds or stores or to shop without feelings of dizziness and disorientation. Clinical and laboratory findings revealed bilaterally reduced vestibular evoked myogenic potentials and a unilateral caloric weakness on the right. The patient reported onset of her symptoms one month ago with tinnitus and difficulty walking in crowds and in grocery stores. She was referred to physical therapy by a neuro-otologist. Mrs. S. signed informed consent to participate in a virtual reality (VR) treatment trial. The VR treatment trial consisted of testing of her function and symptoms pretreatment, during six intervention sessions, immediately posttreatment, and at a 6-month follow-up.

PROCEDURES

The Virtual Reality Protocol

Each VR session consisted of six 4-minute exposures walking and “shopping” on the treadmill. The Balance Near Automatic Virtual Environment (BNAVE) was used as the Virtual Intervention.¹⁸¹ (See Figure 38-10.)

The BNAVE consists of three walls that surround the person with a treadmill in the center. The patient was instructed to push the instrumented grocery cart (which had a force sensor on the push bar of the grocery cart) at the speed at which she wanted to ambulate through the store. The upper speed limit of the treadmill was fixed at 1.2 m/s. The specially designed treadmill was built to be wider than a normal treadmill to accommodate the turning required at the end of the grocery store aisle.

Continued

CASE STUDY 38-1 ■ BEFORE AND AFTER VESTIBULAR REHABILITATION TRAINING USING A VIRTUAL REALITY ENVIRONMENT—cont'd

The three rear-projected scenes were merged to form one image on the BNAVE screens with the hope that persons would be immersed and “feel” as though they were shopping in a grocery store.¹⁸¹ During the 4-minute exposures to the scene, Mrs. S. was introduced first to the easiest aisle (the white paper products). There were 16 different aisles, and they were designed to be increasingly more complex either via a greater number of products on the shelves, more vibrant colors, or a greater population density of products per square inch.

Mrs. S. was asked throughout the VR experience to “find” certain products in each aisle. She reported verbally when she found the product on the shelves and then continued walking. Some patients are able to continue to “walk” and “shop” at the same time. Mrs. S. was able to fairly smoothly ambulate through the store without stopping. She would occasionally slow down significantly if she was having difficulty finding a particular product and then would continue walking in the “store.”

Safety

The patient was secured to an overhead harness to prevent a fall. In addition, the therapist held a switch and could stop the treadmill if there was any indication that Mrs. S. was having a problem. The patient could also stop pushing on the grocery cart in order to stop the treadmill, plus the technician who ran the computer also had the ability to immediately stop the treadmill with a stroke of a key.

One last safety measure was incorporated into the design of the study. If the patient’s leg went too far back toward the edge of the treadmill, the motor turned off the treadmill immediately in order to prevent a fall. A physical therapist stood behind and toward the side of the patient and monitored the patient’s condition.

OUTCOMES

Mrs. S. tolerated the treatment well and the sessions never were terminated because of patient intolerance of the visual surround. Mrs. S. provided subjective ratings on a visual analog scale at the beginning and end of each VR treatment session (Table 38-3).¹⁸² The following symptoms were rated: nausea, headache, dizziness, and visual blurring. No nausea

was experienced, but she did rate symptoms of headache, dizziness, and visual blurring over the six sessions. Headache was experienced during only the first VR exposure. Dizziness decreased from 1.8 (10 is the maximum score) to 0.1 at the end of the last session. Visual blurring had the highest rating at the start, at 1.9; at the end of the last session her visual blurring was self-reported to be 0.1. She appeared to be better able to tolerate the virtual experience over the six treatment sessions. Over the six treatment sessions, she was able to progress from the first aisle to aisle 16, the most difficult aisle, where the products were much smaller and more closely packed on the shelves.

At the beginning of physical therapy, Mrs. S. was asked to complete the Dizziness Handicap Inventory (DHI),¹⁸² the Situational Characteristics Questionnaire parts A and B (SCQ-A and SCQ-B),¹⁸³ the Dynamic Gait Index (DGI),¹⁸⁴ the Functional Gait Assessment (FGA),¹⁸⁵ the Timed Up-and-Go Test (TUG),¹⁸⁶ a gait speed assessment, and the Sensory Organization Test (SOT) of computerized dynamic posturography.^{187,188} Data for all of these tests before therapy, after therapy, and at 6-month follow-up for Mrs. S. are included in Table 38-4. Scores on all measures were better after the 6-week VR intervention program except for the TUG, and the scores remained relatively stable at 6 months. Lower scores on the DHI, SCQ-A, SCQ-B, and TUG indicate improvement, and higher scores on the DGI, the FGA, gait speed, and the SOT are “better” scores.

Mrs. S. was very satisfied, as she was able to shop again without symptoms. A clinically meaningful change on the DHI has been reported to be 18,¹⁸² and Mrs. S. improved 34 points. The Activities-specific Balance Scale (ABC) change from 29% to 69% over the course of the VR intervention was probably meaningful, as Lajoie and colleagues¹⁸⁹ have reported that scores of less than 67% are related to increased risk of falling. Her DGI score improved by 4, which has also been reported to be clinically meaningful.¹⁸² Gait speed over the course of the intervention improved only by 0.07 m/s, and 0.1 m/s has been reported as a clinically meaningful change.¹⁸⁵ Overall, Mrs. S. made positive changes after the VR physical therapy intervention.

Figure 38-10 ■ The Balance Near Automatic Virtual Environment (BNAVE). A patient walking on the treadmill through the virtual grocery store while pushing a cart. The vest was worn to ensure safety.

Patient Simulator Robotics

Purpose

One area of robotics contributing both to improved rehabilitative care and education of rehabilitation professionals is the development of human programmable patient simulators. This section of the chapter describes programmable patient simulators that are currently available. Human programmable patient simulators can be used to replicate common physiological symptoms, as well as acute, critical care events that require quick, safe, and appropriate intervention so that when rehabilitation professionals encounter a similar situation with a patient they can respond more effectively.

Introduction

Simulation using task trainers, actors, and standardized patients is not new to the education of rehabilitation professionals. What is new is robotics.

Currently available robotic patient simulators can be programmed to demonstrate clinical signs and symptoms consistent with a diverse group of clinical conditions. The patient simulator can be programmed to present signs and symptoms that require a participant to analyze and differentiate the urgency of the situation, make a diagnosis, determine an appropriate intervention, and see the consequences of the action or inaction without compromising patient safety. A wide variety of clinical conditions and situations can be presented in an effort to ensure that during each simulation the participant has an opportunity to practice and receive feedback regarding performance. Simulation experience is critical for practicing how to respond to common as well as rare but critical events—for example, acute myocardial infarction (MI). The learner's ability to respond appropriately during a simulated event can increase the likelihood that rehabilitation professionals are adequately prepared to respond efficiently and effectively when encountering an actual emergency situation.

Technology

At the beginning of 2011 there were two primary manufacturers of human programmable patient simulators: METI Learning (www.meti.com/products_ps_hps.htm) in Sarasota, Florida, and Laerdal Corporation (www.laerdal.com/doc/86/SimMan) based in Wappingers Falls, New York. In this chapter on rehabilitation robotics, the properties and capacities of programmable patient simulators are discussed based on currently available models. This analysis will hopefully help rehabilitation professionals evaluate the benefits of new robotic simulators for professional education.

Features

The number of features available on programmable human patient simulators continues to increase the degree of realism (fidelity) and reflect both basic and advanced clinical features that are extremely useful for training rehabilitation professionals. In addition, there are several noteworthy observable features that can be used to elevate the degree of realism during simulation.

Size. The size of the adult human programmable patient simulator mannequins is similar to an average-sized full grown adult, but the weight is significantly less than average (approximately 85 pounds). In addition to adult models, there are baby simulators, child simulators, and birthing simulators. Some models are wireless. This discussion focuses on the features and properties of the adult high-fidelity simulators available in 2011.

Limb and Chest Mobility. The upper and lower extremities of most programmable patient simulator models have very limited passive mobility with the exception of the shoulders, hips, knees, and ankles which approach “normal” for an adult. The limited mobility of the limbs allows for some range of motion and bed exercises to be simulated, but clinicians will note the completely passive nature of the movement and that the limb weight is significantly less than normal. The chest wall moves and the excursion of the chest can be programmed to be symmetrical or asymmetrical. In addition, the rate and depth of ventilation can be manipulated during the course of a simulation.

Physiological Features. Many programmable patient simulators have the capacity to produce realistic physiological features. A library of normal and abnormal breath sounds, heart tones, bowel sounds, and other symptoms is available for simulating a variety of clinical conditions. The sounds and tones produced can change during the course of a simulation to reflect a change in “patient” status.

The simulator mannequins are typically connected to a series of lines and tubes to simulate a critical care environment (e.g., arterial line, intravenous line, electrocardiograph wires, nasal cannula). This allows the simulation participant an opportunity to identify the lines and tubes, verify their status, and practice “clearing” them. The simulator is connected to a patient monitor similar to those found in critical care settings. The monitor can be changed to display a number of different physiological variables including arterial blood pressure, pulmonary blood pressure, respiratory rate, cardiac rhythm, hemoglobin saturation, oxygen consumption, pH, temperature, and others. The value and number of variables shown on the monitor can be programmed to

change during the course of the simulation to mimic clinical conditions and/or a change in patient status.

Pulses are palpable in a variety of locations including carotid, brachial, radial, femoral, popliteal, and dorsalis pedis pulses. The pulse is synchronized with the electrocardiogram (ECG), and the pulse strength can be varied and changed during a simulation. When a simulation participant palpates the pulse, a notation is made in the computer log that specifies which pulse was palpated and at what point in time during the simulation the pulse was taken. In addition, when blood pressure is low, some pulses (e.g., the dorsalis pedis) are no longer palpable, simulating the clinical condition of hypotension.

High-fidelity patient simulators are capable of vocalizations. The simulation operator is able to speak through a microphone and/or use audio files to produce sounds that appear to come from the mouth of the mannequin. Cyanosis is simulated through the use of a light contained within the mouth that makes the lips and gums appear blue. The eyes can form tears, the eyelids blink, and the pupils are reactive to light. The skin in the forehead is capable of diaphoresis. In some areas the skin has “wound modules” that can be inserted and connected to ports that contain “blood” used to simulate bleeding from the wound site.

Cerebrovascular System Features. High-fidelity patient simulators can be programmed to replicate and display signs and symptoms (physiological features) consistent with an acute cerebrovascular accident (CVA). The simulator has the potential to display a slurred speech pattern, a drooping eyelid, asymmetrical pupils, and emotional lability. The simulator can state that its arm or leg feels heavy and that it cannot feel the limb. The patient monitor can be programmed to show a variety of changes consistent with an evolving CVA such as blood pressure, heart rate, and respiratory rate.

Cardiovascular and Cardiopulmonary System Features. The onset of an acute MI is a scenario commonly used in simulation. The patient simulator can be programmed to complain of chest pain while simultaneously developing diaphoresis. The patient monitor can show the changes in the blood pressure, heart rate, respiratory rate, and cardiac arrhythmias consistent with an acute MI. This scenario can be used to practice recognizing the signs and symptoms related to acute conditions as well as to practice health care team responses to acute crises. The advanced features of the cardiovascular system include the capacity to bleed from a variety of portals; the system permits health care personnel to practice advanced cardiac life support (ACLS) protocols and to practice team responses to medical emergencies. The ACLS features built into the patient simulators measure and record the rate and depth of chest compressions. In addition, the physiological response to a variety of drugs and clinical conditions is programmed into some models, allowing participants to witness the response to the administration of medications as well as adverse drug reactions and/or the acute onset of a clinical condition (e.g., acute MI). The advanced clinical features for the pulmonary system include the ability to intubate (esophageal and endotracheal) and insert chest tubes into the mannequin, allowing students and clinicians an opportunity to practice their clinical skills with “patients” who are intubated and/or have a chest tube.

A variety of cardiac arrhythmias are programmed into the patient simulators, allowing the operator to alter the ECG

tracing on the patient monitor during the course of a simulation. All of this physiological information is stored in the computer log and can be used during the debriefing session after the simulation to enhance the learning experience for participants.

Programmability of Patient Simulators

In addition to the features discussed previously, high-fidelity simulators have the capacity to be defibrillated and undergo cardioversion. The physiological response to many drugs and clinical conditions is programmed into some models so that participants can witness the acute response to the administration of medications as well as adverse drug reactions and/or the acute onset of a clinical condition (e.g., acute MI).

Costs of Establishing a Simulation Laboratory

The costs associated with establishing a simulation laboratory will vary with the type of programmable patient simulator selected, additional equipment required and/or desired, and the amount of training needed. The price for a mid-fidelity programmable patient simulator is \$10,000 or higher depending on the features; high-fidelity programmable simulators can cost \$100,000 to \$200,000 for top-of-the-line models with state-of-the-art features. However, the price of the simulator(s) is only a portion of the setup costs. Establishing a simulation laboratory will also require (1) space designed for the simulation laboratory; (2) audiovisual equipment; (3) networking infrastructure; and (4) training in how to operate the system. The cost for each of these individual components can vary markedly depending on the type of equipment and infrastructure present as well as the level of sophistication desired in terms of audiovisual and networking capacity.

Summary

Each new generation of programmable human patient simulators has improved our ability to teach excellence in analysis and problem solving in acute, critical care situations. Programmable patient simulators have advanced in (1) the degree of realism provided by the technology and (2) the ability of the operator to manipulate and alter the “patient” status at any point in time. These simulators are now placed in multidisciplinary clinical teaching centers in academic health care institutions. They are also incorporated into community-based training courses for practicing health care professionals. A high degree of realism can be provided during simulation using currently available robotics when high-fidelity simulators are placed in a realistic mock intensive care unit. The combination of a high-fidelity patient simulator and a realistic environmental setting provides an opportunity to train rehabilitation professionals to recognize and respond to changes in patient status and to practice working as members of a health care team without compromising patient safety.

Technology and Computer-Assisted Gaming for Learning at Home

Most of the programs developed for improving memory, learning, and physical skills are based on the principles of scientific research on how the brain learns. Scientific expertise is combined with new technologies, innovation, and

creative game playing. At a minimum, the effectiveness of this modality of learning must meet the criteria listed in Box 38-18.

A number of game formats are available to improve memory and physical abilities (Tables 38-5 and 38-6). Some of the programs involve the purchase of training CDs, some are free applications for smart phones, and others can be accessed from the World Wide Web by paying a monthly fee. Some gaming programs include packages of hardware and software, and others require purchase of individual components. Some components are mobile and others are nonportable. Some are for one user and others for multiple users.

Fitness of the Brain

Over the last few years, keeping physically fit has been emphasized for general positive health and aging. The evidence is accumulating that people can sharpen their brains. The computerized gaming industry has made a significant contribution to creating fun, interactive gaming activities for children and adults. Although some of the games can be played just for fun, others can improve physical fitness, memory, balance, and fine motor skills.

Current research suggests that regular brain exercises¹⁹⁰ and regular physical exercise can increase attention, improve efficiency and reliability of information processing, and maintain the length of our telomeres (a method of measuring aging).¹⁹¹ Intense, forced exercise may also be neuroprotective in terms of maintaining memory skills and motor function and decreasing depression, particularly in patients with neurodegenerative disease such as Parkinson disease.^{64,65} However, to be successful, the learner must invest some time to keep the brain fit and active. Not only should individuals participate in fun, rewarded, progressive learning activities, but older individuals need to be willing to learn something new each day, avoid habit and routine, take some risks, get out of the house, and have fun. Some companies offering brain fitness programs are summarized in Table 38-5.

BOX 38-18 ■ LEARNING-BASED CRITERIA FOR COMPUTER-ASSISTED GAMING FOR LEARNING AT HOME

1. There is an opportunity to practice with appropriate frequency and intensity.
2. The practice is matched to the ability of the learner.
3. The task is advanced in difficulty to challenge but not exceed learner ability.
4. Task practice and skill development are cross-trained, including redundancy to help facilitate lasting improvement.
5. Motivation is maximized with timely and positive feedback and reward.
6. The learning environment is safe enough that individuals will take some learning risks.
7. The content of training is age appropriate, engaging, and fun.
8. The learner is committed to complete the learning series.

Motivation for proactive brain training may be further enhanced by changes in social practices. For example, Geico (one U.S. insurance agency) noted that there were fewer automobile accidents in older individuals when they maintained their memory skills. As a result of this information, the company offers a discount on automobile insurance if individuals over the age of 55 years perform standardized brain fitness and driving simulated exercises.

Physical Motor Skills

A variety of gaming systems can be used to enhance physical motor skills of children and adults. In 2011, the most well known commercialized programs included Nintendo (e.g., Wii), Sony (EyeToy, PlayStation 2 and 3), and Microsoft Xbox 360 (Kinect). Each company produces new games on a regular basis. The games vary among the companies, but there are some similarities. Each company has sports games, balance games, competitive cognitive games, and physical skill performance games. All systems include games that can be played by one person or by two or more individuals. For the most part, scores are kept for the games, and the player tries to improve performance every time he or she plays. Feedback regarding success is provided both during the game and at the end.

These computerized game-oriented training systems can supplement “one-on-one” training in a rehabilitation environment. For each individual, the games should be selected to achieve a particular performance goal matched to the ability of the individual and integrated into the broader neurological rehabilitation program. Selecting the best system depends on costs, capability of the individual, space limitations, cognitive ability of the individual, and setup requirements. Some of the games can be played with the person standing or sitting. The similarities and differences among the systems by Nintendo, Sony, and Microsoft are summarized in Table 38-6.

In addition to commercially available game training for improving physical abilities, some researchers are developing special game training programs for patients with neurodegenerative diseases such as Parkinson disease. In one case, therapeutic interactive games are being designed to improve gait and balance in patients with Parkinson disease. Red Hill Studios has partnered with Dr. Glenna Dowling at the University of California, San Francisco and Dr. Marsha Melnick to develop a wearable suit with more sensitive sensor controllers in multiple sites. After donning the suit, the individual engages in virtual games that challenge body and limb movements. These types of programs are not yet commercially available but are likely to continue to be developed in the near future. It is important for individuals to remain both physically and cognitively fit as they age, and integrating these types of games is important not only for aging individuals but also for individuals aging with chronic impairments, progressive disease processes, and newly acquired medical conditions. Aging will become a part of most individuals’ future as long as their health or life activities do not limit their life expectancy. As the world’s population ages, the potential to use these types of preventative strategies not only enlarges in everyday life but should become common practice in neurorehabilitation.

TABLE 38-5 ■ EXAMPLES OF GAMING-TYPE PROGRAMS FOR IMPROVING BRAIN FITNESS

COMPANY	PURPOSE OF PROGRAM	DESCRIPTION OF PROGRAM	MODALITIES ADDRESSED	SPECIFIC PROGRAMS	EQUIPMENT NEEDED AND PROGRAM REQUIREMENTS
Posit Science (www.positscience.com)	<p>Programs built on the principle that the brain is adaptable across the life span based on continued challenges and engaging, attended activities.</p> <p>Purpose of programming is to improve alertness, attention, accuracy of short- and long-term memory skills as well as speed of remembering and thinking.</p>	<p>Computerized, fun, rewarded game-type programs created as a translation of the research on neuroplasticity carried out by Michael Merzenich. Exercises provide feedback on progressive accomplishments.</p> <p>Total of 40 hours of learning exercises and programs.</p> <p>Can track multiple users.</p> <p>Posit Science is also working on the development of other sensorimotor training modalities to improve balance, fine motor control, and sensory processing.</p>	<p>Brain Fitness emphasizes accurate, reliable, and quick auditory and spatial memory.</p> <p>InSight uses useful field-of-view “visual training technology” to help individuals increase processing speed and peripheral vision, improve driving skills, and be safe.</p>	<p>Brain Fitness (auditory and spatial memory).</p> <p>InSight (visual and visual perceptual memory).</p>	<p>Computer (PC or Mac), keyboard, Internet access, headphones, mouse.</p> <p>Must register program online after opening.</p> <p>Can purchase multiuser systems.</p> <p>When there are questions, it is possible to visit the Cognitive Club at www.cognitiveclub.com to find an answer, ask questions of other users, or send a message to Posit Science; or users can call a customer service agent.</p>
Lumosity www.lumosity.com	<p>The programs are built on the theoretical construct that the brain is adaptable and new neurons can be trained across the life span.</p> <p>The exercises are appropriate for the young and the old, with an emphasis on improving cognitive thinking through spatial working memory and visual attention.</p> <p>The games progress in difficulty as the individual plays.</p>	<p>The three neuroscience and cognitive psychological specialists who created this software program were Kunal Sarkar, Michael Scanlon, and David Drescher.</p>	<p>Game-oriented learning.</p> <p>New games are developed and posted on a regular basis.</p> <p>The games are interesting and motivating.</p> <p>The games can be easy or hard.</p> <p>Games can progress in difficulty.</p> <p>The goal is to force the brain to learn.</p>	<p>Programs change with new ideas.</p> <p>Programs can be personalized to client defined issues.</p>	<p>Computer, Internet access, keyboard, mouse.</p> <p>Membership based; anyone can join.</p> <p>Can purchase monthly or life-time membership.</p> <p>Member can go online at any time to engage in training.</p> <p>It is possible to download the games to a smart cell phone to create opportunities to train any at any time.</p>
Scientific Learning	<p>Program based on the translation of science on neuroplasticity to training kids with dyslexia and other reading and learning problems.</p> <p>The product enhances brain fitness (memory, attention, processing, and sequencing) as well as cognition (accelerated acquisition of knowledge, improved ability to use and organize information, and readiness to improve strategies for lifelong learning).</p>	<p>The company was also founded by Michael Merzenich, William Jenkins, and Paula Tallal.</p> <p>The program is called Fast ForWord.</p>	<p>The Fast ForWord program is sold to school districts for working with children with reading problems.</p> <p>Some of the programs can be initiated and practiced at home.</p> <p>The programs are particularly beneficial for learners who have difficulty paying attention and difficulty remembering what they are taught.</p>	<p>The evidence suggests that learners can progress 1-2 years in reading in as little as 8-12 weeks.</p> <p>The success of this program appears to be integrating brain fitness exercises with standard-based curriculum-based instructions.</p>	<p>Computer, Internet access, keyboard, mouse, headset.</p> <p>Primarily available at the school.</p> <p>Families can purchase home reinforcement programs.</p> <p>Parents can help their children by using online instructions.</p>

TABLE 38-6 ■ COMPARISON OF LEARNING-BASED GAMING SYSTEMS TO IMPROVE PHYSICAL ABILITIES (2012)

NAME	CONTROLLER	CAMERA	MICROPHONE	SENSOR METHOD	LIGHTING	NUMBER OF PLAYERS	OTHER USES	ADVANTAGES	DISADVANTAGES	OPTIONS
Wii (Nintendo)	Hand-held	No	No	Accelerometer. Must hold controller and move; need to encourage large movements. Each person must have controller.	Normal room lighting	One to six; tracked by controller numbers.	Can get Weather Channel	Portable if on a movable platform; price includes full program. Games are fun. Allows competition between players. Can use indoors or outdoors.	Each player has to hold own controller; tracks simple movements, not complex movements. A cartoon figure is shown, not the user.	In 2012 the reasonable price included controller, balance platform, and two games.
EyeToy (Sony)	Movement	Yes, but needs webcam	Yes	Movement of body and limbs of individuals.	Has a lighted ball	At least two and can be more. Players are camera monitored.	Can use screen for TV	Portable if monitor and cameras on a mobile platform. Cannot be used in sunlight. Games are fun. User sees self, not a cartoon. Monitors more complex movements than Wii.	Limited camera recognition of multiple players. No other uses (e.g., cannot use with TV or CDs).	In 2012, must buy as separate parts; more expensive than Wii.
Kinect	Movement	Yes; complex camera; can track multiple players	Yes	Movement of body and limbs of individuals.	Needs some extra lighting for the camera	Up to six individuals, tracked with camera.	Can use for TV, CDs, and going online	Monitors more than one person. Monitors complex motions. Fun to play games. Large movements followed. Players see themselves. Allows high exertional movements. Can also be used as TV and to play CDs. Company released applications for research purposes (www.pointsclooud.org).	Not portable. Must use indoors. Cannot be used in sunlight. Hard to interface with exoskeleton, as must see whole person.	In 2012, the Xbox 360 is more expensive than Wii and EyeToy. Must buy separate parts.

Effectiveness of Learning-Based Gaming to Improve Cognitive Ability and Physical Motor Skills

General exercise in addition to learning-based training can improve mental alertness and sense of well-being. As our society ages, the combination of engaging in forced exercise and forced learning can be effective in maintaining physiological function despite aging or chronic disease. The use of gaming strategies to enable progressive learning-based training is fun and positively correlated with improved skills.^{175,179,190,192-204} If an individual were to force himself or herself to engage in new learning activities every day along with general, forced moderate- to high-intensity exercise, then gaming-type learning would not be necessary. On the other hand, when a learning activity is fun, individuals are more likely to be compliant.

Using Technology to Create Home Exercise Programs

A less complex but nonetheless important aspect of merging technology is the link between teaching a home exercise program to patients by using verbal or written instruction or demonstration, and the availability of the World Wide Web network, through which complex exercises can be explained, simple and complex movements can be demonstrated, and compliance can be recorded. Clinicians are able to identify, select, and change home exercises based on patient need, then direct the patient to view the program for visual feedback and reinforcement. Patients can then easily practice and review how to do those exercises each time they choose to perform the home program.

The current reimbursement system in health care (see Chapter 10) limits the billable time a physical therapist can spend with the patient. When a practitioner has to make a choice between providing professional expertise for hands-on care (e.g., manual therapy, neuromuscular facilitation, advanced balance, and mobility training) versus instructing patients on therapeutic exercises the patient needs to do at home, the therapist frequently chooses the former rather than the latter. All too often, the patient's exercise instructions include a quick demonstration of the exercise and a sheet of exercise instructions, with or without illustrations. This limited instruction usually occurs because the therapist does not have an efficient way to teach the desired exercises or reinforce the quality of exercise performance when the patient goes home. Fortunately, the advances available on cell phones, the Internet, videophones, and other personal devices offer a possible solution that links technology to potential home exercise programs. Similarly, we have learned that individuals activate the brain not only when physically practicing a new movement but also when watching movements, imagining movements, and mentally rehearsing movements. Thus, clinicians should consider the integration of visually enhanced Web-based teaching programs to more effectively and efficiently teach home exercises to patients.

Background

Early theories of motor learning viewed feedback as a simple stimulus-response event that was used to reinforce learning and conditioned responses.²⁰⁵ Later, the importance of the information contained in the feedback was found to be

more important than the reinforcement characteristics. As a result of this research, motor learning was divided into three artificial phases of learning: declarative-cognitive (i.e., a verbalizable representation of the movement), associative (i.e., comparing and contrasting the current task and performance with prior memories), and autonomous (i.e., relatively automatic performance of the well learned task with minor modifications).^{206,207} Refer to Chapter 4 for additional concepts and applications regarding principles of motor control, motor learning, and neuroplasticity.

There is one major exception and conflicting method of learning that appears to “skip” the declarative or cognitive stage of learning: learning by observation and imitation. Although learning by imitation appears to skip the verbal instruction stage, a human would be able to verbally describe the movement. In some pathological instances, such as severe autism, there are exceptions to this ability to imitate, but for the most part observational learning is pervasive in the natural world.^{208,209}

Research into observational learning has spanned the last 150 years. Initially it was concluded that observational learning was of no importance and not helpful.^{210,211} Other authors have described it as useful but not cognitive in nature.^{212,213} Badets and colleagues²¹⁴ argued in favor of a role for observational learning aiding in the cognitive phase of learning and that it is useful in error detection. Observational learning has also been described as highly beneficial for the associative phase of learning, most beneficial when combined with physical practice. It has been found to be very similar to actual practice in terms of learning benefits, performance, retention (memory), and cortical activation patterns.^{215,216} With the increased availability of neuroimaging techniques, more research has been done looking at areas of brain activation during *performance* of a motor skill, *mental imagery* of the performance of a motor skill, and *observation* of a motor skill.²¹⁷⁻²¹⁹

In research studies using relatively simple hand and finger tasks, the activated areas of the brain were generally expected regions, including all the major motor cortices and the cerebellum.²¹⁷ Similar tasks were then used to test the cortical activation levels of the brain when the subject was instructed to imagine performing the movement. The resulting cortical activation levels were also similar, with the expected exception of the primary motor strip that would activate the response. Other researchers have reported that the same major areas of the brain are activated when imagining or observing movement (or parts of movement) as when performing the movement.²¹⁵ About 30% of the neurons are activated during imagined compared with actual task performance.

Most of the previously cited work has been performed based on hand and finger movements. The ability to generalize the findings to more complex movements of the body may be questioned. However, Brown and colleagues²²⁰ performed work using a dance movement of the foot and lower extremity. This task used a relatively simple component of an Argentine tango dance step. The activation patterns were very similar to those found in hand tasks.²²¹

Research studies²²²⁻²²⁴ have repeatedly reported that observing movement with the intent to learn the movement engages the brain in a similar pattern as performing the task. In general, this research supports a contention that when teaching a patient an exercise, rehabilitation practitioners

should first demonstrate the exercise to the patient. A second study²²⁵ suggests that using written instructions for teaching a motor task may help with the sequencing of the task; however, written instructions do not provide the observational practice that is provided by a moving image. This is particularly important to remember when patients may have experienced some type of brain insult. In an applied study, Weeks and colleagues²²⁶ reported superior performance, motivation, and perceived confidence of subjects when performing simple and complex exercises after viewing videotaped instruction compared with reading written instruction.

Technologies Can Assist Patient Exercise Performance

In this day of moving pictures and digital video, it may be time to leave behind text-based movement instruction, with the exception of the listing of complex sequences of movements. Clinicians can videotape the exercises they want patients to perform or demonstrate the exercises for their patients during a video conference using smart phones, iPads, and Skype. The exercises can even be animated. Therapists' options are now almost limitless.

Current technology allows the clinician to instruct the patient through the use of the Web by doing the following:

- Designing home exercise programs for later use with multiple patients
- Modifying existing home exercise programs
- Entering minimal patient identifying information to keep track of the individual patient while avoiding any Health Insurance Portability and Accountability Act (HIPAA) infringement problems
- Assigning a home exercise program to a patient and providing a brief handout containing a username, password, and some minimal printed information about the exercise program
- Controlling the period of time for which the current home exercise program is considered valid or acceptable by changing, updating, or extending the time period for which the patient has access to the exercises
- In some situations, recording the number of times the patient accesses the program in order to determine compliance

Several companies provide home exercise instruction using a Web link. Each company has its strengths and weaknesses (Table 38-7). Some have newsletters that can be scheduled to be emailed to patients as reminders. Some providers allow the clinician to make a DVD of their patient's exercise program. One provider even allows users to upload their own video for the patient to watch at home, similar to YouTube services. Some of the websites are multilingual, and all will create specific exercises on request of the therapist or clinic using their services. The potential of all current as well as future companies is limited only by the vision of the individuals developing the services as well as the technology available at the time. Technology is constantly evolving and can only improve the potential methods therapists use to teach home exercise programs to patients.

How to Use Web-Based Home Exercise Programs with Patients

One option for demonstrating exercises for the patient has been developed by HomeExPro (www.homeexpro.com). In this system, the therapist has the option of selecting from a catalog of therapeutic exercises. The clinician can then combine a group of exercises into a customized home exercise program for the patient. The clinician can actually provide the patient a link to a personalized exercise program that only he or she can see by entering a username and password. As the patient improves, the clinician can change the exercise program, the frequency, and/or the intensity in order for the patient to optimally benefit from the individualized home program.

HomeExPro and similar companies offer the user an excellent method of giving the patient additional instruction regarding his or her home exercise program as well as being a reminder to continue those exercises without a therapist being present. Using corresponding links, clinicians should be able to determine whether a patient is accessing the exercise program. In the future, placing a camera recording the patient during the exercise itself may be able to give the clinician feedback regarding whether the patient is not only completing the exercises but doing them accurately.

Examples of a Specific Exercise Routine Using Online Access. Access to the two exercises can be found on the Elsevier Evolve site. These two exercises were chosen because

PRINTED MATERIALS	MULTILINGUAL	MULTIPLE CAMERA ANGLES	DVD	BLOG	VIDEO OR ANIMATION	SEND MESSAGES	UPLOAD VIDEOS
Y	Y	Y	Y	N	A	N	N
?	Y	N	N	?	V	Y	Y
Y	N	N	N	Y	A	Y	N
Y	Y	N	N	Y	V	?	Y
Y	Y	N	N	?	A	?	N
Y	N	N	N	Y	V	Y	N

they both might be used by a therapist for instructing a patient in a home program after a neurological insult. These two exercises were developed by Dr. Clayton Gable, who collaborated with others to develop Home Exercise Pro. These exercises are not necessarily typical of exercises developed by programs identified in Table 38-7. Most exercises have been illustrated to augment home exercises given to patients with orthopedic-type impairments. The two exercises presented illustrate the possibility of developing more thorough home exercise programs for patients with neurological movement impairments.

Conclusion

This section has briefly presented evidence that observation of an exercise in motion is better for motor learning, quality of movements, and recall of therapeutic exercise than printed instructions. There are many possible methods available to rehabilitation professionals to overcome the limitations of printed material.

Clinicians might consider making their own library of video exercise programs. However, this endeavor is complex. There are many steps to consider, such as the lighting, the camera angle, the model to be used within the video program, and what generic exercises should be included within the video library. Production of such a library can be expensive to develop and maintain. Another approach would be to use commercially available videos of exercises. However, by using available videos, the clinician has no control over the content of the video and even less control over the camera angle and other factors that can affect the patient's ability to learn the exercise from the video.

There are numerous resources on the Internet for exercise instruction. However, most of them are designed for individuals without pathology or patients with common conditions such as low back pain. In addition, the expertise reflected in publicly available exercise videos varies tremendously. The exercises may be presented by someone who had personal experience with acute back pain and found some exercises that helped. Or the exercises may be presented by extraordinarily well qualified professionals offering excellent information. Very few patients can differentiate the expertise of those individuals presenting the exercise programs.

Another problem with the common approaches to video or a media-based approach to therapeutic exercise is the lack of customization. The very best low back pain exercise program in a therapist's library or on the Internet may not be appropriate for a specific patient, especially if that patient has additional impairments owing to CNS involvement. The Web-based companies included in Table 38-7 can help mitigate this risk with customized exercise programs. The ability to control the patient's access to his or her home exercise program via password management also gives the therapist control over the length of time that particular exercise program is considered valid. Additional home exercise programs developed by professional clinicians and available online will become an important tool for physical and occupational therapists as familiarity and ease of access grow.

The costs of the service for the Internet-based presentation of therapeutic exercise vary broadly. Some providers offer a limited version of their service for free. Others offer access to a full-service website for free to students. None of the providers actually charge patients. The cost is absorbed by the clinic or practice that purchases the service each month. These prices range from \$15 to \$150 USD per month for basic to the highest level of service. Although the higher-end price might seem high, there is no limit on the number of home exercise programs that can be generated per month by a practice. The potential to purchase the service for three to five clinics within a practice with three or four providers at each clinic makes the cost per patient drop to very little. This cost could easily be incorporated into the cost of service, and the outcomes from the home program bring recognition to the practice.

The needs of the therapeutic setting should determine which of the various options best matches what is needed for the specific patients seen by the clinicians within that practice. Although it seems obvious that private practices could benefit from this type of technological access, hospital-based rehabilitation centers or outpatient rehabilitation practices could also take advantage of programs that would help patients regain functional movement. Even if the patient is practicing independently in a rehabilitation gym, this type of reinforced learning can be an alternative to having a clinician constantly attend to that patient. Options are going to

change as technology enhances access to online exercise programs that optimize motor learning and enhance desired outcomes.

LEARNING MORE ABOUT THE ENGINEERING PRINCIPLES IN REHABILITATION ROBOTICS

The usefulness of a rehabilitative and assistive robotic device will always be limited by its design. A robot's passive mechanical structure, sensing capabilities, types of actuation, and control are all key issues for both performance and safety. The way a robot is interfaced to a human, both physically and cognitively, can determine its effectiveness. This section discusses each of these issues briefly. The intention is to give a general overview of rehabilitation robotic engineering, to enable a medical professional to converse with the engineers who develop such devices, and to educate physical and occupational therapists who are challenged with the task of selecting robotic technology regarding relevant issues.

Robot Dynamics, Kinematics, and Control

The position, force, and control of a robot end effector are key concerns during human movement tasks and thus key categories within the field of robotics. The term *end effector* will be defined more precisely; however, for now assume that it is simply a tool of interest (e.g., a fingertip) that exists at the end of a potentially complicated limb and interacts with something in the outside world (e.g., a key on a keyboard). The success of the end effector depends on the relationship between force and motion. This relationship is known as *mechanical impedance*. It quantifies the resistance a mechanical system provides against motions when a force is applied.

Intuitively, one might assume the most useful goal for most motor tasks is to control *both* force and position. In daily lives, individuals want to accurately contact objects, but they also want to apply the appropriate contact forces. For example, if the end effector of interest is a human fingertip and the goal is to hit a note on a piano keyboard, then one must have accurate positioning to hit the correct notes, but one must apply the correct level of force so that each note is played just as loudly (*forte*) or softly (*piano*) as desired.

In a way, the physics of the real world necessitates a tradeoff to achieve both positional accuracy and desired force as simultaneous goals. It is generally impossible to achieve both exact position control and exact force control along the same direction (axis) of motion, except perhaps in specially contrived situations in which the environment is perfectly known and the goals are artificially chosen. For example, imagine an individual wishes to push down on the surface of a pillow, as shown in Figure 38-11, until he feels 1 pound of force, and that he also wishes to push down until his hand is 1 inch below the resting surface of the couch. A reasonable model for the pillow is that it is a spring with the following relationship between force (F), displacement (Δx), and the spring constant of the pillow (k_p):

Equation 38-1

$$F = k_p \Delta x$$

As seen in Equation 38-1, it may turn out that the spring constant of the pillow is such that pressing down with a 1-pound weight depresses the pillow more than 1 inch (if the

Figure 38-11 ■ Pressing a finger into a pillow is an example of how it is not possible to directly control both the position of an end effector and the force applied by the end effector. Because the stiffness of the pillow is unknown, either the force applied or the desired displacement Δx can be controlled.

pillow is soft, with a small value for k_p) or less than 1 inch (if the pillow is very firm). Alternatively, one might create a fantastically strong robot that can compress the pillow downward by precisely 1 inch “come hell or high water,” but the force that is required to do so depends entirely on the properties of the pillow, not on the clever robot. It will always require more force to compress a firm pillow 1 inch than to compress a softer pillow the same amount, by definition.

Hybrid Position and Force Control

In many real-world situations, a human is required to control both force and position during a task. Take, for example, the task of pushing a button, shown in Figure 38-12. In this task a human is required both to control the position of the finger in the x dimension precisely and to simultaneously control the force applied to the button in the y direction. As in the previous example, it is not possible to specify both position and force independently along the x -axis. Nor can one accomplish both for motion along the y -axis. However, it *is* possible to choose *either* position or force to control in x and to choose *either* position or force to control in y . In Figure 38-12, for example, we control position in x and force in y . There is a wide range of tasks in which an individual wishes to control force in one direction while controlling position in a plane perpendicular to this direction. Classic examples include washing a window, sanding a floor, writing text, or painting a canvas. In each case, an individual needs to press *into* a surface with controlled force while tracing a desired trajectory of positions *across* the surface.

Figure 38-12 ■ Pressing a button is an example of a task in which a human must simultaneously control both position and force. In this case, the position of the finger in the X dimension must be precisely controlled while the amount of force applied to the Y dimension is also controlled. Creating control strategies for robots that replicate this behavior, particularly when environmental parameters such as k_b are unknown, is a significant challenge and is the focus of ongoing research and development.

Humans accomplish such tasks fairly easily because during early motor development children have learned to seamlessly prescribe motor control strategies for force control and position control with seemingly little active thought. Hybrid position and force control is a well-known technique used to accomplish this interaction in a robot arm. Such control techniques are still a significant engineering challenge when real-world environmental parameters, such as the spring force coefficient, k_p , are unknown before contact. Individuals often know from the context of the situation that scraping paint, for example, will require much greater forces than frosting a cake. Anticipating the resistance of the environment is still an important problem in mobile robot manipulation.

Now, imagine that instead of pillows and buttons, the capable robot is interacting with a human. As in the case of interacting with pillows, different humans will tend to resist a robot's motions with different amounts of force. A well-designed robot will anticipate the response of a human before a robot-human interaction occurs. Humans anticipate this natural variability in human response intuitively, and this guides decisions about how to interact with other people in daily life. For example, one might decide to use a very different style of motion to shake hands with a professional athlete than with a 2-year-old child or a 102-year-old senior. An individual knows intuitively that he or she is controlling important aspects about both position and force in moving a hand during a handshake. From the point of view of an engineer, human limbs have rather sophisticated kinematics, dynamics, sensing, and control, which allow individuals to perform a wide range of tasks—typically without requiring much high-level thought.

Figure 38-13 ■ One way humans safely explore their environment is to treat their end effector, in this case a finger, as a spring. Either engineers can replicate this effect using a complex suite of actuators, sensors, and computation, or they can add series compliant elements to the limb.

Series Compliance in Robot Limbs

Engineers have come up with several approaches that attempt to replicate the human ability to interact “gently” with an unknown environment. Take the example shown in [Figure 38-13](#), in which a person is pushing a finger against a wall of unknown properties. One model of how a human does this is that the human end effector, in this case a finger, is treated as a spring with a stiffness k . As one explores the properties of the wall, the finger is allowed to interact *gently* with the wall, preventing both damage to the wall and injury to the end effector. In robots, the same effect can be achieved through a suite of sensors, actuators, and computation, which must work perfectly together to “simulate” a passive spring, or one can simply include a real passive spring in line with, or in engineering language *in series* with, the rest of the limb. This is an increasingly popular strategy, and the included spring is technically known as a *series compliant element*. Intuitively, a series compliant element in a limb plays the role of bumper on a car. If the car hits something unexpected, the bumper can absorb the shock to reduce damage to the car. In humans, the softness of the skin, connective tissue, and muscle provides a natural series elastic element between the stiff bones and the outside world. In the past 20 years, engineers have increasingly realized that including compliance in robot limbs can improve both performance and safety as a robot interacts with its environment. An excellent and approachable paper that discusses the advantages of including series elastic elements in real-world robotics was presented by Pratt and colleagues at the 4th International Symposium on Experimental Robotics.²²⁷

Underdetermined Kinematics

One of the other major challenges faced by engineers building multilink robots is that the robot limbs are typically underdetermined as they interact with the environment. In underdetermined systems, the number of degrees of freedom exceeds the number of constraints on the system. For example, engineering constraints may define how a grasper at the end of an arm is to be positioned and oriented, but the engineer may be allowed to use all the limb joints (and perhaps motions of the robot body, as well), which means that many possible solutions exist. In such cases, engineers must

give the robot a practical strategy for determining which solution(s) work best for a particular situation.

An example of an underdetermined problem is a person reaching out to pick up an object, such as a coffee cup. Figure 38-14 shows a two-dimensional representation of a person reaching for a cup at position (X_c, Y_c) . Here, a simplified, four-link model of a human performing a reaching task is used. One link is the distance between the center of the torso to the center of the shoulder L_1 , a second represents the upper arm L_2 , a third is the lower arm L_3 , and the fourth link, L_4 , goes between the wrist and the virtual center of the gripping fingers. The position of the hand with respect to the body can then be calculated based on the orientation of the

Figure 38-14 ■ A person reaching for a cup of coffee is an example of an “underdetermined” system.

torso θ_1 , the shoulder angle θ_2 , the angle of the elbow θ_3 , and the angle of the wrist θ_4 as shown in Equation 38-2.

Equation 38-2

$$(X_c, Y_c) = f(L_1, L_2, L_3, L_4, \theta_1, \theta_2, \theta_3, \theta_4)$$

Here, the linkage lengths are all set constants, whereas the angles are all controlled variables. Thus this system has four degrees of freedom (the angles) but only two constraints (the X and Y positions of the cup). Even with the body position fixed, there are an infinite number of joint angle combinations that would allow the person to successfully pick up the cup of coffee. Allowing for repositioning of the body provides even more flexibility in how to grasp the cup.

Challenges an engineer faces when trying to control a humanoid robot reaching for a cup of coffee include deciding what trajectory the hand will follow in such a situation and what joint angles are to be used to achieve the trajectory. If the robot is a wearable robot intended to assist a human, the choice of poses and trajectories is also critical to the safe operation of the robot. Figure 38-15 shows three sets of joint angles that would position the end effector to pick up the cup. Figure 38-15, A, shows the person in an achievable and comfortable pose. Figure 38-15, B, shows the person in an achievable but potentially uncomfortable pose. Lastly, Figure 38-15, C, shows a pose that might be possible for a robot but is not achievable for a normal human. Although all three solutions may be mathematically feasible for a robot device, solution A is likely the preferred solution for compatibility with human biomechanics. Correctly identifying optimal solutions for robot manipulation is a nontrivial engineering challenge that involves problems in both kinematics and dynamics.

In the next few sections, some common terminology in robotics will be defined and engineering solutions for controlling a multilink limb will be investigated. As a side note, the reader should consider that solutions for upper- and lower-limb control are distinct in some important ways. In particular,

Figure 38-15 ■ Because a person reaching for a cup of coffee is an “underdetermined” system, the same end effector position can be achieved with an infinite combination of joint angles. **A**, A set of joint angles that might be selected that results in a “comfortable” and achievable pose. **B**, A set of joint angles that is achievable but results in an “uncomfortable” pose. **C**, An unachievable set of joint angles.

walking involves a more repetitive, cyclical motion that is punctuated with intermittent contact with the ground, whereas upper-limb tasks generally involve smoother, more variable motions—usually without such dramatic collision with the environment, as compared with heel strike, stance phase, and push off during the gait cycle.

Robot Kinematics

Both human and robot kinematics determine how angles of the joints map to positions of the limbs; they are a *geometric* description of a system. Kinematics gives the mathematical relationships from angles of joints to positions of particular points on the limbs or body. In problems of robot manipulation, one is often primarily interested in how a particular tool, gripper, or anthropomorphic hand at the end of a limb interacts with the environment. This end-part of a robot limb is typically referred to as the *end effector*. For an engineer, it is most useful to consider the end effector more formally to be a particular point located on a link near the end of a robot limb, along with the rotational orientation of this link. For example, it might be the tip of a pencil, used for drawing. A traditional goal in factory robotics is to get an end effector to track a desired reference trajectory over time, such as following a set of desired positional motions. Engineers have gotten good at commanding positions of robot limbs. In common language, however, when one sees a task being performed in an overly repetitive way, one may derogatorily refer to such motions as seeming *robotic*. Many real-world tasks require control of both position and force, as well as some intelligence about the context of the situation. Controlling position alone is not always adequate in robotics.

In rehabilitation robotics, it is often important to determine not only where an end effector of a robot is, but also what forces it applies and where intermittent points are located between the robot body and the end effector. For example, contact with a human must be gentle, and it may also be important to attach a human to a robot limb at multiple points of contact, to ensure that a patient is comfortable, is recruiting the correct muscle groups, and is achieving the correct range of motion for various joints.

In robotics, engineers care about both *forward kinematics*, which map the angles of the joints to the position of the end effector, and *inverse kinematics* (IK), which is the problem of determining what set of angles to use to get the end effector into a desired position and orientation. (For example, Figure 38-15 gives three IK solutions for grasping a cup.) As previously discussed, there are generally multiple solutions to the IK problem of placing an end effector at a desired position. This is true for both a robot limb and a human one.

Velocity Kinematics: The Jacobian

Just as robotics engineers are concerned with the geometric (i.e., kinematic) mapping from joint angle positions to Cartesian (x, y, z) coordinates in a robot, they also care about the mapping from joint angle *velocity* to the velocity of an end effector in Cartesian coordinates. In general, robots have many actuated joints, and six coordinates are needed to fully define the position and orientation of an end effector: three positions ($x, y,$ and z coordinates in space) and three rotations (pitch, roll, and yaw). To help with all the bookkeeping for these mathematical relationships, engineers typically

represent these equations in matrix form. The *Jacobian* is an important matrix in robotics that describes the velocity mapping, or “velocity kinematics,” between joint angle velocities and the translational and rotational velocities of a robot end effector.

The Jacobian is simply a tool to understand how the current configuration of a robot influences the relationship between actuator velocities and the end effector velocities. Physics dictates that the Jacobian also describes how the current configuration determines the relationship between static torques applied by motors and static forces exerted at the end effector.

Because the Jacobian is such a fundamental concept in robotics engineering, it may be worth having some intuition about the information it conveys. A toy example will be used to describe the basic physics that the Jacobian captures. In Figure 38-16, a seesaw-style pivot point is used to represent the geometric relationship between a motor actuator, at the pivot point, and the y position of the end effector, y_{ee} . For the configuration at the left, the velocity relationship between the rotational speed of the motor, $d\theta/dt$, and vertical velocity of the end effector, dy_{ee}/dt , is $dy_{ee}/dt = R \cdot d\theta/dt$. Here, R is the Jacobian. (Usually the Jacobian is a much larger matrix, but this is a special case in which it is a 1×1 matrix.) If the arm length, R , were two times the shown value, the end effector would move twice as fast for a given motor speed. However, for a given motor torque, the longer arm would be capable of supporting only half ($1/2$) the weight at the end effector. To generalize, changing the velocity relationship by a factor of N always changes the force relationship by a factor of $1/N$; the same rate of mechanical work (force times velocity) is performed as the robot starts to move.

In Figure 38-16, the orientation of the arm matters, as well as its length. Given a particular motor speed, the vertical velocity of the end effector, dy_{ee}/dt , is greater for the orientation shown at the left, with the arm in horizontal abduction, than for the configuration at the right. To visualize this, imagine if the angle, θ , were nearly vertical. Then all motion of the end effector would be left-to-right instead of up-and-down. The vertical velocity, dy_{ee}/dt , would be exactly zero when the arm is aligned to be perfectly vertical.

The concluding message for this section is that the range of speeds and forces a robot arm is capable of producing depends not only on the actuators used, but also on the current configuration of the robot. This is intuitive from our

Figure 38-16 ■ A robot arm essentially acts like a lever. The Jacobian matrix is used to describe the leverage relationship between actuator angular velocities (or torques) and limb velocities (or forces).

daily life, as well. It is more difficult to support a heavy object with arms fully extended than by using a more comfortable configuration with arms closer to the trunk. As another example, the speed when hitting a tennis ball depends not only on the strength of the muscles but also on how the individual commands joint trajectories of the arms, exploiting velocity kinematics to achieve a high-speed swing.

Robot Dynamics

Dynamics is the study of how forces affect motion in a system. By contrast, kinematics is not concerned with forces. Rather, kinematics describes only geometric relationships.

The most fundamental concept in dynamics is that force equals mass times acceleration, or, in equation form, $F = ma$. This relationship is known as *Newton's second law of motion*. It means that a body at rest will stay at rest unless a force is applied. Furthermore, a body in motion keeps moving with the same velocity unless a force is applied to change that motion. In practice, there are many forces (e.g., friction, viscous damping, or air resistance) that tend to apply natural forces to slow down objects that are in motion. These are some of the many ways in which forces act to change velocity over time.

Equations of motion (EOMs) are used to describe the forces in a dynamic system and the way these forces affect the acceleration(s) of various degrees of freedom (e.g., joint angles of a robot). In robotics, EOMs are typically described using matrix equations. Without delving into the details of such equations, it is still useful to examine the general structure of the EOMs for a typical robot manipulator. Although exact variable notation will vary, the usual form for such matrix equations is as shown in [Equation 38-3](#).

Equation 38-3

$$\tau = M(\theta)\ddot{\theta} + V(\theta, \dot{\theta}) + G(\theta)$$

The parentheses in [Equation 38-3](#) merely show whether each matrix is a function of position (θ) only or of both position and angular velocity ($\dot{\theta}$). Thus engineers can simply rewrite the equation as follows:

$$\tau = M\ddot{\theta} + V + G$$

On the left-hand side are the controlled input torques (i.e., rotational efforts), τ , which are generally supplied by electric motors in most modern robot manipulators for rehabilitation robotics. On the right-hand side are the natural dynamics of the mechanical system. M represents the mass distribution, known formally as the *inertia matrix*, of the links of the robot, which depends on the robot configuration. V gives all the velocity-dependent torques. These include losses caused by friction and viscous damping, as well as centrifugal forces and Coriolis forces caused by rotations of joints. Finally, G is the torque resulting from gravity. Note that G also depends on the geometry of the robot: holding an arm fully extended outward requires greater torque, to counteract gravity, than does holding an arm near one's side. G captures this relationship more exactly.

The term $M\ddot{\theta}$ is analogous to ma in Newton's $F = ma$ equation. All other terms τ together represent the net torque (analogous to F). That is, the torques that affect angular accelerations of the robot links include both the controlled input torque, (i.e., τ , V , G) and the natural dynamics of the

system prescribed by V and G . One popular approach in robot manipulator control is to attempt to “cancel out” the natural dynamics of the robot, to the extent possible. For example, if engineers can set the motor torques such that $\tau = G$, then apparent effects of gravity can be cancelled out, to make a robot arm seem weightless. Similarly, engineers can attempt to cancel out the forces caused by friction and other velocity-dependent terms that are captured in V .

Although canceling out the natural robot manipulator dynamics may sometimes be an elegant solution in theory and in simulation, it requires a very good model of the natural dynamics of the robot. In practice, this may be difficult to achieve, and the true dynamics may vary over time, as a robot ages or is deliberately modified or updated. Joints may begin to stick more, and a user may wish to modify a robot by attaching additional components (cameras, straps, or other tools) that may change the mass and inertia of the limbs.

The overall dynamics of a robot depend on both its natural dynamics, given by $M\ddot{\theta} + V + G$, and on the control laws that determine motor torques, τ . In general, it is safer, when practical, to obtain as much of the possible dynamics of a system as possible through the use of natural dynamics, as will be discussed later. Control is always extremely important, however, and the next section describes some general control techniques used in rehabilitation robotics.

Robot Control Techniques

For a given degree of freedom, engineers can control either position or force of a robot end effector. (Recall our earlier example of pushing a pillow, illustrated in [Figure 38-11](#).) Force and position at the end effector are related through the *mechanical impedance* of the environment. Classical factory robotics, developed in the 1970s and 1980s, emphasized position control of end effectors. The goals of such control were to have higher repeatability and, often, to apply high forces at the end effector. For example, a robotic device might be used to machine a part for an assembly. Here the grinding or cutting forces during the machining process would be quite high, and the tool would need to move in a very exact pattern.

For applications in which a robot interacts with humans and in human environments, forces must be more gentle, and the control over force is typically more important than control over exact position trajectories. Forces may be dictated either directly, through force control, or indirectly, through impedance control. In traditional force control, one designs a controller to specify, directly, the force that an end effector exerts. This might be useful in regulating the pressure exerted by a roller, for example. In manipulating a human or object, however, it is often desirable to keep the robot limb motions close to some nominal positional path, as well. Here, it may be more desirable to control the force “indirectly,” by employing control to actively set the mechanical impedance of the robot limb. Recall that a mechanical impedance enforces a relationship between forces exerted and the motions (position, velocity, and acceleration) that occur. Intuitively, an impedance controller can create a “force field” to push a patient arm gently, if it deviates only mildly from a planned trajectory, and to provide firmer resistance if a patient tends to move in an erratic manner or to drift too far from a desired range of motions. The impedance of a robot assistant interacting with a human

can also be adjusted over time, to provide more or less guidance and correction as a person regains strength and/or relearns motor skills.

Hogan introduced the concept of impedance control for manipulation over 25 years ago in his seminal work.²²⁸ Despite theoretical advances (largely during the 1980s and early 1990s) in force and impedance control, most industrial robotics for manufacturing purposes have continued to favor position control over either force or impedance control. As robotics has moved out of highly controlled factory settings and into real-world environments, two particular factors have encouraged the use of force feedback techniques. First, unlike many factory assembly machines, robots in clinics or in the home must now interact directly with humans. Therefore they must be gentle. Second, real-world environments involve a lot more uncertainty than a factory setting. Because the mechanical impedance of the objects a robot will touch will vary drastically (e.g., a very stiff wall or doorway versus a soft curtain or pillow), it could be quite dangerous to command only position references to a robot limb. A position-controlled robot could simply put a hole in the wall if it were too strong, and it might not produce enough force to open a simple door if it were simply designed to be “less strong.” Controlling the impedance of the robot limb allows for a much greater range of physical interactions in the real world.

There are many ways to define the exact goals for a rehabilitation robot controller, corresponding to the task of the device. It may be used to provide physical therapy, to retrain motor skills in a human, or more directly as a means of surrogate motor compensation for performing daily activities. In both cases, one must assume that the robot will interact directly with a human and, potentially, with objects (e.g., walls, doors, chairs, coffee cups, remote controls) in human

environments. Because of the wide range of possible situations that may arise, safety and dependability are significant challenges in developing control techniques for such robotic devices, and thus discussion of safety issues is very important with human-robotic interactions.

A wide body of literature exists on control methods for both human and robot motor tasks.²²⁹⁻²⁴⁴ Two good introductory texts on general engineering principles for robot kinematics, dynamics, and control are *Introduction to Robotics: Mechanics and Control* by J. J. Craig²⁴⁵ and *Robot Modeling and Control* by M. W. Spong and colleagues.²⁴⁶

Human-Robot Interactions and Interfaces

There are two important classes of interplay between humans and rehabilitation robots: *physical* and *cognitive*. The first type discussed is physical human-robot interaction (pHRI); later, cognitive human-robot interaction (cHRI) is described. In both cases the interactions that are possible between a human and a robot depend on the *interface* that links them, which consists of both hardware and software. In most cases the cHRI and the pHRI are not independent. For example, typing at a keyboard allows the user to have a cognitive interaction of communicating information to a computer through a physical interaction of depressing buttons on a keyboard. Table 38-8 lists some common terms associated with cognitive and physical interactions.

Physical Interactions

From an engineer's point of view, physical interaction is the *exchange of mechanical work*²²⁹: how systems push (or pull) one another and subsequently move. In rehabilitation robotics, we care both about how a robot is physically related to a human, for example, while providing assistance, and how

TABLE 38-8 ■ COMMON TERMS FOR HUMAN-ROBOT INTERACTIONS, INTERFACES, AND DEVICES¹¹

TERM	DESCRIPTION
Human-machine interface (HMI)	The HMI is the means by which a human and a machine interact. This interaction can include touch, sight, sound, heat transference, exchange of electrical signals, or any other physical or cognitive function. The HMI is also commonly known as a man-machine interface (MMI) or human-computer interface (HCI).
Brain-computer interface (BCI)	The BCI is a direct communication pathway between the brain and an external device. This interface may be either unidirectional or bidirectional.
Physical human-robot interaction (pHRI)	A pHRI is the physical interaction between a human and a robot that explicitly involves the flow of power. This interaction may be either unidirectional or bidirectional.
Cognitive human-robot interaction (cHRI)	A cHRI involves the transmission of information between the human and the robot with the goal of allowing the human to control a robot. This interaction may be either unidirectional or bidirectional.
Physical human-robot interface (pHRi)	A pHRi is the interface by which the robot and the human exchange power. Typically a pHRi is based around a rigid structure with actuators that transmit forces to and from the human.
Cognitive human-robot interface (cHRi)	A cHRi is used to exchange information between the human and robot. In the human-to-robot direction, data are acquired through sensors that may measure bioelectrical and biomechanical variables such as neural activity and limb position. The robot-to-human direction can involve direct neural stimulus, physical stimulus, visual stimulus, and auditory stimulus.
Neural interface (NI)	This is an all-encompassing term for artificially stimulating or sensing neural activity.
Brain-machine interface (BMI)	In this interface, the brain directly communicates with some sort of machine. BMI is often used interchangeably with brain-computer interface (BCI), in which the brain is communicating directly with a computer.
Neural prosthetics (NP)	A prosthetic device under the direct control of the brain.
Neural motor prosthetic (NMP)	Here, the motor cortex is used to drive a prosthetic device directly.

a robot physically contacts the environment, for example, to help manipulate objects during daily activities.

In describing dynamics and control, there are two distinct meanings for the word *passive*. Often, *passive* is meant simply to indicate that no actuation is used: *passive* in this context means *not actively controlled*. However, passivity is also used within the controls literature to indicate a dynamic system, either actuated or unactuated, in which one *can imagine* creating an equivalent dynamic system entirely out of stable, passive mechanical elements: traditional springs, masses, and dampers.

By using actuated control instead of using unactuated parts, one can actively modify the stiffness, damping, and apparent inertia of an actively controlled system as desired. For example, in impedance control, one can use active control to create a dynamic system that responds in essentially the same way as a passive one that is built only from springs, dashpots, and inertias. There are significant advantages of using active control instead of a truly nonactuated mechanical device. For example, one can tune the mechanical impedance over time, to provide more or less of the total effort required for a person to perform a given motion. Also, one can change the set point for an actively-simulated mechanical impedance (e.g., spring) element, to track a desired continuous motion.

An alternate strategy is to attempt to compensate for the anticipated dynamics of the environment. One may know from experience that it will take a lot of force to push against a particular door—for example, if it is heavy (great inertia), if it sticks (great friction), or if it has a strong spring-loaded closing mechanism (great stiffness). By anticipating the properties of the door, one can plan ahead and attempt to “cancel out” the natural dynamics of the situation. This type of compensation amounts to *feed-forward* control. Attempting to cancel out the natural dynamics of the environment can be destabilizing, however, if the environment is not perfectly known. Therefore in any realistic situation, one must also use appropriate *feedback* control to ensure stability. The combination of feed-forward (anticipatory) control and feedback (error-driven) control is the basis of most human and robotic motor control.

As an example, imagine you wish to pick up a flower vase, assuming it is full of water and heavy. If it is actually nearly empty and weighs much less than expected, a person might attempt to grasp it and lose control by throwing it into the air. As another example, imagine grasping a rope to pull a heavy object or to play “tug of war” with someone. If there is suddenly no resistance to motion, a person can easily lose control and might even fall down backward.

Similarly, a robot that expects to encounter a particular human response during an interaction may react in an unexpected way if the human dynamics are not as anticipated. In a worst-case scenario, as both robot and human react to try to recover from an unexpected situation, they may interact in such a way as to cause unwanted or dangerous oscillations or to push and pull in such a way that the robot arm acts like the person who has overcompensated when lifting the lightweight vase. Although our controller might have performed just fine had the vase been full, we must always plan for a worst-case scenario (robust control) when the environment is unknown, to ensure stability of the system. This scenario could also occur when a human attempts to

move in the opposite direction to what is anticipated by the robot controller. If the task requires shoulder flexion for example, and the human moves the shoulder into extension or abduction rather than flexion, to err on the side of safety the robot may have to stop assisting the patient when the arm moves incorrectly. This can lead to a nontherapeutic “push-pull” situation.

Control engineers have, of course, studied the requirements for stability for robot manipulators in depth. One basic—and intuitive—rule of thumb is that a device is generally both dynamically safer and more forgiving if the dynamics of the device can be implemented through mechanical elements, rather than through clever control to achieve similar dynamics through powered actuators. This has two big advantages. First, the easiest way to implement dynamics with the “passivity” property desired for our dynamics is to use passive (i.e., unactuated) mechanical elements. Second, active control solutions would require additional sensing and powered actuators. However, sometimes actuated control is the only practical way to allow for flexibility in unweighting part of a patient and providing a range of resistance or support during motion. Even if a device is actively controlled with sophisticated actuators, it is possible to do so with a control strategy that mimics a passive system. Such a system would correspondingly be classified as demonstrating the desirable passivity property mentioned earlier.

Force and Pressure Loads from Physical Interfaces

During pHRI, forces are of course exerted between the human and the robot, for example to achieve desired task-specific motions and/or to facilitate motor training. There are several factors to consider in how these forces are applied to a person. The interface should be both comfortable and safe, and it should not unnecessarily inhibit the range of human motion.

Pressure is the measure of force distributed per unit area. As an example, a snowshoe is used to distribute the weight of a person across a larger area, thus lowering the pressure applied to the snow. By contrast, a high-heeled shoe concentrates force onto a small area, increasing pressure, which is why pointed heels can leave prominent marks on carpeting. Distribution of force is also important in dictating the pressure characteristics of human-robot interactions. Applying too much pressure to human skin can cause discomfort or pain, and it can also cut off the flow of blood. Force loads should therefore be distributed across a region of skin to avoid high contact pressure. One should also avoid applying concentrated loads where there is little natural, fleshy tissue to buffer contact and to help in distributing loads. Contact with bony regions can concentrate forces, increasing pressure, and can cause pain and injury. As a simple experiment, find a bony region of your forearm or, alternatively, along your shin. If you slowly press this region against the edge of a desk or table nearby, you should notice that the pressure from the tabletop can quickly become uncomfortable. The same experiment on a fleshier part of the body is significantly more tolerable. Contact should also be avoided or minimized in sensitive tissue regions rich with surface nerves. Contact between a human and robot should also be planned such that forces push

downward directly on the skin, to avoid pain or discomfort from undesirable twisting (shear forces) and chafing.

More detailed coverage of this important topic can be found in the text by Pons¹¹ in Chapter 5 in the discussion of wearable robots and biomechatronic exoskeletons.

Manipulation and Locomotion: Dual Problems

Limbs can be used for either manipulation or locomotion. From an engineering perspective, these are essentially twin problems. In manipulation, one uses limbs (usually arms) to move other objects in the environment. In locomotion, limbs (usually legs) are used to move oneself around with respect to the environment. In both cases, accomplishing a desired task requires generating joint trajectories and forces to achieve desired motions.

However, there are also obvious differences between the two tasks. Most manipulation tasks require coordination between gross and fine motor skills. Manipulation also generally involves smooth, continuous motions. Humans are capable of learning a vast range of motor skills with the arms and hands. These include putting on clothing, using utensils for eating, and performing a tremendous number of other daily activities. In manipulation, one uses limbs to move other objects in the environment.

By contrast, locomotion is punctuated by periodic discontinuities. One leg is used for support and stability while the other leg swings in free space to position itself for the next heel strike. At each step, the two legs swap roles, following a near-repeating pattern over time. Contact with the ground may trigger signals to reset the timing of this periodic cycle. There is usually very little variability in step length during normal human walking, and the swing foot end effector typically swings only a couple of centimeters clear of the ground below.²⁴⁷ Stated briefly, although we have the capacity to vary our gait if desired, the basic task of locomotion is distinct from and more periodic than that of manipulation, and it is likely that robot technologies for upper and lower limbs should correspondingly differ, to match these differences.

Humans use both feedback and feed-forward in controlling both locomotion and manipulation. As mentioned, in *feed-forward* control, one commands movements based on past experience. Essentially, one anticipates the motor commands that are required to achieve a desired limb motion. By contrast, *feedback* control uses error signals, such as the difference between the desired and actual position of a limb, and motor commands are generated to reduce these sensed errors. Generally speaking, the advantage of feed-forward control is speed: it takes significant time for information (e.g., vision, touch, proprioception) to be transmitted and processed by the brain or a feedback mechanism.

Feedback is important because of the variability that exists from trial to trial in performing a task. Manipulation tasks generally involve direct interaction with the environment. There are many parameters defining this interaction that may be slightly different each time a given task is performed. For example, the pose of one's body may be oriented a bit differently, and the object one wishes to manipulate may have a different trajectory over time and/or a different mechanical impedance than anticipated. Also, one may not be able to perform a given motion in exactly the

same way owing to muscle fatigue or other variability in human capabilities.

Both therapists' and engineers' understanding of the roles of feed-forward and feedback in various motor tasks is still incomplete. For example, although both feed-forward and feedback control are traditionally considered to be important in both upper- and lower-limb tasks, recent literature suggests that feedback control without feed-forward control is theoretically sufficient for maintaining a stable, upright posture.²⁴⁸ This is a particularly interesting result, given the significant time delays (roughly on the order of $\frac{1}{10}$ of a second) involved for regulation of balance by the CNS. Understanding what is theoretically necessary for stable balance control in turn has direct application in the design of reliable devices and control algorithms for neuroprostheses,²⁴⁹ rehabilitation robotics, and other equipment relying on human-robot interaction to accomplish motor tasks.

This section has provided only a brief overview of some of the issues in common between and differentiating locomotion and manipulation. Additional references on human and other animal locomotion and manipulation are available to those interested in additional reading.²⁵⁰⁻²⁵⁹

Cognitive Interfaces

Cognitive interfaces are another means by which information is passed between the human and the robot. A cognitive human-robot interface (cHRI) is an interface that allows information to be passed between a human and a robot. As noted earlier, the cHRI is rarely independent of the physical human-robot interface (pHRI), with many types of cHRI accomplished through a pHRI. For example, the human-to-robot direction of the cHRI can be accomplished through the use of keyboards and mice, the measurement of limb positions, voice activation, eye tracking, or measurement of neural activity. Similarly, the robot-to-human directions of the cHRI can be accomplished through mechanical stimulation (vibration or force feedback), auditory stimulation (voice or tonal feedback), visual feedback (flashing lights, or graphics on a screen), or direct neural feedback. Cognitive interface design is a developing field with technical contributions coming from many different fields including but certainly not limited to clinical medicine, neuroscience, biology, engineering, and computer science. As one might expect with such a diverse range of contributors, the terminology defining the cognitive interface has many overlapping and conflicting terms used to define the characteristics of the cognitive interface, with each contributing specialty having a preferred terminology. In this section the reader will not be given a comprehensive description of all possible cognitive interfaces. Instead the reader is provided an introduction to the engineering challenges and some of the associated terminology.

From an engineering perspective, there are two classes of cognitive interface(s): direct and indirect. In a direct interface, the cognitive interface attempts to replicate the original relationships between the input measurement and the output robot motion. An example of a direct measurement is using electroencephalography to monitor motor cortex activity that corresponds to arm motion and then using that measurement to control a prosthetic arm. In an indirect interface, measurements are taken of signals or motions that are *not* normally used to control a particular activity directly. An

example of this would be using voice commands to control a lower-limb prosthetic. Clearly these are “fuzzy” distinctions because humans rarely use a single modality to achieve a task. For example, an individual can choose to move a box by picking it up himself, direct control; or he can ask a colleague across the room who is closer to the box to bring it to him, via indirect control.

Neural Interfaces

A relatively new type of direct interface is the emerging field of neural interfaces. Although neural interfaces may seem far-fetched, the U.S. Food and Drug Administration (FDA) estimates that as of December 2010, approximately 219,000 individuals worldwide had received cochlear implants.²⁶⁰ The cochlear implant relays sounds from a microphone to directly stimulate the auditory nerve to restore hearing. Neural interfaces currently have a huge potential to expand in capabilities owing to recent innovations of computer technology. Computers supporting brain-machine interfaces (BMIs) can now record and process large amounts of neural data.

When creating a neural interface, there is a tradeoff between the invasiveness of a device and the fidelity of the signal. Although measuring with electrodes directly placed in or on the brain yields high-fidelity signals, the hazards of surgery have motivated researchers to use indirect measurements. One of the least invasive methods is to use the electroencephalogram (EEG). Electroencephalography measures scalp voltages, which correlate to neural firing on the surface of the brain. The drawback of electroencephalography is that there is little time and spatial sensitivity to individual neurons. The readings for individual sensors can be considered gross time and spatial averages of the neural activity occurring next to the sensor. A notable example of how electroencephalography can be used cheaply and easily is the Mindflex by Mattel, which uses a modified EEG to control a fan. Whereas this may seem promising, the practicality of electroencephalography is limited owing to the intense concentration and training that each subject must undergo to control this device. One limiting example is that subjects are unable to talk or multi-task when using this interface, further limiting its utility.²⁶¹ Figure 38-17 shows an EEG recording net being used on a study participant.

As mentioned earlier, placing the electrical sensors on the exterior of the skull significantly reduces sensor sensitivity owing to both signal attenuation as a result of distance (electric and magnetic field strength are inversely proportional to distance squared) and “smear” in the nonuniform tissues between the source and sensor. Thus the performance of an electrical sensor is substantially increased with the more invasive option of implantation.²⁶² Implanted electrodes on the surface of the brain (Figure 38-18) are capable of measuring the neuron action potential (the electrical signal across the neuron’s membranes). The close proximity to the neuron gives good signal sensitivity, enhances spatial localization, and allows higher data rates than external sensors. One must be aware that although embedded electrodes have good neuron specificity, they do not measure many neurons. The number of neurons being sampled is important for neural-controlled prosthetics because even the most routine task, such as moving one’s hands, uses millions of neurons.

Figure 38-17 ■ A subject with an electroencephalogram net placed on his scalp for a research experiment. There is some variability in the placement of the net, which may affect the calibration required each time the net is placed.

Although researchers have been able to decode hand movement commands with only six neurons, this comes at the sacrifice of reliability in the measurement. Generally, the more neurons measured, the more reliable the motor signals that may be decoded.²⁶³ Figure 38-18 shows an example of an intracranial sensor. Sarpeshkar and colleagues²⁶⁴ have identified some of the challenges

Figure 38-18 ■ An electrode array design by Richard Normann and colleagues in 1998. **A**, The mounting pedestal that runs through the skull. **B**, The array of 100 tapered 1.5-mm-long microelectrodes arranged in a 10×10 grid. **C**, Electron microscope view of the electrode. (From Donoghue JP, Nurmikko A, Black M, Hochberg LR: Assistive technology and robotic control using motor cortex ensemble-based neural interface systems in humans with tetraplegia, *J Physiol* 579(Pt 3): 603–611, 2007.)

associated with intracranial devices. These include the following:

- Size restrictions—The device must be safely contained within the skull.
- Material biocompatibility—There is a growing list of materials that have been tested, but long-term use and subject-specific sensitivities remain issues.
- Heat dissipation—These devices must not generate excessive heat that could damage surrounding tissues.
- Power consumption—Frequent battery replacement is not practical owing to complications and risks from operating on the skull. In addition, high power consumption may lead to excessive heat dissipation.
- Risk of infection—Implementation of the device requires a surgical procedure, and infection is always a risk with surgery.

Another commonly used method of creating a neural interface is functional magnetic resonance imaging (fMRI). An fMRI is a specialized magnetic resonance imaging (MRI) scan in which measured change in blood flow in the brain or spinal cord is correlated with neural activity. In contrast to electroencephalography, this method has good spatial resolution over a large area of the brain. Drawbacks to fMRI are that it does not directly measure a neuron firing and that the slow response of blood flow to neuron firing does not make this practical as a real-time neural interface. For example, in 2004, researchers used fMRI to allow subjects to neurally control a mouse in four directions. Although selecting “north” versus “west” may seem like a simple enough command, it took on average 2 minutes and 15 seconds for the users to enter a single command.²⁶⁵ Also note that MRI machines are not practical outside of a research or clinical setting because of the high cost and large size of the instruments and limitations on the types of materials (i.e., nonmagnetic) that can be used near an MRI machine owing to the strong magnetic fields generated.

Biomechanical Interfaces

As with the definition of cognitive interfaces, there is no universal definition of what a *biomechanical interface* is. For the purposes of this chapter, a biomechanical interface will be defined as a subtype of cognitive interface in which various measurements are used to estimate the mechanical state and intentions of a biological system (in this case a human) and then use traditional engineering assumptions to translate those state measurements into signals that control a robot or machine. In the context of this discussion of direct versus indirect measurement, a biomechanical interface is usually an indirect measurement. Thus, although it could be argued that electromyography should be categorized as a neural interface (a direct measurement), it is more typically employed in practice as a biomechanical interface, because the amplitude of muscle activation that is output must then be interpreted to estimate the desired robot actuator force or actuator motion.

There are many means of achieving a biomechanical interface, including the following:

- The aforementioned electromyography, which measures muscle activation levels
- Wearable sensors and exoskeletons that directly measure joint angles and body postures and indirectly measure joint torques and limb forces

- Motion capture systems such as the Kinect system from Microsoft that uses cameras to measure the pose and motion of the subject
- Semiactive prosthetics that sense the wearer’s intent based on the magnitude and frequency of a single input angle

All of these interfaces share the characteristics that they take a series of mechanical (or electrical) measurements and then fit those measurements to an engineering model, which is then used to estimate the desired state of a robot or prosthesis and the most likely intentions of the user. These engineering models are often called *finite-state machines* (FSMs), in which the current state of the system is used to determine the forces and actions required to move the system from its current state into a desired next state. As an example, walking gaits are often described using a series of phases that are performed in a consistent order in normal walking. An FSM can be used to describe this repeating series of phases, allowing a robot controller to anticipate the next motions required to continue walking normally.

Just as in the case of neural interfaces, there are many challenges associated with successfully achieving a functional and safe biomechanical interface. Sometimes it is not possible to directly measure, nor to indirectly estimate, all of the states (e.g., joint angles and angular velocities) in a dynamic system. Such systems are not fully observable. Also, it is often not possible to actuate each degree of freedom (e.g., joint angle) independently. Such systems are not fully actuated—that is, they are underactuated. One of the keys to successful interface design is to select a combination of measurements, modeling assumptions, and control outputs that allows for the stable operation of a robot when neither full observability nor full actuation is possible.

For example, if a robot arm is assisting a human in a reaching task, such as grasping a cup (see [Figure 38-15](#)), the exact orientation of all the joints in the arm will probably not be known and forces will not be applied directly to all joints to help to control the motion. Proper use of a biomechanical interface in such situations depends on proper interpretation of the context in which a device is being used.

Context

One of the things a cognitive interface must successfully communicate is context. Let us return to the planar arm example. So far we have discussed this problem in the context of picking up a cup of coffee. In this context, we would like to have good position control of the hand while we minimize the velocity of the hand as we pick up the coffee to avoid spilling it. What if, instead, we were attempting to hit a nail with a hammer? In this context, we would still want to have good positional accuracy but we would like to maximize the velocity of the hammer so that we have good energy transfer from the hammer to the nail. In both cases, the system would have the same state variables and state measurements, but the cognitive interface needs to understand the context in order to achieve the desired outcome.

The common feature of nearly all cognitive interfaces is that both the human and machine components must be trained. An important takeaway point is that the human needs to learn how the machine responds, and typically the machine also needs to be trained such that the parameters of the state model match those of the controlling human.

Safety Issues for Robotic Technology

There is a tremendous range of issues relating to safety when interfacing robotic technology with a human. For example, a robot may unintentionally encourage poor kinematic positioning and orientation of a patient limb, part of the robot may collide with a person, or the forces applied at an attachment point may be dangerously high or may unintentionally excite or accentuate tremor-style oscillatory motions. In addition, intentions of a user may be misinterpreted, faults may occur in power or other wiring, a device may be improperly calibrated, or bugs may exist in software. Although all are important concerns, this section will focus on inherent engineering design aspects for the device when used as intended, as opposed to the wide variety of possible failure modes that might occur in any electromechanical device.

In the following section, safety issues caused by mechanical design, type of actuation, and/or control techniques employed are highlighted. This summary will parallel the earlier discussions of kinematics and dynamics for robots by briefly summarizing engineering design issues related to each. More detailed information on pHRI safety may be found in the article “An Atlas of Physical Human-Robot Interaction”²⁶⁶ or in the text *Wearable Robots: Biomechatronic Exoskeletons*.¹¹

Kinematics and Geometry of the Device

Kinematically, it is important to avoid positioning a patient in such a way that joints may be encouraged or forced into abnormal, painful, and/or damaging configurations. Recall from the earlier discussions that there are typically multiple solutions to get a desired end effector to a particular position. It is correspondingly important how and where a robot limb interfaces with a human arm or leg. If they are joined at only their respective end effectors, for example, one runs the risk of hyperextension of human joints because the robot simply does not track exactly what is happening to all joints along the way to the human end effector. There various other, common sense issues involving the shape or geometry of the device. For example, sharp corners or edges should be avoided to minimize any damage that might occur owing to unplanned collisions between the robot and the human. A much more thorough discussion of this topic can be found in Chapter 5 of *Wearable Robots: Biomechatronic Exoskeletons*.¹¹

Dynamics and Stability of Man-Machine Systems

Once a robot interacts with another dynamic system or the environment, stability depends on the coupled dynamics of the two systems together.* Time delay may also cause instability,^{238,243,268} as may backlash in the transmission mechanism.¹³¹ There may be time delays in the system owing to the slow response time of the human in the loop (i.e., slow compared with the sensing and computation of a robot). *Backlash* refers to the play that exists in mechanical gears or other transmission elements: when a motor first reverses direction, it may first need to “take up the slack” that exists in real-world gears before a reversal in the motion of a robot joint actually occurs.

Several principles can be employed to make the mechanical impedance (mass, damping, and stiffness) of the device safer. Robotic limbs should have low mass and inertia. Imagine a robot limb, in a worst case scenario, as being roughly similar to a baseball bat: a lightweight design will cause less damage during unintended impacts. In addition, both the joints and the “skin” of the robot (if any) can employ mechanical compliance and damping. Essentially, this provides shock absorption for the human-robot interface. One way to achieve both a lightweight and a compliant arm is to hide motors or other actuators within the body or base of the robot and to control the joints through the use of cables. Practically speaking, cables (e.g., like the ones used to control bike brakes by squeezing levers on the handlebars) stretch when they are pulled. Thus the cables naturally act as both a means of transmission and a compliant spring element in a design. This mechanical compliance may limit the speed with which robot limb motions can be commanded. However, for rehabilitation robotics, this compliance versus speed tradeoff is likely a reasonable one to make, because desired motions are generally smooth and slow.

In summary, when considering engineering issues in rehabilitation robotics, both passive and dynamic mechanical structure as well as active control of forces and positions are important for both performance and safety. Where and how a robotic device interfaces with a human is also important, both physically and cognitively. These are all areas of active research. Furthermore, a variety of solutions are currently employed or are under development for research and commercial purposes. This field will continue to grow and be refined. As this field expands, therapists will more likely interact with engineers in order to provide the best practice for individuals who might potentially benefit from robotics.

ANALYZING COST-EFFECTIVENESS AND EFFICIENCY OF REHABILITATION ROBOTICS

Costs of Rehabilitation Robotics

At this time, the cost of rehabilitation robotics is very high. There are not a lot of robotic devices available; thus there has been little price reduction based on quantity. The costs vary from \$3000 to more than \$300,000 depending on whether the device is individualized to one person or whether the device can be used in locations to serve many individuals. Technology between \$75,000 and \$90,000 is considered to be in the low range. The appearance of the robot is important from esthetic and psychological points of view. Safety is a major consideration. Because rehabilitation robotics are complicated devices and are produced in small numbers, at this time the costs are high. It is also not clear whether insurance companies will ultimately contribute to the purchase of these assistive devices or whether the cost will be the problem of the end user. However, as demand, acceptance, use, and production increase, it is expected that the manufacturing prices could go down. This is an especially volatile market when there is economic stress.

If research confirms increased function and increased independence with rehabilitation robotics and there is a decrease in the need for long-term care support in a nursing home, and less demand for one-on-one therapeutic treatment, it is possible that initial investment in the device may be considered cost-effective. This has been the case with

*References 231, 232, 235, 239, 243, 267.

cochlear implants. For example, for children and elders, the investment in the implant is associated with maintained functional hearing, improved communication, safety, and greater independence. Thus third-party payers have determined the investment in the implant is cost-effective.

Effectiveness of Robotic Technology

The commercialization of rehabilitation robotics and assistive devices will depend both on the costs of the device as well as the effectiveness. When deciding to pursue the integration of rehabilitation technology and robotics, a number of questions should be answered by the user, the health care

provider, and the health care system in order to determine cost-effectiveness (Box 38-19).

The Manus upper-limb assistive robotic device (Manus ARM) can be used as an example of practicality and cost-effectiveness.²⁶⁹ The Manus ARM is an assistive robot that is mounted to a wheelchair. It has six degrees of freedom and a gripper to capture objects (up to 1.5 kg). It is controlled by a keypad, a joystick, a headband or spectacle-mounted laser pointer, or a mouse. Initial evaluation programs have been developed to analyze cost-effectiveness. Two studies were conducted in the Netherlands relative to the cost-effectiveness and safety of the Manus ARM. The Manus ARM allows a

BOX 38-19 ■ QUESTIONS TO ASK TO DETERMINE COST-EFFECTIVENESS OF REHABILITATION ROBOTICS AND ADVANCED TECHNOLOGY

I. UTILITY OF THE ROBOTIC DEVICE

- A. With what types of activities will the robot assist?
- B. Are the activities and tasks enabled important for everyday life and movement freedom?
- C. Is there still a gap between academic laboratory research activities and practical, efficient robotic applications at home (e.g., eating, bathing, manipulating objects)?
- D. Can the robot help the patient maintain privacy to perform personal activities (e.g., changing clothes, bathing, and toileting)?
- E. Can the robot assist with movement across a broad spectrum of movement impairments?
- F. How much does the robot contribute to completing the full task (e.g., can the robot help prepare the food, serve the food, and assist the patient in eating)?
- G. How many hours in the day will the robot be able to replace a human helper (e.g., many hours—just a few hours, or possibly enough hours to afford complete independence except for house cleaning and yard work)?
- H. Compared with the time required for common tasks, what are the time constraints of robotic assistance (e.g., does it take an hour to eat a sandwich, or 10 minutes; is the intensity of effort the same)?
- I. Does the human interface require additional sensory attachments initially or continually to enable individuals to use it?
- J. What is the reliability of the robot? Does it break down a lot? Is it easy to have it repaired? What is the feedback of previous users?
- K. Does the robot effectively assist in task performance, or does it get in the way?
- L. Does the robot perform needed tasks accurately, or are there risks for destroying other objects in the area or work surfaces?
- M. Do patients effectively learn to improve their performance of a task, or is the task practice irrelevant?
- N. How much noise is there when the robot is operating (e.g., does it interfere with conversation or bother others)?
- O. What kind of energy is needed for robot operation, and how long does the energy source last?

- P. What space does the robot access (e.g., can it easily fit into the house without special modifications)?
- Q. What is the limit of the space the robot can access to help perform functional tasks?
- R. How much does the robot weigh, and what are the parameters of its size?
- S. If the robot attaches to a wheelchair, how hard is it to mount and what space does it occupy (e.g., does it limit the ability of the wheelchair to go through fixed spaces)?
- T. How much time during the day will the robot be used?
- U. Is the robot gripper precise enough to be functional?

II. QUESTIONS TO ASK ABOUT EASE OF CONTROL

- A. Can the robot be used only at home in the house, or can it be transported to other sites?
- B. How easy is it to get the robot into the car?
- C. Does it take special training to use the robotic device?
- D. How long does it take the user to get comfortable and efficient in using the device (e.g., does it get easier to use the more it is used)?
- E. Are instructions for use in languages other than English?
- F. What type of controls are demanded (e.g., does it mostly require attention at execution, or does it require attention throughout task completion)?
- G. Is there any automatic part of the task performance?
- H. Is the robot flexible in responding to commands, or does the command have to be precise and delivered in only one mode?
- I. Can the robot be used in a variety of environments (e.g., home, school, work)?
- J. Are there speeds of execution differences for certain tasks?
- K. What type of sensor attachments are needed?

III. QUESTIONS TO ASK ABOUT APPEARANCE AND PRACTICAL USE

- A. Does the robotic device attract negative attention when out in the community or when people come to visit at home?
- B. Will the robot fit into the household without disrupting others (e.g., if used in the kitchen or the

- bathroom, does it interfere with others functioning in the same space)?
- C. If the robotic device must be applied to equipment, does it keep others from using the equipment (e.g., if hand devices are integrated in the car, can others still use the car using the foot pedals)?
 - D. What is the extent of construction or changes needed in the house to accommodate the assistive device (e.g., sensors and actuators mounted on the ceilings)?
 - E. Can the robot be integrated with other robotic subsystems in terms of control features?
 - F. Will it be required to have multiple robots, or is the robot a complete system?
 - G. Can the robot pick up information from the user about errors, problems, possible injuries, or unmet needs?
 - H. Are there multisensory control systems embedded (e.g., vision, movement, auditory, verbal)?
 - I. If the device is to help with functional activities at home, can it also be used for a health monitoring or alert system?
 - J. Does the control system interfere with other household activities (e.g., does the electrical or magnetic monitoring system interfere with TV signals or mobile phone signals)?
 - K. Is the system potentially flexible to integrate with other service systems that are expected to develop in the future?

IV. QUESTIONS TO ASK ABOUT INITIAL AND MAINTENANCE COSTS

- A. How much does the robotic device cost at initial purchase?
- B. What type of maintenance is required on the robotic device, and how much does it cost (labor and parts)?
- C. Is the user able to meet some of the costs both initially and on an ongoing basis?
- D. Will insurance help cover the costs for initial purchase as well as maintenance?
- E. Is the price of the robotic device increasing or decreasing?
- F. What is the demand for the robotic device; can it help a variety of people, particularly the aging population?
- G. Will the assistive robotic technology allow the patient to maintain independence at home (e.g., instead of having to go to a nursing home)?
- H. Is there evidence the price will go down with increased demand and supply (e.g., or is the technology itself so complex that the price will continue to stay high regardless of supply)?

variety of ADLs to be carried out at home including drinking from a glass, removing an item from a desk, scratching one's head, discarding an item into the trash, handling a floppy disk, shopping, and posting a letter.

In order for insurance companies to pay for the Manus ARM, the user must meet certain qualifications:

- Possess very limited or nonexistent arm and/or hand function
- Be dependent on the assistance of another person for help
- Use a power wheelchair
- Have sufficient cognitive skills to operate and control the ARM device
- Possess a strong determination to gain independence
- Possess adequate social and environmental support to achieve independence, such as caregivers, friends, and relatives

If the criteria are met, then the user is given an opportunity to use the ARM using different control devices. The appropriate control device is selected. Most individuals use the joystick and their original wheelchair. The ARM is purchased with a 5-year service warranty.

The process of approval and purchase can take several months. The installation takes several days. Each client is trained in his or her own home, where safety issues are discussed. Additional training sessions may be arranged at 2-week intervals with a 3-month evaluation.

In the Netherlands, the support for assistive robotics is funded by a governmental exploratory grant, not by Social Security or a social health insurance system. Follow-up studies indicate that at least 0.7 to 1.8 hours per day of caregiver help can be saved.²⁷⁰ However, this estimate of cost

savings may be an underestimate. For example, the cost for the standard ARM (plus 3-year warranty) is about \$30,000. With the savings on caretaker help, the return on the investment was 1 to 1.5 years. The cost savings were even higher if the user returned to work.²⁷¹

COMMERCIALIZATION OF REHABILITATION ROBOTICS

The greatest impediments to rehabilitation robots are the high cost, low efficiency, and welfare regulations. Despite these limitations, some rehabilitation robots have become commercially available for patients to use on a daily basis.

Increasing demand for the rehabilitation robotics will depend not only on costs, but on clarifying the benefits of the robotic device. This must be done with adequate protection of privacy. It should be possible to list the activities that need to be assisted, the user's movement freedom, what kind of movement impairments the robot can address, the importance of each activity for everyday use, and whether the robot can contribute to the completion of the task.

There are many other questions that need to be asked to determine cost-effectiveness and how to promote the use of these devices. Further details are also needed regarding the time required for the user to learn how to operate the robot, whether the robot control demands some user instructions each moment of the task execution, what level of automatic task performance is needed, and whether the robot responds to exact user commands or can respond correctly even if there is some inexactness (see Box 38-19).

FUTURE REHABILITATION ROBOTICS

Neural Plasticity

Activity-dependent plasticity will continue to underlie neurorecovery. More and more technology and robotic devices will become available over the next 10 years. It is conceivable that neurorehabilitation clinics of the future may need to become “gyms” for rehabilitation. Therapists will need to tailor the exercise routine to the patient’s needs to optimize recovery but at the same time will increase clinic productivity by seeing more than one patient at a time; they will incorporate current rehabilitation robotics to enable more effective, controlled, and progressive practice. Efforts must also be made to optimize efficient and effective operation of the robots to make them more accessible.

Advances in Technology

Rehabilitation robotics will continue to grow over the next 10 years as our population ages, medical care advances in saving lives, science continues to document plasticity and recovery, there are changes in technology, and wireless opportunities expand.²⁷²

Advances in technology in the future will be driven by an increasing demand for robotic technology to assist in the rehabilitation of an increasing number of elderly and an increasing number of individuals with impairments. Advances in computer technology, software programming, and materials will also drive an increase in the development and types of robotics. Visionary developers and the marketplace will drive leading-edge solutions for challenging problems.

There must be a drive in the current health care market to encourage investors to provide financial support for the development of visionary robots. Research on the cost-effectiveness of rehabilitation robotics will also drive development. If rehabilitation and service robots can decrease the number of caregivers needed and decrease the costs of transportation of patients with impairments, the demand and need for robotic devices will increase. Furthermore, with the emphasis on telecommunication systems, wireless technology, and Internet-based possibilities, patients with impairments may be able to train at home as well as work at home, particularly if they can be safe and independent in that environment using smart robotic devices.

Robotic technology for rehabilitation will also increase as materials, computer chips, design engineering advances, wireless communication electronics, computers, and robustness of sensory, transducers, and actuators improve. The computer devices must continue to be smaller, lighter, more convenient, easy to control, and more mobile. This advancement in computerized technology is definitely taking place right now with advances in cell phones and Global Positioning System (GPS) technology, high-speed storage systems, flexible display technologies, and alarm systems. This area of advancement is well underway.

Most people think of robots as stiff and inflexible, connected and run by motors. As wearable robotic devices are improved to better interact and adapt to humans, then the character of the material may have to soften and become more flexible—like a shirt rather than a metallic or wire-based exoskeleton. One can imagine the possibility of putting on a shirt with unobtrusive motors to help a patient lift

an object; wearing robotic boots with actuators to prevent accidents for patients who tend to fall; or wearing a special helmet with sensors that can sense danger and actuators that can correct the situation.

Brain-Machine Interfaces

There are already high-frequency electrical stimulation devices that can be placed on the surface of the spinal cord to facilitate locomotion (see Chapter 16). Deep brain stimulators now exist to help decrease abnormal involuntary movements, improve motor control, or control seizures (see Chapter 20). As advances are made in understanding brain specialization, neuronal networks, and communication pathways through the brain and the spinal cord, more rehabilitation robotic devices that facilitate CNS-machine interfaces will also grow in popularity and availability. Intel, Google, and Microsoft have already created brain-machine divisions to work on developing noninvasive methods to sample high-resolution brain activities to make BMIs a practical robotic reality.

For example, the Walk Again Project is a project that links living brain tissue to a variety of artificial tools to develop and implement the first BMI that is capable of restoring full body mobility to patients with severe body paralysis. A full neuroprosthetic device is a wearable robotic device wired to the premotor cortex and the primary motor cortex. It was designed by Gordon Cheng.²⁷³ The objective is to give the patient control over his or her upper and lower limbs to sustain and carry his or her body weight. This device requires the safe implantation of high-density micro-electrode cubes in the human brain. This robot can provide reliable, long-term simultaneous recordings of the electrical activity of thousands of neurons distributed across multiple brain locations.

Ideally, to make the BMIs clinically relevant and affordable, the large-scale brain activity recordings will have to be stable for at least a decade without need for surgical repair. The BMIs will have to incorporate low-power multichannel wireless technology transmitting the collective information generated by thousands of individual brain cells to a wearable processing unit about the size of a modern cell phone. A BMI will have to run independent computational program models to optimize function through actuators distributed across the joints of a robotic exoskeleton to mimic reflexes and trigger postural and gait adjustments in response to unexpected changes in the terrain. Electromechanical circuits will enable motor adjustments. The major blocks to the advancement of robotics are the high financial investments that will be required, variability in human factors, and safety issues.

Wireless Opportunities

Information and communication technologies will be integrated to extend opportunities for patients to rehabilitate at home under wireless conditions of supervision and advisement. Telemedicine has grown over the last few years to extend care into rural communities and allow sharing of databases and information across multiple sites for integrative management of individual patients. Real-time interactions (verbal and visual) will be possible between participants and providers through videoconferencing. However, other methods will need to be incorporated to maintain the dynamic interaction between clinicians and clients. User-friendly

telemedicine designs are just in their infancy. In addition, shifting the paradigm from one-on-one management to self-care management will also need to be integrated into telemedicine methods. Telemedicine may help shift our resources to efficiently and effectively manage the rehabilitation needs of elders and other patients with impairments.

CONCLUSION

Although the field of rehabilitation robotics is still in its infancy, it has already made important contributions to many individual patients' quality of life. Regaining functional control over impaired movements will remain a primary objective for patients with movement dysfunctions after CNS insult, whether through traditional physical or occupational therapy services, retraining using a nonwearable robotic, movement assistance from a wearable exoskeleton, or some combination of those three areas. Finding the most efficacious and cost-effective way for physical and occupational therapists to provide services for individuals with movement dysfunction will incorporate the potential use of robotics as intervention options. To what extent robotics will be integrated into inpatient

and outpatient rehabilitation as the intervention of choice will depend on many factors discussed in this chapter. This chapter was developed to provide to the reader the opportunity to widen clinical understanding and envision clinical options for patients who will be receiving occupational and physical therapy services in the future. The options are numerous, and whether to use or not use robotics as part of clinical services is not easily answered with a yes or no. But no matter the final decision regarding choice of intervention strategies, having options always helps provide a therapist with alternative treatment approaches when traditional approaches do not seem to be effective.

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 273 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

CASE STUDY 38-2

Lena is a 30-year-old occupational therapist employed by a transitional care and rehabilitation center, a 55-bed inpatient care center that is part of a large nursing and rehabilitation care network. She had a major stroke 13 years ago, resulting in profound right-sided hemiparesis, which physicians at the time predicted she was unlikely to reverse.

After about 2 weeks in local hospitals, she began a month of inpatient and 3 years of outpatient physical, occupational and speech therapy. Her arm and hand function came back faster than her gait. During this time, she had multiple surgeries on her right leg and ankle owing to repetitive ankle sprains, decreased balance, decreased strength, and decreased motor control.

Her experience as a patient inspired her to pursue a degree in occupational therapy. After completing her studies, she took a position as an occupational therapist at a skilled nursing facility. After a few years, she realized that she was limping and tripping more often. Simultaneously, a speech therapist brought in some information about a new lower-limb exoskeleton, the Bionic Leg by Tibion. She called the company to find out how she could take advantage of training with this technology. The following is a transcript of an interview with Lena and her physical therapist (Dr. A.).

Question: What was your reaction to putting the Tibion Bionic Leg on for the first time?

Lena: It seemed too good to be true. Almost immediately I could walk without my ankle-foot orthosis [AFO] without tripping. I could see improvement from the very first session.

Question: How long was that first session? Did you see any carryover?

Lena: My first session was an hour and a half. There was a lot of repetition, and I was exhausted. But afterward, I did see a little carryover for 15 to 20 minutes. And the

more I've used the Bionic Leg since that time, the longer the carryover lasts. At this point I have used the Bionic Leg for about 16 sessions, twice a week for 8 weeks.

Question to Dr. A.: Can you describe your impressions of Lena's gait when you first evaluated her?

Dr. A.: My impression was that Lena could walk with a better gait pattern. Lena had a lot of muscle wasting in her right leg, much more noticeable in her leg than her right arm. This recovery pattern is somewhat unusual for a patient poststroke. Part of this could possibly be explained by her work as an OT and her insight about how to rehabilitate her arm. On the other hand, the location of the ischemia was also important. Her arm appeared to be spared a little more than her leg.

If Lena was sitting in a chair and using her arms to talk to you, you would never know she had a stroke. But as soon as she would rise from the chair to walk, she had a very typical gait for a patient poststroke. She had circumduction of the hip, decreased weight-bearing time on the right affected lower limb, hyperextension of the knee, and a tendency to drag her toes when she would swing the right leg. Her gait was very asymmetric. When she would complete the swing phase of gait, given the circumduction, her leg was out to the side and it was difficult to shift her weight over her center of support to roll off the forefoot and prepare for the next step. She was off balance and had to make a quick step with the left leg.

In addition, Lena could not lift or dorsiflex her ankle or extend her toes. This weakness and ankle instability was addressed surgically with a tendon transplant to aid dorsiflexion and modification of the ligaments to increase stability. She had a dynamic (spring-loaded, hinged) AFO to keep her ankle in neutral dorsiflexion to

Continued

CASE STUDY 38-2—cont'd

minimize tripping. She had minimal strength in knee flexion (with hypertonicity in extension) and weak hip flexors. This imbalance in strength and motor control made it very hard to go up and down stairs reciprocally. She reported great frustration at having to go one step at a time. She works as a busy professional under a tight schedule and needs to be able to move quickly.

Question to Lena: As both a therapist and a patient, how do you evaluate the results of the first 16 Bionic Leg sessions?

Lena: I have more endurance and a more efficient and effective gait pattern. I can walk faster and straighter. I don't turn my foot out as much as I did, and I can roll or push off my right forefoot, which helps facilitate knee flexion, hip flexion, and dorsiflexion for the next step. I am able to clear my toes when walking and also when going up and down stairs, reciprocally.

Dr. A.: She has gained more flexibility in her gait. Interestingly, this included increased arm swing and increased trunk and pelvic rotation. She's improved her awareness of balance. She has learned to walk sideways and walk forward kicking a ball as if she were playing soccer. She has decreased circumduction of the right leg and improved the symmetry of the single-leg stance as she walks. She also has learned to decrease foot slapping after heel strike.

Question to Lena: It sounds as though someday, if you keep up this kind of progress, you might get rid of the AFO.

Lena: That's what I'm hoping—something I never thought would be possible. I had come to the conclusion that I would need the AFO for life. On the other hand, I remain guarded because of my ankle surgery.

Question to Dr. A.: What impact has the Bionic Leg had on Lena's gait speed? Just seeing her walking in your clinic is very impressive. Is she likely to ever be able to run?

Dr. A.: We initially kept her speed relatively slow when wearing the Tibion Bionic Leg, both walking over ground as well as walking on a regular treadmill and then walking on a BWSTS. Our goal has been to improve quality of gait including the integration of sagittal plane movements rather than circumduction at the hip joint. After improvement in quality and stability, we began to push Lena to the limit of her abilities (forced intense exercise). When you push people to the limit of their ability, it is important to avoid facilitating the abnormal patterns. One way to push the limits and try to promote quality of gait is with unweighting. Unweighting on a treadmill provides the opportunity to decrease GRFs, decrease the risk of falling, improve balance, and maximize gait symmetry and quality.

Once Lena was walking with a better pattern of gait over ground, we had her walk on a treadmill with the Bionic Leg. Then we slowly increased the speed of the treadmill. She progressed to 4.0 mph with good quality, good sagittal plane movement, and a stable ankle.

Patients with motor control problems and hypertonicity must initially learn to concentrate 100% on walking. If they are walking and talking they can trip, risking a fall. With hypertonicity and weakness, often there is a

decrease in the speed of postural righting reflexes to protect against falling. This was the case with Lena. If she was not thinking about her walking, she returned to her bad habits and tended to trip. She needed to practice enough to make these patterns automatic without conscious awareness.

Lena is clearly a community ambulator (>1.0 mph). Our functional objective is to help her become a better, safer, more integrated community ambulator. She works very hard, but she has to think about it. With every step, she's got to say, okay, where's my balance? Where's my weight? She needs to integrate quality of gait without attention.

Lena: Thinking and concentrating is especially true when I'm going down stairs, stepping off curbs, and looking out for uneven sidewalks. I'm always looking down. Only recently, I've started to be able to walk more spontaneously without thinking about every step. I am hoping that one day my walking will be more spontaneous.

Dr. A.: The gait pattern she demonstrated when she walked into our clinic the first day was partly compensatory and partly learned. When she used the Bionic Leg, it helped her to replace the abnormal learned gait pattern with a better pattern. She could also use the mirror to reinforce a better pattern of gait.

Question to Lena: You've commented that your gait is better since you started training with the Bionic Leg. Have you seen your toe clearance improve with training with the Bionic Leg?

Lena: I can see improved toe clearance since I started therapy with the Bionic Leg. In fact, if I'm not wearing shoes, when I'm at home, I'm now able to clear my toes on my own without wearing the AFO.

Dr. A.: Right before Christmas, I noted the carryover and integration of her gains in mobility. With less cognitive attention to her walking, her gait pattern was more symmetrical with less circumduction, a longer stride, and better toe clearance. Her mom and dad both commented about the improvement in the speed and quality of her gait.

Lena remains critical of her own achievements and she would like to be even better. However, the fact that she is walking faster, walking better, and tripping less and can walk at home without her AFO indicates her progress. She's a very dedicated patient, and I'm optimistic she will achieve the highest goals she has set for herself. I wish all patients had Lena's commitment and motivation.

NOTE from Dr. A.: Lena progressed in training to be able to jog aerobically for 30 minutes at 3.5 to 4.0 mph while unweighted to 50% of her weight. Unfortunately, she developed a repetitive strain injury in the unaffected foot (left), interpreted as a stress fracture (without MRI to confirm). She was treated with steroid injections and non-weight bearing and was fitted with new orthotics. Over 3 months without training, she put on weight and developed some pain in her unaffected knee. She thinks this is a result of the additional weight and a tendency to return to

CASE STUDY 38-2—cont'd

her abnormal, asymmetric pattern of gait with increased circumduction. However, she has maintained the speed of her walking and she performed her balance tasks within normative time. She wants to resume forced intense exercise in a body-weight-supported environment to restore the quality of her gait as well as improve endurance and lose weight. She also notes that she has less pain and is happier when she is exercising more aggressively.

Although this is a case of a specific patient and a specific exoskeleton, the reader needs to be aware that the principles presented within Chapter 4 in the discussion of motor learning and motor control, and discussed throughout the entire text, have been used to facilitate neuroplasticity in this patient. Repetition of practice of the correct motor programs has been

shown both in the literature and with this specific individual to create change even after 13 years poststroke. However, just as aerobic exercises are recommended for positive health for all individuals, especially as we age, aerobic and specific exercises have to be an ongoing investment for Lena as well. Exercise also has to be specific, and general exercises have to be an investment for the rest of her life. The case study was presented to help the reader identify and analyze how rehabilitation robotics can help individuals improve motor control for gait. Each therapist needs to analyze which of the many available therapeutic robotic tools can best assist an individual to maximize quality of life and independence after CNS insult. The reader is referred to the online video where the effectiveness of this exoskeleton can be observed.

CHAPTER 39

Complementary and Alternative Therapies: Beyond Traditional Approaches to Intervention in Neurological Diseases and Movement Disorders

DARCY A. UMPHRED, PT, PhD, FAPTA, CAROL M. DAVIS, DPT, EdD, MS, FAPTA,
and MARY LOU GALANTINO, PT, PhD, MSCE

KEY TERMS

alternative therapies
belief based theories
complementary models
complementary therapy interventions
energy-based theories
evidence-based practice
movement diagnosis
movement therapies
transdisciplinary models

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Differentiate the four historical to modern worldviews of health care delivery.
2. Analyze how complementary and alternative-based health care practices overlap with allopathic traditional medical models and movement diagnoses.
3. Analyze how mind, body, and spiritual interactions have the potential to lead to health, healing, and quality of life.
4. Compare and contrast the various therapeutic models discussed and identify similarities and differences between these and the traditions of Western medicine, OT and PT practice, and the International Classification of Functioning, Disability and Health (ICF) World Health Organization (WHO) model.
5. Appreciate the role of complementary and alternative approaches in the examination and intervention of individuals with movement-based problems as a result of neurological disorders.
6. Use evidence-based practice to measure outcomes in body system functions, functional activities, and life participation.

The use of complementary and alternative methods (CAMs) in the treatment of patients with neurological disorders and resultant movement problems is evolving into common practice. Clinicians and patients/clients are seeking nontraditional approaches to relieve signs and symptoms of neurological diseases, syndromes, and movement disorders as well as to attempt to alter the progression of diseases of the central nervous system (CNS) through unconventional movement therapies and manual therapeutic approaches. It is important that professionals working within a traditional rehabilitation environment understand the principles and practices of complementary, alternative, and even transdisciplinary approaches to the treatment of movement problems because many of these therapeutic approaches are being proposed as options in the management of body system problems and restrictions in daily life activities and independence resulting from neurological problems. The clinician needs to be cautious in the application of these treatment modalities. We do not want to accept alternative therapies as intervention solutions without significant evidenced-based research substantiating the use of these approaches. The reader must also be reminded that evidence comes from effectiveness, and many complementary approaches have established effectiveness.¹

This chapter presents a sampling of alternative therapeutic models and philosophies that are available and could potentially assist patients/clients who have movement dysfunction because of CNS pathology. Most of the techniques discussed in this chapter have been firmly established by sound research; some less-evidenced-based models are also included to widen the scope of therapeutic models. Clinicians are continually being exposed to the therapeutic potentials of less scientifically established theories and therefore need to be aware of their existence and potential. Creating evidence-based practice is not an all-or-none principle, nor do we suggest that models that do not have a strong research base are ineffective. We do suggest that to adopt a model because of belief or the charisma of the founder will be and should be challenged by colleagues today and in the future. Models whose theoretical constructs are based on sound rationale or that link effective-based practice across multiple areas need to be scrutinized and approached cautiously but should not be nullified as potential alternatives. In time, if those models maintain their sound base, more research will be developed and their efficacy established. New models will also be created in the future that link and integrate theories with practice, and our professions will continue to evolve and offer better-quality care to the consumer.

HISTORICAL PERSPECTIVE

Jennifer M. Bottomley

Darcy A. Umphred

A historical perspective of how complementary and alternative therapeutic approaches have evolved to become increasingly part of the medical and rehabilitation landscape can be helpful to obtaining a broader scope of how they link to allopathic medicine of today. The language and rationale encountered in alternative methods can seem confusing and foreign to clinicians unfamiliar with modalities outside of the realm in which they were taught. With many of our patients/clients seeking alternative methods of intervention beyond what the traditional Western medical model can offer, the time has arrived for us to explore and understand the scientific basis for the apparent effectiveness of these interventions. The positive results experienced by many patients/clients who have received alternative interventions cannot be ignored. This is the impetus for the growing acceptance of alternative forms of therapy by the general public and many health care practitioners. Can we scientifically explain the effects of complementary and alternative interventions? And if so, how can we best integrate complementary and alternative approaches into our accepted, current, and changing approaches to neurological rehabilitation?

Looking at the evolution of health care throughout the world over hundreds and even thousands of years, general categories or worldviews have developed that best categorize philosophy of management of individuals with health care issues and their respective rationales for practice. In the following paragraphs a further discussion of these four worldviews will help the reader identify how the practice of health care today still fits within the second worldview but has begun to fractionate into the third worldview as linear research based on two variables does not explain the multiple variables involved both in disease or pathology and in recovery of function. In their book *The Second Medical Revolution*, Laurence Foss and Kenneth Rothenberg described levels of academic learning as being three tiered.^{2,3} Starting at the top, the third tier comprises the applied studies and subjects for therapists, such as therapeutic exercise and electrotherapy. The second tier is the pure sciences on which these subjects are founded, such as anatomy, chemistry, physiology, and biology. The first tier is the “assumption of reality” (day-to-day observations) on which the pure sciences are based. This first tier consists of the basic assumptions found in “worldviews” today. Different worldviews yield different scientific bases, whether pure or applied. Alternative approaches used in medicine and rehabilitation are well established in “premodern” and “postmodern” worldviews. This is in contrast to the “modern worldview” customarily taught in current Western medical training. To present these methods in overview, it would be helpful to discuss these worldviews and how physical therapy (PT) and occupational therapy (OT) may fit into the scheme.

Essentially, there are four worldviews⁴: the premodern, modern, “fracturing or splintering,” and postmodern views. The first worldview developed during prehistoric times and lasted until the sixteenth century. This is called the *premodern view*. In this perspective, time is cyclical rather than linear. In other words, it was believed that the sun, the moon, and the stars circle around the earth, the tides ebb and rise cyclically, and the seasons circle back again and again, using

the same patterns each time, connecting with “deep time.” Deep time is compared with profane time. Profane time is tangible, as in the time it takes rice to boil; or visible, as in the sundial; or sensible, as in the heartbeat. In deep time such perceptions are suspended, profane time stands still, and one becomes a part of time. It is in deep time that premodern man finds reality. Infused in this thinking is that life and death, the earth and the sky, are mysterious or mystical. In other words, they contain truth beyond human comprehension.

This is a hard perspective for many to grasp, yet the role of the scientist is to be a passive observer. Numbers were used to describe observed events, such as the days between the circling of the sun and the moon, and the number of hours between the ebb and high tide, but “there was no widespread assumption in the western world that natural processes in general had any intrinsic relation to numbers, to mathematics.”⁵ In other words, in Western science, these perspectives were not tangible, visible, or sensible...and so, historically, science moved on.

The second worldview, which began with Copernicus, is known as the *modern worldview*. It is the one with which the majority of the Western population would be most familiar and feel at home. In this view time is linear, progressing from start to finish. “The world is a rational, predictable, clockwork universe. Every bit of it can be predicted if you know one part of it. Purpose in life is to describe, generalize, predict, and control. Human beings are fairly mechanistic, separate, discrete entities from the rest of the universe.”⁴

René Descartes (1596-1650), French philosopher and mathematician, and Isaac Newton (1642-1727) were two of the most important figures ushering in the “modern era.” To Descartes, the world was logical, predictable, and intrinsically expressible through mathematics. The whole was obviously equal to the sum of the parts—categorical and hierarchical. The role of the scientist became that of an active, experimental, objective observer. If the numbers did not fit, it could not be real.

The modern era of the second worldview spanned the 1500s through the twentieth century. However, the near perfection of the view began to falter in the early 1900s with important discoveries in the field of physics. Although the hold of the second worldview on Western culture is still immense, it is splintering, as can be seen within our own professions.

Worldview 3 is about this fracturing, about the realization that the categorical, orderly clockwork is not a complete or necessarily accurate picture. It is a prelude to worldview 4. A small but growing number of people see the world in worldview 3, and fewer yet in worldview 4, but the effects are starting to be felt.

Worldview 4, postmodern, is complex, integrated, and nonlinear. It is about self-organizing and self-regulating systems, looking for patterns, and knowing that a small variation in the pattern can produce large changes. Time is a dimension, interwoven with the dimensions of space. Time and space can change, expand or shrink, speed up and slow down. Rituals are an important means for creating order. The whole is greater than the sum of the parts, and “we know and yet don’t know.” Worldview 4 has a lot of similarities with worldview 1. The pure sciences that arise from this worldview include systems theory, quantum physics, cybernetics, string theory, and fractal mathematics, which in

turn affect many other fields of study, such as meteorology, ecology, business and economics, medicine, theology, movement science, and computer science, to name but a few. Research parameters, technology, and interpretation differ significantly from the assumptions of worldview 2 because scientific description is no longer considered purely objective, but rather *epistemology* (the view from which knowledge is gathered) is becoming “an integral part of every scientific theory.”⁶ Western medicine has begun to shift from the second worldview into the third worldview because a total linear approach to explain efficacy has not proven inclusive and cannot always explain why individuals do and do not recover from disease or pathology or the functional loss they produced. The professions of PT and OT have run into the same dilemma as Western medicine and are also making similar shifts. The incorporation of alternative or complementary approaches that take into consideration the mind, body, and spirit is becoming more acceptable as colleagues embrace the shift in thought process. Change will come. The rate and the depth of that change will depend on the openness of all of us to accepting different research methodology and outcomes while still embracing those linear research models of today that we believe lead to efficacy or evidence-based practice.

Today we practice within the paradigms of our professions, which have in the past aligned with Western medicine. Thus, for our ease, we can first start where we are, look at the medical profession, and discuss models or strategies that parallel the worldviews.

The roots of Western medicine extend back to Hippocrates, 400 BC, who provided a holistic picture of the state of health, writing that “Health depends upon a state of equilibrium among the various internal factors which govern the operations of the body and the mind, the equilibrium in turn is reached only when man lives in harmony with his external environment” (p. 23).² The basic assumption in this perspective is that health depended on a balance with mind-body and nature or the environment, and disease was a disturbance of this balance. Preserving the balance was the priority for the practitioner. Three means were used to ascertain the characteristics of an illness: a dialogue with the patient, observational assessment of the patient’s appearance, and palpation of the soft tissues and pulses. The most important component of this approach was considered the dialogue with the patient/client. It was believed that the “meaning” of the illness to the patient/client, and his or her attitude and expectations were valuable diagnostic and prognostic factors. This coincides closely with the World Health Organization (WHO) International Classification of Functioning, Disability and Health (ICF) model accepted by rehabilitation professionals around the world.⁷

Descartes largely initiated the shift from a preservative approach for mind-body-environment integrity to the conventional curative thinking found in medicine today. He conceptualized reality as having two separate domains, one the body or matter, the other the mind. “The body is a machine,” said Descartes, “so built up and composed of nerves, muscles, veins, blood and skin, that though there were no mind in it at all, it would not cease to have the same [functions]” (p. 32).² His ideas were closely tied to Newtonian physics, which conceives the universe as a harmonious and well ordered machine. These concepts gave rise to the

view that matter and nature were separate from humans, and thus one could observe without affecting what was being observed. The physician, then, could have complete objectivity when assessing the patient. The patient could be viewed as a biological organism whose function was reducible to interrelating physical parts.

The resulting medical model, known as *biomedicine*, was fully in place by the middle of the nineteenth century. Its characteristics may be considered as follows:

1. Disease or dysfunction is a “deviation from the norm of measurable biological parameters” (p. 23).² A patient/client is a biological organism whose dysfunction is reduced to the identified deviations. Treatments or procedures are then used to cure or at least improve the deviations, which in turn improves the biological condition.
2. Objectivity provides the basis for diagnosis or assessment and the subsequent rationale for treatment. Patients’/clients’ descriptions of what they are experiencing and the clinician’s observation are considered “subjective” and not given as great a value as the “objective” findings, such as laboratory or other measured tests.
3. Eventually biomedicine can address virtually all medical problems at least adequately, if not fully, through more knowledge and research.

It goes without saying that the biomedical model has produced stunning and tremendous accomplishments. Yet its restriction to physical causes of disease, in light of diseases and dysfunctions that are more widely recognized as having multiple causes, is creating a search for other answers. More of the public and some physicians and other health professionals are turning to alternative forms of intervention and healing. As stated in *Life* magazine in September 1996, “Why have alternative therapies in this country started to migrate from the margins to the center? One reason is that as allopathic medicine, a term commonly used to describe western techniques, becomes better at what it *can* do well, its limitations become more conspicuous. Allopathy is clearly superb at dealing with trauma and bacterial infections. It is far less successful with asthma, chronic pain and autoimmune diseases.”⁸

Many of the alternative practices used in a medical setting today clearly come from premodern worldview sources, such as acupuncture, yoga, meditation, herbal remedies, and prayer. Just how some of these therapies work to restore health is difficult to perceive from a linear worldview 2 perspective. Frequently what happens is that alternative approaches are used to address areas of limitations in the biomedical model, in a complementary fashion. Alternative practices used this way do not supplant traditional medicine; rather, they support and enhance the options available in health care. A new worldview and medical model would not necessarily arise from this relationship, yet the conceptual framework is no longer cohesive. Ideas from ancient sources, as well as postmodern sources, are changing the previously complete and adequate image of the second worldview and consequent medical model. Grappling with these issues places one in worldview 3.

Evidence of these dynamics is apparent in the professions of PT and OT. In neurorehabilitation, for example, proprioceptive neuromuscular facilitation and neurodevelopmental techniques were developed in the middle of the twentieth century at a time when “rehabilitation” was being

established as an integral part of unquestioned biomedical order. Both approaches, in their early form, worked primarily with the nervous system, and both used hierarchy and order. Patients/clients were to progress through a sequence of skills, such as the *developmental sequence*, that was invariable. The hierarchy was also found regarding the role of the therapist as the professional who could identify the pathokinesiology and “fix” it with the appropriate technique. The patient was the recipient of the treatment. With the advent of *motor control, motor learning, and neuroplasticity theories* over the last couple of decades, these fixed approaches have changed because the new concepts have influenced them. The developmental sequence, now termed *learning sequence*, no longer uses a strict hierarchy based on movement development of a child. Its treatment approach is moving away from emphasizing the therapist’s role in identification and resolution of pathological movement and moving toward a science of functional movement that is based to a large extent on the role of the patient in his or her own capacity to problem solve, self-monitor the motor control system, and help establish outcome expectations on the basis of function, not pathological conditions. Last, an entirely new entity of neurorehabilitation has been formed recently as a result of concepts from motor control, motor learning, dynamical systems theory, and the understanding of neuroplasticity, which is known as the *task-oriented or functional approach*. Masters of the past used the available science to justify their respective approaches, but the one thing that all masters seemed to hold in common was a close relationship with their clients. They all let that relationship and the needs of the client determine how treatment progressed irrespective of the verbal explanation given for any sequential progression of treatment. They wanted the client to become functionally independent and have the highest quality of life that was possible for that individual. Those masters in the past did not have the science of today to explain why a treatment was effective. The fact that they created an environment that brought about the functional change in the patients would suggest that they intuitively used motor learning, motor control, and neuroplasticity because their patients improved in function over time.

One of the tenets of dynamical systems theory, as noted in the journal of the American Physical Therapy Association (APTA) in 1990, is that “biological organisms are complex, multidimensional, cooperative systems. No one subsystem has logical priority for organizing the behavior of the system” (p. 770).⁹ The nervous system, then, is no longer a dominant subsystem with neurological patients. Rather, it is part of a self-organizing system that has multiple subsystems such as arousal, gravity, learning style, body weight, center of gravity, cardiovascular function, and so on. “No one subsystem contains the instructions for [an action]. . . . The behavior of the system is instead an emergent property of the interaction of multiple subsystems” (p. 771) (see Chapters 4 and 5).⁹

Added to these developments was the emergence in the 1980s of a new field of therapy intervention: vestibular habilitation for posture and balance, which is multisystem and multifunctional and inherently demands the use of motor control and learning principles and understanding of the mechanism of neuroplasticity and interactive systems theories. Systems concepts are used for both balance and the task-oriented approach, the concept being that “movement

emerges from an interaction between the individual, the task, and the environment”¹⁰ (see Chapters 11 through 17 and 19 through 31).

Orthopedic, or manual, PT appears to be firmly committed to the biomedical model, yet there is interest found in “being holistic,” and treatment and exercise approaches are continually being developed that endeavor, to various degrees, to work with movement and function in a broader and more integrated manner (see Chapter 18).

Thus we find that today therapists are incorporating systems concepts, motor control, and motor learning theories into practice and experimenting with ancient sources of healing, such as yoga, tai chi, acupressure, and meditation, as well as refining skills in the traditional biomedical aspects of therapy. For our professions, holistic approaches have created and will continue to create change, and change can be confusing, threatening, and exciting all at the same time.

Worldview 2 still remains the dominant model within the Western allopathic health care delivery system. Two distinct observations may be made that show the prevalence of a worldview 2 approach. The first is that many colleagues continue to consider themselves to be objective observers separate from our patients. The second is that we endeavor to understand ancient, modern, and postmodern therapeutic concepts and research, frequently from a linear, mechanistic, categorical worldview 2 epistemology. Yet such a view at times does not suffice to explain what is happening. That is the dilemma of worldview 3.

Further changes will be experienced when a critical mass of the population turns fully, in all aspects of personhood, to “worldview 4,” which, again, has great similarities to worldview 1. A big difference, though, is that at this time in history, we have scientific methods for understanding our nonlinear, complex, evolving, multidimensional, multilevel, continually interacting, irreducible world. Through systems theory we can handle, with sophistication, this multitude of complex detail, by working with its “sweeping simplicity and order in overall design.”³ Throughout the twenty-first century, as the growth of worldview 4 continues to evolve on many levels and in many fields of endeavor, it is entirely possible that it and its sciences will indeed replace, and not simply complement, worldview 2. And from there, the future has yet to be conceptualized and belongs to future students willing to venture beyond what is comfortable to best meet the health care needs of a world society.

ALTERNATIVE MODELS AND PHILOSOPHICAL APPROACHES

Darcy A. Umphred

Approaches to patient management that do not fall within a traditional allopathic medical model are often considered alternative or complementary. Although many of these therapeutic approaches have not been able to show effectiveness or efficacy in totality as an approach to medical management, neither has Western medicine. Although the *evidence-based method of medicine* is the accepted term for identifying outcome measures by reliable and valid instrumentations and interventions, there is controversy within the literature as to the validity of evidence-based medicine.⁸⁻¹⁶ Personally, I have been a patient for the last two decades with interactive health issues that medical practitioners cannot explain. I have been told by at least seven excellent medical specialists that,

when looking at their specific area of specialization, they have never seen the specific system problem that my body system presented. Thus, not knowing what it is, each doctor does not know specifically how to treat the problem. Medical doctors know there is some genetic basis and understand the specific system problem from a descriptive perspective, but cannot explain how and why the system problems interact. Thus a syndrome exists without a medical diagnosis. My medical case was submitted to the National Institutes of Health (NIH) as a potential syndrome for which they might find a diagnosis. NIH returned the case saying they do not have the ability to determine the diagnosis because it is much too complex. Doctors have had to stretch beyond their comfort zone to help me and work with me in order for me to remain on this plane we call life.

Medical practice is evolving, as are the practices of PT and OT. Future research will help validate many aspects of Western medicine, and some areas will be discarded. The same will happen to OT and PT practice. Similarly, research will demonstrate the effectiveness of many components of complementary approaches, although some components will need to be eliminated and new creative ideas and therapeutic techniques developed. One research problem encountered with complementary approaches is that these approaches consistently focus on the patient as a total human being with all the interactions of all bodily systems. This philosophy of the whole does not coincide with the linear, reductionistic physical research accepted by Western medicine, in which one variable is studied while another is controlled. PT and OT involve the same approach to research, in which one approach may be compared with another, such as overground walking versus body-weight-supported treadmill training. One may or may not be more efficacious, but the investigations as to why it is or is not, and what other variables are affecting the results of the study may be needed. These answers are still beyond our understanding. Until research models are developed and instrumentation becomes available that measures multiple systems at multiple levels of consciousness simultaneously, it will be difficult to prove the strengths of many aspects of alternative approaches to patient management. That does not mean the evidence is not there. It means our research skill may not have developed to the level of measuring all the influences that are interacting simultaneously during a complementary approach intervention. Finding those research models with supporting instrumentation is and will continue to be a challenge to therapists who choose to incorporate these interventions as part of their professional management of patients with neurological disabilities. If doctors had made the decision to stay within their respective branches of evidence-based medicine, I (D. Umphred) would no longer be editing this textbook. There are many holes in our understanding of movement science, just as there are holes in medical science. Answers to questions often do not come from research scientists but from clinicians finding solutions to specific patient problems. Once those potential solutions have been identified, research may be able to refine and identify the specific components that are affecting change as long as the tools are available to accurately identify the initial problem(s) and the intervention(s) creating change.

All of the models for patient management presented in this chapter have a common thread. All approaches focus on

helping the patient/client maintain or regain a quality of life that is within that person's potential. The specific philosophy or conceptual framework embraced by any one approach varies. As various approaches are introduced in the following sections, subheadings will help the reader categorize similarities of philosophies. Even with the discussion of any or all of these approaches, whether accepted by our professions as the best available today or considered complementary, it still seems that we are looking through holes at what is total. The whole or total is made of all possible interventions that have, are having, and will have efficacy. When we no longer need to view problems with a specific model influencing our approach but are able to base our decisions on truth, we will finally be able to access what is truly available to us as practitioners and give the best possible guidance and suggestions to our patients to help them regain or maintain motor function as they experience life on a daily basis.

Movement Therapy Approaches

Equine-Assisted Therapy

Kerri Sowers, USEF National Paraequestrian Classifier

Introduction to Hippotherapy and Therapeutic

Riding. At the 1952 Helsinki Olympic Games, a Danish dressage rider named Liz Hartel won the silver medal and inspired a renewed interest in the field of hippotherapy and therapeutic horseback riding (THR). Liz used horseback riding as a form of rehabilitation to aid her recovery from poliomyelitis, which left her lower extremities paralyzed.^{17,18} The use of horses in therapy to improve physical and mental health has its founding roots in Greek culture. The term *hippotherapy* originated from the Greek word *hippos*, meaning "horse."¹⁹ The renewed interest in hippotherapy and THR grew first in Europe and was especially popular throughout England. In 1969, the North American Riding for the Handicapped Association (NARHA) was founded; this organization established standards for the developing THR centers in the United States.¹⁷⁻²⁰ Recent studies conducted in North America show that approximately 90% of children with disabilities participate in THR programs, and the remaining 10% participate in hippotherapy sessions.²¹

It is crucial to understand the differences between hippotherapy and THR, as both programs are commonly offered at the same facility and are often mistakenly thought to accomplish the same goals. The American Hippotherapy Association (AHA) defines hippotherapy as "a term that refers to the movement of the horse as a tool by physical therapists, occupational therapists and speech-language pathologists to address impairments, functional limitations and disabilities in patients with neuromuscular dysfunction. Hippotherapy is used as part of an integrated treatment program to achieve functional outcomes."²⁰ During hippotherapy, the horse is used as a modality or treatment tool; the therapist and his or her assistants control the horse in order to effect a change in the patient/client. In contrast, THR teaches the client specific riding skills that allow the rider control of the horse's movement; the focus is on teaching horseback riding skills to riders with disabilities. AHA attempts to clarify the difference by stating that hippotherapy "treatment takes place in a controlled environment where graded sensory input can elicit appropriate adaptive responses from the client. Specific riding skills are not taught as in therapeutic riding but rather,

a foundation is established to improve neurological function and sensory processing.”²⁰

Benefits, Indications, and Precautions. Hippotherapy and THR are felt to be beneficial because the equine walk provides a multidirectional input resulting in movement responses that closely mimic the movement of the pelvis during the normal human gait. The movement is both rhythmic and repetitive and allows for variations in speed and cadence. In hippotherapy the horse is used as a dynamic base of support (BOS) to assist in improving trunk control, postural stability, core strength, and righting reactions to improve balance.²² Vestibular, proprioceptive, tactile, and visual sensory inputs are incorporated during a hippotherapy session. As stated by the AHA, “the effects of equine movement on postural control, sensory systems and motor planning can be used to facilitate coordination and timing, grading of responses, respiratory control, sensory integration skills and attentional skills.”²²

Hippotherapy is indicated for neuromuscular conditions characterized by reduced gross motor skills, decreased mobility, abnormal muscle tone, impaired balance responses, poor motor planning, decreased body awareness, impaired coordination, postural instability or asymmetry, sensory integration deficits, impaired communication, and limbic system dysfunction (impaired arousal or attention skills).^{18,22,23}

Common conditions that may benefit from hippotherapy and THR include autism spectrum disorder, cerebral palsy, developmental delay, genetic syndromes, learning disabilities, sensory integrational disorders, speech-language disorders, traumatic brain injury (TBI), and cerebral vascular accidents.²²

There have been a multitude of suggested therapeutic benefits from hippotherapy and THR, which affect many body systems. Suggested physical benefits include improvements in endurance, symmetry, and body awareness; development of trunk and postural control; improvements in head righting and equilibrium responses; normalization of muscle tone; mobilization of the pelvis, lumbar spine, and hip joints; and improved sensory awareness. Suggested cognitive, social, and emotional benefits include improvement in self-esteem, confidence, interaction with others, concentration, attention span, and communication skills.^{18,19,24}

Contraindications for the use of hippotherapy or THR include excessive hip adductor or internal rotator tone accompanied by potential hip subluxation or dislocation, lack of head control (in large children or adults), pressure sores, spinal instability, or anxiety around animals.^{18,24}

Regulations. AHA offers a Clinical Specialty Certification for therapists demonstrating advanced knowledge and experience in the practice of hippotherapy. Physical therapists, occupational therapists, and speech-language pathologists must have been practicing in their profession for 3 years (6000 hours) and have had 100 hours of hippotherapy practice within the 3 years prior to application. Certification is valid for 5 years; once applicants pass a multiple choice test they are entitled to use the designation HPCS.^{22,25}

APTA recognizes hippotherapy as a treatment tool to address impairments and functional limitations in patients with neuromusculoskeletal dysfunction. APTA recommends that PT sessions that incorporate hippotherapy be billed as neuromuscular education, therapeutic exercise, or therapeutic activities based on the treatments completed. The American Occupational Therapy Association (AOTA) also recognizes

hippotherapy as an interventional tool, which can be billed as neuromuscular education, therapeutic exercise, therapeutic activities, or sensory integrative activities.

Evidence and Clinical Implications. Research and studies concerning the use of hippotherapy and THR are limited but expanding. At the time of publication of this text, there have been no large, well designed, randomized controlled trials investigating the use of hippotherapy or THR. There have been several fair-quality randomized controlled trials and many nonrandomized trials that do support the use of hippotherapy in children with cerebral palsy. One systematic review investigating the use of hippotherapy and THR found improved gross motor function; normalization of pelvic motion; improvements in weight shifting, postural and equilibrium responses, muscle control, and joint stability; improved recovery from perturbations; and improved dynamic postural stabilization.²¹ Studies have supported that hippotherapy can improve postural stability in individuals with multiple sclerosis (MS) and can assist in treatment of balance disorders.^{26,27} Hippotherapy has also been shown to reduce lower-extremity spasticity in patients with spinal cord injury.²⁸ Support for hippotherapy has been shown by improvements in the areas of muscle symmetry, gross motor function (as measured by valid and reliable tools), energy expenditure, and postural control. Researchers suggest that hippotherapy will lead to improved head righting and equilibrium reactions and dynamic postural control, normalization of abnormal muscle tone or symmetry, improved muscle control, and better endurance. In addition, hippotherapy has the potential to contribute to psychosocial well-being and improved motivation by allowing interaction and acceptance with another living being and the opportunity to be mobile while astride the horse; being positioned high up on a horse gives the child the chance to be at eye level with his or her peers, and the fun of riding encourages participation and enjoyment of the therapy sessions. Continued research into hippotherapy and THR using larger, randomized controlled studies that investigate specific outcomes and account for the variations within a variety of neuromusculoskeletal conditions will be necessary to conclusively determine all potential benefits that exist.

Feldenkrais Method of Somatic Education

James Stephens

The Feldenkrais method is about learning the following:

I do not treat patients. I give lessons to help people learn about themselves. Learning comes from the experience. I tell them stories [and give them experiences of movement] because I believe learning is the most important thing for a human being” (p. 117).²⁹ [parentheses added by the author].

Development of the Feldenkrais Method. As a boy in Palestine, Moshe Feldenkrais developed a method of hand-to-hand combat that was used by settlers for self-defense. Later, as a student in Paris where he trained in physics at the Sorbonne, he studied judo and became the first person in Europe to receive a black belt. When he injured his knee playing soccer, he relearned pain-free walking on his own. Later he studied with F. M. Alexander, Elsa Gindler, and Gurdieff. He also studied psychology, progressive relaxation, bioenergetics, and the hypnosis methods of Milton Erickson. And he was familiar with the physiology of his

day: Sherrington, Magnus, Fulton, and Schilder. With this background, Feldenkrais developed two approaches to facilitating learning that are now known as Awareness Through Movement (ATM) and Functional Integration (FI).³⁰

Feldenkrais was ultimately interested in the development of human potential. He saw that, although all people encounter trauma and difficulty in their lives, those who are most successful develop new, adaptive behaviors to overcome those difficulties. He proposed that a type of learning that reconnected the brain to the control of the musculoskeletal system would be the most effective way to approach this problem of adaptation. His initial thinking in this area is set out in his first book, *Body and Mature Behavior: A Study of Anxiety, Sex, Gravitation, and Learning*.³¹

Background Theory—Dynamical Systems Theory.

For Feldenkrais, learning was an organic process in which cognitive and somatic aspects were completely integrated and interactive. Presented first in 1949, this idea prefigured our current sense of dynamic systems functioning of the brain and body.³² The learning should proceed at its own pace in an individualized way following the learner's intention and guided by the learner's perception that the performance of the task, movements of the body, and interaction with the environment become easier.³¹ This interactive cycle of action and perception has been described well by the motor learning model proposed by Newell.³³

Learning is a complex process with overlays from the intention of the learner, interference from environmental distraction, misperception of the task and the body, desire related to self-image, fear of injury, or incorrect performance. Thus it is possible to learn poorly, incorrectly, or in such a way as to interfere with performance and not improve it. This kind of process has been suggested by Byl and co-workers³⁴ as the underlying cause of focal dystonia. One of the definitions Feldenkrais gave for learning took this process into account: "Learning is the acquisition of the skill to inhibit parasitic action (components of the action unrelated to the intention behind an action but resulting from a secondary intention) and the ability to direct clear motivations as a result of self-knowledge."³¹ An adult engaged in learning to walk again after a stroke with a fear-related reluctance to bear weight on the involved limb would be an example of such a secondary intention.

The process of learning proposed by Feldenkrais is one of discovery. The outcome desired is one of increased awareness. Vereijken and Whiting³⁵ have proposed that discovery learning, in which learners are free to explore any range of solutions in learning to perform a task in any way that they want, is as effective as or more effective than any formal approach to motor learning involving controlled schedules of practice or feedback. This process of discovery has the added dimension of allowing learners to focus on the perceptual understanding of the body/task/environment as a component of the learning process. In the Feldenkrais method this discovery and perceptual learning process is explicit.

Our understanding of how experience and learning restructure almost all areas of the CNS is expanding rapidly.³⁶ A large focus of current thinking in rehabilitation is how to translate neuroplasticity concepts into more effective techniques for rehabilitation.³⁷⁻³⁹ The method developed by Feldenkrais and practiced by people around the world who

are trained in this method is clearly explained by these new principles, creating new approaches to rehabilitation.

Approaches to Feldenkrais Method. The two approaches to facilitating learning created by Feldenkrais, ATM and FI, are similar in principle and process although they differ in practice. They are essentially two methods for communicating a sensory experience that the client can consider and act on. The first requirement of the process is to create an environment that is comfortable, safe, and conducive to learning, whether the learner is being moved passively or creating the movement experience voluntarily. The second requirement is that the amount of effort associated with making the movements be reduced greatly so that it is possible to make fine discriminations about the effects of force acting on the system from outside, from inside, or both. The goal is to develop a rich understanding of changes throughout the system produced by small perturbations. This understanding becomes the basis for creating new solutions to movement problems as the client progressively approaches functional movements that she or he desires to perform.⁴⁰

In FI the practitioner will manually introduce small perturbations into the learner's system after placing the learner into a safe position closely approximating some desired activity to be learned. Here the practitioner is providing the force inputs and the client is asked to attend to the changes created in response to the perturbation. For example, the practitioner might press gently into the bottom of the client's foot and ask the client to notice where in the body movement and pressure are felt as a result. This will be repeated a number of times and then some other forces or movements will be introduced. The guiding idea for the practitioner might be to build sensory experiences in the body that are associated with a particular movement, such as rolling. This goal is rarely explicitly expressed to the client and is left to emerge in the client's understanding of the experience: "Oh, now I am rolling," or "This feels like rolling to me." Also there is no strict expectation by the practitioner about what specific movement might emerge. Thus it is possible to create novel and unexpected outcomes of how a particular task might be best performed by this particular person at this time. This allows for a process of assessment that is continually evolving as the intervention is unfolding.⁴⁰

In ATM the practitioner verbally provides suggestions for movements for a client to explore and asks the client to focus on the sensory outcomes throughout the body. Thus the client introduces the experimental forces into his or her own system with the intention of understanding how the body as a whole responds. The underlying idea, however, is the same. In my practice, I use FI as a form of communication when clients do not understand how a force might act on the body or when they are unable to produce a range of movements that we might desire to explore. An example might be in a case where spasticity prevents fine discrimination in both sensory and motor realms.

In practice with an individual client, it is common to move back and forth between ATM and FI during the same session. The session is usually focused on the development of understanding and performing a specific function: turning, rolling, standing, stepping, and so on. ATM is a verbal process in which clients perform their own movements; thus a practitioner can work with many individuals simultaneously. At the same time individuals

within the learning group are free to respond differently from one another in ways that may be appropriate only for them as individuals.⁴¹ Because ATM is under the

active control of the client, this method is often a more effective tool in reestablishing voluntary control (*Case Study 39-1*).

CASE STUDY 39-1 ■ SUE: HEREDITARY SPASTIC PARAPARESIS

Sue was a toe walker as a young child. She remembered her father sitting in a chair all the time, his legs too stiff and weak to walk. In her mid 20s, she too began to develop weakness and stiffness in her legs. At the age of 36 years she was diagnosed as having “uncomplicated” hereditary spastic paraparesis (HSP).

Uncomplicated HSP involves extreme spastic weakness, some loss of sensation in the lower extremities, and hypertonic bladder reflexes. It progresses slowly over many years without exacerbations or remissions. Individuals experience progressive difficulty walking and often require canes, walkers, or wheelchairs. They typically retain normal strength and dexterity of the upper extremities, have no involvement of speech, chewing, or swallowing, and have a normal life expectancy.

Sue was first seen in our outpatient clinic when she was 38 years old. She worked as an office manager at a local college. Her office was up a set of stairs that was becoming more difficult to negotiate. She also owned a horse that she had not been able to ride because she was no longer able to mount because of her increased spasticity. Sue was a large, muscular woman at 5 feet 10 inches and 175 pounds.

On initial examination she reported pain in her right knee with weight bearing (8/10) and pain in her low back (5/10). Her proprioception appeared to be intact. She had decreased passive range of motion (ROM) in dorsiflexion bilaterally and hyperextension of her knees bilaterally, greater on the right. There was tightness in the iliotibial band and hip adductors, flexors, and rotators bilaterally and the extensors of the back from the lumbar through the cervical spine. Her muscle strength was 3+ to 4–/5 at all joints of both lower extremities, with the right being generally weaker than the left. She also had mild weakness in her trunk flexors (3+/5). There was sustained clonus in plantar flexors bilaterally and one beat clonus in her quads on the right. She had normal active ROM throughout her upper extremities with normal (5/5) strength throughout. Sue stood statically with her hips externally rotated, knees hyperextended, hips forward with her back extended in a stiff swayback posture. Her shoulders were retracted and tight. She was unstable to a moderate challenge and reported falling frequently. Her gait was stiff with knees hyperextended and toe drag bilaterally. She achieved swing by doing a lateral trunk tilt with contralateral circumduction with each leg, no arm swing and a foot flat landing. She used a straight cane for balance. Her self-paced gait speed was greater than 75 ft/min (1 mph = 88 ft/min). She reported “it feels like I have a stick up my back and if I try to go faster, my knees lock and I’m really in trouble.” Sue was assessed to be a good candidate for a Feldenkrais intervention, and a series of FI and ATM lessons was planned.

The first FI lesson was an exploration of the organization of turning and rolling from supine. I began this exploration with Sue supine and observed her postural organization in that position. She lay with her arms flat at her sides, palms up. Her legs were adducted and externally rotated and her back arched away from the mat table. I put a small towel roll under her neck and

back and a 4-inch roller under her knees to allow her extensors to relax somewhat. I began the exploration by rolling her head gently and found a lot of resistance to that movement. Attempts to do small amounts of turning of a leg or bending of the knee also met with similar resistance. I then began working through a process of manually shortening muscles that were tight and overworking. I began with neck extensors by gently holding the cervical spine in a slightly more extended position progressing to the extensors of the trunk by compressing the ribs from the side to cause a slight lateral flexion first on the right then on the left. The relaxation focused last on the legs by holding the knee and hip in a slightly more externally rotated and flexed position first on the right, then on the left. Going back to the neck, pressure was exerted down through the first rib on the right to cause a slight lateral flexion to the left through the spine. This movement was now easier than before, with force being translated further down the spine into the lumbar area. Next the pressure was combined with rolling of the head to the right, first passively, then with small active movements. The instruction was to turn the head only as much as could be done with almost no effort. The same process of compression of the spine and turning of the head was repeated from the left side of the neck. The interaction then progressed to the right leg by pushing through the right foot so that the force translating up the leg caused lateral flexion of the spine to the left, then again from the left leg. The right foot was then turned to initiate external rotation and flexion of the right leg first passively and then actively. Sue began to be able to control that small movement on the right leg with minimal effort and then repeated on the left. We then began to link the movement of the legs, trunk, and head together in a sequence in which she began to be able to roll her head to the right, flex her right leg and left leg together toward the right, and allow her trunk to flex and turn toward the right. During this process, Sue’s attention was directed to sensing the movement and timing of different body segments; to feel the forces created in her body by the movement of one segment and how they impeded or facilitated movement of other segments. This lesson ended with Sue being able to roll more easily onto her side from supine than she had been able to do in a long time. This session took about 45 minutes, during which I was doing some work with another patient at the same time. When Sue came up to standing after this lesson, she reported feeling like she was stuck into the ground solidly. She felt shorter, softer, and better balanced. Her feet were flatter on the floor, and when she walked she did not drag her toes on the floor.

At the beginning of the second session on the following day, Sue was tested again on the treadmill and was now able to walk about 120 ft/min. The second lesson began again in supine and reinforced and developed the movements of the first lesson. Sue learned to slowly roll to her right side, moving her arms at the same time so that she could take weight on them, flex her legs until they came over the side of the mat table and then push

CASE STUDY 39-1 ■ SUE: HEREDITARY SPASTIC PARAPARESIS—cont'd

herself up to sitting all in one motion and then reverse this process slowly until she was lying supine again. She learned to roll herself into a fetal position back and forth from the left to the right without her legs stiffening in between, and when she sat up she was able to actively flex her legs up to put her shoes on, which she had not been able to do for at least a year. After this lesson she reported that she had been able to move her foot easily from the gas to the brake in the car without slipping and that she was able to get onto and ride her horse for the first time in several years.

In the third lesson, we worked more purely with ATM because Sue was now able to control more movement more easily herself. During this lesson Sue learned to roll with minimal effort to the left and right while holding her knees and then to reach to her ankles and roll while holding her ankles without stiffening her neck in the process. Flexing her hips had become easy.

The fourth lesson involved standing, weight shifting, and turning. The instructions related to keeping movements small and slow and maintaining a feeling of softness that she now had developed. She explored movements of allowing her knees to flex while she shifted weight to one foot and moving her body over the weight-bearing foot to get a sense of how she could distribute weight differently across her foot on the basis of changing the configuration of her upper body and movements of her hips. These movements included exploring the effects of intentionally stiffening and softening her back and neck to feel any changes that happened in control of her weight bearing, knee flexion, and ankle. Weight on one side was increased while the other was unweighted, and the unweighted leg was lifted in

a controlled manner, easily and effortlessly, feeling the support of the skeleton for the process of lifting. At the end of this lesson, Sue was able to lift her foot easily up onto the 19-inch-high surface of the mat table and bring it back to the floor without disturbing her balance. At home she was now able to step up onto her horse from a low step without other assistance.

In the fifth and final session, more time was spent doing an ATM lesson related to standing balance, turns in walking, and bending to the floor. In this session and at the end of the previous one, we also spent time in transfer training with toilet, tub, car, and floor transfers and gait training on smooth and uneven surfaces and for speed on the treadmill. She still used a cane for balance (or a single hand support on the treadmill) but now was able to walk on the treadmill at 175 ft/min, well more than double her initial speed, without dragging her toes or hyperextending her knees. She did complain of some back pain and calf pain, but this was determined to be from exercising muscles that had not been used in years and resolved after several days. I recorded the ATM lessons with a lapel microphone and recorder as we did them and gave her the tapes to use at home as part of her home exercise program.

Three months after discharge, as a passenger in her sister's car, Sue was in an auto accident and sustained a herniated disk at C5-6. After this she had decreased mobility for several months. During this time she lost her understanding of how to control her movement and returned to us 6 months after her initial visit to review what she had done earlier. After several series of lessons over a period of several months, she achieved a level of function higher than previously so that she was able to walk and go up and down stairs without any support.

Evidence of Effectiveness. The theory underlying the Feldenkrais method predicts that there should be changes in perception of the body or body image. Although there have not been a lot of studies in this area, there are several that support this prediction. Elgelid⁴² reported positive changes in body perception, as evaluated by the semantic differentiation scale in a group of four subjects after a series of ATM lessons. Dunn and colleagues⁴³ reported that subjects who had had a unilateral sensory imagery ATM lesson perceived their experimental sides to be longer and lighter and demonstrated increased forward flexion on that side, linking the changes in perception to changes in motor control. Batson and co-workers⁴⁴ have shown that ability to image movement is improved in people poststroke after a series of ATM lessons, and furthermore that there is a high positive correlation between the Movement Imagery Questionnaire (MIQ) score and improvements in balance assessed by the Berg Balance Scale.

There is not a lot of literature evaluating the efficacy of the Feldenkrais method in general and even less specifically for people with neurological diagnoses, as a result of the complexity of the problems and the multiple system involvement of the individuals. Evidence-based studies on effectiveness are more easily identified. In a review, Stephens and Miller⁴⁰ divided the literature into four different areas: pain management, postural and motor control, functional mobility, and psychological and quality-of-life

impact. Much of the literature is in case report format. A small amount of the literature is controlled study format, with some of that using randomized control groups. The work on pain management suggests that the Feldenkrais method may be especially effective in treating pain that is biomechanical in origin. This concept may be applied to work with pain in patients with neurological diagnoses, especially pain caused by biomechanical malalignment. No research has been done in this area with neurological patients. Hall and colleagues⁴⁵ found improvements in balance (Berg Balance Scale [BBS]), mobility (Timed Up-and-Go Test [TUG]), functional activity (Frenchay, Short Form 36 [SF-36]), and vitality (SF-36) in a large group of elderly women compared with control subjects as a result of a 16-week ATM intervention. These results have been confirmed by Vratsidis and colleagues⁴⁶ and Connors,⁴⁷ also using ATM with a group of elderly women. In the areas of psychological and quality-of-life impact, Kerr and colleagues⁴⁸ have shown decrease in state anxiety in subjects who participated in ATM lessons, and Laumer and colleagues,⁴⁹ working with young women with eating disorders, have demonstrated positive changes in self-concept, self-confidence, and behavior resulting from participation in ATM lessons. Many of these findings are beginning to be reproduced in clinical populations with neurological diagnoses. Most of the studies to date have been done with people with MS. Colleagues are beginning

to look at ATM effectiveness in patients after a stroke (cerebrovascular accident [CVA]).

Research

Multiple Sclerosis. The initial study, done in Germany in 1994, looked qualitatively at the effects of a 30-day ATM experience on a group of people with MS. The investigators concluded that ATM improved overall well-being, resulted in greater self-reliance of the participants, and led to better self-acceptance and a more positive self-image.⁵⁰ After that, Johnson and colleagues⁵¹ studied the effects of FI in people with MS. Although they did not find any significant mobility changes, they did report a decrease in perceived stress in the FI compared with the massage controls. Stephens and colleagues⁴¹ reported the cases of four individuals who participated in the same ATM classes over a period of 10 weeks. Three of four reported large improvements in their Index of Well-Being score. All subjectively reported improvements in gait. However, there were no measures of gait that consistently improved across the group. Instead, it was found that changes were appropriate to the participant's individual needs and resulted in a greater sense of control. In a follow-up to this study, using a randomized controlled group design, Stephens and colleagues⁵² found improvements in postural control and balance confidence measures, along with a strong tendency toward an increase in self-efficacy and decreased falling. It was also found⁵³ that the ATM group had significant improvements in memory of recent events and perception of positive social support. It is interesting to note that they also had a decrease in pain effects.

Cerebrovascular Accident. The original publication in this area is the classic work, *The Case of Nora*, in which Feldenkrais explained his work in great detail and described improvements in sensation, perception, and mobility of a woman several years after a right-sided CVA.⁵⁴ More recently, results from pilot studies are just beginning to be reported in patients with diagnoses of CVA. Connors and Grenough⁵⁵ reported a decrease in spatial neglect as measured by line and star cancellation tests in a patient after a series of ATM lessons. Nair and colleagues⁵⁶ reported the recovery of upper-extremity function and the return to playing golf in a 68-year-old man after an 8-week program of ATM and FI. This Feldenkrais program was begun only after a 9-month program of traditional rehabilitation had left him with a non-functional hand. The Feldenkrais program included mental imagery and bimanual activities. This subject was also studied before, during, and after the Feldenkrais program with functional magnetic resonance imaging. The magnetic resonance imaging analysis showed that there was a return to higher activity in the involved contralateral primary motor cortex with activity of the right hand compared with higher activity in the ipsilateral M1 and SMA that has been shown in other reports of CVA recovery⁵⁷ before the Feldenkrais sessions began. This finding suggests a return to more normal brain function even after a period of 1 year after the stroke. A small pilot study (three subjects)⁵⁸ found an average 33% decrease in movement times on the Wolf Motor Function Test. In another pilot with four subjects, Batson⁵⁹ found significant improvements in Dynamic Gait Index ($P = .033$, 55% average) and the BBS score ($P = .034$, 11% average) and a 35% improvement on the Stroke Impact Scale (SIS). A larger study is in progress to further assess these findings.

Other Medical Diagnoses. There are some preliminary findings with other neurological diagnoses. Shelhav-Silberbush⁶⁰ reported improvements in motor, sensory, kinesthetic, perceptual, and learning functions in two case studies of children with cerebral palsy. Shenkman and colleagues⁶¹ reported improvements in balance, gait, and functional movement in two people with Parkinson disease as a result of interventions that were based partly on a Feldenkrais approach. Gilman and Yaruss⁶² have reported significant improvements in several young children who had problems with stuttering. Ofir⁶³ reported improvements in flexibility, mobility, and level of dependence in two young women who had sustained traumatic brain injuries.

Conclusion. The Feldenkrais method, in its two forms, embodies a process of somatic learning that aims to develop the perceptual capabilities of clients as it underlies the control of movement. Recent literature suggests that predicted results of improved body perception and motor control are supported in work with people with neurological diagnoses. These findings are encouraging and suggest that the Feldenkrais method will make positive contributions to our understanding and methods of rehabilitation. However, we must approach these findings with caution because many are from case studies or pilot studies done with a small number of people. Research continues to substantiate these claims at a higher evidence-based level. Refer to [Box 39-1](#).

The Pilates Method

Brent Anderson*

German-born Joseph H. Pilates developed his unique form of movement therapy in the early 1900s. As a young man, Pilates was affected by a multitude of illnesses that left him physically weak. In an effort to strengthen his frail body, Pilates studied yoga, martial arts, Zen meditation, and ancient Greek and Roman exercise. His experiences led him to develop his own unique method of physical and mental conditioning. In 1926 Pilates brought his movement exercise program with him to New York City. Joseph Pilates's studio was soon embraced by many artists and choreographers from the dance companies of Martha Graham, George Balanchine, and Jerome Robbins. At the time, traditional allopathic medicine lacked the knowledge of how to restore injured dancers to their prior level of activity. Pilates encouraged nondestructive movement early in the rehabilitation process and worked to correct underlying biomechanical problems. This early movement intervention without pain was believed to hasten the healing process and allowed dancers to quickly return to the stage.

Almost a century later, the Pilates method has gained popularity within the rehabilitation setting because of its assistive nature in restoring functional movement. Rehabilitation practitioners are currently using the method in a variety of fields including orthopedics,⁶⁴⁻⁶⁷ pain management, women's health,⁶⁸ neurological rehabilitation, geriatrics, pediatrics,^{69,70} and even acute care. Most Pilates exercises in the rehabilitation setting are performed on specifically designed apparatus: the Reformer (Figure 39-1), the Cadillac table (Figure 39-2), the Wunda Chair (Figure 39-3), and the Ladder Barrel (Figure 39-4). The apparatus regimen evolved from Joseph Pilates's original mat

*The author wants to thank Matt Butler for his contribution to the Pilates section in the fifth edition of this textbook.

BOX 39-1 ■ RESOURCES AND TRAINING

1. Only people who have graduated from accredited training programs may practice the Feldenkrais method. Training in the Feldenkrais method in North America is overseen and accredited by the Feldenkrais Guild of North America (FGNA).
2. For information about training programs and the Feldenkrais method, contact the FGNA at (800) 775-2118 or e-mail to info@feldenkraiguild.com. There are more than 1000 certified practitioners in the United States and Canada. To find a certified practitioner in your local area, go to the FGNA website: www.feldenkraiguild.com.
3. In 2004, the International Feldenkrais Federation (IFF) founded the *IFF Academy Feldenkrais Research Journal* as an online resource for research on the Feldenkrais method. You can find this journal on the Web at <http://iffresearchjournal.org>.

Figure 39-3 ■ The Wunda Chair apparatus used in Pilates.

Figure 39-4 ■ The Ladder Barrel apparatus used in Pilates.

Figure 39-2 ■ The Cadillac table apparatus used in Pilates.

work, which was shown to be too difficult for many injured individuals. On the apparatus, springs and orientation to gravity are modified to assist an injured individual to successfully complete movements that would otherwise be difficult or limited. Ultimately, by altering the spring tension or increasing the challenge of gravity, an individual may progress toward functional movement safely, efficiently, and without pain.

Pilates Principles. Joseph Pilates espoused only three guiding principles according to the Pilates Method Alliance: (1) Whole Body Healthy, (2) Whole Body Commitment, and (3) Breath. A number of the first-generation Pilates practitioners known as *the Elders* expanded Pilates principles to include concentration, control, precision/coordination, isolation/integration, centering, flowing movement, breathing,

and routine. Polestar Pilates has modified the eight first-generation principles into six principles that have a greater practicality in the rehabilitation environment and stronger scientific support than the classic principles. The six Polestar Pilates principles include breathing, core control and axial elongation, spine articulation, efficiency of movement, alignment, and movement integration.*

Breathing. Faulty breath patterns can be associated with complaints of pain and movement dysfunction.⁷¹ Pilates movements create an environment where breath facilitates improved air exchange, breath capacity, and posture. During Pilates exercise, breathing is used to facilitate stability and mobility of the spine and extremities. Because of the movement of the rib cage on the thoracic spine, inhalation can promote spinal extension while exhalation can promote spinal flexion. Breath may or may not facilitate movement based on where the breath is occurring. If accessory breath were to occur while attempting spine extension, it would not have a positive movement on the spine articulating into extension. It is then important to realize that the direction of movement in the ribs facilitated by breath determines whether or not breath facilitates movement or not. Likewise, breath may assist with stability of the spine through the coordinated contraction of the diaphragm and the lower abdominal muscles, which both attach to the lumbar spine and pelvis.^{72,73}

Core Control and Axial Elongation. Core control is the optimal recruitment of the trunk musculature required to perform a given task in relation to the anticipated load. The transversus abdominis, internal abdominal obliques, external abdominal obliques, multifidi, erector spinae, diaphragm, and pelvic floor muscles are key organizational muscles that work together during movement in healthy individuals.⁷⁴⁻⁷⁶ Motor control studies indicate that the coordinated, sub-threshold contraction of these local and global stabilization muscles modulate the level of spinal stability required to safely perform activities of daily living.⁷⁷

Axial elongation is the proper alignment of the head, spine, and pelvis that provides optimal joint spacing during movement. Correct joint spacing avoids working or resting at the end of range, which can place undue stress on the inert and contractile structures of the trunk and extremities.^{78,79} Through emphasis on axial elongation of the spine and maintaining appropriate joint spacing, soft tissue surrounding the joint can move more freely and the risk of injury can be minimized. Recent discussion has challenged the Pilates approach to core control, attempting to minimize its benefit. As yet, there have been no studies that show that the use of the local stabilizing muscles interferes with or minimizes core stability compared with increasing the intraabdominal pressure by pushing out into the abdominal wall and the hypertrophy of the musculature inside the thoracolumbar fascia. This is more likely to represent rigidity and stability and might serve a population lifting severely heavy weights.

Spine Articulation. Spine articulation is the equal distribution of movement throughout the cervical, thoracic, and lumbar spine. As a motor control principle, spine articulation is where distribution of movement equals distribution of force. It has been suggested that repetitive movement at a hypermobile spinal segment may result in microtrauma or

macrotrauma.⁸⁰⁻⁸² Hypermobility is often a result of a lack of movement in a neighboring segment or joint.⁸³ Pilates exercise attempts to facilitate a change in movement strategy during functional tasks. Patients are trained to distribute movement in the spine over a greater number of spinal segments, thereby decreasing potentially harmful forces at the hypermobile segment. The ability to segmentally move the spine decreases unwanted stress and shear of the spinal segments and increases the efficiency and fluidity of movement. The clinical findings of decreased low back pain as a result of Pilates exercise may be due to changed strategy that reduces the stress afforded to the pathological segment.

Efficiency of Movement. Efficiency of movement is the minimization of unnecessary muscle contractions that tend to interfere with healthy movement. The excessive recruitment of antagonist muscles is obstructive and significantly increases the amount of energy required to perform a task.^{84,85} This principle can be applied to functional movement skills as well as performance skills. Inefficient motor recruitment can often be recognized by the amount of tension or faulty posture in the head, face, neck, and shoulder girdle, in relation to the thoracic spine and trunk.

Alignment and Weight Bearing of Extremities. Alignment and posture are concepts often incorporated in the field of rehabilitation. The Pilates principle of *alignment* refers to the most energy-efficient posture (static or dynamic) of the body for a given task. Proper postural organization can significantly decrease energy expenditure during daily activities by improving mechanical advantage.^{86,87} Faulty alignment in the extremities and the spine can be a source of decreased ROM, loss of joint congruency, early fatigue of muscle groups, or abnormal stresses on inert structures and may potentially cause degeneration and injury.^{88,89}

Pilates provides a closed chain environment that facilitates compression and decompression forces on the axial skeleton and extremities through a full ROM. Adjusting the spring resistance or patient's orientation to gravity can alter the amount of load. The ability to regulate load on the basis of an individual's physiological limits, set by age or pathological condition, allows practitioners to more safely and effectively stress the skeletal and soft tissue systems. Theoretically, these forces can help stimulate osteoblastic activity and provide nutrition to a larger surface area of the joint and its surrounding connective tissue.⁹⁰⁻⁹²

Movement Integration. Many forms of rehabilitation focus on treating limitations of anatomical structures and neglect the neuromuscular reeducation required to learn to regain the motor control necessary to perform a complex task. Pilates provides a more holistic approach by emphasizing the synthesis of mind (motor control) and body (physical strength and flexibility) to achieve fluid movement. Mobility, control, and coordination of the extremities with the trunk and the trunk with the extremities are examined and trained through motor learning and repetition of practice. In addition to the physical and mental capacity to complete a task, the environment in which a task is performed can greatly affect the success of movement organization.^{93,94} Pilates provides an environment that can be modified on the basis of a patient's impairments and limitations, providing a safe, successful, and pain-free movement experience.

Clinical Application. Within the Pilates environment, faulty movement strategies are broken down into components

*The six modified Pilates principles were developed by the Polestar Pilates method.

and addressed through task-oriented interventions. By adaptation of the environmental constraints, such as gravity, assistance, and BOS, the degrees of freedom that must be controlled by the nervous system are reduced.⁹⁵ The successful manipulation of the environment can hasten the functional reeducation process and allow exercises to be safely progressed until the desired outcome is achieved. Pilates practitioners are also trained to be able to modify any exercise so it is pain free for the patient. It has been suggested that successful, pain-free movement, in addition to enhancing physical attributes, helps to alleviate anxiety.^{96,97} By decreasing anxiety levels and improving self-efficacy, the development of chronic pain and dysfunction related to the injury may be prevented.⁹⁸⁻¹⁰⁰

The potential causes of faulty movement patterns include congenital defects and abnormalities, habitual adaptations, and compensation because of injury. Motor control problems associated with the pathological condition need to be addressed before the application of therapeutic interventions that are temporary coverups for problems that have deeper roots. For example, a pathological condition at the L4/L5 segment could be a result of faulty movement patterns in the hips and other lumbar vertebrae. The lack of movement in surrounding joints might be the mechanism of the lesion; however, treatments are often focused on the site of the lesion rather than the mechanism of the lesion.

One problem often encountered in the rehabilitation setting is flawed movement progression. On a spectrum of movement progression, practitioners often jump from passive movement to resistive movement too quickly. Through facilitation of assistive movement, a pattern can be practiced without irritating the lesion. Assisted movement with the use of springs can allow for a decrease in unwanted muscle activity or guarding that is often associated with pain, weakness, or abnormal tone. As the pattern progresses and symptoms decrease, assistance decreases and dynamic stabilization can be emphasized to challenge the newly acquired mobility or stability in a more functional and gravity-dependent position. Resistive movements are introduced only after adequate dynamic stability of the trunk is demonstrated through controlled movements that prevent excessive loading of the injured tissue. The five environmental conditions in Pilates that are altered to allow a therapist to facilitate motor changes are the following^{93,101}:

1. Narrow or widen the BOS.
2. Raise or lower the center of gravity.
3. Lengthen or shorten the length of the levers.
4. Decrease or increase the degree of assistance (spring tension).
5. Progress from a foreign environment to a familiar environment.

Traditional modes of muscle conditioning focus on isolating specific muscles and producing a maximal voluntary contraction. Although this has been found to positively alter the targeted muscle, the gains achieved have not always been shown to correlate with functional return. Pilates progresses patients through stages of motor learning via neuromuscular reeducation of functional movement patterns and emphasizes efficient recruitment of motor units. The patient is first trained to become aware of or gain a perception of current movement strategies. Then the patient must cognitively learn a new strategy. Finally, the patient must practice or take action until efficient with the new

strategy of movement. Task-specific interventions are progressed from a foreign to familiar environment by altering the level of assistance and the patient's orientation to gravity.

Summary. Pilates is an effective exercise system that works well in conjunction with traditional PT and OT practice. The Pilates-evolved apparatuses allow patients to safely perform exercises that improve strength, flexibility, balance, coordination, and motor control in an environment that can be easily progressed as they advance in their rehabilitation process. In addition, Pilates is thought to address the psychosocial components of an injury that lead to chronic pain or disability by decreasing anxiety and improving self-efficacy.^{98,99} Early return of functional movement after an injury helps to physically and mentally empower individuals with regard to the demands of life and is crucial in the long-term success of patient outcomes. The Pilates environment is a clinical tool that can be used by practitioners to provide patients with a safe, successful, and pain-free way of restoring function and quality of life.

Tae Kwon Do

Clinton Robinson, Jr., 9th Degree, Grand Master
Darcy A. Umphred, 4th Degree

Philosophy. The overall philosophy of Tae Kwon Do (TKD) can be summed up in the student oath recited by all practitioners at the beginning of each class: *"I shall observe the tenets of Tae Kwon Do: courtesy, integrity, perseverance, self-control, and indomitable spirit."* The tenets are to be practiced outside as well as inside the training hall in all aspects of life. All aspects of these tenets reflect CNS control and neuroplasticity and incorporate cognitive, emotional, and motor aspects into an integrated whole. The oath continues with, *"I shall respect the instructors and seniors,"* which refers to having respect for all people—our teachers, our parents, our peers, our students, our patients—all individuals with whom the student may interact throughout a lifetime. *"I shall never misuse Tae Kwon Do."* No matter what motor skill a student develops, it is not to be used to build one's ego or to injure another unnecessarily. *"I will be a champion of freedom and justice."* Individuals are expected to develop a sense of responsibility for those less fortunate than themselves and to be active participants in the development of humanity as a whole. These tenets are basic philosophies of both OT and PT. Empowering our patients to overcome their movement limitations and once again actively participate in life should be the goal of all therapeutic treatment outcomes. *"I will build a more peaceful world."* Understanding that change begins with self, and developing and integrating the mind, body, and spirit while helping others do the same, will set an example not only in the classroom but in our society both nationally and worldwide, so that others may improve themselves. The profession of OT has identified similar educational outcome criteria for students who graduate from an accredited educational program. PT has begun to integrate the mind, body, and spirit into outcomes, but as of today PT has not embraced the interactions of those three human characteristics as part of the accreditation criteria set forth by the Commission on Accreditation in Physical Therapy Education (CAPTE). Yet there are commonalities between the

practice of TKD and some of the expectations of students in educational programs in both PT and OT.

The overall goal of TKD training is the development of self-sufficiency through rigorous physical and mental practice. With this training, an inner balance or peace can be attained, thus balancing all aspects of a person's life. Students are expected to strive for their own personal excellence versus comparing that skill with another's. Thus, individuals with physical challenges are always encouraged to participate. Their challenges and expectations are different, but achieving personal excellence gives them the same respect and confidence that any other student would receive. Thus, TKD as a movement science empowers participants to gain or regain a feeling of empowerment over the mind, the spirit, and the physical body. It engages all students to participation in a community of people who all begin as novices and advance only as each respective mind, body, and spirit grows as a whole unit. At times an individual may have physical restrictions that limit the ability to do specific techniques, but that never limits one's ability to grow and advance as a human being and continue to learn as a student of TKD.

Philosophy of Training. Training in TKD consists of three primary components: forms, breaking of solid objects, and sparring. Other martial arts focus on some of the same components. The practice of tai chi focuses on the first component, forms. But with practice a TKD student not only will have the skill to perform a sequential pattern or combinations of simple and complex movements (forms), but also will overcome a perceived obstacle (board), and interact with another person using quick movement techniques with control (sparring).

Poomsee. Poomsee is a prearranged dance of defensive and offensive techniques against an imaginary opponent. The practice of poomsee increases the practitioner's memory, coordination, balance, and body awareness. All poomsee components have predetermined patterns of movements with a proper beginning and ending point that include various stances, along with hand and kicking techniques. The complexity and difficulty of these forms increase as the student progresses. Simple movements and combinations of patterns challenge beginners, and appropriate levels of complex patterns challenge the highest-ranking black belts. Thus all individuals studying TKD are challenged to be in a state of growth and learning.¹⁵⁵

Kyukpa. Kyukpa is breaking of solid objects such as boards, concrete, and bricks using a body part as a weapon. Kyukpa represents overcoming limitations and obstacles and facing fear. It requires tremendous concentration and belief in one's abilities. In addition, it allows participants to demonstrate the power they have attained, thereby increasing self-confidence. Self-confidence is the primary attribute in conflict resolution skills and leads to the understanding that there are few situations in life in which physical confrontation is necessary. Board breaking helps teach the student that an object, such as a board, is only an obstacle if you, the student, empower that object to have that role. Once the board is broken and the limb has passed through the obstacle, it no longer is an obstacle. This philosophy reflects life and plays a role in the establishment of values and motivation by teaching practitioners to go beyond the known and through the obstacles that life poses.

Kyorugi. Kyorugi is actual sparring between two people using both defensive and offensive techniques learned

through fundamental TKD practice. Kyorugi can be further broken down into two types. (1) In *one-step sparring*, practitioners take turns initiating a prearranged attack—one person attacks while the other defends. This allows the practitioners to engage each other without risk of injury to either party. It also allows them to practice proper distancing and execution of the techniques. This develops confidence in the ability to use the techniques properly if the need arises. (2) In *free sparring*, neither opponent knows what the other is going to do. Although free sparring may appear dangerous to one untrained in TKD, it is a relatively safe activity. Free sparring requires respect for your partner and absolutely controlled motions at all times. It is an exercise in which the aim is for all involved to increase their skill level.¹⁵⁶ It develops the practitioner's quick motor responses, confidence in his or her abilities, and overall awareness as well as a cooperative learning environment.

Although both offensive and defensive techniques are viewed as equally important, all training is begun with blocking techniques to indicate that TKD never allows any initial offensive attack in its technique. Blocking techniques are practiced diligently so that they may function equally as offensive techniques. This way one can defeat an opponent, whether in the classroom or in real life, without either suffering or inflicting serious injuries. This builds self-confidence and replaces a perception of the "role of a victim."¹⁵⁷ Defensive techniques are not only power against power but truly reflect power of the attacker and deflection by the opposition. This deflection can stop the attacker, redirect the power back onto the attacker, or incapacitate the attacker in order for the opposition to get away. The skill in redirecting the force and intent of an attacker is not too different from redirecting a patient's motor pattern into a direction that would be functional as a motor program. The TKD practitioner and the therapist are working with the pattern of movement presented to them. The intent of the TKD student would be to disempower the attacker, and the intent of the therapist would be to empower the patient.¹⁵⁸⁻¹⁶⁰

In TKD training, all students begin in the same place. There is no concern for one's status in life. The white belt is used to denote the beginning student. With all students beginning at that level, it allows another aspect of training that is critical to all students and individualized. Training encompasses setting and achieving goals or empowering oneself toward excellence and to one's own quality of life. In TKD, there is a belt ranking system, and the object is to progress through the various levels of proficiency, culminating in attainment of the black belt. Everyone, regardless of social status or physical skill, has the same opportunity to advance in TKD. Students who persevere and obtain a first-degree black belt learn that they have only begun their circle of growth and learning. With additional years of training, students may advance in black belt ranks that should reflect a greater understanding and acceptance of those initial tenets. The circle of growth will always lead to further integration of mind, body, and spirit and an inner peace and balance.¹⁶¹ The balance of mind, body, and spirit is the core of other complementary therapy paradigms and ultimately seems to be an element linked to health and healing.¹⁶²

Tae Kwon Do and Complementary Therapy.^{154,161,163-167} Although TKD is a martial arts style whose original intent was not to heal a body system condition or to allow one to regain a functional movement activity lost after some acute health care crisis, the concepts

and procedures learned, repetitively practiced, and transformed into life behavior have established the foundation for health and healing in individuals. Most students in TKD fall within a health and wellness model of life. *Their choice to participate is not based on a bodily system problem as often seen in a PT or OT clinic. These individuals are looking to participate from a wellness perspective and expect that Tae Kwon Do will enhance their balance and their cardiopulmonary and musculoskeletal systems through exercise.* Yet many individuals have experienced some aspect of musculoskeletal system problems during their lives. These individuals, as a result of life activities, have forced the CNS to adapt and accommodate to prior bodily system problems such as ligament tears or *physical or emotional* trauma from bullying in school. These experiences create change whether the deficits are motor, cognitive, or affective.^{168,169} Similarly, with identified chronic motor limitations that have caused functional *activity* restriction after a birth trauma, an external head trauma, or an internal insult, TKD can help maintain existing motor function, cognitive integrity, emotional balance, and a feeling of self-worth in the face of a long-term and possibly progressive neurological problem. All these components encourage an individual to participate in life and base advancement not only on the standards of TKD but also the individual goals set by each student.

As in all martial arts, TKD requires active participation by the student. When any TKD movement pattern is examined, certain motor control components are seen to be interacting. There are a variety of activities that generally occur during a class. First there are warmup exercises, after which the student will work on (1) her or his respective form or poomsee or hyung (dancelike patterns that may have 18 to 100 different movement sequences), depending on the level of advancement; (2) sparring, which is done either with one partner moving with an identified pattern while the other stays in one position or with both moving and learning to respond to the movements or feints of the other; or (3) learning to focus and perform specific strikes or blows that will lead to skills in board or brick breaking or defending oneself against a life-threatening attack.

During warmup, a student stretches and builds up power, using specific movement, balance, timing, concentration, and cardiopulmonary functions that set the stage for the remainder of the class. When doing the forms, the student will need to work on balance, postural tone, the state of the motor generator, synergistic patterns of movement, trajectory, speed, force, directionality, sequencing, reciprocal patterns, and the context within which the movement is being done. Similarly, memory of the specific pattern, movement sequences, and direction of the movements requires concentration. As the student progresses in rank, the specific patterns become more and more complex, increase in number of specific movements, and frequently change from quick movements to slow, controlled patterns. This repetition of practice and increase in difficulty leads to higher skill and cortical representation.^{170,171} If other students are also practicing in class, then each individual needs to be aware of the total environment to respect the space of all other students. This unique individual experience during a group activity allows for variance during each class and thus should lead to greater motor learning and cortical representation.^{171,172}

When students are learning and practicing either one-step sparring or free sparring, they are not only working on learning combinations of movement patterns and how they interact or conflict with those of their partners, but they are also learning how to control their emotional responses to threatening situations. Little in life is worth hurting another—a basic principle of TKD. During sparring, the potential for injury is directly correlated with the control over the force and direction of movement of each individual. That control can be dramatically affected by emotion (see Chapter 5). Once students learn to control the emotional aspect, their skill and techniques become procedural, which allows their cognitive analytical ability to drive responses (see Chapter 6). The student is then ready to begin study of the mind, body, emotional, and spiritual connections that need to intertwine and become harmonious if the student is to learn the true meaning of TKD. Sparring *should be* a controlled situation in which injury or damage to another person is never acceptable. Research over the last 10 years has pointed out the danger a student faces during TKD competition. Mistakes both in techniques themselves and in emotional force placed behind the techniques do create a potential danger to students.¹⁷³⁻¹⁷⁸ Therefore safety gear is required at all TKD competitive events for color belt students. Mouth guards are always required no matter the level of the student. As in other contact sports, injuries do happen, but fortunately most are minor, and a quick recovery the result. During class the instructor is never to spar above the skill level of the student, nor is the student to enter into a sparring match with the intent to show the teacher or another student just how good he or she is. In reality, when a student does take that emotional stance, the motor skills reflect only just how much more that student needs to learn. Feedback from others is a powerful learning tool for students at all levels. It is the teacher's responsibility to help redirect students' emotional stances and help to teach that TKD represents control, not lack thereof. Board and brick breaking is the activity in which a student can demonstrate force production as it interlocks with trajectory, speed, and position in space. If any of these perceptual or motor variables are incorrect, the student will not succeed at going through the obstacle. These skills are taught and practiced not to damage or destroy the wood or brick, but rather to learn to go beyond or through the obstacle. Once the specific body part used as a trajectory goes beyond the obstacle, it no longer remains an obstacle and the student feels great satisfaction. In reality, to be successful at these tasks, the hand, elbow, or foot that is used to go through the brick or wood is only an extension of the body. Success is based on the learner's ability to tie the entire body's motor response, its rotation, its balance, its trajectory, its force, and its speed into a motor program that will project through one or more obstacles as a knife cuts butter. If the student, emotionally, believes that the obstacle will not break, it will not! The student will stop the movement before completing the task and often empower the wood or brick as a successful obstacle versus empowering herself or himself to overcome that obstacle as if it were not there. This concept is a critical element of TKD. It is also a critical component of any client's learning of any motor program, turning the program into a functional

activity, and improving one's quality of life and ability to participate in that life's adventure. If a patient's CNS is convinced that the movement is not possible, then that individual will fail. Without internal motivation by an individual to accept the possibility of success, acceptance of failure is embraced. This internal environment plays a key role in any individual's overcoming what he or she perceives as an obstacle in life.¹⁷⁹ It is the role of the TKD teacher and the therapist teacher to empower the student to the possibility of success while creating an external environment that will enhance the probability of that success.^{155,170} To ask TKD students to perform motor skills above their level of competence can lead to injury and the embracing of failure. Failure often stops the motivation to continue to learn. Patients in a therapeutic environment are no different. They need an environment that creates safety, promotes success, and empowers the individual to overcome life obstacles.

Those who respond best to TKD training to maintain motor function are individuals who are motivated to move, enjoy interactions with others, have cognitive integrity, and have some control over their motor system. When instructing a TKD club of individuals who had all had traumatic head injuries, the teacher, a TKD instructor and therapist who had worked for more than 25 years in the area of neurological rehabilitation, found that using therapeutic skills through TKD movement patterns augmented the students' learning and helped them to regain motor function through guided activities without the students ever realizing there had been any kind of therapeutic intervention. To those students, they were learning and advancing in a martial arts style, were tested and judged according to their development of skills, and felt accomplished as adults participating in an adult activity. Carryover and improvement in balance, postural integrity, reciprocal patterns of movement, and control of trajectory, force, and speed, as well as development of emotional stability and confidence, could be easily identified and evaluated by the use of standard objective measurement tools if so desired. Expected outcomes would be improvement in those areas of motor control just mentioned. As long as the student continued training, improvement would be expected and carryover into other life activities anticipated. These are the principles of neuroplasticity and have meaning both within the pre-disease or wellness model as seen in TKD^{37,180} and after acute injury, disease, or insult to the CNS.¹⁸¹⁻¹⁸⁵ Whether sequential movements are taught as new movements as in TKD or require relearning of functional movements taught by physical and occupational therapists, the end result leads to an individual participating in a life activity.

As therapists, we want individuals who have been discharged to continue with movement activities that encourage their participating in life as a whole individual. TKD provides an excellent movement-based activity that leads to physical fitness¹⁸⁶⁻¹⁹² and has been studied in relation to changes in vitamin and hormonal levels in elite athletes.¹⁹³⁻¹⁹⁶ One systematic review studied martial arts training, looking at a variety of martial arts styles including TKD and tai chi. Both styles lead to an increase in health status of participating individuals.¹⁹⁷

When considering the elderly population, a group frequently referred to both PT and OT for movement and balance disorders, TKD training has been shown to improve balance, walking abilities, and somatosensory organization in standing.^{198,199} Owing to immobility, muscle weakness, and decrease in balance in standing, the elderly population certainly presents a fall risk within the community. Falls obviously can lead to hip fractures and months of medical and therapeutic interventions. Looking at a martial art that encourages participants to stretch to their respective limits of stability both with fast and slow movement patterns, a valid question must be asked: "Would TKD be harmful to this population, especially if the participants had osteoporosis?" Two research studies investigated that question and determined that training in martial arts such as TKD can teach fall training, prevent hip fractures, and be safe for individuals with osteoporosis.^{200,201} Literature has shown that accelerated patterns of the head and pelvis during upright walking can lead to falling in community-dwelling elderly people.²⁰² Individuals with Parkinson disease show evidence of body system problems causing impaired head and trunk control, thus increasing their risk of falling.²⁰³ During TKD practice as a beginner or advanced student, individuals learn to use the head and hips in rotational patterns while maintaining an upright posture and moving their upper extremities.^{204,205} It has also been shown that as students increase their skill with practice and time, they also increase their "neural efficiency," which increases their reaction time and the ability of their brains to make spatial judgments.²⁰⁶ All these components should help maintain the physical capabilities of an elderly individual while providing a social environment in which to practice.

TKD not only affects the physical and mental capabilities of the learner, but it also has the benefit of changing one's mood to a more positive feeling.²⁰⁷ This emotional response helps to motivate all students to return to practice and once again regain that positive reaction. This drive becomes deeper and deeper as an individual advances from a white belt to degrees within the black belt ranks.

Over the last decade many research articles have been written that look at one aspect of TKD training, whether it be strength, balance, coordination, motivation, cardiac fitness, emotional self-control, or the effect on the many other bodily systems that interact during a TKD workout. The reader must understand that it is all those elements that make up a TKD student, teacher, or master. In the future, more research will identify this martial art as a potential form of physical exercise for all populations of individuals who have comorbidities after CNS injury (*Case Study 39-2*). Physicians and therapists should consider recommending this martial art as an exercise activity for individuals who wish to maintain or regain their abilities to participate in life activities.¹⁹⁸ Until then, students of all ages will be welcomed into TKD studios and encouraged to reach beyond their perceived potential. The age ranges of TKD students now include the elderly population, with classes focusing on strength, balance, and core work without the need for strenuous sparring or board breaking.²⁰⁸ A TKD instructor will modify each senior's class experience to allow each individual to reach his or her potential without injury or trauma.

CASE STUDY 39-2 ■ A TAE KWON DO CLASS OF SIX INDIVIDUALS AFTER TRAUMATIC HEAD INJURY

This case study is not of an individual patient but rather a group of individuals who had previously had TBI. (Refer to Chapter 24.) All participants were at least 2 years postinjury. They received services at an Easter Seals facility, where they participated in adult swimming twice a week as well as having unlimited use of the gym and strength training equipment. They all had inquired about receiving martial arts training from that specific facility. Holding a fourth-degree black belt in TKD and as a physical therapist whose focus had always been directed toward individuals with brain injury, I was asked if I was willing to instruct these individuals in TKD twice a week. I agreed to volunteer as long as the students agreed to continue for 3 months. The students ranged in age from 23 to 35 years, and all were male. Four of the students had had one TBI; one student had experienced two TBIs, and one had sustained three. Four students had been injured initially in auto accidents, and two in motorcycle accidents. One student had received his second injury in a fight. The individual who had experienced three head injuries had sustained all three on his motorcycle. All students communicated using English, and all were independent in basic activities of daily living. Two members shared an apartment, three lived in a group home, and one lived with his parents. They all were on public assistance for their primary income, although three worked part time in a job-training program. Four students had a high school education, and two had Associate of Arts (AA) degrees.

Each individual student had slightly different movement problems; however, they all had balance and postural issues as well as impairments in force and directional control of their upper and lower extremities during gross mobility skills and during activities that required fine motor functional control in the upper extremities. As they were all friends and worked out together on exercise equipment at the facility at least three times a week, they all looked physically fit with large muscle mass in the arms, shoulder girdles, hips, and quadriceps. All were independently ambulatory, although one did have mild gait ataxia during the swing phase of either leg. Similarly, that individual exhibited mild ataxia in the upper extremities but had learned to compensate using pure muscle power to slow the movements. All participants stated that falling was an issue but that they did not know exactly what caused them to fall. Three of the participants had mild to moderate hypertonicity primarily in the lower extremities and axial muscles and thus moved slowly and with cognitive attention. No individual could do rapidly alternating movements when performing alternating punches or blocks with the upper extremities. Initially no student's balance allowed him to independently stand on one foot while kicking with the other. All students would either fall or take a step with the kicking foot in order not to fall. No formal evaluation was done to assess baseline motor control because it was not a therapeutic environment but rather a training environment for a martial art that was considered a sports activity for fun.

As stated earlier, the TKD instructor had a fourth-degree black belt as well as having been a physical therapist for over 20 years. She wondered, if she used her handling skills while teaching TKD, would the students recognize her PT skills?

Or would they accept only that she was the instructor and thus was teaching them the skill of TKD? The answer to that question came quickly. The students acknowledged her martial arts skill and were amazed at their own ability to learn. They never thought that they were doing anything other than learning TKD while in the class.

Three basic kicks were taught. A *front kick* required the student to balance on one leg while picking up the opposite leg in hip, knee, and dorsiflexion and then extending the entire leg forward with the foot in plantarflexion while the toes remained in dorsiflexion. The leg remains in neutral rotation throughout the entire kick. Obviously, the higher the instructor asked a student to kick, the more difficult it became for the student. The second kick is called a *sidekick*. This kick requires the student to first abduct with slight external rotation and flex the hip with the knee flexed and foot in dorsiflexion and slight inversion, then to extend the hip and knee into full extension, abduction, and neutral to slight internal rotation while the foot remains in strong dorsiflexion and slight inversion so that the strike from the kick is at the heel. The higher the kick, the more abduction the student must control and maintain throughout the kick. Refer to Chapter 5, Figure 5-10, in which the instructor is performing a sidekick while in the air, but has chosen to hold back full extension. If he did not have control and chose to finish the kick, the individual standing would probably have her neck broken. The last kick is called a *roundhouse kick* and it requires that the leg be picked up into hip abduction, external rotation and extension with the knee flexed and the foot in flexion and eversion. The kick then progresses from hip extension into hip flexion as the hip rotates out of external rotation to slight internal rotation with knee extension. The foot can strike either with the top of the foot in total plantarflexion-inversion or with the ball of the foot with the ankle in plantarflexion-inversion while the toes remain strongly flexed. The height of the kick will depend on the ability of the student to control and contract the flexors and abductors while performing the kick from the beginning to the end. Figure 5-11, in Chapter 5, is an example of the roundhouse kick at the end of the excursion. All kicks were practiced first with the instructor guiding the students' movements. Then the students were asked to visualize the kick and to perform the movement independently as they progressed. The instructor could easily correct errors in movement using handling. With time and practice each student was able to perform all three kicks. Initially, they were asked to do the movements slowly with control. This required each student to gain the postural power to control his trunk and weight-bearing leg while holding and controlling the kicking leg as it moved in space from the initial position to the end. In time each student was asked to control this pattern while kicking at a target in space. Finally, the mitt or bag target was moved after each kick, requiring the student to adjust to the changing requirement for the second kick.

The upper-extremity patterns taught were reciprocal punches, overhead blocks, low or groin blocks, and knife hand strikes. The reciprocal punches began with the arm first, beginning at the side with the shoulder in external rotation and adduction, elbow flexed, the wrist in supination-neutral extension-flexion and the fingers strongly flexed. The arm then

Continued

CASE STUDY 39-2 ■ A TAE KWON DO CLASS OF SIX INDIVIDUALS AFTER TRAUMATIC HEAD INJURY—cont'd

moves into shoulder internal rotation and flexion with elbow extension, forearm pronation, and neutral position of the wrist, with the fingers remaining flexed. The final position of the arm should be directly in front of the person. The arm should be straight with the line of force coming from initial scapular retraction to scapular protraction as the force goes down through a straight arm with the wrist stabilized and the fist clenched. The other arm begins at the end of the first arm's trajectory and then is moved back toward the initial position of the first arm. All upper-body movements, whether a punch, a downward block across the body to block a punch or kick to the groin, a strike to the side, or an overhead block to protect the head from a round kick or a punch, required learning these new motor patterns with the final goal of controlled movement by each student. All patterns required a combination of movements that began in one type of rotation at the shoulder and wrist and ended in the reverse pattern. The diagonal patterns required a combination of flexion, extension, and rotation and were taught either as a blow to an opponent attack or as a block from an opponent punch or kick. Initially none of the students could perform any of the kicks or blocks taught, and they enjoyed kidding each other about coordination and balance problems. As the activities were considered fun, no one expected anything other than enjoyment and success from the practice.

In reality, no student had the coordination to perform any of the kicks or upper-body movements, *but* they were told truthfully that no TKD student can perform these movement with coordination when they start at the beginner level as white belts.

Obviously, increasing the ROM in the axial joints was an important aspect of their martial arts training, as was gaining stability in the distal joints in order to prevent injury. All students had previously learned to gain control over their axial joint activities by reducing ROM and building muscle mass. Although their axial muscles could produce power for short periods of time, learning to develop control throughout an entire movement pattern was difficult, especially if the student was asked to hold the kicking leg or the punching arm in a position for 30 seconds, 1 minute, or longer. The instructor was able to help the students learn to slow down movements while retaining control over each movement itself from the beginning to the end of the range. Through handling techniques that guided the student through these specific movement patterns, or the use of resistance by the instructor to slow down the movement, the student learned not only the specific patterns required for TKD, but also to control various degrees of speed of each movement. With practice and motor learning, each student began to gain motor control. The focus was on accuracy of the kick itself and not on the force produced. In fact, the students were asked not to produce a high level of force until they had the control over the movement itself.

As the students practiced kicking against a heavy suspended punching bag or against a padded mitt held by the

instructor or another student, they all improved in their ability to perform these movements. They were then taught to perform these movements in patterns similar to a dance, which in TKD is considered a form. This combination of movements encouraged forward motion as well as turning in both left or right directions. As they practiced shifting their weight from foot to foot or balancing over one foot while kicking with the other, their posture and balance automatically improved. At the end of each week the instructor would ask each student how many times he had lost his balance or fallen during the week? The numbers went from multiple times per day, to daily, to a few times per week, to very seldom over a 3-month period of practicing TKD with formal instruction two times per week.

The therapist-instructor could see that the ambulatory skills of each student had also improved, as did their balance, even though the students were not in class to improve motor control over either of those activities. As the students learned to perform the upper-body patterns first slowly and then with more speed and power, they all talked about how activities such as eating were so much easier and more social. They would also comment that they didn't have to think about controlling the fork or keeping the food on the spoon. Other activities of daily living were also improving. They thought the instructor asked those questions just because she was social and interactive, not because she was using her PT skill to help them regain motor control, and wondered if there was carryover. It was truly a wonderful learning experience for the therapist because she watched motor learning and neuroplasticity change the way these people moved and interacted. They practiced on their own and together. They encouraged one another while enjoying the learning. They would laugh at their lack of coordination but also acknowledged the improvement they saw in each other. They were taught to work together, with one performing a kick or punch while another blocked or redirected the movement. These activities caused a huge variety of perturbations with inconsistent force and direction, requiring the student to spontaneously respond while remaining in vertical control of his body in space and ready for the next movement. They knew they not only gained control over their bodies but also had the ability to avoid injuring their partners and friends.

Each student's skill improved to the extent that all of them were ready to advance from a white belt to a yellow belt rank. They were able to enter a regular class with other TKD students and had earned the respect from all the students in the new class and the belt they wore with pride. This experience certainly proved to one therapist that integrating normal TKD activities while using the professional skill of a clinician helped six individuals dramatically improve motor control in their daily lives and positively affected the way they felt about themselves.

Yoga

Mary Lou Galantino

Yoga is an ancient Indian mind-body practice that has been around for more than 2000 years.²⁰⁹ It focuses on a combination of meditation, mindfulness, self-exploration, breathing control, and body movement to improve flexibility, focus, balance, and strength. The two types of yoga popular in the United States are Hatha and Iyengar. Hatha involves holding the body in particular postures known as *asanas* for periods of time while controlling breathing rate and focus.²¹⁰ Iyengar yoga uses the aid of supports, props, and belts to allow better control to perform the *asanas*.^{211,212} Although yoga has been accepted in other countries for centuries, the evolution in the United States has been a recent phenomenon. Research on the effect of yoga in the musculoskeletal areas is promising,²¹²⁻²¹⁴ yet research in the neurological population is still in its infancy and in need of larger randomized clinical trials. This section will present a general analysis of the benefits and efficacy of yoga for individuals with a variety of common neurological issues.

Carpal Tunnel Syndrome. Physical and occupational therapists treat carpal tunnel syndrome (CTS), an upper-limb neuropathy caused by compression of the median nerve. Symptoms involve numbness, tingling, and pain from repetitive movements that respond to a variety of treatments.^{215,216} Two studies specifically explored the use of yoga to treat subjects with CTS. A yoga trial with 42 individuals (median age 52, range 24 to 77 years) tested the effectiveness of a yoga regimen on CTS symptoms. Those in the experimental yoga group were given 11 postures designed to stretch and strengthen the upper limbs, along with relaxation techniques, twice a week for 8 weeks at a local geriatric center. A control group was given wrist splints or no treatment at all.²¹⁷ Significant improvements in grip strength, pain reduction, and Phalen sign were noted. However, no statistically significant change was recorded in sleep improvement, Tinel sign, or median nerve conduction. Participants showed improvements in pain and function 4 weeks later.²¹⁷ A second study investigated the impact of yoga in patients with osteoarthritis. Twenty-six patients (52 to 79 years) performed 1-hour yoga sessions each week for 8 weeks. Subjects reported significant improvement in joint and hand pain during activity.²¹⁸ Larger randomized clinical trials could provide definitive evidence for patients with CTS.

Stroke and Hemiparesis. Strokes are the number one cause of adult disability in the United States and Europe, with 4.7 million individuals in the United States living with the sequelae of stroke. Extreme difficulties encountered while performing simple movements result in a sedentary lifestyle in this population. Resultant muscle atrophy further potentiates fall risk.²¹⁹

A pilot study with four subjects observed the impact of yoga as a treatment for impairments poststroke. Baseline measurements included the BBS, Timed Movement Battery (TMB), and SIS version 2.0. Three of the four participants in this study had statistically improved BBS scores indicating improved balance, improved self-selected speed on the TMB indicating improved ability to perform everyday tasks, and positive changes in quality of life based on the SIS.²¹⁹

Other factors may have affected the outcome of this pilot study, including differing adherence to the home exercise program with varying participation levels, degree of

impairment, and fear of pain, which reduce participation with certain *asanas*. This preliminary study showed that those who adhered to the program improved more than those who did not follow it as closely. Yoga appears to have some level of positive impact on function in poststroke patients; however, future research is needed to confirm these findings.²¹⁹

Multiple Sclerosis. Individuals with MS can suffer from virtually any neuropathy, fatigue, ataxia, and chronic or acute pain. Cognitive, digestive, visual, and speech problems may also occur. Although there is no cure for MS, patients have life expectancies similar to those unaffected by the disease, and yoga may be an option to manage the various impairments encountered through the years.²²⁰ It is interesting to note that 65% of those diagnosed with MS use some CAM, with yoga being the most popular.²²¹ Perhaps the best study to date was a 6-month study that compared Iyengar yoga and exercise interventions. Participants underwent multiple cognitive assessment tests such as the Stroop Color and Word Test and the Cambridge Neuropsychological Test Automated Battery to test reaction times in performance of certain tasks that are difficult for individuals with MS. These tests measure attention and visual and auditory abilities to determine the impact of cognitive abilities. Alertness, mood, fatigue, and quality of life were also measured using tests such as the Profile of Mood States (POMS), the SF-36, electroencephalography, and physical activities such as a timed walk.²²⁰ Of those who completed the study, both the exercise and yoga intervention groups had greater quality of life based on data from self-assessment forms (SF-36), a reported increase in vitality and energy, and a decrease in fatigue.²²⁰ This is the first study on the use of yoga for patients with MS, and the findings need to be confirmed using larger randomized controlled trials.²²⁰

Epilepsy. Yoga, as well as other mind-body practices, has shown promise in helping control seizures. One yoga meditation trial reported a 62% decrease in seizure occurrence at 3 months, 86% at 6 months, and 40% of the subjects becoming seizure free.^{221,222} The patients in this study had hyperventilation-related epilepsy caused by anxiety, so the meditation and controlled breathing exercises along with the *asanas* may have led to a better understanding of how the subjects could control their diaphragm, resulting in the high success rates. In this study, electroencephalographic data recorded a large shift in frequency from 0 to 8 Hz to 8 to 20 Hz, with an increase in A-band power and a decrease in D-band power. These results showed improvement in control and power of breathing. It is hypothesized that the yogic meditation regulates the limbic system, providing better control over endocrine secretions and lowering the chance of over-firing neurons.²²² Another investigation tested the use of yogic meditation for 1 year versus a control of no meditation in patients with drug-resistant epilepsy.²²³ Data showed significant differences between the experimental and control groups, with the experimental group having significantly lower seizure activity over the observation period.²²²

A study done in an epilepsy care center in 2006 assessed the efficacy of yoga meditation protocol (YMP) as an adjunctive treatment in patients with drug-resistant chronic epilepsy.²²⁴ It was a supervised trial based on the frequency of complex partial seizures, which was assessed after 3, 6, and

12 months. There were 20 patients, who sat in a relaxed position with legs crossed (sukhasana) and focused on deep, slow, controlled breathing (pranayama) for 5 to 7 minutes, followed by silent meditation.²²⁴ Patients were instructed to perform YMP daily for 20 minutes in the morning and evening at home and at supervised sessions.²²⁴ Individuals with greater than or equal to a 50% reduction in the rate of monthly seizures were classified as responders, whereas patients with less than this percentage in seizure reduction were classified as nonresponders.²²⁴ After the first 3 months there was a reduction in the frequency of seizures in all but one patient. Fourteen patients continued the YMP for 6 months or more and were tested again. Of these, six had been seizure free for a 3-month period, and three had been seizure free for 6 months.²²⁴ The authors of this study concluded that yoga was a less expensive and an adverse effect-free way to treat patients with drug-resistant forms of epilepsy.

Human Immunodeficiency Virus. A pilot study examined the use of a yoga intervention for individuals with human immunodeficiency virus (HIV) infection who experienced pain and anxiety.²²⁵ Results indicated a decrease in pain and anxiety symptoms and a reduction in amount of pain medication after an 8-week yoga program.

Another study examined the effect of yoga practice that included breathing, movement, and meditation techniques for 47 participants with HIV disease. Positive changes were noted in mental health on the Mental Health Index (MHI), and general physical health on the Medical Outcomes Study HIV Health Survey (MOS-HIV).²²⁶ The Daily Stress Inventory showed a decrease in stress after the yoga program. Improvements in activities of daily living were reported by all yoga participants.

Fear of Falling and Insufficient Balance. A recent study investigated the use of a 12-week yoga practice for adults over the age of 65 years old with fear of falling and balance problems. Sessions of yoga postures and breathing exercises were completed in sitting and standing.²²⁷ Fear of falling was measured using the Illinois Fear of Falling Measure and balance was captured with the BBS before and after the yoga intervention. Results showed a 6% decrease in fear of falling, 4% increase in static balance, and 34% increase in lower-body flexibility.²²⁷

An observational cohort study explored the effect of yoga on balance, fear of falling, and quality of life in 26 postmenopausal and osteoporotic women over age 55 years. Results of the Quality of Life Questionnaire of the European Foundation for Osteoporosis (QALEFFO) and a neuromuscular test battery revealed improvements in all aspects of the QALEFFO for the yoga participants, as well as improved ability to stand on one leg and improved perception of general health.²²⁸ Yoga may prove to be a promising intervention to improve balance and reduce fear of falling.

Conclusion. Available data on the use of yoga as a therapeutic intervention for people with various neurological disorders are sparse. However, preliminary data show promise for the use of yoga as a treatment for CTS, stroke, MS, and epilepsy and for fall prevention. Most studies have small sample sizes but do show trends toward improved function and reduced impairments. In general, yoga can assist in the establishment of the mind-body connection and awareness of self. Greater self-awareness may explain why patients report improvements in quality of life, improved ability to better

manage their disease, and a deeper understanding of their own bodies. Relaxation that results from yogic meditation fosters stress management and may improve the outlook on long-term management of neurological conditions. Yoga may serve as an alternative to traditional exercise and can be adapted for elderly patients who are unable to perform strenuous exercise. Yoga can be modified to accommodate patients with almost any physical or cognitive disability, and potentially provide mental enhancement, which can create a significant relaxation effect. Further research is needed specific to the effects of yoga practice in neurological populations.

Energy Therapy Approaches

Therapeutic Touch

Ellen Zambo Anderson

Therapeutic Touch (TT) is a complementary therapy categorized by the National Center for Complementary and Alternative Medicine as a therapy based on the concept of energy fields (biofields).²²⁹ It is practiced by nurses, rehabilitation specialists, and others for the purposes of reducing pain and anxiety, accelerating the healing process, and promoting a sense of well-being.²³⁰

Assumptions. There are four assumptions that form the foundation for TT as an intervention that can facilitate healing and health. The first assumption, described by Delores Krieger, RN, PhD, the developer of TT, is that the body is an open energy system. The open system allows energy, often referred to as *subtle energy*, to flow within and through the body. This flow allows for a dynamic interface with the environment.²³¹ The second assumption suggests that individuals are bilaterally symmetrical so that the right and left, front and back mirror each other. This symmetry allows for a balanced energy flow. The third assumption is that an imbalance or an irregular flow of subtle energy is associated with physiological impairments, illness, and disease. The fourth assumption is that the body can initiate and achieve a process of self-healing through manipulation of biofields and restoration of subtle energy balance and flow.²³¹

The concept of internal and external subtle energies and their relationship to health and illness can be found in many whole medical systems such as Ayurveda,²³² traditional Chinese medicine,²³³ and Navajo medicine.²³⁴ More specifically, the assumptions of TT described by Krieger have their roots in the ancient concepts of prana and chakras.^{235,236} Prana, which is coined *chi* or *qi* in other systems of medicine, is the universal life force or energy that circulates through the universe and all living things. Chakras are the centrally aligned energy centers that are able to receive, transform, and send prana throughout the body. A blockage, interruption, void, or imbalance of prana is thought to exist when there is pathology or disease. Restoration of an individual's energy flow and balance is important for self-healing and health.²³⁷

Krieger, along with her colleague Dora Kunz, investigated the phenomenon and characteristics of people known as "healers" and concluded that healers possess a heightened sensitivity to their clients' state of health and being and are able to effect change through intention and energy. Through her description of sensing and effecting change in an individual's energy or biofield, Krieger has elucidated a four-step process that defines TT as a distinct therapeutic intervention

different from other energy-based therapies such as reiki and Healing Touch.

Procedure. TT is often performed with the patient or client fully dressed and sitting. Despite the name, TT can be administered without actually touching the patient because TT practitioners are able to sense and manipulate the patient's subtle energies from a distance of 2 or more inches away from the patient's body. The first step in the TT process is called *centering*. During centering, practitioners center their consciousness so that a state of integration and quiet can be achieved. From the state of centeredness, practitioners initiate the assessment step by placing their hands 2 to 3 inches from the client's head and slowly moving their hands down the patient's body, noting the patient's biofield. Practitioners may perceive the patient's energy as hot or cold or sense that a patient's energy is blocked in a particular area. Perceived disturbances in a biofield suggest that the practitioner should return to that area later in the process.

Krieger has described the next step in the TT process as "unruffling the field."²³¹ To unruffle the field, TT practitioners sweep away bound up or congested energy, which allows the patient's energy field to become open and unrestricted. Opening the energy field sets the stage for the final step of the TT process. During the final step, TT practitioners direct and modulate the transfer and flow of energy so that the patient's energy fields can achieve balance and symmetry and healing can occur. Krieger points out that TT does not "cure" people of their diseases. Rather, she suggests that TT can have positive effects on energy fields and the flow of energy, and that these effects create an environment in which the patient's own self-healing processes can be optimized.^{230,231} Sessions usually take 20 to 30 minutes, but TT practitioners have reported that frail patients and children can benefit from as little as 5 to 8 minutes of TT; other patients may require 60 minutes of TT to achieve a state of relative energy balance.

Scientific Literature. The application of TT for persons with neurological diseases and disorders has not been widely investigated in the scientific literature. Researchers have, however, investigated the efficacy of TT for the reduction of anxiety and pain in a variety of patient populations and for the reduction of disruptive behaviors in persons with AD.

Anxiety. *Anxiety* is a general term associated with nervousness, fear, apprehension, and worrying. An anxiety disorder differs from feelings of anxiety associated with a specific event and is characterized by an irrational dread of everyday situations or excessive and long-standing anxiousness regarding nonspecific events and objects.

Robinson, Biley, and Dolk²³⁸ performed a systematic review of the effect of TT on symptoms related to anxiety disorders but were unable to identify any studies in which subjects met the definition of anxiety disorder as defined by the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) or the *International Classification of Diseases* (ICD-10). In all of the studies of TT and anxiety included in the review, Robinson and colleagues²³⁸ noted that pretest anxiety was measured in all subjects, but these subjects did not have "anxiety disorder" as their primary diagnosis. This systematic review helps to show that individuals with neurological disorders and other medical diagnoses may not be diagnosed with an anxiety disorder but may experience some anxiety as they face the challenges of their condition.

Several researchers have investigated the effect of TT in different patient populations such as those with severe burns,²³⁹ cardiovascular diagnoses,^{240,241} and breast cancer.^{242,243} Turner and colleagues²³⁹ found that for hospitalized patients with severe burns, TT was associated with a reduction in anxiety with no adverse effects. Quinn²⁴⁰ and Heidt²⁴¹ investigated the application of TT in persons with cardiovascular conditions and determined that compared with sham TT, subjects who received TT reported significant reductions in anxiety on the State-Trait Anxiety Inventory (STAI). Women with breast cancer were studied by Samarel and colleagues²⁴² and Frank and colleagues.²⁴³ Samarel and co-workers²⁴² found that women who received 10 minutes of TT and 20 minutes of dialogue before surgery reported significantly lower preoperative anxiety than women who received quiet sitting and dialogue, but no differences in anxiety were observed postoperatively. Frank and colleagues²⁴³ found that TT was helpful for reducing restlessness, fear, and nervousness in women who were scheduled to undergo a stereotactic core biopsy (SCB) but that the results were similar between the TT group and the sham TT group.

The application of TT with older adults has been reported by Simington and Laing²⁴⁴ and Lin and Taylor.²⁴⁵ Both research studies found that older subjects who received TT had significant postintervention reductions of anxiety as measured by the STAI. In the study by Simington and Laing, TT was paired with a backrub in the experimental group. The control group received just a backrub.²⁴⁴ In the study by Lin, TT was compared with sham TT.²⁴⁵ For inpatients with psychiatric diagnoses, TT was compared with sham TT and relaxation therapy.²⁴⁶ The researchers found that TT was more effective than sham TT but no more effective than relaxation therapy for reducing anxiety in this population.

A review of the TT literature and anxiety suggests that TT's efficacy for reducing anxiety is inconclusive. Several researchers have reported benefits of TT, yet others have found no effects when comparing use of TT with a control group or with use in patients with another condition. Reasons for the inconclusive results may be differences in the criteria for anxiety and variability in the measurement instruments. Other reasons may include research design issues such as assignment methods, blinding, and the frequency and duration of the TT intervention and comparison conditions.

Pain. Patients' pain can severely interfere with their ability to function efficiently and effectively. Nonpharmacological methods for managing pain have the potential for assisting patients in their rehabilitation and achievement of functional independence without adverse effects. Investigations of TT for pain associated with neurological conditions are extremely limited. In a case report of a subject with long-standing phantom limb pain, Leskowitz²⁴⁷ found that TT was effective in reducing the subject's pain from an 8 to 10 out of 10 on a visual analog scale (VAS) to a 0 in one session. Self-administered TT was then able to maintain pain at a 0 to 1 on a VAS in which 10 is the maximum intensity. Before TT, medication, stress management, hypnosis, transcutaneous electrical nerve stimulation (TENS), and ultrasound had been successful in temporarily reducing the subject's pain to 6 to 8, but long-term pain management with these approaches was inadequate.

TT was investigated in subjects with chronic pain associated with fibromyalgia syndrome²⁴⁸ and CTS.²⁴⁹

Denison²⁴⁸ found no significant improvement on the Short-Form McGill Pain Questionnaire (SF-MPQ), VAS, or Fibromyalgia Health Assessment Questionnaire (FHAQ) after subjects received 6 weekly sessions of TT. TT and sham TT groups both demonstrated immediate significant improvement in median motor nerve distal latencies, pain scores, and relaxation scores; however, there were no significant differences between the two groups on any of the outcome measures.

Other researchers have investigated the use of TT with older adults,^{245,250} cancer pain,^{242,243,251} osteoarthritis,^{252,253} headache,²⁵⁴ postoperative pain,^{255,256} burns,²³⁹ and various chronic pain complaints.²⁴⁵ The results of studies that have included TT and measures of pain suggest that TT may be helpful in managing phantom limb pain, headaches, and pain associated with burns. There are, however, inconsistencies across the studies that raise questions about both significant and insignificant findings. Inclusion of a control group, use of sham TT, sample size, measurement instruments, and the duration and frequency of TT are factors related to the studies' validity that limit the ability to draw firm conclusions about the efficacy of TT for reducing pain.

Disruptive Behaviors. TT has been investigated for its effect on disruptive behaviors in persons with AD. Although most patients with neurological conditions do not typically manifest AD, alterations in cognitive functioning and behavior are often observed. In a within-subjects study by Woods and Dimond,²⁵⁷ long-term care residents with AD received 5 to 7 minutes of TT twice a day. Disruptive behaviors were measured using the Brief Agitation Rating Scale (BARS). The researchers found a significant reduction in overall agitation and in two specific behaviors, vocalization and pacing during the treatment and posttreatment period. In a randomized controlled trial, TT was also applied 5 to 7 minutes twice a day with persons with AD.²⁵⁸ Similar to the observations of Woods and Dimond,²⁵⁷ TT was found to be helpful for significantly decreasing overall behavioral symptoms of dementia including restlessness and vocalizations when compared with the usual care and placebo group. Hawranik, Johnston, and Deatrich²⁵⁹ studied TT's effect on three forms of disruptive behavior—physical aggression, physical nonaggression, and verbal agitation—in persons with AD. They found a significant reduction in physical nonaggressive behaviors but no differences in physically aggressive and verbally agitated behaviors in subjects who received TT compared with subjects who received sham TT or routine care. These studies have provided some preliminary evidence for TT's potential use for modifying at least some forms of agitated behaviors. Application of TT to patient populations other than AD for the reduction of disruptive behaviors needs to be investigated.

Conclusion. As a noninvasive, nonpharmacological intervention, TT may be helpful to patients with AD who demonstrate disruptive behaviors and patients with pain or anxiety. Research that investigates the mechanism by which TT may alleviate pain and the physiological changes that may occur with TT will advance the acceptance of TT as a useful modality and suggest patient diagnoses that might benefit from the incorporation of TT into a rehabilitation plan of care.

Physical Body Systems Approaches

Craniosacral Therapy

John Upledger

Mary Lou Galantino

Craniosacral therapy (CST) is a gentle, noninvasive, yet powerful and effective treatment approach that relies primarily on hands-on evaluation and treatment. It focuses in the normalization of bodily functions that are either part of or related to a semiclosed hydraulic physiological system, which has been named the *craniosacral system*.

Structure of the Craniosacral System. The anatomy of the craniosacral system includes a water-tight compartment formed by the dura mater, the cerebrospinal fluid (CSF) within this compartment, the inflow and outflow systems that regulate the quantity and pressure of the bones to which the dura mater attaches, the joints or sutures that interconnect these bones, and other bones not anatomically connected to the dura mater. The bones of the cranium and the second and third cervical vertebrae, the sacrum, and the coccyx are also included in the structures of the craniosacral system.^{260,261} In combination with the message sent to the patient through the intentional touch of the therapist is the corrective work that is done on a basic physiological level by gentle hands-on manipulations applied both directly and indirectly to the craniosacral system. The semiclosed hydraulic system includes the dural sleeves, which invest the spinal nerve roots outside the vertebral canal as far as the intervertebral foramina, and the caudal end of the dural tube, which ultimately becomes the cauda equina and blends with the coccygeal periosteum. The fluid within the semiclosed hydraulic system is CSF. The inflow and outflow of CSF are regulated by the choroid plexuses within the brain's ventricular system and arachnoid granulation bodies, respectively. CSF outflow is not rhythmically interrupted, but its rate may be adjusted by intracranial membrane tension patterns, which are broadcast primarily by the falx cerebri and tentorium cerebelli to the anterior end of the straight venous sinus, where an aggregation of arachnoid granulation bodies is located. This concentration of arachnoid granulation bodies is known to affect venous backpressure, which has an effect on the rate of reabsorption of CSF into the blood-vascular system.²⁶²⁻²⁶⁴

Technique. The therapist, after mobilization of bony restrictions, focuses on the correction of abnormal dural membrane restrictions, perceived CSF activities, and energy patterns and fluctuations as they relate to the craniosacral system. It is during this time that the patient often moves from a phase of being corrected and having obstacles removed to a phase of self-healing, with the therapist serving as a facilitator of the process. The tenets of CST include the concept that the dura mater within the vertebral canal (dural tube) has the freedom to glide up and down within that canal for a range of 0.5 to 2.0 cm. This movement is allowed by the slackness and directionality of the dural sleeves as they depart the dural tube and attach to the intertransverse foramina of the spinal column.²⁶⁰

A basic assumption in CST, as it has evolved, is that the patient's body contains the necessary information for the discovery of the cause of any health problem. The treatment relies primarily on hands-on evaluation and treatment. The hands-on contact is tender and supportive. It is accompanied by a sincere intention to assist the patient in any way that is

possible. In short, the therapist serves primarily as a facilitator of the patient's own healing processes. The rapport that develops during the patient-therapist interaction lends itself powerfully to the positive therapeutic effect that many patients experience.

Western medicine imparts a therapeutic modality for curative measures, whereas CST fosters facilitation, wherein the client directs the treatment session. The inherent participation of the patient through CST promotes a holistic approach to healing. Conventional medical diagnosis will usually be more closely related to what the therapist views as the result rather than the cause. For example, the therapist would search for a cause of strabismus within the intracranial membrane system and the motor control system of the eyes, rather than considering the strabismus as a diagnosed condition to be corrected by surgery. The cause of strabismus can be found as an abnormal tension pattern in the tentorium cerebelli. The therapist then searches for the cause of the abnormal tentorial tension pattern. Quite often, these tension patterns are referred from the occiput or from the low back or the pelvis. If this is the case, the CST "diagnosis" would be intracranial membranous strain of the tentorium cerebelli as a result of occipital or low back or pelvic dysfunction, individually or severally, resulting in secondary motor dysfunction of the eyes (strabismus). The therapist would focus on the sacrum, the pelvis, the occiput, and then the tentorium cerebelli. Correct evaluation and treatment would be signified by a "spontaneous correction" of the strabismus.

Somatoemotional release is a technique that involves the bodily, and usually conscious, reexperiencing of episodes, the energies for which have been stored in the totality of body tissues. A powerful emotional content is typically connected with this technique, and it has proved to be extremely effective in cases of severe posttraumatic stress disorder. It was tested through qualitative research with a group of six Vietnam veterans in 1993. It proved to be successful in all six of these patients.^{260,261,265,266}

Outcomes. Objective responses to CST are based on the removal of obstructions to smooth and easy physiological motions of the patient's body, the absence of energy cysts, the free movement of the dural tube in the spinal or vertebral canal and the rate and quality of the craniosacral rhythm, the absence of pressing responses during the somatoemotional release process, and statements from the deeper levels of consciousness through dialogue with various images encountered in the session that "all is well."^{260,261,265}

Subjectively, clients report an increased sense of well-being, improved sleep patterns, reduced manifestation of stress, reduction in or disappearance of pain, increased energy levels, and fewer episodes of transitory illness. How long it takes to achieve these results is extremely variable and dependent on the complexity of the layers of adaptation, the defense mechanism, and the level of spiritual evolution of the patient.

Use in Treatment Intervention. CST is useful as a primary treatment modality and as an adjunct to a wide variety of visceral dysfunctions. It works well to balance autonomic function, specifically reducing sympathetic nervous tonus. It has proved beneficial in chronic headache problems, temporomandibular joint problems,²⁶⁷ whiplash sequelae, and chronic pain syndromes. We have used it as

an intensive treatment for persons rehabilitating from head injuries, craniotomies, spinal cord injuries, poststroke syndromes, transient ischemic attacks, seizure disorders, and a wide variety of rare brain and spinal cord dysfunctions.²⁶⁸⁻²⁷¹ Little positive effect has been reported in people with amyotrophic lateral sclerosis. However, some remarkable success has been seen in patients with MS.²⁷⁰

CST has been used extensively and effectively in a great number of children with spastic cerebral palsy, seizure disorders, Down syndrome, and a wide variety of motor system disorders, including problems with the oculomotor system, learning disabilities, attention deficit disorder, speech problems, childhood allergies, and autonomic dysfunction.²⁷²⁻²⁷⁴

We have used CST for people living with HIV disease who have HIV-related peripheral neuropathy and other chronic musculoskeletal and neurological problems. Pain management techniques can be used by the therapist and also taught to the family members to implement for a home program.²⁷⁵ Future studies addressing the interaction of the immune system with the craniosacral system would be helpful in elucidating the neuroendocrine response to this technique. CST has been found to be an effective means for treating lower urinary tract symptoms and improving quality of life in patients with MS.²⁷⁶

Clinical experiences also suggest that CST is a powerful evaluative and treatment modality for patients with vertigo who have not responded well to or have not found relief from traditional medical treatments. Osseous, dural membrane, and fascial restrictions leading to asymmetric temporal bone movement and hence vertigo are some of the dysfunctions of the craniosacral system. More clinical trials are necessary to verify that CST is an effective treatment as well as to determine the full range of symptoms for which CST is beneficial.

Recent studies have found a connection between patients with fibromyalgia and CST. CST improved quality of life in this population, reducing the perception of pain and fatigue and improving night rest and mood with an increase in physical function.²⁷⁷

The latest research includes using CST along with other osteopathic techniques to treat chronic lateral epicondylitis as opposed to treating it with traditional orthopedic techniques. The results have revealed increased strength and decreased pain for both osteopathic and orthopedic groups. The assumption is that osteopathic techniques such as CST can be successful in treating chronic lateral epicondylitis;²⁷⁸ however, future studies will need to isolate CST to ultimately reveal its efficacy in treatment for this problem.

To date, there have been several studies refuting the value of CST. One example is in *The Scientific Review of Alternative Medicine*. According to this group of researchers, inter-examiner reliability among CST practitioners is zero.²⁷⁹ Other studies suggest that the sutures that CST practitioners are attempting to mobilize are fused in the adult population, and therefore the techniques are ineffective.²⁸⁰⁻²⁸⁴ Future studies are necessary for CST to achieve recognition as a valid and reliable treatment option.

Training. The prerequisites for training in CST by the Upledger Institute are quite simple. It is believed that any kind of therapist who has a license to see and treat patients/clients might find CST, in its more basic form, a useful adjunct to practice. Therefore a license as a health care practitioner is all

that is required to enroll in the Upledger Institute's CST seminar series.

There are six levels of training within the series that are required before one can enroll in the advanced-level workshops. The workshops are all 4 or 5 days in length and are about evenly divided between academic work and hands-on supervised practice. The training program is designed to develop the sense of touch, motion, and energy perception slightly before the academic material is presented.

A certification process started in 1995 is now in place. There is a newly formed International Association of Healthcare Practitioners of which the American CranioSacral Therapy Association is a subdivision. The American CranioSacral Therapy Association, a nonprofit organization, was founded by a group of therapists and concerned laypersons in 1994. Its stated objectives are to bring CST into public awareness, to enhance networking among practitioners who use CST, to develop a certification program that will result in the recognition of CST as a specialty for persons who are licensed as health care practitioners in other fields, and to ultimately develop CST as an independently licensed and freestanding profession.

Reimbursement by third-party carriers is done largely on a case-by-case basis. A few insurance companies have recognized CST, but there is much work to be done on this front. The Upledger Institute published a book listing all the practitioners who have completed training. It is available to all health care professionals.

Myofascial Release (Barnes Method)

Carol M. Davis

Before beginning the discussion on myofascial release, a discussion of the research on fascia is appropriate. This discussion applies to the topic of CST and myofascial release as well as any other therapeutic technique within which fascia is affected. As fascia is part of the human body, both occupational and physical therapists need to accept that it influences their treatment and analyze its importance as a body system that can cause functional problems, prevent an individual from participating in daily living activities, and limit quality of life.

Research on Fascia: A Summary of Recent and Rediscovered Research on the Nature and Function of the Fasciae. Since the last edition of *Neurological Rehabilitation* was published, much has been learned, re-discovered, and published about the nature and function of the various connective tissue fasciae in humans. Fascial tissue turns out to be quite complex, is intimately involved in the moment-to-moment function of all of our cells, and is intricately involved with central, peripheral, and autonomic nervous system tissue. It is no longer useful to view the body or the fascial system as a mechanical system alone. Nonlinear system dynamics are at work as we now understand the involvement of fascia with the neuroendocrine system, the brain, and the neurological plexus in the lining of organs such as the stomach and gut. Fascia must be viewed by practitioners and patients not as static, but as innervated, alive, functional, fluid, and self-regulatory. Involving the patient or client in the process of manipulation of fascia and its embedded tissue enhances the response of the tissue and the patient.²⁸⁵

Central to the complete understanding of the effectiveness of energy-based myofascial release for the relief of pain and the facilitation of healing are the following points:

- There are 12 different fasciae or connective tissues in the body, each with varying concentrations of collagen, elastin, and ground substance.²⁸⁶
- "Our richest and largest sensory organ is not the eyes, ears, skin, or vestibular system, but is in fact our muscles with their related fascia. Our central nervous system receives its greatest amount of sensory nerves from our myofascial tissue."²⁸⁵
- "The presence of smooth muscle cells within fascia, along with the widespread presence of myelinated and unmyelinated sensory and motor nerve fibers and capillaries has led to an hypothesis that fascia is an actively adapting organ with functional importance, rather than a passive structural organ alone. This may be the root of myofascial pain syndromes."²⁸⁵
- There are nine or 10 sensory nerve endings in the fascia for every one sensory nerve ending in the muscle. Thus fascia plays a major role in helping us to sense where we are in space and sense our inner tissue in ways not fully appreciated previously.²⁸⁷
- Fascia contains myofibroblasts that can tense or release in fascial sheets.²⁸⁸
- Fascia has been hypothesized to play a role as the seat of consciousness in the body-mind system.²⁸⁹ As one example, there are 10 times as many connective tissue cells as nerve cells in the brain. Previously thought only to provide support and nutritional pathways to nerve, the latest brain scan research indicates glial cells "light up" during certain brain states, particularly emotional states. They have been shown also to play a role in regulating neuropeptides and neurotransmitters, thus thought to play a role in helping to regulate mood.²⁹⁰
- Fascia plays a role in the maturation of stem cells. The fascia that surrounds all cells as the cell wall, and the fascia of the extracellular matrix, which is the environment of all cells in the body, determine the pressures sustained on developing stem cells into their mature forms.²⁹¹
- Three specialized stretch receptor nerve endings in fascial structures play a role in helping us to be able to sense what is happening in our tissue moment to moment as well as when receiving manual therapy. Golgi tendon organs in both tendons and in aponeuroses give feedback about the straightening of the fibers in the tendon. Paciniform endings in the myotendinous junction, joint capsules, and ligaments report vibration and rapidly changing pressures in the fascial net. Ruffini endings respond to deep and sustained pressure.²⁸⁵
- Fascia is piezoelectric tissue. Myofascial release that emphasizes sustained pressure and tension over fascial restrictions generates a flow of electrical activity, or information, throughout the fascial system. Electrical impulses are generated in the collagen by compressive and distraction forces within the musculoskeletal system. These impulses trigger a cascade of cellular, biomechanical, neural, and extracellular events as the body adapts to external stress. In response to internal stress,

components of the extracellular fluid change in polarity and charge, affecting fascial motion.²⁹²

- With myofascial release, the extracellular matrix softens from “gel” to “sol,” allowing the fascial restriction to melt and release pressure on pain-sensitive tissue, and to rehydrate to allow for conduction of flow of photons and vibration.²⁹³ It is hypothesized that this action facilitates the cell-to-cell communication required in homeostasis and self-regulation and thus facilitates the body-mind’s ability to heal itself.²⁹⁴

Myofascial Release. Myofascial release is a manual (“hands-on”) energetic therapy designed to treat the fascia that surrounds every cell and tissue in the body as a living crystal matrix within which all of our cells are embedded.²⁸⁹ John Barnes, the physical therapist credited for developing this holistic, physical and energy-based treatment technique, has pointed out that it is a mistake to think of muscle as being a tissue in and of itself. Just as we now recognize that the mind and body cannot be separated, we also realize that there is no such entity as muscle; rather, the fascial-muscle unit is the more accurate anatomical and physiological entity. As Janet Travell²⁹⁵ first described it, the fascia that surrounds each muscle fiber and fibril is inextricably interconnected with the muscle, and it is impossible to treat the muscle alone. Until the fascial barriers are released, the muscle, no matter how often stretched or contracted, will tend to resume its original shape. If that shape is distorted by a central or peripheral nervous system pathological condition, as is so often the case with our clients, or distorted from hypertonicity, if the muscle group has taken a postural position of ease from prolonged positioning or emotional protection, or if the fascia surrounding the cells of skin nearby is contorted from a surgical scar, then the muscle is not free to contract in the way it was created to function.

It is also important to emphasize that fascia has been referred to as the structural base of the “living matrix” of all cells in the body.²⁸⁹ Fascia surrounds not only skin and muscle cells, but each and every cell in our bodies and even penetrates each cell as a cytoskeleton. In sum, the cellular matrix is connected with the extracellular matrix by way of fascia. Thus, as therapists when we touch the skin, “we contact a continuous interconnected webwork that extends throughout the body” (p. 47).²⁹⁶

The Physiology of the Fascial System. To understand how myofascial release is administered and why it seems to result in such positive outcomes to patients, it is necessary to understand the physiology of the fascial system. This section should enhance understanding of the fascial system as discussed earlier. Because fascia exists as a three-dimensional web surrounding all our cells, from the top of our head to the bottom of our feet, functional biomechanical movements depend on intact, properly distributed fasciae.²⁹⁶ There are three topographical groupings of twelve different types of fascia,²⁸⁶ and each kind of fascia is composed of connective tissue of similar structure. The fascia just below the dermis is known as *superficial fascia*. The fascia that surrounds and fuses with bone, muscle, nerves, blood vessels, and organs is termed *deep fascia*. The third grouping of fascia is the *dura*, which surrounds the brain and spinal cord. All 12 forms of fascia are composed of collagen, elastin, and a ground substance of polysaccharide composition. This connective tissue plays a vital role in holding the body together. Without fascia, the body could not remain intact and erect, supported by

bones, joints, tendons, and ligaments alone. The fascia functions much like the stays of a tent, supporting the structure of the body but also facilitating metabolism and blood and lymph flow and separating organs and other structures from one another, down to the cellular level.²⁹⁶

Intervention. In contrast to traditional stretching of tissue, during myofascial release practitioners and their clients experience a sensation of softening, or melting similar to melting butter, or stretching, like pulling taffy under the palms of the therapist. Once tight tissue is located by palpation or observation, the slack is taken out of the tissue under the hands, and the therapist gently leans into his or her hands and waits for the tissue to respond. Within 90 to 120 seconds, the therapist’s hands will sink deeper, and a feeling of flow results. The therapist then simply follows that twisting and deepening flow of tissue until it stops (indicating a fascial barrier), when she or he again waits, maintaining slight tension until the tissue begins to flow again, and the therapist can follow the fascia, as it flows or releases, to the next collagenous barrier. The collagen fibers seem to be rearranging themselves back to a position of alignment, or self-correction. Often an area of heat and redness under the release occurs, but curiously, at times an area of erythema occurs distant from the release itself.²⁹⁷ It is hypothesized that the feeling of flow occurs when the polysaccharide ground substance of the fascia becomes more in solution, less gel-like, by way of a piezoelectric effect. Mechanical pressure from the therapist’s hands is converted to chemical energy. Recent research has shown that “actin filaments and microtubules...could function as conduits for the spread of biochemical agents” once they are mechanically stimulated. In other words, human cells have been filmed instantly messaging one another by way of mechanical energy being transmitted to biochemical messages.²⁹⁸

The effect of myofascial release can be enhanced by prolonged, corrective positioning with use of postural wedges or therapeutic balls, or both, to sustain the appropriate pressure to release the fascia over time. For example, for a rotated pelvis, wedges will sustain a correcting derotation while the patient is lying supine or prone.²⁹⁸ In addition, once fascia has been released, it is important to maintain fascial length and to exercise muscles to strengthen resistance to the fascia tightening up once again in gravity. Yoga, Pilates, TKD, and tai chi are excellent exercises to use to maintain length of released fascia. Inversion tables also assist in maintaining fascial length but should not be used for patients restricted from inverting, such as patients or clients with uncontrolled blood pressure or glaucoma.

The purpose of myofascial release is to lengthen the fascia that has been abnormally constricted, thus allowing a more efficient and effective contraction of muscles, release of trapped energy, a more barrier-free blood and lymph supply to nerves and organs, an upright posture that responds in a neutral way to the forces of gravity, and a body-mind that is more in balance from a less restricted flow of body energy, or chi. Myofascial release, along with soft tissue mobilization, therapeutic exercise, and movement reeducation, is an excellent holistic therapeutic approach for musculoskeletal, neuromuscular, and integumentary disorders in function.

Myofascial Release Intervention. Myofascial release treatment consists of a thorough examination of the client, including an in-depth history of symptoms and a thorough musculoskeletal and neuromuscular examination, noting

pain; impairments in strength, ROM, or endurance; and any disorders in function. The client's posture and specifically the position of the pelvis are noted. In many people, the hips will appear uneven, palpation of the anterior superior iliac spines will reveal an iliac rotation, and many times there will be a leg-length discrepancy associated with pelvic rotation. In the case of stroke, TBI, or cerebral palsy, abnormal tone will have resulted in fasciae frozen along with their spastic muscles as a result of disorganized nerve conduction. No matter what the cause of the fascial tightening, the treatment remains to release the connective tissue, the fascia. This is done with manual releases, soft tissue mobilization techniques, traction, positioning on wedges, facilitation of whole-body release (unwinding or somatoemotional release), craniosacral techniques, and a technique called "rebounding." The technique of rebounding, which is especially useful with CNS pathological conditions, involves a passive rocking of tissue, exploiting the hydrophilic aspect of tissue to the maximum. As the therapist rhythmically rocks chest, legs, thorax, or arms, the tissue reverberates with the rhythm of the motion, often resulting in a spontaneous release of tense and hypertonic tissue. Patients respond positively to this technique.

The actual techniques of myofascial release, a holistic complementary therapy, may at first appear to be exactly like mechanical manual therapies, but soon the novice recognizes the need to quiet the mind and body and learns to wait and feel gently with an enhanced proprioceptive sense for the tissue to "move up into the hands" and then gently to follow it as the collagen releases or melts and the fascia lengthens with twists and turns. It is an art that is greatly enhanced by a calm and centered proprioceptive listening that is not linear or mechanical in nature but energetic and holistic.²⁹⁹ Palpating for the cranial rhythm takes the same centered, quiet "listening with one's hands." Eventually, we learn to feel with the whole self.³⁰⁰

As science increasingly focuses on researching the effects of subatomic particles on tissue, and on the nature of "consciousness" and "mind," the hypothesis that consciousness resides not in the cranium, but in the fascial matrix will be further clarified. Energy-based myofascial release facilitates the release of holding patterns, and the emergence of body memories and buried emotions and awarenesses that were difficult to access, allowing patients to become increasingly aware, thus helping to restore balance and homeostasis. In this way, energy-based myofascial release is far more than a structural therapeutic process, but facilitates a reorganization of the entire awareness of one's self within the body-mind.²⁹⁶

Models of Health Care Belief Systems

American Indian Healing Traditions of North and South America

Richard W. Voss

Bob Prue, Member of the Rosebud Sioux Tribe

American Indians are understandably wary of the written word. Some may criticize the inclusion of this section in this chapter. This criticism is understandable because the written word objectifies understandings out of the cultural context and can be manipulated outside the relationship in which the understanding was shared. However, not to include a discussion of American Indian views about medicine and health

care is also a concern because it perpetuates the invisibility of American Indian peoples. The purpose here is to honor the continuing journey of understanding between medical science practitioners and traditional American Indian medicine practitioners to see how these two medicine paths can help restore health to the people and to bring about increased understanding—wo 'wableza—among peoples.

Contemporary American Indian Health Care and Traditional Healing: North and South American Indian or Indigenous Perspectives. In a report to NIH, *Alternative Medicine: Expanding Medical Horizons*,³⁰¹ the Lakota (a Sioux people) were cited for the use of healing ceremonies by specialists who are essentially shamanic in their approach to treatment. To understand American Indian medicine ways, one cannot rely solely on written accounts. Although written ethnographical studies may provide a wealth of descriptive data, it is best to talk to authoritative sources personally. Professionals interested in learning more about traditional approaches to help and healing should contact any one of the federally recognized tribal headquarters and the tribally sponsored American Indian colleges and universities for more specific information. Many colleges conduct summer courses on Lakota culture and philosophy that are open to non-American Indians, as well as American Indians, interested in learning the culture. This information may be found on the Internet under tribal colleges and federally recognized tribes.

Today, many of the old American Indian healing traditions are experiencing a renaissance and are beginning to be viewed with a renewed sense of respect and credibility as an alternative and complement to more invasive or secular Western medical models of treatment.³⁰¹⁻³⁰⁷ For example, on the Cheyenne River Sioux Reservation at Eagle Butte, South Dakota, the tribe has incorporated traditional methods and approaches to a variety of social service programs, including services for at-risk youth and care for people with alcoholism, which is viewed as a problem with social, emotional, physical, and spiritual dimensions.^{303,304,306,307} These traditional methods include the inipi, or purification ceremony (popularly called the "sweat lodge"), the hanblecaya, or pipe fast (often called the "vision quest"), and the wiwang wacipi, or the Sundance. The inclusion of these ceremonies within the treatment process has collectively been called the "Red Road approach."^{303,304,307}

A number of medical facilities on various reservations include medicine men as consultants on a formal and informal basis,³⁰⁷⁻³¹⁰ and the use of traditional ceremonies in health care settings is encouraged and respected.³¹¹ Where the ceremonial burning of sage (a common medicinal herb burned for purification) had been discouraged in the past, hospital staff report increased acceptance of this practice and now arrange appropriate space for traditional ceremonial practices both within the health care facility and outside on hospital grounds.^{310,312} One Lakota friend commented on his recent hospitalization at an allopathic hospital. He was visited by a medicine man that placed a bundle of sage under his pillow. This made him feel better and showed how simple cooperation among allopathic medicine, health care practices, and alternative, complementary health care practices can be.

A Lakotacentric Perspective on Health. A traditional American Indian perspective on health care and medicine begins with the spiritual reality of the human being who is

part of all creation and dependent on creation. Traditional understanding views human beings as intimately related to plants and all other creations in the natural world that sustain life. Reality is not linear, it is circular. Everything is connected to everything else. Good and bad, sickness and health, physician and patient are not separate processes, they are all related aspects and part of the whole. For the Lakotas and other traditional American Indian peoples there is no split or dualism in reality or creation. This traditional view challenges the intervention model and offers a prevention model as the starting place for social health and assistance. The emphasis from a Lakotacentric view is on building up the immune system and seeing the important role of the community in promoting good health care and well-being, a cultural emphasis often overlooked in conventional health care practices.

Traditional Lakota values of health and well-being emphasize the participation of the family in the healing process, including the extended family and the larger kinship community, to bring about good health to the individual. The health of the individual is connected to the health of the community, so there is an important tribal dimension to this understanding. For traditional Lakota people the health and healing process is not impersonal but highly personalized and individualized around specific needs. The roles of medicine practitioners are multidimensional and include those of healer, counselor, politician, and priest.

Another important contribution of the Native American perspective on health is that it provides a rich topology of spirit. The human creation, like all creations, is a spirit being composed of multilayered aspects of spirit. “Spirit” here is not some supernatural reality outside the human being but an intrinsic dimension of everything that is, including the human creation (person). To speak of human beings is to speak of spiritual reality. For traditional American Indians, medical treatment or any kind of social, human, or mental health service is first and foremost a spiritual endeavor.

Ayahuasca: A Spiritual Pathway to Consciousness and Healing. Traditional Indian peoples of South America have similar and yet distinctive traditions of help and healing where the rain forest provides the pharmacopoeia of medicinal plants, bark, herbs, and vines. Of course, the forest itself is viewed as a powerful source of spiritual healing. During a recent field study to the Tambopata River area of the southeastern Peruvian Amazon (through the Amazon Center for Environmental Education and Research), I had an opportunity to meet with various shamans, their patients, and public health care representatives at a local community center where the regional public school and health care station are located. It is interesting to note that all members of the health care staff rotate, making visits to the area community members, including both indigenous traditional people, who mainly live dispersed through the forest (Amazon), and mestizo or mixed-blood settlers, many of whose families have lived in the river settlements since the mid 1970s.³¹³ Both indigenous natives and mestizo settlers seek assistance from the shaman, the curanderos, and the health station outpost, staffed by nurses and a visiting physician. The South American indigenous community I visited in the Tambopata River region of the southeast Peruvian Amazon used both herbal remedies and spirit-calling ceremonies, often incorporating the use of forest tobacco and other

vegetation gathered from the forest as a means of purification. The use of ayahuasca, a concoction or tea made from various plants, tree bark, and vines gathered from the forest, is administered to both patient and shaman and is a common shamanic practice throughout Amazonia, according to the shamans I interviewed.³¹³ A detailed description of an ayahuasca ceremony is reported by Salak,³¹⁴ providing a fascinating participant observer’s experience of an ayahuasca ceremony. A brief audio-video capture of the beginning of an ayahuasca ceremony may be viewed at www.national-geographic.com/adventure. Clinical applications of ayahuasca are being studied by Jacques Mabit, Director del Centro de Rehabilitacion de Toxicomanos (Rehabilitation and Detoxification Center) at the Takiwasi Center, Peru. Mabit combines the traditional use of ayahuasca and psychotherapy techniques, and holistic methods (consciousness expansion methods such as fasting, hyperventilation, and nonaddictive plants), largely in treatment of coca paste addictions. The center is funded by the French government. Conventional allopathic medicines are not used, except in unusual circumstances.

Riba and colleagues³¹⁵ have published their neuropsychobiology study on the effects of ayahuasca, so traditional medicine has captured both the imagination and the attention of medical science.

Physical detoxification is accomplished through the use of medicinal plants. Conventional Peruvian approaches to addiction treatment are based on prison or military models, which have raised human rights concerns among health care workers. All studies on the clinical use of ayahuasca have European or South American sponsorship, and most have been published in Spanish.³¹⁶

Health Risks Associated with Ayahuasca. Religious groups in the United States have obtained a First Amendment exemption to use ayahuasca in their ceremonies. Despite the U.S. government’s opposition to the use of dimethyltryptamine (DMT), which is the main chemical substance found in ayahuasca, the government could not meet the burden of showing that ayahuasca posed a serious health risk to church members who use it in their ceremonies.³¹⁷ Gable reports that there have been no deaths caused by hoasca or any other traditional DMT/ β -carboline ayahuasca brews. Furthermore, he writes, “The probability of a toxic overdose of ayahuasca is seemingly minimized by serotonin’s stimulation of the vagus nerve, which, in turn, induces emesis near the level of an effective ayahuasca dose. The risk of overdose appears to be related primarily to the concurrent or prior use of an additional serotonergic substance. People who have an abnormal metabolism or a compromised health status are obviously at greater risk than the normal population, and might prudently avoid the use of ayahuasca preparations” (p. 29).³¹⁷

Although there is generally no known harm to ingesting ayahuasca in a ceremonial context, common sense about nonceremonial use is called for. Using watchers to sit with the person while using ayahuasca and of course not allowing driving or use of heavy machinery is common sense. Therefore a harm reduction approach is called for. That said, the pharmacology of ayahuasca is such that “selective serotonin reuptake inhibitors can have potentially harmful interactions with MAO inhibitors, so people taking these kinds of medications are advised to avoid ayahuasca” (p. 301).³¹⁸ This is consistent with Gable’s findings. There are no significant

associations between the typical dosage of ayahuasca in ceremonial usage and long-term psychosis. Gable reports that “Many or most of UDV [União do Vegetal] psychiatric episodes were transient in nature and resolved spontaneously” (p. 30).³¹⁷

Gable notes, “The ritual context in which ayahuasca is ingested provides some control of dosage and subsequent psychological effects. Because the natural sources used in preparation of the tea do not allow UDV members to standardize their hoasca brew with respect to DMT or β -carbolines, the person conducting the ceremony drinks the brew before administering it to UDV members as a means of testing for potency. Different amounts of the brew are initially offered to individual participants, and, depending on reactions, a participant may be offered a second cup at his or her request” (p. 26).³¹⁷

Another area of concern is risk of dependency on ayahuasca. There is no convincing evidence that ayahuasca leads to physiological dependence. Of course, this is an area worth careful attention in continuing research, although Gable notes that the general psychopharmacological profile of hoasca “suggests that it lacks the abuse potential of amphetamines, cocaine, opiates or other widely abused substances.” Elsewhere, Gable notes that “tryptamine derivatives such as DMT (found in ayahuasca) result in erratic patterns of self-administration indicating that ‘these compounds have weak reinforcing effects, or alternatively, mixed reinforcing and aversive effects.’” (p. 31).³¹⁷ Gable notes, “The unpredictable occurrence of frightening images and thoughts, plus predictable nausea and diarrhea, makes it a very unlikely candidate for a ‘club drug’” (p. 32).³¹⁷ On the other hand, Grob reported that “all of the 15 UDV subjects claimed that their experience with ritual use of hoasca as a psychoactive ritual sacrament had had a profound [positive] impact on the course of their lives.” Most of the UDV members had a history of moderate to severe alcohol use prior to joining the UDV” (p. 30).³¹⁷

Traditional Acupuncture

Jeffrey Kauffman

It has been gratifying to see Western medicine, as it is practiced by allopathic physicians, come around to include many of the holistic practices that were once considered quackery. This is happening with chiropractic, massage, and other forms of body work; nutrition and diet; and exercise practices such as hatha yoga and tai chi, and so on. A research study designed by David Eisenberg of Harvard Medical School, published in the *New England Journal of Medicine* in 1993 and again in 1998,^{319,320} showed just how extensive alternative or holistic practices are and how a large percentage of patients are using these practices, with or without knowledge of their personal physicians. Alternative health therapeutic modes are on the rise, are being used by more and more of the general population of the United States, and are being more and more accepted by Western medical practitioners. Many medical schools now have courses teaching alternative healing practices to medical students.

The question arises as to why people are drawn to therapeutic approaches outside the medical sphere. The answer is relatively straightforward. They are not getting everything they need in health care from traditional allopathic, Western-trained medical doctors. People are looking for something

that works better. More and more people are disenchanted by the lack of compassion of a large percentage of the medical profession. This involves the patient being approached by the physician as a disease rather than a person, as a gallbladder case or a case of appendicitis or chronic fatigue instead of Sherri Jackson or Marvin Jones. This involves the hurried 5- to 10-minute visits created and encouraged by health maintenance organizations. It involves the use of pharmaceuticals over the use of any other therapeutic modality. The side effects of such medications add to the problem. Along with the decrease in or lack of compassion comes the inability of many physicians to develop rapport with their patients.

There is one other important principle that separates allopathic medicine as it is practiced in the United States from holistic healing, and that is the attention paid to the symptoms. Allopathic medicine traditionally treats the symptoms. In fact, the diagnosis is usually the symptom with the name changed to something that has “-itis” on it at the end as a suffix. For example, *arthritis* means inflammation of the joints, *appendicitis* means inflammation of the appendix, and *iritis* means inflammation of the iris. Tension headache or migraine headache is simply a headache. It means an ache or pain in the head. Western medicine is essentially treating the symptoms, most commonly with drugs. Even the medications are named after the symptoms, for example, antiinflammatories, antihypertensives, antimetabolites, antacids, antiarrhythmic agents, and diuretics (to increase output of fluid through the urine).

On the other hand, holistic healing is aimed at determining the cause of the disease (even the Western medical term *disease* means dis-ease or lack of ease). In determining the cause of dis-ease, one looks for the underlying imbalances that all human beings have. None of us is born with a perfect body-mind that never breaks down. We all have an underlying imbalance or constitutional imbalance that is the weak or vulnerable area of our body-mind that will always be the first to show symptoms and illness when we are under pressure or stress.

The pressure or stress coming from the outside world, outside of our body, can be in the form of physical agents such as physical trauma (accidents), which cause bruised tissues, strained or torn ligaments, or broken bones; toxic agents from the environment, such as poison or chemicals in the water or foods or air; carcinogens from contaminants; or poor nutrition and poor diet, not taking in enough nutrients or taking in too much of a particular kind. There are also external causes that are related to weather, such as excessive exposure to heat or cold, humidity or dryness, or wind or dampness; being struck by lightning; or near drowning. These causes were much more prevalent 200 years ago and even more so further back in the past. In modern civilization the much more common causes of illness come from the inside. These would be in the mental or emotional spheres. Generally, it is an emotion that is in excess or deficient in the person’s life, such as too much fear or not enough, too much grief or not enough expression of grief, too much anger or not enough, too much joy (that’s right, too much joy or inappropriate joy) or not enough, too much sympathy or not enough. Feelings and emotions that are in excess or in deficient states affect particular organs, which in turn can cause imbalance, symptoms, and disease in a particular organ,

which then manifests as a heart attack or arthritis or constipation or cancer, and so on. For example, too much anger or not enough anger imbalances the gallbladder and/or the liver, making those organs susceptible to gallstones or hepatitis, respectively; too much grief or not enough affects the lungs and the colon, and could cause bronchitis or asthma or constipation. This occurs with our thoughts as well; we can focus to excess on particular negative thoughts, which creates imbalance, illness, and disease.

There is also the most important sphere for all human beings, which is the spirit. There can be, and often are, imbalances in this realm that have everything to do with not recognizing one's true value, which means not acknowledging the spirit that lives inside each and every human being. When one is aware of the spiritual energy inside and focuses on it daily, then that person knows and experiences the infinite energy of spirit whose nature is bliss. Unfortunately, most human beings have lost sight of this and consequently are suffering deep inside because of a lack of recognition of self-worth or self-esteem. The latter comes from knowing the Divinity inside. This, in turn, causes physical or mental disease.

There are also genetic causes of disease that are not adequately addressed. Generally, this is rather a cross that the person must bear; balancing and integrating the body, mind, and spirit still help that person lead an enjoyable and valuable life. Imbalances can also come from excess or deficiencies of other things such as too much work or not enough, too much exercise or not enough, too much sex (or not enough?), too much food or not enough. These are usually related to underlying emotional imbalances as well. Holistic modes of therapy address either these external causes or the internal causes, or preferably both.

Once alternative health practices are well entrenched in medical training in medical colleges, their efficacy can be proved easily over a 5-year period by simply measuring monies spent on pharmaceuticals and the quantities of pharmaceuticals used before, during, and after holistic programs are introduced. This would also include measuring and comparing outpatient visits to physicians, visits to emergency departments, hospital admissions, need for surgery, and some kind of standard for measuring quality of life. Improvements in some of these categories have already been proved in research studies done by Herbert Benson,³²¹ who noted the effect on patients using his relaxation response (a form of meditation) on a daily basis for 3 years.

History. Acupuncture as it is practiced in the United States is a huge conglomerate of different styles of acupuncture coming from China, Japan, Korea, Thailand, Vietnam, and Western Europe. The styles differ radically depending on who is doing the acupuncture, where he or she learned it, and how much individuality has been instilled into the practice. Within this discussion, the similarities among practices are described, followed by an in-depth analysis of the style that I use.

Acupuncture is one of the five categories that make up Chinese medicine. The other four are herbal medicine, diet and nutrition, exercise, and massage. Acupuncture is a healing method that tunes a human being. Just as a piano tuner tunes a piano or one tunes a guitar or an auto mechanic does a tune-up on a car, it is possible to tune a human being.

After this process, or intervention, is done, the body-mind functions more efficiently in a balanced, harmonious fashion. As a result, the aches and pains often are eliminated and illnesses and diseases reversed. Acupuncture can be used by itself and, even better, in combination with other holistic and traditional Western medical methods.

Methods. Acupuncture involves the use of tiny needles made of stainless steel, their diameter two or three times the width of a human hair, sharpened by a diamond. These needles are put into particular points on the surface of the body. There are at least a thousand of these points all over the human body. They have a lower electrical potential compared with the surrounding skin, as is evidenced by a galvanometer. These points are also known as *acupuncture points*, *acupressure points*, *trigger points*, and perhaps by other names as well. These points are about 1 mm in diameter and are located pretty much in the same place for everyone, according to bony landmarks, skin landmarks, anatomical structures such as nipples, umbilicus, fingernails and toenails, eyes, ears, nose and mouth, and so on. The points can be found with practice by the trained finger of the practitioner. There are electrical instruments that can help locate these points, but their reliability has not been established. Needles are put into these acupuncture points, and after being inserted, the needles are turned either clockwise or counterclockwise one revolution. They are either taken out immediately or left in for a period of time, depending on the individual patient's imbalance and illness.

Examination and Evaluation. Deciding where to insert the needles is really the key and the most difficult and important part of acupuncture diagnosis. This is where styles of acupuncture come into play. There is a spectrum of acupuncture styles or methods that ranges from completely symptomatic to perfectly holistic, just as there is in traditional Western medicine. The symptomatic methods involve simply putting needles into acupuncture points at anatomical sites that are specifically related to symptoms. For example, for shoulder pain, or arthritis or bursitis, an acupuncturist using a symptomatic method would select acupuncture points that are in or around the shoulder area. Headache would be treated with needles in the head area. Constipation would be treated with needles in the belly area. Hemorrhoids would be treated with needles around the anus and coccygeal area. This method pays little attention to where the constitutional imbalance exists within each person. An opposite philosophy, which is called *holistic acupuncture*, treats the underlying constitutional imbalance within the person. Described earlier, such imbalances are considered the vulnerable, or weak, links in the chain in each human being, that part that always gives out first because it is not as strong or disease resistant as the rest of the body-mind. The type of acupuncture I use is a holistic form. Specifically, it is called *five-element acupuncture*. It is based on the Law of Five Elements, which is a law of nature that comes from Chinese philosophy and is one of the basic foundations of Chinese medicine. It is sometimes known as the *Five Phases* and is considered the most holistic form of acupuncture available.

The Law of Five Elements. The Law of Five Elements states that there are five elements in nature (fire, earth, metal, water, and wood) and that these elements all relate to one another in a particular fashion (Figure 39-5). The diagram in Figure 39-5 shows an outer creative cycle (known as *Shen*)

Figure 39-5 ■ Law of five elements: demonstrating the Shên (creative) and K'ô (controlling) cycles.

that goes in a clockwise fashion and demonstrates that fire creates earth, earth creates metal, metal creates water, water creates wood, and wood creates fire again. Also, a star-shaped control, or destructive, cycle (known as *K'ô*) shows that fire destroys or controls metal, metal does the same to wood, wood to earth, earth to water, and water to fire. These two cycles, the creative and destructive cycles, are necessary to keep balance in nature. These five elements are also found in human beings because the body is composed of elements that come from nature and return to nature when the body dies. The emotions and feelings in our personality align themselves with these same elements (Figure 39-6).

People in Western society have not been taught to think of their bodies in elemental forms, but nevertheless these elements are there. The concept of fire is present in each and every cell. The cells burn glucose to survive and this is referred to as “burning calories.” It is this burning that causes our body temperature to remain at 98.6° F throughout most of our lives. It is not difficult to picture each cell of the body having a little bonfire in the center with mitochondria sitting around roasting pieces of glucose on a stick. Obviously, water is present in our bodies. Students in grammar school are taught that our bodies are 98% water with all the tears and urine and lymph and blood. Similarly, metal can be found in the body in the form of calcium in the bones and iron in the blood, in our teeth, and so on. The concept of wood is most easily seen in the fingernails and toenails, which are similar to the bark of a tree. Also, the ligaments and tendons are much like a strong fiber. The concept of earth is best seen in the gastrointestinal tract. Picture taking a microscopic journey

down the gastrointestinal tract starting from the mouth, going down the esophagus into the stomach and the intestines; the further down you get, the more the material seems earthlike, until it is excreted into the outside world.

Each of the elements has a particular color that emanates from the face, a particular emotion that comes from the personality, a particular odor that comes from the body, and a particular sound that comes from the voice, as well as a particular taste, season, climate, secretion, and body part or system that it fortifies.

Every human being has a constitutional imbalance in one of these elements. The explanation for how this happens lies in spiritual law. Suffice it to say that this imbalance is well engrained some time during the first 5 years of life. Diagnosing this constitutional imbalance is both an art and a science and is done primarily by determining the color, emotion, odor, and sound belonging to each human being. The reader probably has noticed these colors, emotions, odors, and sounds previously with friends or even with strangers. Yet the realization that these are diagnostic clues that reveal a person's constitutional imbalance may not be as self-evident. The person who is always angry, no matter what, is displaying the emotion that goes with the wood element. The person who is always happy, joyful, bubbling over (or the opposite, more commonly seen—very sad, depressed) goes with the element of fire. The person who is always sympathetic and loves to take care of you or is always caring for children is displaying the emotion of sympathy, and that goes with earth. The person who is always grieving, who has tremendous loss and cannot seem to get over it, goes with the element of metal. The

Figure 39-6 ■ Law of five elements linking fire, earth, metal, water, and wood with interlocking variables.

person who is always fearful, paranoid, and afraid of life fits into the water element. People have different sounds to their voice. People who laugh excessively and are always humorous go with the fire element. People who shout a lot, their voices very powerful and strong, knocking you over, go with the wood element. People who have a singsong quality to their voice go with the earth element; groaning goes with the water element; and a weeping sound of the voice, although the person is not crying, goes with the metal element. You have probably smelled people who have a strong body odor and wondered why they did not bathe or use deodorant. There are five different odors and each one belongs to one of these elements. And perhaps you have seen a person who is green with envy or ash white, white as a sheet, or has pallor in the face. Each one of these colors goes with an element as described in the diagram (see Figure 39-6).

Each element also has organs relevant to it, with energetic pathways, called *meridians*, which are housed by that element. These pathways, or meridians, are just under the surface of the skin, throughout the body, and serve as channels for an electrical form of energy that flows in all human beings. This energy is the life force. In Chinese it is called *chi*. In the East Indian culture it is known as *prana*. This life force is always circulating round and round the body-mind along these pathways. And the acupuncturist can get in touch with this energy at certain points on these meridians, which are the acupuncture points.

Intervention. Once the examination is complete and the diagnosis is made, paying close attention to the color, emotion, odor, and sound and the elemental constitutional imbalance determined, it is simply a matter of treating the points along the meridians that are housed by that element on a week-to-week basis. Generally, this tunes the human being and everything starts to function more efficiently and more harmoniously, enhancing the person's quality of life.

There are 12 major meridians, two in each element, except for fire, which has four. Each of these meridians is named after the organ to which it is connected, which is also described in the diagram. Each meridian has 9 to 67 points on it. Each point has a name described by the Chinese that has been translated into English. It is the names and the functions of the

different points that allow the acupuncturist to decide which points are to be used on which day and time and treatment. For example, the point Kidney-24 is actually named *spirit burial ground* and can be used to help a person suffering from grief, having lost a loved one. Taking the history at each visit, and determining blockage of the chi energy flowing in the meridians, is used as well to select the points used in treatment.

As patients get better, not only do their symptoms decrease in intensity and dissolve and often totally disappear with time, their emotional and feeling states also change for the better. People tend to become happier and peaceful and calm, more able to handle stress. They often will say, "I feel better in myself." The reason for this is that the patient is not just having her or his symptoms treated. This form of acupuncture, the five-element style, treats the body, the mind, and the spirit and integrates these three spheres of the human being. The point names are particularly revealing. There are names connected to nature and physical objects such as *small sea*, *greater mountain stream*, *blazing valley*, *sea of chi*, and *skull breathing*. There are also point names that have to do with emotions and feelings, such as *palace of weariness*, *gate of hope*, *rushing the frontier gate*, *intermediary*, *little merchant*, and *abdominal sorrow*. And then there are the points that relate to the spiritual qualities of life, such as *spirit burial ground*, *heavenly ancestor*, *heavenly pond*, *heavenly window*, *gate of destiny*, *inner frontier gate*, *soul door*, and *spirit deficiency*. When these spirit points are used, the person's spirit is buoyed up—it turns back on.

Each treatment lasts 15 to 60 minutes, depending on the individual practitioner. The practitioner can also include any of the following in the treatment sessions: conversation, history taking, massage, joint adjustments, instructions on diet and nutrition, psychosocial counseling, exercise recommendations, and so on. The initial visit takes longer because a history and physical examination are done and sometimes the initial treatment as well. This depends on the technique and abilities of the practitioner. Generally, the treatments are done twice a week for the first two to four visits and then once a week as the patient starts to get better. The interval continues to lengthen to every 2 to 4 weeks,

and as the patient improves, the optimal interval is once every 3 months—once every season, the patient comes in for a tune-up for maintenance and prevention. Generally, a series of 10 treatments is a good way to start this type of therapy. Improvement in the patient's condition may be noticed as soon as the first treatment is done. It may take five or 10 treatments before it is noticed by the patient. Depending on the ability of the practitioner, improvement in the patient's condition generally occurs in 80% to 90% of patients. This, of course, also depends on the severity of the patient's imbalance and illness.

When acupuncture treatment is combined with psychosocial counseling, nutritional advice, exercise instruction, massage, or other forms of body work, in which the person is touched with warmth, peace, and love by another human being, great healing can take place.

Benefits of Intervention. Five-element acupuncture can be used for all sorts of clinical problems: physical, mental, emotional, and spiritual. Any and every type of person can and does respond. There are always exceptions to this, but the general rule is one of success. This includes acute problems and chronic problems, outpatients and hospitalized patients. In China, all patients with stroke are automatically treated with acupuncture as well as the more traditional Western methods. It works on babies, toddlers, adolescents, and the elderly. It can be used as a primary form of therapy to which other therapies are added, or it can be an adjunct to surgery, radiation, and medication or to other holistic therapies.

Future Treatments. The amount of time it takes for a person to heal depends on how long the person has been ill. A rule of thumb is that for every year a person has had a particular physical or mental problem, it is going to take about a month's worth of treatment, with each session done weekly. So, if a person has had arthritis for 20 years, 20 months of treatment should be expected.

On the other hand, if symptoms have been present for only a month or two, it is possible that they could go away with one or two treatments unless they are the result of some kind of serious illness, such as the sudden onset of cancer or heart disease or something that has been present for 1 or 2 years but has been subclinical. The general average is 10 treatments over a 4- to 8-week period, with a good possibility of illness being relieved partially or almost completely during that period, depending on the severity.

Summary. In summary, acupuncture is a healing therapy that is both an art and a science that comes from the Orient, specifically starting in China approximately 4500 years ago. There are many styles of acupuncture, and the most holistic style is known as *five-element acupuncture*. It truly helps to integrate the body, mind, and spirit. When acupuncture is combined with teaching the patient how to live a more healthy lifestyle, including eating a healthy diet, reducing stress, making healthy choices, thinking healthy thoughts, and including fun and relaxation, true healing can occur. Because of the chronic and degenerative nature of many illnesses in the United States, it is possible that total healing would not occur. Nevertheless, this type of therapy, along with the adjuncts mentioned earlier, should definitely help to create a healthier human being.

Allopathic Links to Models of Health Care Belief Systems

Electroacupuncture

Mary Lou Galantino

Acupuncture, a part of traditional Chinese medicine, has been used for more than 4500 years. Mapping of 12 meridian points, which are named primarily after the visceral organs they transverse, incorporates 361 regular points. There are also "Ashi points," which are typically tender points that are used for treatment of pain syndromes.³²² The acupuncturist must make a decision as to which acupuncture points to stimulate on the basis of a specific diagnosis. The goal is to balance chi, which is considered vital energy. If there is an imbalance caused by disease, the altered flow of chi can be detected and subsequently treated through needles or electrical stimulation over specific acupuncture points.

Therapeutic Effects of Electroacupuncture. The use of acupuncture is growing in popularity in most Western countries,³²³ and the effectiveness of electroacupuncture as a modality for the treatment of pain has been shown by significant decreases in VAS scores.³²⁴ The therapeutic effects of acupuncture have generally been applied for the treatment of pain; with the increasing acceptance of acupuncture as an effective modality for pain relief, the scope of research on this modality has widened considerably to include other health care conditions. The intensive research efforts on other therapeutic effects of acupuncture have produced encouraging results.³²⁵⁻³²⁷ These results point to a reduction in pain, improvement in motor function, better balance, and improved gait; the results therefore have a neurophysiological interpretation. The effect of spasticity has been explored by researchers for multiple diagnoses such as spinal cord injury and stroke. Electroacupuncture has been found to have more of an effect on spasticity the earlier treatment is implemented, ideally within 3 weeks of injury. Findings reveal positive short- and long-term effects³²⁸⁻³³⁰; however, future research needs to include frequency of treatment and specific points of stimulation for a more comprehensive understanding. Some of the possible mechanisms by which acupuncture may affect motor function include the following:

1. Stimulation of the release of endogenous opioids.³³¹
2. Changing of the amplitude of end plate potential, thus facilitating the events at the neuromuscular junctions. It has been suggested that peripheral factors contributing to the potentiation of a reflex (e.g., the H reflex) may affect the afferents and the neuromuscular junction.³³²
3. Stimulation of the sensory system, which will result in integrative actions at the spinal cord level, where acupuncture may facilitate the stretch reflex arc through both the gamma and alpha motor neurons. Facilitation may depend on the intensity and timing of the stimuli used to activate muscle afferents.³³³
4. Revealed on neuroimaging of acupuncture in patients with chronic pain, changes in cerebral blood flow associated with pain and acupuncture analgesia that correspond to areas of the brain involved in such phenomena.³³³

Training for acupuncture varies throughout the United States (refer to section on traditional acupuncture). Because needling is considered an invasive technique, physical therapists are prohibited from using it. Therefore an alternative to needle acupuncture is noninvasive electroacupuncture or

electrical neurostimulation. Concerning the effects of electrical neurostimulation, there are various interpretations of the methods and underlying physiological mechanisms. One mechanism is neural.³³⁴ Another study has indicated that electrical stimulation applied to acupuncture points may activate both neurological and endocrine functions that control pain.³³⁴ Anderson and Lundeberg's study supported the release of β -endorphin and oxytocin, which are important for the control of pain and the regulation of blood pressure and body temperature.³³⁴

Research. Research on the effects of electroacupuncture on HIV-related neuropathy found significant reduction in pain, which suggests an excitatory effect on the neuromuscular system. Such an effect may be on membrane potential (possibly through influencing ionic transport) and improvement in body fluid circulation.³³⁵ The effect on the sympathetic system is often reported and more or less explained. The same explanation is proposed for the action of electrical stimulation on pain,^{336,337} with some effects on pain-mediating neurotransmitters at the level of the spinal cord and an endogenous modulation from the brain stem.³³⁸

Even in patients after cardiac surgery, relief of pain through electroacupuncture was shown to reduce the use of opioids such as fentanyl.³³⁹ One case report showed excellent results in chronic pain reduction over a 2-year period in a patient with a pacemaker. In answer to the initial question regarding safety, electroacupuncture was shown to be an excellent alternative for individuals with pacemakers.³⁴⁰

Studies have shown that electroacupuncture may enhance the effect of strength training on motor function. One study compared upper-limb motor functional improvement in chronic stroke survivors who received a combination of electroacupuncture and strength training with that of subjects who received strength training alone. After the combined treatment, the quantitative spastic level, active wrist extension ROM, and Fugl-Meyer upper-limb motor score changed significantly. No significant changes were noted in isometric wrist strength. The strength training alone resulted in no significant changes to any measured variable. These results indicate that the combined acupuncture and strength training treatment reduced muscle spasticity and may have improved motor function for chronic stroke survivors with moderate or severe muscle spasticity.³⁴¹

Although two mechanisms underlying the physiological mechanisms of electroacupuncture were presented previously, it would be prudent for physical therapists to consider maximizing the benefits of electrical modalities in various musculoskeletal and neurological disorders.³⁴² One prospective study³⁴³ investigated the physiological effects of stimulation of acupuncture points ST36 and ST39 of the stomach meridian with Dynatron 200 microcurrent. Hemodynamic functions and skin temperature were monitored, with no significant differences found. However, further research is necessary to elucidate the nature of physiological effects of specific surface electrodes and various types of stimulation to determine the efficacy of electroacupuncture treatment.

Music Therapy

Therese Marie West

Music therapy is the clinical and evidence-based use of music interventions to accomplish individualized goals within a therapeutic relationship by a credentialed professional who has completed an approved music therapy program.⁴³³

Although music is not a “universal language” in the sense that a particular piece of music would have the same meaning and effect for any person anywhere, music *is* a universal human phenomenon. Most people today could describe ways in which music might be used to enhance health or well-being, and we find evidence of the use of music as part of healing practices throughout history.^{434,435} Within a first worldview perspective, magical or mystical powers were attributed to music, and healing occurred within a context of social structures and shared beliefs. Music was often a part of rituals conducted by a shaman or healer who served as a spiritual intercessor or guide in a process designed to reestablish balance and harmony for the individual. Music, sometimes with dance, served as a gateway to altered states of consciousness and entry to deep altered states of consciousness, where creative experiences manifested multiple sources of information not available through observation alone. This process supported insights about the causes of and remedies for physical, emotional, social, and spiritual imbalance. Where patient, healer, family, and community members participated together in healing rituals involving the use of music, treatment occurred within the natural environment and social fabric of everyday life. Examples of music healing within a first worldview perspective can still be found within indigenous cultural groups to this day.

The rise of the second worldview brought new values that emphasized logical and rational approaches to the use of music to address health issues. During this phase in history, we see the first examples of published work asserting the theory that music could influence emotions and mood states and thereby improve physical or mental health.⁴³⁴ Anecdotal evidence and case reports were used to support emerging theories and practices into the early twentieth century. In the latter part of the twentieth century, we began to see the scientific method applied systematically to the study of music in relation to single variable changes in (1) disease and pathological states or (2) functional activities and willingness to participate in rehabilitation treatment settings. Researchers continue to explore possible mechanisms through which music may contribute to improved physical or mental health via its influence on various factors such as emotional responses, mood states, relaxation, activation, or motivation.

History of Music Therapy. In the United States, music therapy began to develop as a profession after World War II, when it was found that music could facilitate both physical rehabilitation and recovery from emotional trauma in veterans returned from the war. Although early music therapists were often musician volunteers, music educators, or musician-physicians, it had become clear that specific education and training were needed, and music therapy curricula and academic programs were developed beginning in the mid 1940s. The first professional music therapy organization (the National Association for Music Therapy [NAMT]) was formed in 1950. A second professional organization, the American Association for Music Therapy (AAMT), formed in 1971. The NAMT and AAMT merged in 1998 to form the American Music Therapy Association (AMTA). The AMTA sets standards for education and clinical training in music therapy programs accredited at more than 70 colleges and universities in the United States and Canada. The Certification Board for Music Therapists (CBMT) was accredited in 1986 by the National Commission for Certifying Agencies and certifies music therapists to practice throughout the

United States. Certification is via a competency-based certification process that includes specialized coursework, 1200 hours of supervised clinical training, and a certification board examination. There are currently more than 5000 music therapists maintaining the MT-BC (Music Therapist, Board Certified) credential and participating in at least 100 hours of continuing education for recertification every 5 years to maintain and increase competencies for practice in this rapidly evolving field.⁴³⁶ The development of music therapy in the United States parallels the stages of health care development as discussed earlier (see the discussion of historical perspective in this chapter). Stage 2 worldviews were dominant during the formative years of music therapy as a profession in the United States. The concurrent emergence of behavioral psychology, along with a need to provide validation of specific music therapy treatments, led to an emphasis on outcomes understood via behavioral measurements. Meanwhile, the complex and multifaceted interactions between humans and their music remained mysterious as clear evidence for mechanisms eluded early researchers. Although basic science study is now part of the continuing research, applied or clinical research has continued to dominate the literature in music therapy, and there is a great deal of work ahead to better understand many of the powerful effects of music observed in clinical settings. Therapists observe that patients who are unable to speak as a result of stroke or AD are often able to sing coherently when presented with familiar music. How is it that the gait of a patient with Parkinson disease improves markedly in the presence of a rhythmic auditory stimulus⁴³⁷? How does music-evoked imagery (such as experienced with the Bonny Method of Guided Imagery and Music) alter physiological and psychological indicators of stress^{438,439}? Modern research developments in brain neuroscience, gait assessment technology, and psychoneuroimmunology are improving researchers' ability to study mechanisms as well as treatment outcomes. Meanwhile, an important focus in the field of music therapy is the development of clinically validated treatments for specific problems and populations. In the United States, music therapy is recognized as "an established health profession in which music is used within a therapeutic relationship to address physical, emotional, cognitive, and social needs of individuals. After assessing the strengths and needs of each client, the qualified music therapist provides the indicated treatment including creating, singing, moving to, and/or listening to music. Through musical involvement in the therapeutic context, clients' abilities are strengthened and transferred to other areas of their lives."⁴⁴⁰

Specialization. Music therapists develop specialized areas of practice, treating across the life span from perinatal to palliative care, in schools, hospitals, skilled nursing, rehabilitation, outpatient, or community settings. The goals they address support progress in developmental tasks, rehabilitation of physical and cognitive functioning, adaptation and coping, pain management, recovery from trauma, and quality of life. Music therapists work in private practice, as members of interdisciplinary teams, and as consultants and collaborators. Therese West is one of many music therapists who has worked in rehabilitation settings in co-treatment, consultation, or collaboration with speech-language pathologists, physical therapists, and occupational therapists, as well as with a wide range of practitioners from other

professions in medicine and mental health arenas. During early clinical collaborations in rehabilitation settings from the mid 1980s to the early 1990s, West found little research to support an understanding of observed phenomena in the rehabilitation clinic setting and had to depend largely on basic skills of music therapy assessment, careful documentation, and evaluation of treatment outcomes and effectiveness. In recent years, the music therapy profession has focused on increasing the quality and scope of research to support empirically validated best practice with reliable outcomes for a number of specific populations of interest to professionals in rehabilitation settings. Rehabilitation music therapists now have the benefit of empirically supported treatment protocols and continuing research regarding effectiveness and safety of music therapy methods.

Music Therapy in the Neonatal Intensive Care Unit. Low-birth-weight and premature infants are at high risk for developmental disabilities, and given the vulnerabilities of their neurological systems, early sensory experiences in the neonatal intensive care unit (NICU) environment are of particular interest to music therapy researchers. A number of studies have explored the uses of music in the NICU, and results suggest that various clinically significant outcomes may result from carefully controlled application of music treatments for the premature infant. Physiological (autonomic nervous system) responses related to infant stress states (blood pressure, heart rate, respiration rate) have been shown to respond to various music stimuli, with favorable responses to sedative music.^{441,442} Improvements in behavior state, weight gain, and decrease in length of hospital stay have been reported after treatment with recorded vocal music⁴⁴³ and parent training in music and multimodal stimulation (MMS).⁴⁴⁴ A collection of writings on basic theories, research, and clinical practice of music therapy in the NICU from 16 different countries offers an overview of the development of this practice area around the world.⁴⁴⁵ Jayne Standley, a senior researcher and collaborator in the development of empirically supported treatments for premature and low-birth-weight infants in the United States, presents specific music therapy protocols for pacification, stimulation, and parent-infant interaction.⁴⁴⁶ Music therapy treatment protocols have been reviewed and refined with particular attention to audiological issues and safety concerns⁴⁴⁷ and with attention to nursing care models designed to meet individual developmental needs of newborn infants.⁴⁴⁸ The MMS procedure is a comprehensive program engaging the premature infant, parents, and caregivers using auditory, tactile, visual, and vestibular stimulation to support optimal premature infant development.⁴⁴⁹ Research is continuing, and as longitudinal studies are conducted we will know more about longer-term developmental outcomes that may correlate with the immediate benefits associated with music therapy in the NICU.

Music Therapy in Neurological Rehabilitation. Music therapists have been working in neurological rehabilitation settings in the United States for more than 25 years. Tomaino⁴⁵⁰ describes her long professional collaboration with the neurologist Dr. Oliver Sacks and shares insights developed through extensive clinical application of music in the individualized assessment and treatment of various neurological diseases and injuries. Music can access intact neurological functions and is used to facilitate relaxation, to

increase attention and motivation, to improve the readiness for (priming) and timing of motor activities, and to enhance communication and emotional expression while providing supports for coping and adaptation. Tomaino⁴⁵⁰ describes the music therapy process from assessment and treatment planning through treatment and evaluation of outcomes, focusing not only on physical and behavioral changes but also on the engagement of the whole person through a trust-based therapeutic relationship. Familiar music can provide the patient a sense of safety, with predictable elements of rhythm, melody (prosody), words and lyrics, and structure across time within socially and culturally relevant contexts. Musical elements are systematically applied to support functioning in cognition and memory, speech and communication, gait, and upper-extremity activities.

Music therapy has been used in many rehabilitation settings to support cognitive functioning in areas such as attention, sensory filtering and focusing, memory, sequencing, and executive functioning. Ongoing development of theoretical foundations for clinical uses of music in the cognitive treatment of those with brain insult or injury is supported by brain imaging and *in vivo* functional studies providing evidence of shared mechanisms among musical and nonmusical perceptual and cognitive brain functions⁴⁵¹ and effects of music on electroencephalographic activities in cortical networks.⁴⁵²

West has observed the phenomenon commonly reported in rehabilitation music therapy, where persons with various aphasias are able to sing, but not able to speak fluently. The patient is often able to sing clearly in time with the singing of the music therapist, who adapts the tempo and other elements as needed. There appears to be an entrainment process, not only rhythmically, but also in elements of prosody and articulation. The mechanisms are not yet fully understood, but at least one study suggests that singing in synchrony with an auditory model (choral singing) may be more effective than choral speech in improving word intelligibility because choral singing may entrain more than one auditory-vocal interface.⁴⁵³ Kim and Tomaino⁴⁵⁴ have developed and pilot tested a music therapy treatment protocol for persons with nonfluent aphasia, integrating extensive clinical experience with recent findings from experimental studies using cognitive-behavioral, electrophysiological, and brain imaging techniques. Whereas specific brain structures have been well established for speech and language, and were thought to be distinct from music processing areas, it now appears that music and language may share some aspects of neurological processing in bilateral hemispheric activities.⁴⁵⁴ The evolving brain research may help us better understand our clinical observations and will most certainly support increasingly effective treatment protocols for expressive aphasia.

One particularly valuable discovery in music therapy for neurological rehabilitation is the fact that rhythmic elements of music can influence the timing and execution of motor sequences in both gross motor and fine motor activities. A neuroscience approach to understanding potential effects of rhythmic auditory stimulation (RAS) and motor-rhythm synchronization phenomena in neurological rehabilitation is supported by a well developed body of basic research and clinical studies with a number of rehabilitation populations.⁴⁵⁵⁻⁴⁵⁸

Research. One study demonstrated the ability of RAS to enhance treatment when it is added to a conventional PT gait

program for acute hemiparetic stroke patients.⁴⁵⁹ These patients showed significant increases in velocity and stride length and reductions in EMG amplitude variability of gastrocnemius muscle in the RAS-enhanced treatment group compared with the standard PT (control) group.⁴⁵⁹ Studies have also demonstrated benefits of RAS treatments in gait rehabilitation for patients with TBI⁴⁶⁰ and Parkinson disease.⁴³⁷ Research continues to investigate possible applications for RAS in other areas of rehabilitation, such as speech motor control in patients with Parkinson disease, where the largest improvements have been found in patients with the most severe impairments and only minimal benefits in mildly affected patients.⁴⁶¹ The specificity of such findings highlights the importance of careful diagnostic assessment and an understanding of both problem and treatment specifics as we develop evidence-based best practices for music therapy or any other complementary or alternative treatment. Controlled clinical research continues to support the development of music therapy treatment protocols that demonstrate reliable physical outcomes for specific problems encountered in neurological rehabilitation settings.

Other kinds of music therapy investigations commonly conducted at earlier points along the pathway to empirical validation include qualitative research, case studies, and pilot studies. Although empirical research investigates specific outcomes, music therapists often look to qualitative research to help them identify and analyze processes and refine treatments on the basis of their effectiveness in the clinical or community setting. A group of Australian music therapists investigated themes in songs written by patients with TBI.⁴⁶² Such investigations give clinicians insight into the inner experience of the patient and may enable the practitioner to be more effective and supportive of patients' coping and recovery processes.

Case studies illustrate the potential of music therapy to enhance coping and adaptation to enormous losses experienced by patients poststroke. Erdonmez⁴⁶³ describes the piano performance-based treatment of a 54-year-old man whose quality of life as a successful general medical practitioner, linguist, and talented keyboard player was abruptly changed by a stroke with massive damage in left temporal and parietal lobes. New motor skills were developed, as he learned to master with his functional left hand the complex musical tasks originally composed for the right hand. He learned new music and new adaptive skills, and treatment resulted in improvements in speed and manual dexterity. The results of this case study reinforce today's concepts of neuroplasticity and encourage further research into the possibility that music therapy may facilitate development of new neurological pathways and motor strategies. Simultaneously, music therapy gently supports the patient in coping with losses, adapting to limitations, and reconstructing a life with meaning and enjoyment. McMaster⁴⁶⁴ describes a course of individual music therapy treatment for a woman in her early 40s who, after the rupture of a tumor in her heart resulting in a CVA, was blind, without speech, and severely disabled in many areas of functioning. Through a music therapy program, this woman was able to protest and grieve her many losses, discovered and received validation of her inner resources and creativity, and experienced new accomplishments. These experiences supported her sense of self and enabled her to mobilize her physical, emotional, and

spiritual strengths to face life in a body that would never return to what she had always known.

Although loss of short-term memory and other cognitive limitations resulting from neurological insult may be considered contraindications for traditional psychotherapy approaches, Goldberg and colleagues⁴⁶⁵ explored the use of music-evoked imagery with a brain-damaged woman whose behavioral problems had resulted in psychiatric hospitalization. This adaptation of the Bonny Method of Guided Imagery and Music supported a creative interaction between the patient and therapist. These interactions allowed the patient to explore in novel ways losses, role changes, and challenges in accepting help from others. Although these researchers were not able to gather follow-up data, immediate positive behavioral changes observed in the milieu suggested that the imagery may have facilitated psychological processing and change not accessible by verbal therapy alone. Short⁴⁶⁶ suggests that the Bonny Method, through the spontaneous imagery process, can allow patients to convey information about how they are feeling physically and emotionally with regard to the rehabilitation process. She also proposes that the content of the images evoked by the music can be analyzed by the Bonny Method therapist, to discover emergent themes relevant to the clinical treatment. More research is needed to help music therapy researchers, educators, and clinicians understand how music imagery treatments affect neurological functioning.

Music Therapy as a Complementary Modality.

Meanwhile, music therapy continues to play an important role in holistic care, even while some phenomena yet elude our scientific methods. West was asked to assess two different teenage boys, hospitalized and in comatose states after head injuries. The treating neurologist was preparing to recommend longer-term follow-up disposition for these young patients, and while considering all the medical evidence at his disposal, this physician also wanted to see what music therapy might discover in terms of responsiveness to stimuli. Although one patient showed no response of any kind to any auditory or tactile stimuli, the second patient proved to be a most interesting example of the mysterious recovery. His neurological tests indicated that his prognosis would be very poor; “persistent vegetative state” was the expectation. In the absence of any evidence that he could benefit from more intensive rehabilitation services, he would be sent to a facility where he would receive long-term custodial care but no therapies. During the music therapy assessment, this young man began to show signs of responsiveness to musical stimuli. A professional skeptic, West was reluctant to consider his eye gaze changes, head movement, and smiling to be meaningful responses to the music without additional testing. These could be random events coincident with the stimuli. West

presented music in a popular style familiar to the patient (according to family sources) and gently applied tactile rhythmic stimulation to his hands, arms, legs, and feet in time with the music. The patient began to move his own extremities in rhythmic time to the music and continued to do so when the therapist removed her hands. The therapist carefully documented the procedures and patient responses and returned a report to the referring physician. Over the next few days, the patient’s responsiveness increased dramatically. The neurologist had this young man placed in a rehabilitation treatment setting. A month later, he had begun to walk and showed promise of significant recovery of functions in a number of areas, including speech. This patient was initially medically evaluated as having little potential for recovery, yet after music therapy he was interactive and a participant in life. This case is a good example of how music can access and bring forward what is yet intact (whole) within a person whose body has been damaged by illness or injury.

Although basic and clinical research activities are increasing an understanding of “how” and “for what, when, and for whom” music therapy can be of specific benefit in neurological rehabilitation and medicine, music therapists are also facing the new challenges and opportunities of new worldviews. Music therapy is among the complementary modalities provided as part of a response to increasing demand for holistic and patient- and family-centered health care. Because music interacts with every domain of human experience (physical, cognitive, emotional, social, and spiritual), it has the potential to influence multiple needs simultaneously, in a unified way that respects both the uniqueness of the individual and the deep common ground of the person within the whole.

CASE EXAMPLE OF INTEGRATION OF VARIOUS APPROACHES

Carol M. Davis

Darcy A. Umphred

Therese Marie West

The intervention with the following patient reflected awareness by the therapist of using myofascial release, CST, and the Feldenkrais method, as well as more traditional therapeutic interventions. The reader must remember that any one of the other approaches presented within this chapter might also have been implemented as part of this client’s treatment given another therapist’s experience, education, and therapeutic sensitivity, as well as the cultural biases of the client and family. No judgment is being placed on the method or methods selected for this client or any other. What are critically important are the objective outcome measures after the intervention (*Case Study 39-3*).

CASE STUDY 39-3 ■ MRS. P. K.

Mrs. P. K., a 66-year-old woman, presented herself 2 years ago, once she let her diagnosis of Parkinson disease penetrate her consciousness. It was inconceivable to her that she might have the same illness that affected her grandmother and the same illness that the attorney general could not seem to mask in front of the public. As a seasoned lobbyist, she worked with politicians and traveled in powerful circles. Using her intellect and her considerable skill in negotiation, she successfully persuaded powerful people to see things her way for the benefit of her clients. A woman of small stature (5 feet tall and 105 pounds), Mrs. P. K. feared that her illness would be seen as a weakness and was adamant that under no circumstances was anyone to know that she had Parkinson disease. Fortunately for her, her only symptom was a slight right upper-extremity tremor on waking each morning and some “stiffness,” especially in flexion and extension of her right shoulder and extension of her right knee. This aspect of the case is critical. Her endless motivation to exercise was based on this fear of exposure, which she regarded, in spite of her therapist’s attempts to work through this with her, as a death knell for her professional life.

Mrs. P. K. had exercised much of her life and walked a mile on her treadmill each morning at 3.8 miles/hr. Her husband was familiar with massage and Rolfing, and, at her request, he stretched her hips and lower extremities each day as prophylaxis against the return of a low back pain problem from years earlier. Initial examination revealed the following deficits:

- Active right shoulder flexion 130/170
- Active right wrist flexion 45/85
- Cervical rotation, right 60/80
- Cervical rotation, left 45/80

Gait. Mrs. P. K. tended to walk with a narrow stance, heels close together, but with good heel strike. She was unable to ascend or descend stairs, looking straight ahead without severe slowing. She had little head movement or thoracic rotation; her gait looked rather robotic.

Skin. There was slight edema on the right side of the face, with slight swelling of the upper right lip.

Posture. Mrs. P. K.’s pelvis was rotated down to the right, she had a slightly forward head, and although she did not have rounded shoulders per se, the fascia was drawn tight over her pectorals toward her sternum. The fascia of her legs was taut and revealed a lack of tissue hydration.

Mrs. P. K. had no limitations in function. Her primary clinical goal was to prevent physical manifestations of the onset of the rigidity caused by Parkinson disease. If and when the disease itself progressed, we reasoned that the more fluid her tissue was, and the more physically fit she was, the less the impact of a dopamine deficiency, and the more efficient her medication (selegiline) would be in reducing the impact of a dopamine deficiency and controlling the progression of her symptoms. An intervention plan was developed that included a combination of traditional exercises for Parkinson disease, complemented by myofascial release and CST, and Feldenkrais exercises to increase her awareness of her movement.

After we received the referral from her neurologist, her treatments were scheduled for twice monthly, with home exercises. We explained how myofascial release “works” to keep the fascia loose but that how it seems to facilitate a sense of calm

and peacefulness when done in conjunction with craniosacral rhythm was not known. Given the lack of basic science evidence, she still willingly signed her informed consent. The plan of intervention integrated myofascial release techniques (along with Feldenkrais exercises) with her traditional therapeutic interventions focusing on the body system problems (impairments) caused by Parkinson disease and their effect on functional movement. These exercises stressed active rotation, spinal segmental exercises, and controlled, active relaxation of the antagonists. Her prognosis was good, for she was beginning intervention in the early stages of the disease, which would preclude secondary complications; she was fully functional and she was physically fit, if not well hydrated, and was motivated. She was encouraged to drink more water.

Treatment began with several minutes of bouncing on the Swiss ball, working on spinal segment articulation and spinal proprioception, and on lateral and backward balancing to relearn where her center of gravity was in her cone of stability. Next, with the assistance of the therapist, she moved to the bolster, where she lay supine with knees flexed and worked on lower-extremity extension and balance. On the mat she worked with Feldenkrais exercises and rotation of her shoulders and hips in opposite directions, with head rotation, and reviewed the pelvic exercises in her home program to help her differentiate her pelvis from her hips and to keep her lumbosacral junction and sacroiliac joints mobile.

From there she moved to the plinth, where wedges were positioned to derotate her pelvis in the supine position. Myofascial treatment then began with gentle palpation of her cranial rhythm; she was asked to relax, take three large breaths, and in her mind’s eye, “go on vacation.” (Music therapy could be easily introduced at this time to assist her nervous system with relaxation.) This was difficult for her, for her mind is active, constantly thinking about work. As she relaxed, her breathing slowed, and her cranial rhythm became more pronounced. At this point, the thoughts of the clinician became centered and progressed through various activities. First, there was focused intention and reflective thought that asked that energy from the clinician be used to bring about the highest good for the client. Conscious centering included taking deep breaths, visualizing a grounding of the clinician, and seeing that energy flow deep into the earth. Next, the clinician focused attention within the heart (heart chakra according to medical intuitives) and felt deep appreciation for the client, and for the opportunity to help her by use of holistic techniques.

This exchange of healing energy was an important moment for both client and clinician. It might be conjectured that the therapist consciously tapped into the universal healing energy that surrounds all of us at all times and became a kind of transformer for that energy to be used to facilitate the flow of the client’s own chi or healing energy that had been disrupted. No matter the verbal explanation used for this interaction, it created a strong bond of trust and respect that would continue to influence the outcome of the interventions.

The clinician continued treatment by moving into an occipital lobe release, followed by cranial releases and a sphenoid release, reasoning that this would assist the myofascia in the cranium to help ensure proper alignment of the cranial bones and to facilitate blood supply to and from the CNS. At this

Continued

CASE STUDY 39-3 ■ MRS. P. K.—cont'd

point in the treatment, the clinician would usually allow clinical perception or clinical intuition to guide decision making regarding the next movement. In reality, the therapist might just follow the guidance of the client's innate healing or centering aptitude. Occasionally, more time was spent on the neck and upper thorax, with supine or side-lying scapular releases and cervical spine work. Sometimes, after the wedges were removed and the symphysis pubis was in place, a leg pull or diaphragm release was done. If the clinician noticed tightness or imbalance, or if the client indicated that the "fascial voice" was speaking to her, for example, along her right rib cage as the leg pull was carried out, the clinician would follow the lead of what was happening in the body of the client, disregarding any obvious symptoms that needed attention.

This concept is an important facet of myofascial release and many other complementary medical practices. Myofascial release would prescribe that, clinically, it is often shortsighted to go directly to the area of symptoms for treatment, for the problem is often caused by fascial restrictions distant from that area. Specifically, myofascial release as a type of complementary therapy seems to involve subtle or low-intensity nonmaterial stimuli known as "energy medicine." Although various explanations are offered for energy medicine in terms of a vital force or life energy, there is no agreed-on scientific understanding or precise meaning of these ideas in Western scientific concepts. Two proposed mechanisms for healer interventions are (1) that consciousness is causal, that is, the conscious intention of the healer through prayer or other means may physically improve the health and well-being of the patient and (2) that subtle energies may be exchanged or otherwise be involved, for instance, a condition of physical resonance between the energy fields of healer and patient, which may mediate the beneficial effects.

During the 2 years of Mrs. P. K.'s treatment, she had a partial left rotator cuff tear and pain in the right fibular head area of her knee, both of which responded positively to myofascial release: cross-hands release work and soft tissue mobilization. Routinely, her right wrist was mobilized after an arm pull, and both scapulae were released in side lying after cross-hands release to the pectoral area.

On days when the pelvic area stiffness could not be relieved, 5 to 10 minutes of the myofascial release technique of rebounding was used, in which her body and extremities were passively rocked back and forth. This helped the stiffness to release, after which Mrs. P. K. always remarked how much more "alive" her body felt. The treatment usually ended on the plinth with a side-lying dural tube release, helping her balance her energy gently.

Once the myofascial release and craniosacral work was completed, Mrs. P. K. might be asked to lie prone for further scapular extension exercise or go onto all fours for "cat and camel" spinal mobility work, with wrist extension, along with partial push-ups to work on active elbow extension. From there she would go to the stairs, where she practiced step-over-step maneuvers, forward and back and with "grapevine twists," working on fluidity of motion and on masking her tendency to keep her right fingers extended in a parkinsonian posture. A critical component of her intervention was working on her ability to trust herself without needing to watch her feet.

Her home program consisted of pelvic mobility exercises and opposite rotation of arms and legs with cervical rotation.

Extra shoulder exercises were added for her rotator cuff injury, and passive lower-extremity stretch over the side of the bed for iliotibial band release for her knee problem, along with fibular head mobilizations. She also lay supine on a 6-inch rubber ball, which she would roll segmentally up her spine to music to help with segmental mobilization. She then walked the treadmill for 1 mile.

The 3-month follow-up on impairment outcomes revealed the following:

- Active right shoulder flexion 45/180
- Active right wrist flexion 5/85
- Cervical rotation, right 70/80
- Cervical rotation, left 60/80

Gait: There was improved step width distance between the heels. Stair agility was much improved, with ability to ascend and descend on most days looking straight ahead. Her braiding motion was smooth and continuous without needing to look at her feet. In Mrs. P. K.'s own words: "I feel stronger and more limber inside and outside. I feel I look better and function better."

Skin: The edema in the face was reduced and on most days was not noticeable at all.

The degenerative progression of Parkinson disease varies with the individual, but Mrs. P. K. has been fortunate. With careful regulation of her medication, her home program, and her twice-monthly therapy sessions, there has been extraordinary success in preventing any obvious signs of rigidity from manifesting, which was her goal and thus a primary target outcome for the clinician. No one knows how much of the relief of symptoms was a result of her medication, although she was taking the medication for 3 months before she began therapy without showing the results achieved with therapeutic intervention. With this therapeutic intervention demonstrating effective outcomes, it could be argued by both clinician and client that myofascial release and CST helped keep the fascial system elongated and functioning in a self-corrective way. Similarly, integrating traditional personalized exercises with complementary interventions has enhanced the accomplishment of the client's goals for therapy and helped her to regain and maintain a higher quality of life.

The case of Mrs. P. K. offers an opportunity to consider how other complementary and alternative therapies might also be added to her overall plan of care. For instance, music therapy could potentially support three areas of her treatment: (1) music-assisted relaxation during the myofascial treatment, (2) music added as a reinforcing and motivating element for her home exercise program, and (3) individual music therapy to support emotional coping and adaptation during the course of the Parkinson disease.

The music therapist would first assess Mrs. P. K.'s responses to music and her music preferences, as well as her comfort in using musical experiences for relaxation or for emotional expression. For treatment areas 1 or 2, the music therapist would work in consultation and collaboration with the treating physical/myofascial therapist. A co-treatment approach is ideal, but the music therapist can also serve as a consultant, providing musical materials to be used by the physical or occupational therapist. It is important to consider musical elements such as rhythm, harmony, and tone qualities, as well as highly individualized responses such as nonmusical memories and associations that are elicited by the

CASE STUDY 39-3 ■ MRS. P. K.—cont'd

music. Once the music is developed and refined with input from the patient, this music may be recorded for the patient to use during clinic treatments or at home. The music therapist carefully selects appropriate musical styles and instrumentation and matches the music to the breathing rate, tension level, and other individual parameters to enhance relaxation responses. For goal 2, the flow, tense-release, and tempos in the music are carefully selected to support movements during exercising and to provide a pleasant, energizing, and motivating stimulus. Finally, as mentioned in goal area 3, music therapy may augment rehabilitation team treatments by supporting the patient in tasks related to the psychological and emotional aspects of coping with disease and may assist the individual to continue experiencing well-being and improved quality of life. Music may enhance the sensory richness of mental imagery and can support sensory-kinesthetic imagery and body awareness. An advanced technique such as the Bonny Method of Guided Imagery and Music can be used to develop an increased awareness of bodily states through the language of imagery. This work can help the patient develop more sensitive awareness of the body's unique and individual form of nonverbal communication.

The integration of all these methods brings mental, emotional, and spiritual components of self into a more integrated approach for adaptation to change, whether it be caused by a progressive disease, aging, or any other event. One can move beyond merely coping, to thriving and living to full potential. Finally, all these types of therapeutic interventions can continue to provide familiar, comforting, and soothing support when the patient eventually enters the palliative care phase. Certainly, traditional and complementary approaches discussed within this chapter could also be integrated into the previous case. It is not within the scope of this chapter to integrate and synthesize all complementary approaches as if a large holistic approach was available to everyone. However, it is within the hopes of the authors that colleagues will recognize that integration has the potential to exist in future health care environments, but it will evolve only when therapists and patients are willing to accept that there is always more to learn. There are always more options for the patient than any one therapist has available, and new approaches will continue to evolve and become options in the future.

The final case study of Mrs. P. K. was presented not to negate but rather to integrate traditional therapeutic interventions

with complementary approaches. With limitations in health care benefits, consumers experience frustration regarding access to providers such as physical, occupational, speech therapists. Many chronic problems remain unanswered by allopathic medicine. Many clients are looking elsewhere for answers and for hope. When individuals no longer can look toward the Western medical system to regain or maintain health or healing, the only available options exist outside traditional Western medicine. As individual practitioners we can be part of that transition or be left behind with traditional Western medicine. It is interesting that branches of Western medicine are turning toward complementary philosophies and some medical schools are incorporating this training into student physicians' education. If PT and OT remain tethered to the portion of Western medicine that is linear, is reductionistic, and focuses on research that is univariable, not system interaction based, then these two professions have the same potential future as traditional medicine. That future is not clear, but certainly traditional medicine is going to play a significantly reduced role in health care delivery. Our future in neurorehabilitation is up to the breadth and limitations of our leaders and to the willingness of our younger colleagues to follow or become leaders themselves. The future possibilities for both professions are enormous, not only in integrating complementary and alternative medicine into intervention for clients with chronic and degenerative illnesses, but also in acute care and in health and wellness maintenance. The answers to what is the best evidence-based practice lie in functional outcome measurements. Innovative research will play a role in the future direction of competency-based interventions. Until measurement tools are available to analyze the interactions of multiple variables simultaneously, clinicians must continue to use existing objective outcome measures to determine whether an intervention should be stopped, continued, or altered. Selecting intervention strategies on the basis of belief only, without simultaneously measuring objective outcomes, will always lead to questions regarding whether the intervention was worth the financial investment. The challenge will be to remain open and willing to discover new alternatives while staying grounded in the ethical responsibility to establish an evidence base for the practice of PT and OT.

CONCLUSION

Darcy A. Umphred

Before the clinician embraces any complementary approach, the individual needs to identify which philosophy or paradigm matches her or his own belief system and aligns with her or his own emotional safety issues. Tethering an understanding of any complementary approach to an established scientific base will allow clinicians to stretch beyond their comfortable paradigms. When treating patients, clinicians are not recommended to jump from one theory to another or from one intervention strategy to another without clinically reasoning why those choices have been made. Therapists, during their professional education, are taught to use the Western medical model to have an understanding and a scientific basis for disease and pathology. Similarly, the

student and clinician are taught to develop the ability to evaluate and analyze both normal and abnormal movement and synthesize what components within and outside the body will influence those movements. Emphasis is placed on movements that lead to the functional ability to interact in daily living and work environments and those movements that the client considers critical for quality of life. The last category encompasses any activity the client values, such as golf, gold panning, fly fishing, birdwatching, hiking in the mountains, scuba diving, hunting game for food or sport, or any other activity important to the client. The therapeutic variables that might influence the quality of movement of that client may or may not be a result of the disease or pathology commonly considered the reason for medical management (Figure 39-7). No one who studies and works

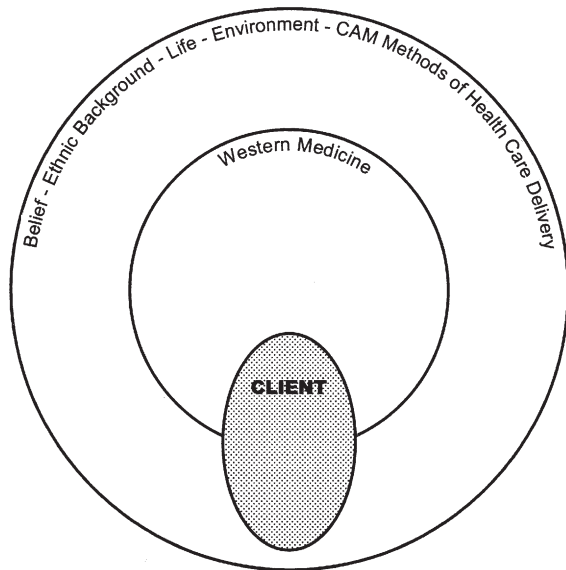

Figure 39-7 ■ Client enters Western medicine owing to disease or pathological condition or with functional limitations that prevent participation in life.

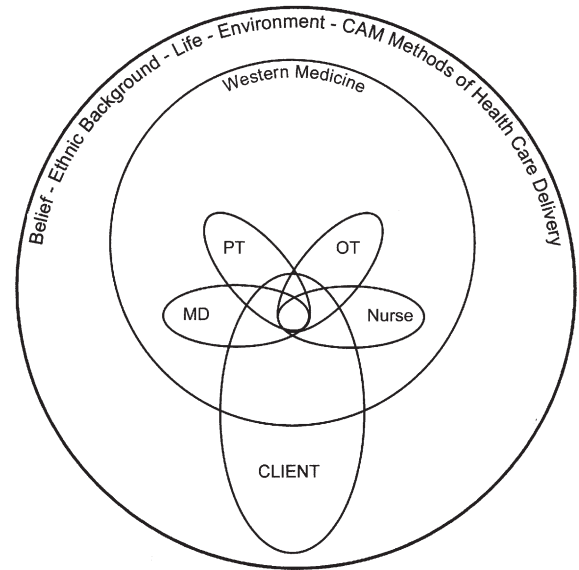

Figure 39-8 ■ Transdisciplinary interactions within Western medical model.

with individuals who have had a CNS injury would imply that the medical management of that injury or disease is not critical to the outcome of the patient’s motor recovery and/or quality of life. Simultaneously, clinicians in the past and today’s students and clinicians with an in-depth scientific knowledge of motor control, motor learning, and neuroplasticity observe, analyze, and influence motor, emotional, and cognitive recovery in patients that physicians might not expect. When treating patients with neurological insults of any kind, students are taught to accept that there is a transdisciplinary interaction among professional disciplines and that each profession not only uniquely affects the client but also has an interactive effect that is dependent on other professions and their respective impact on the patient’s health, wellness, and potential to attain a maximal quality of life (Figure 39-8). When complementary and alternative approaches to health care are introduced into this model, then our colleagues need to determine which approaches interact with Western medicine and which do not (Figure 39-9). Why one approach interacts with the patient and another does not is based on the client’s beliefs, needs, and responses to intervention as well as the clinician’s beliefs and knowledge. Because the professions of OT and PT have always been tethered to Western medicine, therapists need to critically analyze the interactions of those approaches that clearly overlap with our existing paradigm before we let go of the tether and venture totally into the unknown (Figure 39-10). Those components of alternative approaches that obviously overlap with acceptable practice need to be identified and their effectiveness established (Figure 39-11). Evidence-based practice is considered the norm today and not just a gold standard. Yet, clinicians must also accept that evidence is based on comparison of one variable against another and that our research tools cannot look at all variables simultaneously as seen when observing and interacting with a patient. Thus, clinicians need to be constantly vigilant in observing, feeling, and analyzing what variables

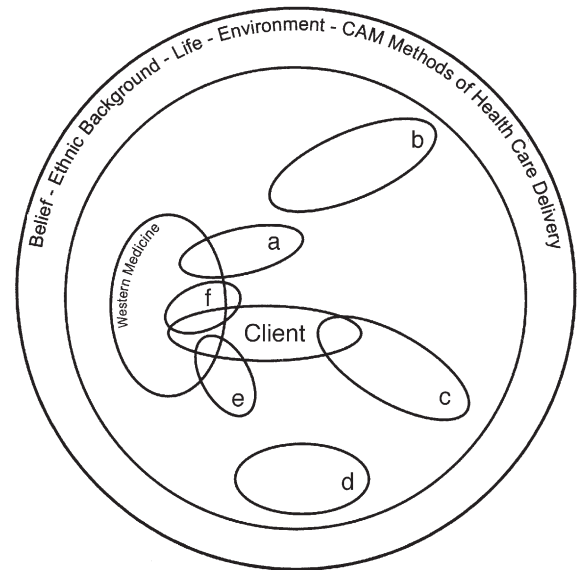

Figure 39-9 ■ Complementary and alternative methods (CAMs) of health care delivery. Some CAMs interact with Western medicine: *a, f, e*. Some alternative models do not interact with Western medicine: *b, c, d*. Some alternative models meet needs of the client: *c, e, f*. Some alternative models do not meet the needs of the client: *a, b, d*.

seem to be affecting the patient’s recovery of functional movement. Just accepting that a treatment will create change because the evidence suggests so does not guarantee that the specific patient will benefit optimally from the intervention. Thus, when considering using an “alternative treatment approach,” therapists need to remain critical in their analytical skill in order to determine whether the patient is actually improving. With the establishment of those clear clinical correlations (those that match Western science models and those that show improvement in the patient), the remaining

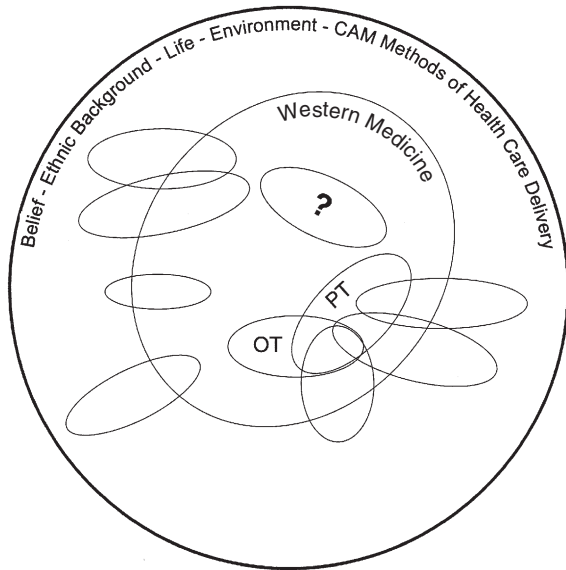

Figure 39-10 ■ Complementary and alternative methods (CAMs) interacting with Western medicine. Some models interact to a large extent with Western medicine and some to a small extent. Some models interact with both Western medicine and other complementary models. The extent of complementary interactions with either physical or occupational therapy or both reflect which models fall within respective scopes of practice and thus become part of the professional's treatment tools.

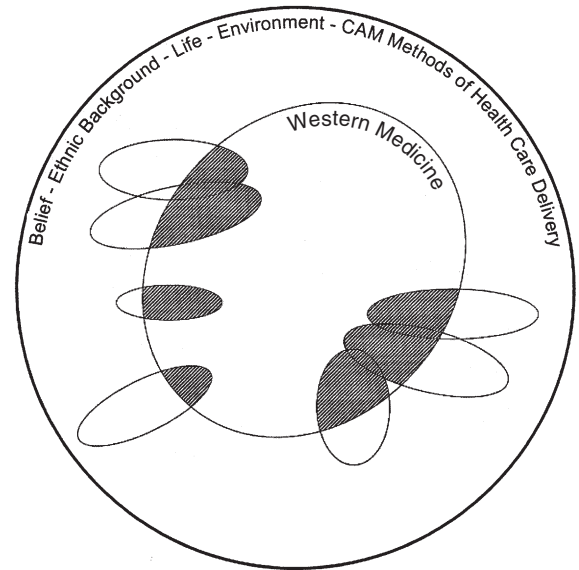

Figure 39-11 ■ The portion of each alternative or complementary model that overlaps with allopathic medicine and traditional occupational and physical therapy has been the focus of this chapter. As efficacy is established for those components that interlock, therapists will more readily accept these approaches as part of their practice.

Figure 39-12 ■ New model of Western health care delivery beyond complementary therapies. As the overlapping components of each alternative model are accepted as part of existing Western health care delivery practice, the barriers to the remaining aspects of these models become transparent. With barriers disappearing a new model with a different shape and different alternative becomes what will be known as traditional medicine in the future.

components of identified alternative paradigms seem naturally to become part of the established delivery system. As a result, a new model for Western health care practice as identified by PT and OT is formed, which continues to allow the therapist to be tethered while enlarging or stretching a

professional comfort zone to encapsulate alternative models without feeling as if the grounded neuroscience background is jeopardized (Figure 39-12). A clinician must always be cognizant of the fact that no matter what methods, philosophies, or interventions he or she selects to help a client reach a desired functional outcome, there is no way to eliminate the fact that other aspects of human system processing may also be active and affecting the outcome. For a century, master clinicians have been observed treating clients. Often colleagues comment that, although those masters seem to use the same methods, they get different outcomes. The question is, are those masters using other alternative interventions without those techniques ever being brought to consciousness? That is, if as a therapist I use myofascial techniques along with traditional intervention, am I also affecting craniosacral rhythm, or affecting chakras and energy fields and setting the stage for the nervous system to learn by optimal augmentation, which allows that nervous system to select better options for motor responses? If so, what truly is leading to somatosensory retraining, motor learning, neuroplasticity, and eventual improved motor control? It may be that master clinicians use *all* approaches but only verbalize the paradigm with which they are most comfortable and that they are most capable of verbally explaining. The adventure is a process of learning, enlarging one's skill to provide the best service to clients and differentiating what is effective within the clinical setting from what is believed to be effective. Differentiating true behavior on a client-by-client basis from what one is taught should happen is the reason for effectiveness of master clinicians. *Best practice is constantly evolving and changing.* As movement specialists we have the responsibility to evolve as well. That change needs to come

flexibly tethered to knowledge, motor skill, emotional openness, and freedom to venture beyond a comfort zone while objectively measuring positive change in the functional abilities of our clients and thus improving their quality of life.
