Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

ELSEVIER

BOOK AID
International

Sabre Foundation

Dedicated to: A sequential process of learning from the first to the sixth edition.

To

Gordon, Jeb, Benjamin, my mother, Janet, my daughters-in-law Julianne and Tassie, and our four grandchildren, Jackson, Jelena, Alexander, and Cameron, whose love, patience, and understanding constantly gave and have continued to give me strength and joy.

To

All those special people whose insights, wisdom, guidance, and patience have helped to give the authors of these chapters their unique gifts and talents, as well as their willingness to share their thoughts with all of you.

To

Very dear friends, colleagues, and past chapter authors who gave so much energy, dedication, and service both scholarly as well as practicing clinicians. Over the last 30 years, the book's family has changed, as has the evolution of the text. With great regret we have had to say good-bye to five authors, Mary Jane Bouska, Jane Schneider, Laura Smith, Donna El-Din, and Christine Nelson. The professions will miss all of you, but your gifts continue to make a difference.

To

Life, to each person's journey and to all those who give opportunities for others' growth along that journey. Special thanks to my immediate family and all my friends and colleagues I hold so close to my heart. Because of all of you, my journey has been constantly renewed with love, warmth, and guidance. No one could feel wealthier than I.

To

Each day we are allowed to walk on this earth. Life is very precious, and how long we will be allowed to stay is an unknown. I have learned to appreciate this time and hope none of us become so busy that we forget its finiteness. Enjoy the journey and always find time to stop and appreciate who you are, what you are, and those gifts you have been given to share with the rest of us. We walk alone in physical form but surrounded by all the energies of others as well as our own. Hopefully, as we continue this adventure we share and give positive thoughts and energy to life and leave having given much more than we have taken. Each person we meet, whether as a student, a teacher, a family member, a friend, a colleague or a patient, has something to teach us and, hopefully, we in turn allow those we meet to grow and learn from us. This is a wondrous journey, and I hope all of you enjoy your path as much as I have mine.

To

My fellow editors, Dr. Gordon Burton, Dr. Rolando Lazaro, and Dr. Margaret Roller, for all the time and total commitment they have made to the sixth edition of this text. Few individuals reading and using this book and the complimentary online video site will ever appreciate the hundreds if not thousands of hours these individuals made editing chapters and videos and the totality of their commitment to the future of our professions.

Preface to the Sixth Edition

Each edition of this book brings new insights, new visions, and new avenues for therapists to advance their respective analytical and clinical skills when assisting individuals with neurological impairments to improve their quality of life. The explosion of new information within neuroscience and its impact on the evidence base of both evaluation and intervention strategies has and will continue to modify and improve services to the many individuals seeking our expertise. With this new knowledge, many individuals within the professions of physical and occupational therapy and other related health care disciplines will assist patients throughout the world to attain a level of life participation that they, as patients, define as quality of life. As the complex interactions of all systems slowly unravel their mysteries in front of the eyes and within the hands of practicing clinician and researchers, the possibilities of new variables that affect outcomes will continue to arise and challenge the mind of the learner. Having a tether to basic neuroscience allows therapists of today and those of the future to stretch to limits and levels of understanding that boggle the rigid linear thinker of yesterday. With the explosion of new research over the last five years, this sixth edition has stretched our professions to the unknowns we might have considered the distant future a few years ago. These doors have led to integration of systems and help us discover what seems like unanswerable questions and continue to ground us to the evidence base of today's practice. This book mirrors a family dedicated to the advancement and quality of life of others. This book does not belong to the publisher, the editor, or even the chapter authors. We are just participants on life's journey and have come together to share what we have learned and to help future colleagues evolve farther than we had at the same age. The book belongs to the learners, those students who are willing to question today's practice and look toward new and innovative ways to provide better and more effective patient care, to prevent loss of life participation, and to enhance the quality of life of all individuals who cross their paths.

Thirty-two years and five previous editions have passed since this book was conceived. In the evolution of a person, the attainment of 32 years usually signifies adulthood approaching middle age. Thirty-two years of evolution of this book has encompassed new visions, greater evidence base to practice within health care delivery, huge advancements in neuroscience and intervention strategies, and without a doubt many more questions. Mastery can never be obtained, because new visions constantly suggest a new beginning while mastery suggests knowledge and wisdom of the whole. The journey has led the reader from a book whose initial problem-solving focus was understanding medical diagnosis and science as it related to neurological problems to a book whose focus is placed on movement diagnosis and the ways to empower individuals in need of our services to the highest quality of life attainable through functional movement. The evolution of the professions encompass in-depth integration of movement science, a comprehension

of disease/pathology, a high level of analysis and skill development in objective measurements of functional behavior, and intervention strategies based on best practice and evidence. During the last three and a half decades, the therapeutic management of clients has undergone many stages of evolution. Evidence-based practice that encompasses both effectiveness and efficacy through clinical studies and basic science research should be guiding the choices of intervention procedures today. This shift in paradigm from specific treatment approaches to a problem-solving model that looks at the functional ability, activity limitations, life participation, and quality of life of the client has led to a transformation of services throughout the world. As these problem-solving approaches become operational, more effective, reliable, and valid therapeutic examinations and management strategies are being presented in the literature. Yet, our understanding of how humans learn, relearn, or adapt is far from reaching closure. Neuroplasticity, once thought impossible, has become widely accepted as fact within the area of neurological rehabilitation. Given the many unknowns and the fact that what is "known" often changes daily, all learners are challenged to keep a mind open to change and to new learning while holding on to a flexible paradigm that allows for effective examination, evaluation, and treatment of clients within a dynamic, ever-changing environment. Client-centered care has shown that willing participation by the consumer of our services leads to the greatest potential outcomes and satisfaction of the client. No longer will therapy be done to the patient but instead will encompass and be enhanced by family's and client's goals and expectations. Master clinicians of the past have always taken these patient goals into consideration whether formally or informally. Thus their outcomes always exceeded others and they never had problems with compliance.

Cost of services, managed care environments, limitations in visits, and practice patterns all create challenges to today's professional. Young therapists are expected to graduate from school and immediately practice as experienced clinical problem solvers. Young colleagues feel they are expected to *know* the answers, not to discover them. Yet, within the clinical arena, problem-solving success is always dependent on one variable, and that variable is the patient. As long as the unique qualities of the patient are considered, a therapist will be able to select examination procedures and appropriate interventions using clinical reasoning. Graduates of today and tomorrow have the knowledge and skill and have practiced clinical problem-solving through their education. The only variables they will always need to add will be those unique characteristics of each patient.

This book is designed to provide the practitioner and advanced therapy student with a variety of problem-solving strategies that can be used to tailor treatment approaches to individual client needs and cognitive style. The treatment of persons with neurological disabilities requires an integrated approach involving therapies and treatment procedures used by physical, occupational, speech and language, music and

recreational therapists; nurses; pharmacists; orthotists; physicians; and a variety of other health care providers as well as the family's expectation, values, and social beliefs. Contributors to this book were selected for their expertise and integrated knowledge of various subject areas. The result is, we hope, a blend of state-of-the-art information about the therapeutic management of persons with neurological disabilities.

This book is organized to provide the student with a comprehensive discussion of all aspects of neurological rehabilitation and to facilitate quick reference in a clinical situation. Section I, "Foundations for Clinical Practice in Neurological Rehabilitation," constitutes an overview of foundational theories. This includes the entire diagnostic process used by movement specialists. The basis for this process ranges across many cognitive areas and theories, and thus concepts and integration are presented in a variety of chapters. Additional emphasis has been placed both on health and wellness along with the visual analysis of functional movement development and change across the life span. Theoretical constructs of motor control, motor learning, and neuroplasticity, as well as the limbic components role in movement science and psychosocial variables are again updated and discussed. The complexity of examination tools and treatment categories and techniques have again been edited to help the learner see and analyze the vast opinions available as part of today's practice. To complete this foundational section, discussion ends with the need for reliable and valid documentation, which should lead to reimbursement for services within various clinical environments. Section II, "Rehabilitation Management of Clients with Neurologic System Pathology," offers an in-depth discussion and analysis of the therapeutic management of the most common neurological disabilities encountered by physical and occupational therapists. As professions are becoming autonomous and entry into practice at a doctoral level of study, the importance of the learner comprehending and analyzing each clinical problem confronted when treating individuals with movement dysfunction caused by neurological problems cannot be overemphasized. Hopefully these chapters will clarify how to examine and treat both general and specific movement problems seen in individuals with injury to specific areas of the central and peripheral nervous system. Section III, "Neurological Disorders and Applications Issues," is devoted to recent advances in general approaches to intervention and rehabilitation that might affect any of the diagnostic categories discussed in Section II. The importance of other system problems, such as cardiopulmonary and chronic movement problems, has been emphasized to help the learner integrate the critical nature of an integrated systems model. Two new chapters, one on robotics and one on imaging, have been added in order to enlarge the reader's comprehension of tools and expectations that will become commonplace in years to come.

Special features within all three parts are examinations, evaluations, prognosis, and intervention strategies using sound clinical reasoning. Case studies are presented within each clinical-based chapter to help the reader with the problem-solving process. Online clinical movement examples have been provided to help the learner visually recognize movement problems commonly seen in individuals with specific neurological diagnoses.

The book continues to evolve in order to meet the changing demands placed upon us as clinicians and educators. As we have finally assumed the role of movement specialists both in wellness and in rehabilitation, our clinical observational skill and the ability to compare normal to abnormal movement patterns when formulating a diagnosis, prognosis, and treatment plan has brought both professions to the obvious evolution of clinical doctorates. Our place in health care and the responsibility we assume should positively impact the quality of life of all those individuals for whom we provide service. We hope this book and the online video site will continue to aid all of you as tools to use when confronted with questions regarding movement problems seen in individuals with neurological problems.

During the conceptualization and preparation of all six editions, many individuals gave time, guidance, and emotional support. To all those individuals I extend my sincere appreciation. There are many people to thank in the preparation of this sixth edition: the authors, the researchers, the illustrators, each person assisting during the process of publication, and the patients. No person could have accomplished the end product alone. Yet, during the editing process of this edition, some specific individuals came to deserve special recognition and thanks:

The staff at Elsevier who worked on the publication of this edition: Christie M. Hart and Carol O'Connell. All the teachers and healers who have crossed our paths in the last 40 years and helped us to continually realize that before we can find answers, design research projects, and establish efficacy, we must identify and acknowledge unknowns and formulate questions.

Each family member or significant other who encouraged and supported all of us from the moment we began the editorial process to the day the book reached the learner, we are forever appreciative.

My entire family, all of whom helped me make the time to complete this manuscript.

My two sons, Jeb and Ben, whose support I have had since the beginning of this book. Both are creative and brilliant young professionals in their own right, yet have tirelessly helped me take very complex concepts and ideas and transform them into illustrations that can be comprehended. As small children during the book's conception, their tolerance far exceeded their age. As children, they allowed me to take pictures, many of which have been used to actualize the chapter on movement development across the life span. As young adults, their support and guidance always gives me strength. As successful professionals, they have continued to teach me. Today, they are also husbands and parents. Their wives have given to me two daughters who also help me learn and grow. But, of course the new life found in our grandchildren forever allows me the opportunity to watch development of the mind, body, and spirit of each of them as they have begun their adventure of life.

As a critical aspect of this edition, the three section editors from the fifth edition stepped into the book editor role. Thus, I cannot extend more gratitude, respect, and love to Gordon Burton, Rolando Lazaro, and Margaret Roller. Three leaders, visionaries, and genuinely caring and loving individuals, they have certainly made a significant impact on the direction this book has taken in this edition and will be in the future.

Last, my husband, Gordon, who is the only one who truly knows what demands this book places on me and everyone around me. His support has never dwindled, nor his acceptance of my choices. The demands of this edition as well as life in general has certainly tried both of us as we have entered the later part of our life adventure. But, as always, he is my best friend and present to support me when needed.

This book was conceived 32 years ago. It was presented in print to the world 27 years ago. Both dates signify young adulthood and the evolution from conception to a responsibility as an adult. We are all interconnected in a tapestry that has allowed this book to evolve into what it is today. For that, I give thanks as an author, as the editor, as a consumer but most importantly as a learner. Our lives are finite but the

quality of those lives is extremely important to us and those around us. It is hoped that this book will guide colleagues to help consumers in attainment of that quality. It is hoped, with the eyes and minds of so many outstanding colleagues sharing their experiences and their desire to ground what they do into evidence-based practice, that the learner will embrace the adventure with the same vigor and enthusiasm that so many have from the past.

For each of us the journey is today and the adventure tomorrow, no matter how many tomorrows we may have. May all of you have the joy, the challenge, the excitement, and the learning adventure I have had throughout my entire professional career.

Enhance Your Learning and Practice Experience

The images below are QR (Quick Response) codes. The codes will take you to the reference lists for each chapter, videos, and a glossary that can be accessed on your mobile device for quick reference in a lab or clinical setting. References are linked to the Medline abstract where available.

For fast and easy access, right from your mobile device, follow these instructions.

You can also find them at:

<http://booksite.elsevier.com/Umphred/neurological6>

What you need:

- A mobile device, such as a smart phone or tablet, equipped with a camera and Internet access
- A QR code reader application (If you do not already have a reader installed on your mobile device, look for free versions in your app store.)

How it works:

- Open the QR code reader application on your mobile device.
- Point the device's camera at the code and scan.
- The codes take you to a main page where you can link to specific chapters for instant viewing of the videos and the references where you can further access the Medline links—no log-on required.

Foundations for Clinical Practice in Neurological Rehabilitation

CHAPTER 1

Foundations for Clinical Practice*

DARCY A. UMPHRED, PT, PhD, FAPTA, ROLANDO T. LAZARO, PT, PhD, DPT, GCS, and
MARGARET L. ROLLER, PT, MS, DPT

KEY TERMS

clinical problem solving
diagnostic model: examination, evaluation, diagnosis,
prognosis, intervention
disablement and enablement models
empowerment
holistic model for health care delivery
International Classification of Functioning, Disability
and Health (ICF)
learning environment
systems model

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Analyze the interlocking concepts of a systems model and discuss how cognitive, affective, sensory, and motor subsystems influence normal and abnormal function of the nervous system.
2. Use an efficacious diagnostic process that considers the whole patient/client and includes evaluation, examination, diagnosis, prognosis, intervention, and related documentation, leading to meaningful, functional outcomes.
3. Apply the International Classification of Functioning, Disability and Health (ICF) to the clinical management of patients/clients with neuromuscular dysfunction.
4. Discuss the evolution of disablement, enablement, and health classification models, neurological therapeutic approaches, and health care environments in the United States and worldwide.
5. Discuss the interactions and importance of the patient, therapist, and environment in the clinical triad.
6. Consider how varying aspects of the clinical therapeutic environment can affect learning, motivation, practice, and ultimate outcomes for patients/clients.
7. Define, discuss, and give examples of a holistic model of health care.

Physical therapists (PTs), occupational therapists (OTs), and other health care individuals involved in improving the function and quality of life of individuals with neuromuscular dysfunction must have a thorough understanding of the client as a total human being. This foundational concept is critical for high-level professional performance. With the use of a clinical problem-solving, diagnosis-prognosis approach, this book orients the student and clinician to the

roles that multiple systems within and outside the human body play in the causation, progression, and recovery process of a variety of common neurological problems. A secondary objective is to orient the clinician to a theoretical framework that uses techniques for enhancing functional movement, enlarges the client's repertoire for movement alternatives, and creates an environment that empowers the client to achieve the highest levels of activity, participation, and quality of life.

Methods of examination, evaluation, prognosis, and intervention must incorporate all aspects of the client's nervous system and the influences of the external environment on those individuals. In the clinical management of patients with neurological disabilities, the overlap of basic knowledge and practical application of examination and intervention

*This chapter and the concepts of this book are dedicated to Dr. Donna El-Din, PT, PhD, FAPTA, who has participated in the evolution and vision of where PT practice is today and will be over the next decade. Dr. El-Din had hoped to participate in the writing of this chapter but was taken from us in May 2010. We will forever be grateful for her dedication, teaching, and friendship to thousands of physical therapists across the world.

techniques among all disciplines involved in the care of the client is great. Delineation of individual professional roles in the treatment of these clients is often based on administrative decisions and current billing practices for services provided, rather than distinct boundaries defined by title. This book emphasizes the selection of examination and intervention strategies that have been demonstrated as evidence based. Clinicians must also be open to generating new hypotheses as clinical problems present themselves without clear evidence to guide practice.

A clinical problem-solving approach is used because it is logical and adaptable, and it has been recommended by many professionals during the past 40 years.¹⁻⁷ The concept of clinical decision making based in problem-solving theory has been stressed throughout the literature over the past decades and has guided the therapist toward an evidence-based approach to patient management. This approach clearly identifies the therapist's responsibility to examine, evaluate, analyze, draw conclusions, and make decisions regarding prognosis and treatment alternatives.⁸⁻²⁴

This book is divided into three sections.

Section I lays the foundation of knowledge necessary to understand and implement a problem-solving approach to clinical care across the span of human life. The basic knowledge of the function of the human body in disease and repair is constantly expanding and often changing in content, theory, and clinical focus. This section reflects that change in both philosophy and scientific research.

Roles that therapists are currently playing and will be asked to play in the future are changing.²⁵⁻²⁷ Therapists are experts in normal human movement across the life span (see Chapter 3) and how that movement is changed after life events, and with disease or pathological conditions. Therapists realize that health and wellness play a critical role in movement function as a client enters the health care system with a neurological disease or condition (see Chapter 2). In many U.S. states, clients are now able to use direct access for therapy services. In this environment, therapists must medically screen for disease and pathology to determine conditions that are outside of the defined scope of practice, and make appropriate referrals to other medical professionals (see Chapter 7). They must also make a *differential diagnosis* regarding movement dysfunctions within that therapist's respective scope of practice (see Chapter 8). Section I has been designed to weave together the issues of evaluation and intervention with components of central nervous system (CNS) function to consider a holistic approach to each client's needs (see Chapters 4, 5, 6, and 9). This section delineates the conceptual areas that permit the reader to synthesize all aspects of the problem-solving process in the care of a client. Basic to the outcomes of care is accurate documentation of the patient management process, as well as the administration and reimbursement for that process (see Chapter 10).

Section II is composed of chapters that deal with specific clinical problems, beginning with pediatric conditions, progressing through neurological problems common in adults, and ending with aging with dignity and chronic impairments. In Section II each author follows the same problem-solving format to enable the reader either to focus more easily on one specific neurological problem or to address the problem from a broader perspective that includes life impact. The multiple

authors of this book use various cognitive strategies and methods of addressing specific neurological deficits. A range of strategies for examining clinical problems is presented to facilitate the reader's ability to identify variations in problem-solving methods. Many of the strategies used by one author may apply to situations presented by other authors. Just as clinicians tend to adapt learning methods to solve specific problems for their clients, readers are encouraged to use flexibility in selecting treatments with which they feel comfortable and to be creative when implementing any therapeutic plan.¹⁶ Although the framework of this text has always focused on evidence-based practice and improvement of quality of life of the patient, the terminology used by professionals has shifted from focusing on impairments and disabilities of an individual after a neurological insult (the International Classification of Impairments, Disability and Health [ICIDH]) to a classification system that considers functioning and health at the forefront: the International Classification of Functioning, Disability and Health (ICF).²⁸ The ICF considers all health conditions, both pathological and non-disease related; provides a framework for examining the status of body structures and functions for the purpose of identifying impairments; includes activities and limitations in the functional performance of mobility skills; and considers participation in societal and family roles that contribute to quality of life of an individual. The personal characteristics of the individual and the environmental factors to which he or she is exposed and in which he or she must function are included as contextual factors that influence health, pathology, and recovery of function.²⁹ The ICF provides a common language for worldwide discussion and classification of health-related patterns in human populations. The language of the ICF has been adopted by the American Physical Therapy Association (APTA), and the revised version of the *Guide to Physical Therapist Practice* reflects this change.³⁰ Each chapter in this book strives to present and use the ICF model, use the language of the ICF, and present a comprehensive, patient-oriented structure for the process of examination, evaluation, diagnosis, prognosis, and intervention for common neurological conditions and resultant functional problems. Consideration of the patient/client as a whole and his or her interactions with the therapist and the learning environment is paramount to this process.

Chapters in Section II also include methods of examination and evaluation for various neurological clinical problems using reliable and valid outcome measures. The psychometric properties of standard outcome measures are continually being established through research methodology. The choice of objective measurement tools that focus on identifying impairments in body structures and functions, activity-based functional limitations, and factors that create restrictions in participation and affect health quality of life and patient empowerment is a critical aspect of each clinical chapter's diagnostic process. Change is inevitable, and the problem-solving philosophy used by each author reflects those changes.

Section III of the text focuses on clinical topics that can be applied to any one of the clinical problems discussed in Section II. Chapters have been added to reflect changes in the focus of therapy as it continues to evolve as an emerging flexible paradigm within a multiple systems approach. A specific body system such as the cardiopulmonary system (see Chapter 30) or complementary approaches used with

interactive systems (see Chapter 39) are also presented as part of Section III. These incorporate not only changes in the interactions of professional disciplines within the Western medical allopathic model of health care delivery, but also present additional delivery approaches that emphasize the importance of cultural and ethnic belief systems, family structure, and quality-of-life issues. Two additional chapters have been added to Section III. Chapter 37 on imaging emphasizes the role of doctoring professions' need to analyze how medical imaging matches and mismatches movement function of patients. Chapter 38 reflects changes in the role of PTs and OTs as they integrate more complex technologies into clinical practice.

Examination tools presented throughout the text should help the reader identify many objective measures. The reader is reminded that although a tool may be discussed in one chapter, its use may have application to many other clinical problems. Chapter 8 summarizes the majority of neurological tools available to therapists today, and the authors of each clinical chapter may discuss specific tools used to evaluate specific clinical problems and diagnostic groups. The same concept is true with regard to general treatment suggestions and problem-solving strategies used to analyze motor control impairments as presented in Chapter 9; authors of clinical chapters will focus on evidence-based treatments identified for specific patient populations.

THE CHANGING WORLD OF HEALTH CARE

To understand how and why disablement, enablement, and health classification models have become the accepted models used by PTs and OTs when evaluating, diagnosing, prognosing, and treating clients with body system impairments, activity limitations, and participation restrictions resulting from neurological problems, it is important for the reader to review the evolution of health care within our culture. This review begins with the allopathic medical model because this model has been the dominant model of health care in Western society and forms the conceptual basis for health care in industrialized countries.³¹ The allopathic model assumes that illness has an organic base that can be traced to discrete molecular elements. The origin of disease is found at the molecular level of the individual's tissue. The first step toward alleviating the disease is to identify the pathogen that has invaded the tissue and, after proper identification, apply appropriate treatment techniques including surgery, drugs (see Chapter 36), and other proven methods.

It is implicit in the model that specialists who are professionally competent have the sole responsibility for the identification of the cause of the illness and for the judgment as to what constitutes appropriate treatment. The medical knowledge required for these judgments is thought to be the domain of the professional medical specialists and therefore inaccessible to the public. PTs and OTs have never been responsible for the diagnosis or treatment of diseases or pathological conditions of a specific client. Instead, we have always focused on the body system impairments resulting in activity limitations and inability to participate in life that have been caused by the specific disease or pathological condition. Therapists are also responsible for analyzing the interactions of all other systems and how they compensate for or are affected by the original medical problem. As our roles within Western health care delivery have expanded and

are becoming clearer, so has the role of the consumer. In today's health care environment, the responsibility of both the therapist and the patient begins with health and wellness and proceeds to regaining optimal health, wellness, and functioning after neurological insult.

Levin³² points out that there is a lot that consumers can do for themselves. Most people can assume responsibility to care for minor health problems. The use of nonpharmaceutical methods (e.g., hypnosis, biofeedback, meditation, and acupuncture) to control pain is becoming common practice. The recognition and value of a holistic approach to illness are receiving increasing attention in society. Treatment designed to improve both the emotional and physical needs of clients during illness has been recognized and advocated as a way to help individuals regain some control over their lives (see Chapters 5 and 6).

A holistic model (*holos*, from the Greek, meaning "whole") of health care seeks to involve the patient in the process and take the mystery out of health care for the consumer. It acknowledges that multiple factors are operating in disease, trauma, and aging and that there are many interactions among those factors. Social, emotional, environmental, political, economic, psychological, and cultural factors are all acknowledged as influences on the individual's potential to maintain health, to regain health after insult, or to maintain a quality of health in spite of existing disease or illness. Measures of success in health care delivery have shifted from the traditional standard of whether the person lives or dies to the assessment of the extent of the person's quality of life and ability to participate in life after some neurological insult. Moreover, "quality of life" or living implies more than physical health. It implies that the individual is mentally and emotionally healthy as well. It takes all dimensions of a person's being into consideration regarding health. From the beginning, even Hippocrates emphasized treatment of the person as a whole, and the influence of society and of the environment on health.

An approach that takes this holistic perspective centers its philosophy on the patient as an individual.³³ The individual with this orientation is less likely to have the physician look only for the chemical basis of his or her difficulty and ignore the psychological factors that may be present. Similarly, the importance of focusing on an individual's strengths while helping to eliminate body system impairments and functional limitations in spite of existing disease or pathological conditions plays a critical role in this model. This influences the roles PT and OT will play in the future of health care delivery and will continue to inspire expanded practice in these professions.

The health care delivery system in Western society is designed to serve all of its citizens. Given the variety of economic, political, cultural, and religious forces at work in American society, education of the people with regard to their health care is probably the only method that can work in the long run. With limitations placed on delivery of medical care, the client's responsibility for health and healing is constantly increasing. The task of PTs and OTs today is to cultivate people's sense of responsibility toward their own health and the health and well-being of the community. The consumer has to accept and play a critical role in the decision-making process within the entire health care delivery model to more thoroughly guarantee compliance

with prescribed treatments and optimal outcomes.³⁴⁻⁴⁰ PTs and many OTs today are entering their professional careers at a doctoral level and beginning to assume the role of primary care providers. A requisite of this new responsibility is the performance of a more diligent examination and evaluation process that includes a comprehensive medical screening of each patient/client.^{41,42} Patient education will continue to be an effective and vital approach to client management and has the greatest potential to move health care delivery toward a concept of preventive care. The high cost of health care is a factor that will continue to drive patients and their families to increase their participation in and take responsibility for their own care.⁴³ Reducing the cost of health care will require providers to empower patients to become active participants in preventing and reducing impairments and practicing methods to regain safe, functional, pain-free control of movement patterns for optimal quality of life.

In-Depth Analysis of the Holistic Model

Carlson⁴⁴ thinks that pressure to change to holistic thinking in medicine continues as a result of a societal change in its perspective of the rights of individuals. A concern to keep the individual central in the care process will continue to grow in response to continued technological growth that threatens to dehumanize care even more. The holistic model takes into account each person's unique psychosocial, political, economic, environmental, and spiritual needs as they affect the individual's health.

The nation faces significant social change in the area of health care. The coming years will change access to health care for our citizens, the benefits, the reimbursement process for providers, and the delivery system. Health care providers have a major role in the success of the final product. The Pew Health Professions Commission⁴⁵ identified issues that must be addressed as any new system is developed and implemented. Most, if not all, of the issues involve close interactions between the provider and client. These issues include (1) the need of the provider to stay in step with client needs; (2) the need for flexible educational structures to address a system that reassigns certain responsibilities to other personnel; (3) the need to redirect national funding priorities away from narrow, pure research access to include broader concepts of health care; (4) the licensing of health care providers; (5) the need to address the issues of minority groups; (6) the need to emphasize general care and at the same time educate specialists; (7) the issue of promoting teamwork; and (8) the need to emphasize the community as the focus of health care. There are other important issues, but the last to be included here is mentioned in more detail because of its relevance to the consumer. Without the consumer's understanding during development of a new system, the system could omit several opportunities for enrichment of design. Without the understanding of the consumer during implementation of a new system, the consumer might block delivery systems because of lack of knowledge. Thus, the delivery of service must be client centered and client and family driven, and the focus of intervention needs to be in alignment with client objectives and desired outcomes.^{33-36,46,47} Today, as stated earlier,⁴³ this need may be driven more by financial necessity than by ethical and best practice philosophy, but

the end result should lead to a higher quality of life for the consumer.

Providers are more willing to include the client by designing individualized plans of care, educating, addressing issues of minority groups, and becoming proactive team caregivers.³⁷⁻⁴⁰ The influence of these methods extends to the community and leads to greater patient/client satisfaction. The research as of 2011 demonstrates the importance of patient participation, and this body of work is expected to grow.

The potential for OTs and PTs to become primary providers of health care in the twenty-first century is becoming a greater reality within the military system as well as in some large health maintenance organizations (HMOs).⁴⁸⁻⁵³ The role a therapist in the future will play as that primary provider will depend on that clinician's ability to screen for disease and pathological conditions, examine and evaluate clinical signs that will lead to diagnoses and prognoses that fall inside and outside of the scope of practice, and select appropriate interventions that will lead to the most efficacious, cost-effective treatment.

The role of therapists in the area of neurological rehabilitation will first be in the area of health and wellness. Medical screening and early detection of neurological problems should facilitate early referral of the consumer to a medical practitioner. This may occur in a wellness center or in physical and occupational therapy clinics where the patient is being seen for some other problem such as back pain. Similarly, patients may reenter physical or occupational therapy after a neurological insult as someone who has a chronic movement dysfunction or degenerative condition that may be getting worse and who needs some instruction to regain motor function.

Neurological rehabilitation is taking place and will continue to take place in a changing health care environment and ever-evolving delivery system. The balance between visionary and pragmatist must be maintained by the practitioner. By the end of the twenty-first century, neurological rehabilitation will have evolved into a new shape and form, will take place within a very different health system, and will involve the client as the center of the dynamic exchange among wellness, disease, function, and empowerment.

THERAPEUTIC MODEL OF NEUROLOGICAL REHABILITATION WITHIN THE HEALTH CARE SYSTEM

Traditional Therapeutic Models

Keen observation of human movement and how impairments in the neuromusculoskeletal system alter motor behavior and functional mobility led several remarkable therapists to develop unique models of therapeutic interventions. These models include those of Ayers (sensory integration), Bobath (NeuroDevelopmental Treatment [NDT]), Brunnstrom (movement therapy approach), Feldenkrais (Functional Integration and Awareness Through Movement), Klein-Vogelbach (Functional Kinetics), Knott and Voss (Proprioceptive Neuromuscular Facilitation [PNF]), and Rood (Rood approach to neuromuscular dysfunction). These were the first behaviorally based models introduced within the health care delivery system, and they have been used by practitioners within the

professions of physical and occupational therapy since the middle of the twentieth century. These individuals, as master clinicians, tried to explain what they were doing and why their respective approaches worked using the science of the time. From their teachings, various philosophical models evolved. These models were isolated models of therapeutic intervention that were based on successful treatment procedures as identified through observation and described and demonstrated by the teachers of those approaches. The general model of health care under which these approaches were used was the allopathic model of Western medicine, which begins with disease and pathology. Today, our models must begin with health and wellness, with an understanding of variables that lead a client into the health care delivery system, and an understanding of how the nervous system works and repairs itself.

During the past decades, both short-term and full-semester courses, as well as literature related to treatment of clients with CNS dysfunction, have been divided into units labeled according to these techniques. Often, interrelation and integration among techniques were not explored. Clinicians bound to one specific treatment approach without considering the theoretical understanding of its step-by-step process may have lacked the basis for a change of direction of intervention when a treatment was ineffective. It was difficult, therefore, to adapt alternative treatment techniques to meet the individual needs of clients. As a result, clinical problem solving was impeded, if not stopped, when one approach failed, because little integration of theories and methods of other approaches was never stressed in the learning process. Similarly, because a specific treatment has a potential effect on multiple body systems and interactions with the unique characteristics of each client's clinical problem, establishing efficacy for interventions using a Western research reductionist model became extremely difficult. This does not negate the potential usefulness of any treatment intervention, but it does create a dilemma regarding efficacy of practice. Similarly, the rationale often used to explain these therapeutic models was based on an understanding of the nervous system as described in the 1940s, 1950s, and 1960s. That understanding has dramatically changed. With the basic neurophysiological rationale for explaining these approaches under fire for validity and the inability to demonstrate efficacy of these approaches using traditional research methods, many of these treatment approaches are no longer introduced to the student during academic training. However, if these master clinicians were much more effective than their clinical counterparts, then the hands-on therapeutic nature of their interventions may still be valid in certain clinical situations, but the neurophysiological explanation for the intervention may be very different. To make statements today saying that these masters did not use theories of motor learning or motor control is obvious because those theories and the studies supporting them had not yet been formulated. Yet patients treated by these master clinicians demonstrated improvements for which, it would seem according to our present-day theories, that concepts of motor learning must have been reinforced and repetitive practice encouraged. Although the verbal understanding of behavior sequences used to promote motor learning did not exist, these behavior sequences

were often demonstrated by the client, and thus the success of the treatments and the skill of these master clinicians cannot be denied.

Physical and Occupational Therapy Practice Models

Disablement models have been used by clinicians since the 1960s. These models are the foundation for clinical outcomes assessment and create a common language for health care professionals worldwide. The first disablement model was presented in 1965 by Saad Nagi, a sociologist.^{54,55} The Nagi model was accepted by APTA and applied in the first *Guide to Physical Therapist Practice*, which was introduced in 2001.³⁰ In 1980 the ICIDH was published by the World Health Organization (WHO).⁵⁶ This model helped expand on the International Classification of Diseases (ICD), which has a narrow focus based on categorizing diseases. The ICIDH was developed to help measure the consequences of health conditions on the individual. The focus of both the Nagi and the ICIDH models was on disablement related to impaired body structures and functions, functional activities, and handicaps in society (Figure 1-1). The WHO ICF model²⁸ evolved from a linear disablement model (Nagi, ICIDH) to a nonlinear, progressive model (ICF) that encompasses more than disease, impairments, and disablement. It includes personal and environmental factors that contribute to the health condition and well-being of individuals. The ICF model is considered an enablement model as it not only considers dysfunctions, but helps practitioners and researchers understand and use an individual's strengths in the clinical presentation. Each of these models provides an international standard to measure health and disability, with the ICF emphasizing the social aspects of disability. The ICF recognizes disability not only as a medical or biological dysfunction, but as a result of multiple overlapping factors including the impact of the environment on the functioning of individuals and populations. The ICF model is presented in Table 1-1 and discussed in greater depth in Chapters 4, 5, and 8.

It is easy to integrate the ICF model into behavioral models for the examination, evaluation, diagnosis, prognosis, and intervention of individuals with neurological system pathologies (see Figure 1-1). Whether an individual's activity limitations, impairments, and strengths lead to a restriction in the ability to participate in life activities, the perception of poor health, or restriction in the ability to adapt and adjust to the new health condition will determine the eventual quality of life of the person and the amount of empowerment or control he or she will have over daily life. The importance of the unique qualities of each person and the influence of the inherent environment helped to drive changes to world health models. The ICF is widely accepted and used by therapists throughout the world and is now the model for health in professional organizations such as APTA in the United States.³⁰

As world health care continues to evolve, so will the WHO models. The sequential evolution of the three models is illustrated in Table 1-1. This evolution has created an alignment with what many therapists and master clinicians have long believed and practiced—focus on the patient, not the disease. The shift from disablement to enablement models of health care is a reflection of this change in perspective.

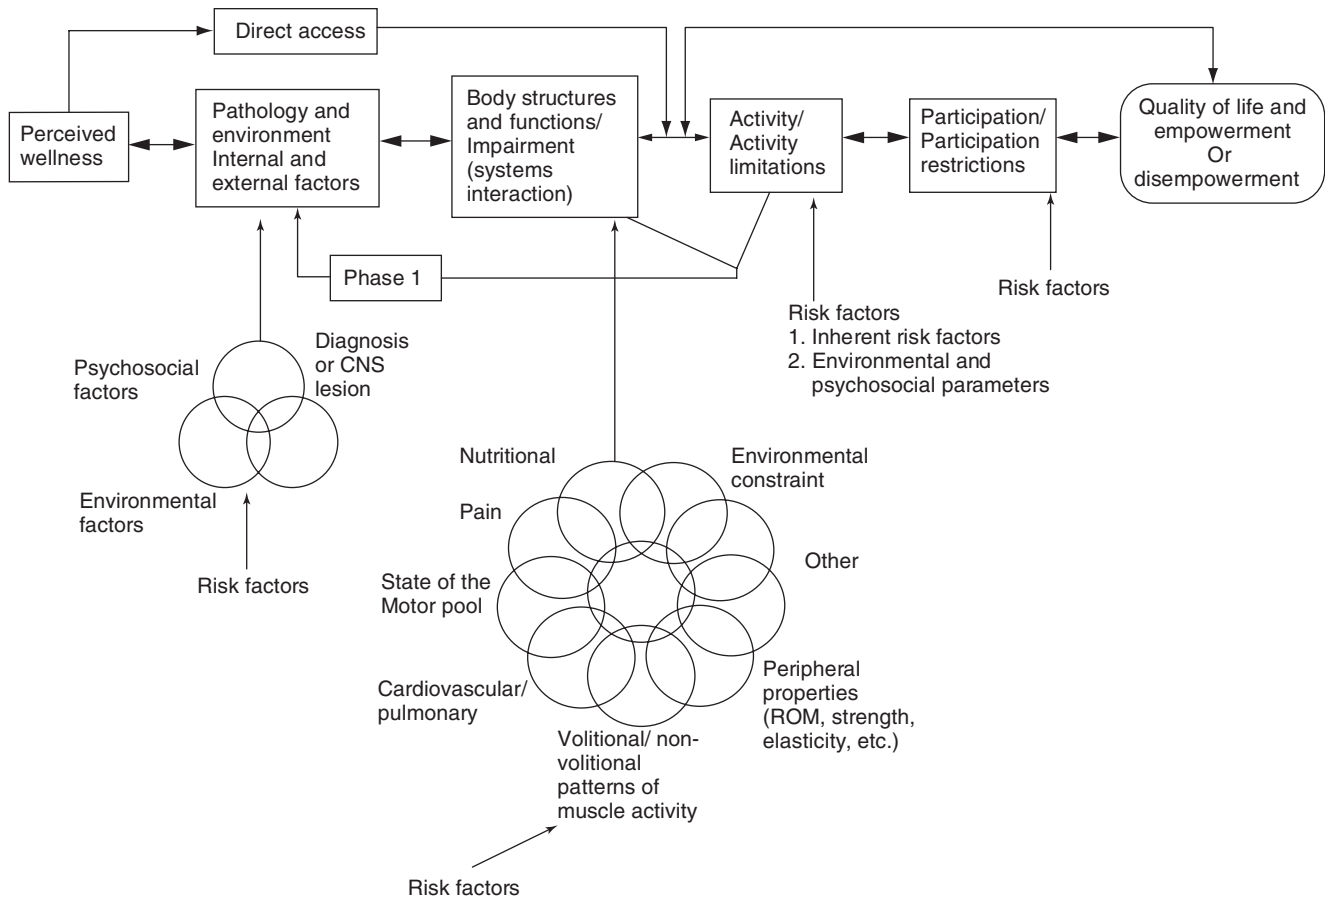

Figure 1-1 ■ Behavioral model for evaluation and treatment based on the International Classification of Functioning, Disability and Health (ICF) enablement schema. ROM, Range of motion.

TABLE 1-1 ■ ENABLEMENT AND DISABLEMENT MODELS WIDELY ACCEPTED THROUGHOUT THE WORLD OVER THE LAST 50 YEARS*

ICF model, WHO 2001 ³⁰	Health condition	Body function and structure (impairments)	Activity (limitations)	Participation (restrictions)
ICIDH model, WHO 1980 ⁵⁶	Disease or pathology	Organ systems (impairments)	Disabilities	Handicaps
Nagi model, 1965 ⁵⁵	Disease or pathology	Organ systems (impairments)	Functional limitations	Disabilities

*Placed in table form to show similarities in concepts across the models. Please note that the ICF is a nonlinear, progressive model of enablement and includes contextual factors (personal and environmental) that contribute to the well-being of the individual. Also refer to Chapter 8 for a more detailed discussion of the ICF model.

Conceptual Frameworks for Client/Provider Interactions

Three conceptual frameworks for client-provider interactions are commonly used in the current health care delivery system. Each framework serves a different purpose and is used according to the goals of the desired outcome and the group interpreting the results (Figure 1-2). The four primary conceptual frameworks include (1) the statistical model, (2) the medical diagnostic model, (3) the behavioral or enablement model, and (4) the philosophical or belief model.

Statistical Model

The statistical model framework considers some predetermined set of mathematical values as the main driver for patient/client management decisions. For example, in today’s health care arena there is often a disconnect between the extent of a patient’s clinical problems and the number of approved, predetermined treatment visits needed to remediate these problems. In this situation the clinician must make certain clinical decisions before deciding service and must determine how best to meet the needs of the patient given

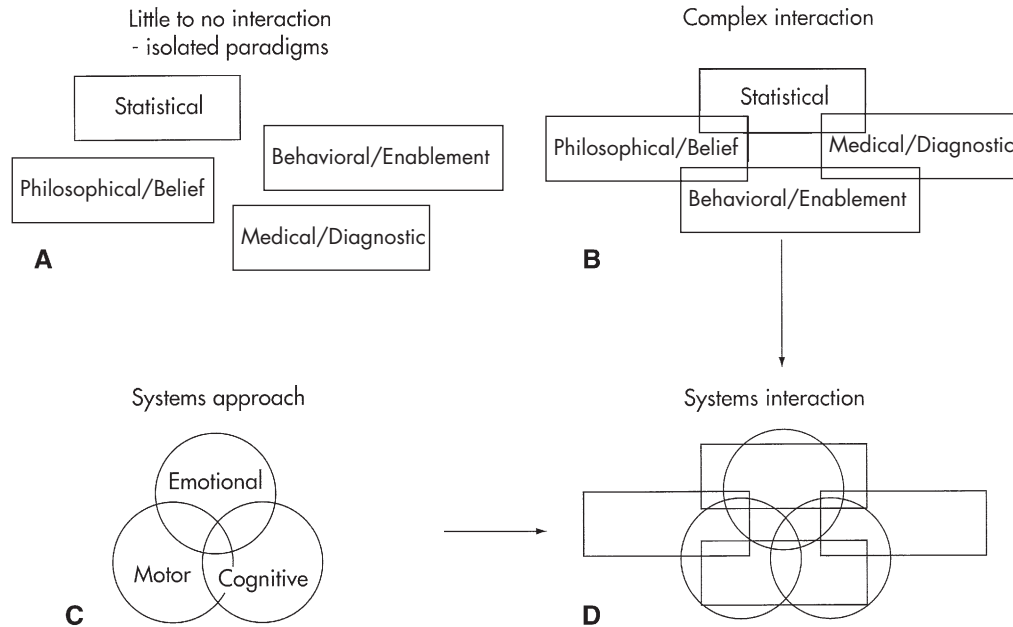

Figure 1-2 ■ Types of clinical models. **A**, Isolated paradigms. **B**, Complex interactive paradigms. **C**, Systems approach or paradigm. **D**, Systems interaction on traditional paradigms.

this limitation. Another illustration of this model involves the use of “numbers” or “grades” obtained from some outcome measure to make a determination on either the extent of functional limitation or the efficacy of a particular intervention. For example, if a patient scores 14 out of 24 points one week and 17 out of 24 points the next, and the payer knows that a score of 19 means the individual’s risk of falling is reduced, then the payer often permits additional therapy visits. Those payers generally have little interest in the reasons why the client moved from a score of 14 to 17, only that the person is improving. If clinicians do not provide these types of quantitative measurements, payment for services often is denied. To be able to optimize care under this model, today’s therapists need to be flexible critical thinkers who are able to skillfully document and communicate progress to individuals who need numbers, as well as provide this information to patients and their families, who are in emotional crisis because of problems associated with the neurological dysfunction, in a manner that they can understand.

Because efficacy of any intervention may be questioned by anyone, including the client, family, physician, third-party payer, or a lawyer, outcome tools that clearly measure problems in all domains must be carefully selected. Before an evaluation tool is chosen, the specific purpose for the request for examination and the model by which to interpret the meaning of the data must be identified.

Medical Diagnostic Model

Physicians are educated to use a medical disease or pathological condition diagnostic model for setting expectations of improvement or lack thereof. In patients with neurological dysfunction, physicians generally formulate their medical diagnosis on the basis of results from complex, highly technical examinations such as magnetic resonance imaging (MRI), functional magnetic resonance imaging (fMRI), computerized axial tomography (CAT or CT scan), positron

emission tomography (PET scan), evoked potentials, and laboratory studies (see Chapter 37). When abnormal test results are correlated with gross clinical signs and patient history such as high blood pressure, diabetes, or head trauma, a medical diagnosis is made along with an anticipated course of recovery or disease progression. This medical diagnostic model is based on an anatomical and physiological belief of how the brain functions and may or may not correlate with the behavioral and enablement models used by therapists.

Behavioral or Enablement Model

The behavioral or enablement model evaluates motor performance on the basis of two types of measurement scales. One type of scale measures functional activities, which range from simple movement patterns such as rolling to complex patterns such as dressing, playing tennis, or using a word processor. These tools identify functional activities or aspects of life performance that the person has been or is able to do and serve as the “strengths” when remediating from activity limitations or participation restrictions. The second scale looks at bodily systems and subsystems and whether they are affecting functional movement. These measurement tools must look at specific components of various systems and measure impairments within those respective areas or bodily systems. For example, if the system to be assessed is biomechanical, a simple tool such as a goniometer that measures joint range of motion might be used, whereas a complex motion analysis tool might be used to look at interactions of all joints during a specific movement. These types of measurements specifically look at movement and can be analyzed from both an impairment and an ability perspective. Chapter 8 has been designed to help the reader clearly differentiate these two types of measurement tools and how they might be used in the diagnosis, prognosis, and selection of intervention strategies when analyzing movement.

Philosophical or Belief Model

A fourth model or framework for client-provider interaction that may still be found in clinical use is a philosophical or belief model such as those described by master clinicians from the past, including Rood, Knott, Bobath, and Ayers, or homeopathic models such as acupuncture or Chinese medicine. These philosophical models, when applied to functional outcomes, would be included with today’s behavioral models and encompass a systems approach. The gap between philosophy and practice is narrowing as evidence is slowly showing that many of these approaches positively affect patient outcomes. Research has also identified approaches that have no efficacy. The link is outcome measures and whether a patient changes in participating in and has a quality of life. Thus the change is seen in the patient. Research today has created an alignment with what many therapists and master clinicians have long believed and practiced—focus on the patient, not the disease.

Therapists appreciate a statistical model through research and acceptance of evidence-based practice. A third-party payer also uses numbers to justify payment for services or to set limits on what will be paid and for specific number of visits that will be covered. Therapists also appreciate physicians’ knowledge and perspective of disease and pathology because of the effect of disease and pathology on functional behavior and the ability to engage and participate in life. On the other hand, third-party payers and physicians may not be aware of the models used by OTs and PTs. It is therefore critical that therapists make the bridge to physicians and third-party payers because research has shown that interdisciplinary interactions help reduce conflict between professionals and provide better consistency for the patient.^{57,58}

It is a medical shift in practice to recognize that patient participation plays a critical role in the delivery of health care. The importance of the patient and what each individual brings to the therapeutic environment has been recognized

and incorporated into patient care by rehabilitation professionals.³⁷⁻⁴⁰ This integration and acceptance will guide health care practice well into the next decade.

The need for students to develop problem-solving strategies is accepted by faculty across the country and by the respective accrediting agencies of health professionals. Unfortunately, we may not be educating students to the level of critical thinking that we hope.^{59,60} The need for this cognitive skill development in clinicians may be emergent as both physical and occupational therapy professions have moved or plan to move to a doctoring professions.⁴⁹ All health-related professions must evolve as patient care demands increase, delineation of professional boundaries become less clear, and collaboration becomes a more integral factor in providing high-quality health care.

All previously presented models (statistical, medical, behavioral, or belief) can stand alone as acceptable models for health care delivery (see Figure 1-2, A) or can interact or interconnect (Figure 1-2, B). These interconnections should validate the accuracy of the data derived from each model. The concept of an integrated problem-solving model for neurological rehabilitation must also identify the functional components within the CNS (Figure 1-2, C).

A model that identifies the three general neurological systems (cognitive, emotional, motor) found within the human nervous system can be incorporated into each of the other models separately or when they are interconnected (Figure 1-2, D). A systems or behavioral model that focuses on the neurological systems is much more than just the motor systems and their components, or cognition with its multiple cortical facets, or the affective or emotion limbic system with all its aspects. The complexity of a neurological systems model (Figure 1-3), whether used for statistics, for medical diagnosis, for behavioral or functional diagnosis, or for documentation or billing, cannot be oversimplified. As the knowledge bank regarding central and peripheral system

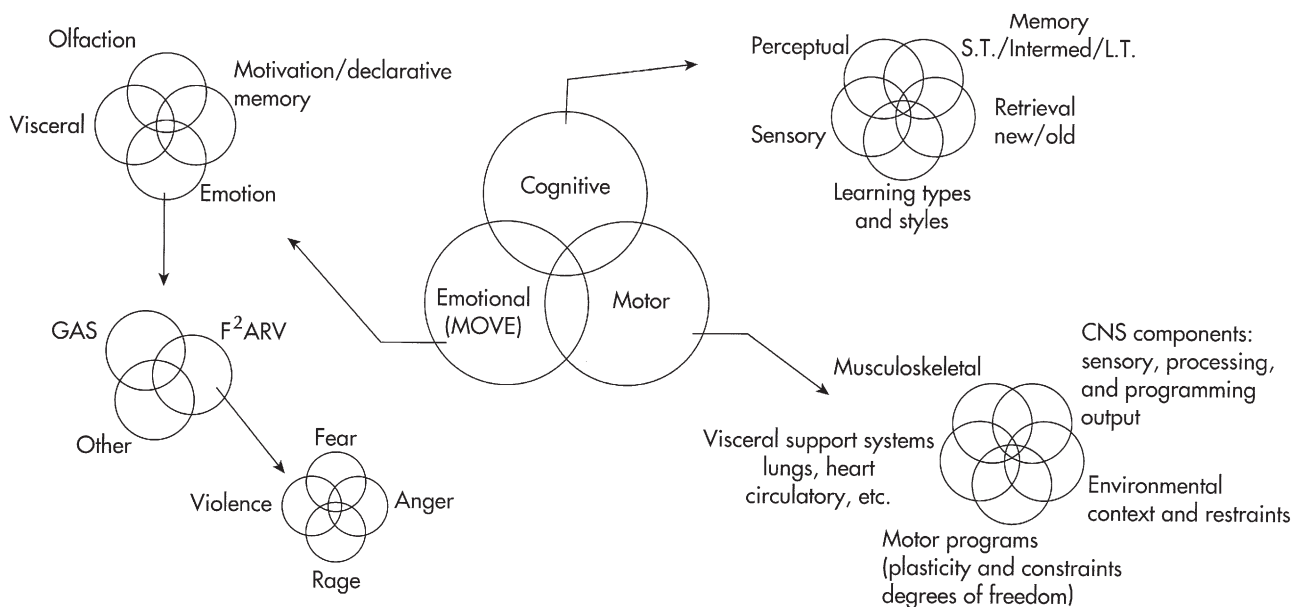

Figure 1-3 ■ Systems model. Dynamic interactive subcomponents: whole to part to whole. F²ARV, Fear and frustration, anger, rage, violence; GAS, general adaptation syndrome; L.T., long term; S.T., short term.

function increases, as well as knowledge about their interactions with other functions within and outside the body, the complexity of a systems model also enlarges.⁶¹ The reader must remember that each component within the nervous system has many interlocking subcomponents and that each of those components may or may not affect movement. Therapists use these movement problems as guidelines to establish problem lists and intervention sequences. These components, considered impairments or reasons why someone has difficulty moving, are critical to therapists but are of little concern within a general statistics model and may have little bearing on the medical diagnosis made by the physician.

In addition to the Western health care delivery paradigms are the interlocking roles identified within an evolving transdisciplinary model (Figure 1-4). Within this model, the environments experienced by the client both within the Western health care delivery system and those environments external to that system are interlocking and forming additional system components; they influence one another and affect the ultimate outcome demonstrated by the client. Because all these once-separate worlds encroach on or overlay one another and ultimately affect the client, practitioners are now operating in a holistic environment and must become open to alternative ways of practice. Some of those alternatives will fit neatly and comfortably with Western medical philosophy and be seen as complementary. Evidence-based practice, which used linear research to establish its reliability and validity, has provided therapists with many effective tools both for assessment and treatment, but we still are unable to do similar analyses while simultaneously measuring multiple subsystem components. We can measure tools and interventions across multiple sites but are a long way from truly understanding the future of best practice. Other evaluation and treatment tools may sharply contrast with Western research practice, having too many variables or variables that cannot be measured; therefore arriving at evidence-based conclusions seems an insurmountable problem. In time many of these other assessment tools and intervention strategies may be accepted, once research

methods have been developed to show evidence of efficacy, or they may be discarded for the same reason. Until these approaches have gone beyond belief in their effects, therapists will always need to expend additional focus measuring quantitative outcomes and analyzing accurately functional responses. Because the research is not available does not mean the approach has no efficacy (see Chapter 39). Thus the clinician needs to learn to be totally honest with outcomes, and quality of care and quality of life remain the primary objective for patient management. Today, models that incorporate health and wellness have been added to these disablement and enablement models to delineate the complexity of the problem-solving process used by therapists^{62,63} (see Chapter 2). This delineation should reflect accurate behavioral diagnoses based on functional limitations and strengths, preexisting system strengths and accommodations, and environmental-social-ethnic variables unique to the client. Similarly, it includes the family, caregiver, financial security, or health care delivery support systems. All these variables guide the direction of intervention⁶⁴ (Figure 1-5). These variables will affect behavioral outcomes and need to be identified through the examination and evaluation process. Many of these variables may not relate to the CNS disease or pathological condition medical diagnosis to which the patient has been assigned.

The client brings to this environment life experiences. Many of these life events may have just been a life experience; others may have caused slight adjustments to behavior (e.g., running into a tree while skiing out of patrolled downhill ski areas and then never doing it again), some may have caused limitations (e.g., after running into the tree, the left knee needed a brace to support the instability of that knee during any strenuous exercising), or caused adjustments in motor behavior and emotional safety before that individual entered the health care delivery system after CNS problems occurred. The accommodations or adjustments can dramatically affect both positively and negatively the course of intervention. To quickly accumulate this type of information regarding a client, the therapist must become open to the needs of the client and family. This openness is not just

sensory, using eyes and ears, but holistic and includes a bond that needs to and should develop during therapy (see Chapters 5 and 6).

EFFICACY

Efficacy has been defined as the “ability of an intervention to produce the desired beneficial effect in expert hands and under ideal circumstances.”⁶⁵ When any model of health care delivery is considered, the question the therapist must ask is “Which model will provide the most efficacious care?” Therapists may not diagnose a pathological disease

or its process, but they are in a position of responsibility to examine body systems for existing impairments and to analyze normal movement to determine appropriate interventions for activity-based functional problems. Some differences in this responsibility may exist between practice settings. Therapists in private practice act independently to select both examination tools and intervention approaches that are efficacious and prove beneficial to the patient. Within a hospital-based system, therapists may be expected to use specific tools that are considered a standard of care for that facility, regardless of the therapy diagnosis

and treatment rendered. In some hospitals and rehabilitation settings a clinical pathway may be employed that defines the roles and responsibilities of each person on a multidisciplinary team of medical professionals. Regardless of which clinical setting or role the therapist plays, it is always the responsibility of the therapist to be sure that the plan of care is appropriate, is consistent with the medical and therapy diagnoses, meets the needs of the patient, and renders successful outcomes. If the needs of the particular client do not match the progression of the pathway, it is the therapist's responsibility to recommend a change in the client's plan of care. Efficacy does not come because one is *taught* that an examination tool or intervention procedure is efficacious, it comes from the judicious use of tools to establish impairments, activity limitations, and participation restrictions, identify movement diagnoses, create functional improvements, and improve quality of life in those individuals who have come to us for therapy.

Today's health care climate demands that the therapeutic care model be efficient, be cost-effective, and result in measurable outcomes.⁶⁶ The message being given today might be considered to reflect the idea that "the end justifies the means." This premise has come to fruition through the linear thought process of established scientific research. Yet when a holistic model is accepted into practice it becomes apparent that outcome tools are not yet available to simultaneously measure the interactions of all body systems that make up the patient, making it difficult to apply models that purport to balance quality and cost of care. Thus we must guard against the reductionist research of today, which has the potential to restrain our evolution and choice of therapeutic interventions. Sometimes the individuals making decisions about what to include and what to eliminate with regard to patient services are not health care providers. They are individuals who are trained to use evidence gained from numbers or statistics to make their decision and do not have knowledge of the patient, his or her situation, or the effect of the neurological condition on function. Therapists should always be able to defend their choice and use of intervention approaches. This becomes even more relevant as the cost of health care rises.

Evidence-based practice is basic to the care process.^{30,67,68} Clinicians need to identify which of their therapeutic interventions have demonstrated positive outcomes for particular clinical problems or patient populations and which have not.⁶⁹ Those that remain in question may still be judged as useful. The basis for that judgment may be a client satisfaction variable that has become a critical variable for many areas in health care delivery.^{70,71} But there is still limited information on patient satisfaction with PT and OT services, although within the last few years more information has become available.⁷²⁻⁷⁶ Although patient satisfaction is a critical variable within the ICF model, there are always problems with satisfaction and outcomes versus identification of specific measurable variables within the CNS that are affecting outcomes. One reason for the problem of integrating patient satisfaction with PT and OT services within a neurorehabilitation environment is the large discrepancy between the variables we can measure and the variables within the environment that are affecting performance. For example, when a neurosurgeon once asked the question to one of the editors, "Do you know how to prove the theories

of intervention you are teaching?" The answer was, "Yes, all I need are two dynamic PET units that can be worn on both the client's and the therapist's heads while performing therapeutic interventions. I also need a computer that will simultaneously correlate all synaptic interactions between the therapist and the client to prove the therapeutic effect." The physician said, "We don't have those tools!" The response was, "You did not ask me if the research tools were available, only if I know how to obtain an efficacious result." Thus, the creativity of the therapist will always bring the professions to new visions of reality. That reality, when proven to be efficacious, assists in validating the accepted interventions used by the professional. The therapist today has a responsibility to provide evidence-based practice to the scientific community...but more important, also to the client. Therapeutic discovery usually precedes validation through scientific research. This discovery leads the way to, first, effective interventions, followed by efficacious care. If research and efficacious care always have to come before the application of therapeutic procedures, nothing new will evolve because discovery of care is most often, if not always, found in the clinic during interaction with a client. Thus the range of therapeutic applications will become severely limited and the evolution of neurological care stopped if that discovery is ignored because there is no efficacy as defined by today's research models. However, performing interventions because the approaches "have been typically done in the past" could be wasteful and irresponsible.

DIAGNOSIS: A PROCESS USED BY ALL PROFESSIONALS WHEN DRAWING CONCLUSIONS

Diagnosis is a conclusion drawn regarding specific diseases and pathological processes within the human body; when made by a physician it is considered a medical diagnosis. Diagnosis made by a PT or an OT is a conclusion drawn regarding the status of body systems, activity and participation, and their interactions considering the patient's personal factors and the environment. Specific activity-based functional limitations and the impairments within the body systems that affect the client's ability to control quiet postures or dynamic movement in any activity become a focus in the diagnostic process. The functional loss itself may or may not reflect specific diseases or pathological conditions within the CNS but does reflect specific impairments within that client's body. PTs and OTs, by use of functional behavioral models, are becoming comfortable with the *diagnosis of body system problems (impairments), activity restrictions (functional limitations), and participation* and the conceptual understanding that the diagnosis made by a PT or an OT is very different from that made by a physician.

Once the interpretation has been made, a therapist must draw conclusions regarding those results and their interactions. That interpretation leads to a therapy diagnosis. The interpretation of the evaluation results and their interaction with therapist's and client's desired outcomes, available resources, and client's potential lead to the prognosis. Selection of the best and most efficient resources to achieve the desired outcome will lead to establishment of the treatment intervention plan or "road map."

The diagnostic process used by therapists is complex and is clearly divided into two specific phases of differential

diagnosis (Figure 1-6). This is further explained in Chapters 7 and 8.

Phase 1: Differential Diagnosis: System Screening for Possible Disease or Pathology

With the increasing use of direct access and the length of time therapists spend with clients, clinicians have become acutely aware of the need to screen systems for signs of disease and pathological conditions.⁵¹ Accreditation standards for both PTs and OTs require the new learner to develop these skills before graduation. This screening process is used to determine whether the client should be referred to another practitioner, such as a physician, or can progress to diagnosis, prognosis, and intervention within the specific discipline. Thus Phase 1 of this differential diagnosis separates a client's clinical problems into those that fall within a therapist's scope of practice and those that do not. If the Phase 1 differential diagnosis shows signs and symptoms totally outside a therapist's scope of practice, then a referral to an appropriate practitioner must be made. If the signs and symptoms both fall within the clinician's scope of practice and overlap with that of other disciplines, the therapist must refer and decide (1) to treat to prevent problems until the other practitioner's treatment can be performed, (2) to manage the limitations in activity and participation in spite of the pathological process, or (3) to manage functional loss and impairments and therefore correct the pathological cause. In some cases the overlapping with other disciplines may not necessitate an immediate referral, but interactions must be made when needed to ensure the best outcome from intervention. However, when the information obtained by the therapist from this phase of differential diagnosis indicates a possible immediate and life-threatening condition, the therapist must act accordingly by calling 911 and referring the patient to a medical physician. Chapter 7 has been designed to help the reader grasp a better understanding of Phase 1 of

differential diagnosis. This form of system screening is part of history taking and may be redone periodically throughout treatment if the therapist has questions regarding changes in body systems. In the *Guide to Physical Therapist Practice*³⁰ this step is called *systems review* and *review of systems*. There may be times when the therapist has received a referral for a chronic problem and during the medical screen the patient demonstrates signs of a potential medical condition that has nothing to do with the referral. In that situation the therapist may continue with treatment but also should refer the patient back to a physician for a more thorough evaluation of the new problem.

For example, a patient was referred to a PT for treatment of chronic back pain caused by degenerative disc disease. During performance of a system screening the therapist determined that the patient had generalized weakness on the left side. On a return visit 2 days later the patient continued to demonstrate mild weakness on the left side. The therapist referred the patient back to the doctor, and the subsequent MRI showed that the woman had a large tumor in the right lower frontal-temporal lobe area. Over subsequent treatments the therapist was able to eliminate most of the chronic pain in her back. The patient to this day feels the therapist saved her life.⁷⁷

Once a clinician determines that the client's need for service falls within his or her respective scope of practice, then Phase 2 differential diagnosis begins.

Phase 2: Differential Diagnosis within a Therapist's Scope of Practice

Once the client's signs and symptoms have been determined to fall clearly within the scope of PT and OT practice, a definitive therapy diagnosis, prognosis, and plan of care can be established. The use of an enablement model such as the ICF will help the therapist best capture the patient's strengths, impairments, activity limitations, and participation restrictions, which can then be used to determine the patient's goals, address the individual's needs, and optimize function and quality of life (see Figure 1-1). The client's functional goals and expectations may include activities of daily living, job skills, recreation and leisure activities, or the skills required for performance of typical societal roles. Each of these goals must have a realistic, objective, measurable outcome that is based on the results of carefully chosen examination tools. An in-depth conceptual framework for selection of appropriate examination procedures needed to evaluate and draw appropriate diagnostic conclusions can be found in Chapter 8.

Two important clinical components affect the accuracy of the diagnostic conclusion. First, the clinician must establish accurate, nonbiased results. This fact seems obvious, but with the pressures of third-party payers, family members, other care providers, and the desire to have the client improve, it is easy to submit to drawing a conclusion based on *desired* outcomes rather than facing what is truly present and realistic. The second factor deals with the honesty of the interaction between the therapist and the client. This "bonding" is critical for obtaining accurate examination results. Safety, trust, and acceptance of the client as a human being play key roles in therapeutic outcomes and thus in efficacy of practice.⁷⁸⁻⁸¹ The reader is referred to Chapters 5 and 6 to develop a greater understanding of the impact this bonding has on clinical outcomes.

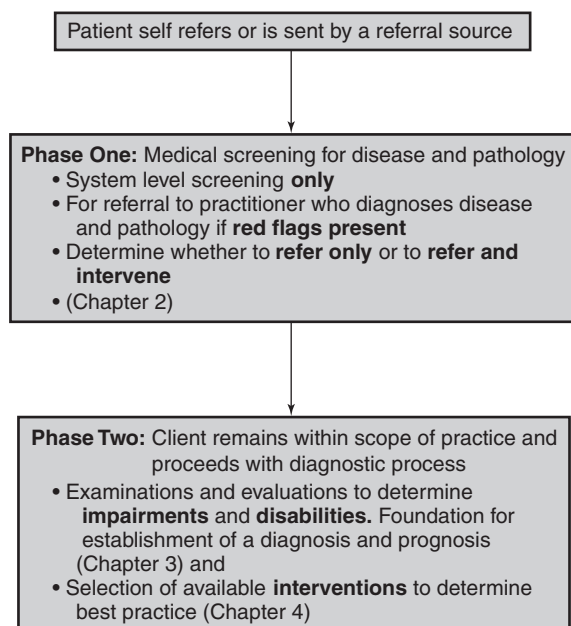

Figure 1-6 ■ The diagnostic process used for best practice by physical and occupational therapists.

The specific cognitive process used by therapists before formulation of a therapy diagnosis might be conceptualized as a nine-step process. As the therapist enters into the clinical environment of the client, he or she starts collecting data that might be relevant to the analysis of the clinical problem (step 1). This includes information obtained through observation, history taking, chart review, and interviews. The therapist must take that array of divergent information and determine what data are relevant to the case while disregarding what may be irrelevant information (step 2). This body of knowledge is then differentiated into various body systems that might be affected by the identified problems. If a specific system does not seem to be affected, then it can be eliminated, at least temporarily, from the diagnostic process (step 3). Generally, a clinician performs activity-based testing at this time to obtain a general understanding of the strengths and limitations of the individual in terms of function (step 4). After performing examination procedures and observing patterns of movement and specific normal and abnormal responses, the therapist once again diverges his or her thought processes back to separate large body systems to classify problems in the appropriate system (step 5). The therapist further subdivides these large systems into their components to assess specific subsystem deficits and strengths (step 6). This will allow the therapist to categorize objective measurements of impairments that are recognized as deficits within subsystems. Clusters of specific signs and symptoms will emerge that will help direct the clinicians to a therapy diagnosis. Once the therapist has obtained these clusters of symptoms within specific subsystems, two additional convergent steps need to be completed. First, the presence and lack of impairments and how those impairments interact to cause dysfunction in a major body system are determined (step 7). Second, how those impairments affect the interaction of the major system with other major body systems is determined (step 8). These eight steps tell the therapist exactly why the client has difficulty performing specific functional activities. The problem list that incorporates the severity of impairments that have interacted to cause loss of function gives the clinician the therapy diagnosis. The number and extent of impairments along with an understanding of the cause of loss of function will lead the therapist to establishment of various prognoses and identification of optimal intervention strategies. The last step (step 9) requires the therapist to diverge his or her thought processes back to the client's total environment to determine the accuracy of the diagnosis, prognosis, and selected treatment interventions as they interact with the client as a whole. Although some completion of this diagnostic process may occur within minutes after a client and therapist begin their interactions, the process is continual, and at any time a therapist may need to go back to previous steps to obtain and analyze new and relevant information.

PROGNOSIS: HOW LONG WILL IT TAKE TO GET FROM POINT A TO POINT B?

If a client has a variety of impairments, activity limitations, and participation restrictions, then a variety of appropriate prognoses may be formulated. These prognoses could be used to speculate the amount of time or number of treatments it will take to get from the existing activity limitations and participation restrictions (point A) to the desired outcomes

(point B). The outcomes will state whether the intervention will (1) eliminate functional limitations through changes, adaptations, and learning within the client as an organism or (2) improve function through compensation and modification of the external environment. Once the therapy diagnosis has been established, a clinician must consider many factors when making a prognosis. Some factors are related to the internal environment of the client, such as number and extent of impairments, level of physical conditioning or deconditioning of the client, the ability and motivation to learn, participate, and change, and the neurological disease or condition that led to the existing problems. The client's support systems have a dramatic impact on prognosis. Cultural and ethnic pressures, financial support to promote independence, availability of appropriate skilled professional services, prescribed medications, and the interaction of all of these factors need to be considered. Specific environmental factors such as belief in health care and agreement about who has the responsibility for healing can create tremendous conflict among current health care delivery systems; the client; the family; and you, the clinician.^{79,82,83} All of these variables affect prognosis. The last aspect of determining prognosis relates to empowerment of the client. Who sets the goals? Who determines function? Who identifies when a therapeutic modality should be used versus a meaningful life activity? If consensus to these questions cannot be found by the therapist and the client, then conflict between anticipated and actual outcome will result and a definitive prognosis will not be achieved.

Once a prognosis has been established, the therapist's next step is to identify the intervention strategies that will guide the client to the desired outcome within the time frame identified. (Refer to Chapter 9 and all chapters in Section II.)

DOCUMENTATION

Documentation of the examination, evaluation, goals, plan, and daily interventions has always been integral to the therapeutic process. However, there is added emphasis in today's health care environment, as well as a renewed respect for the importance of the issue. Documentation must produce a clear framework from which to record and follow client progress. Documentation communicates the process of care and the product or outcome of that process. The outcome is the realistic reflection of the effectiveness of care. The goals should be stated in measurable functional terms and prioritized in order of importance to the client. The number of goals developed by the therapist takes into account the realistic probability of effectiveness of interventions, the environment in which the interventions will likely occur, and support systems available to the client. As the process goes forward, the therapist may add, delete, or change a functional goal, and so states that on the client's record. Refer to Chapter 10 for further information about this process.

INTERVENTION

Clients with neurological diseases or conditions can interact with the medical community for either short or long periods. They possess neurological problems of all types that range from sudden to insidious in onset and presentation. All aspects of human function are represented in the variety of

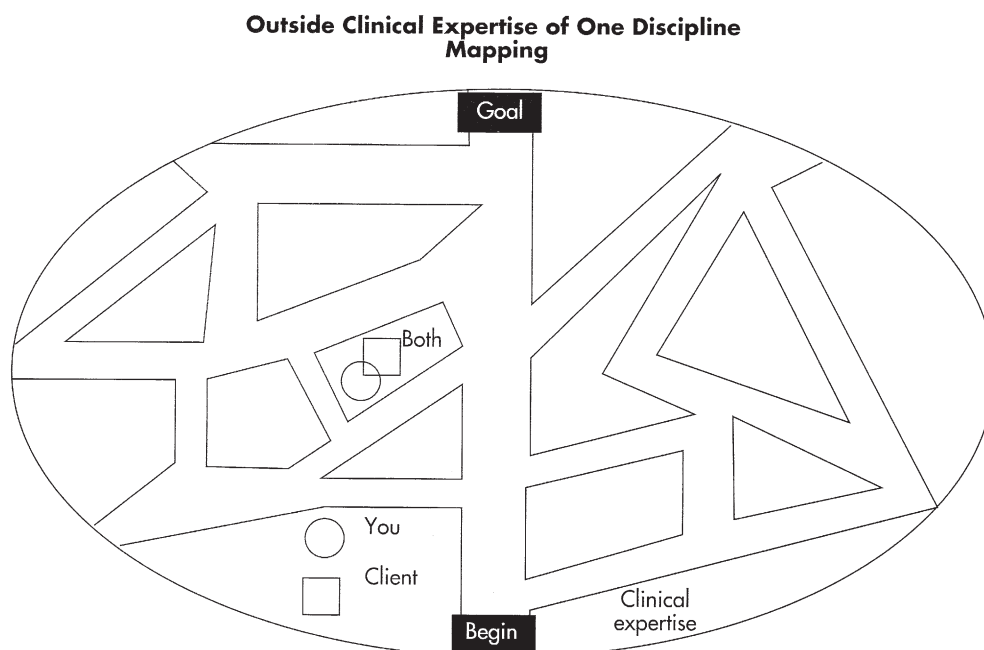

problems. If individual beliefs and values energize and motivate physical behavior, think of the possibilities for stimulating wellness. Return to wellness might be considered return to previous function, maintenance of function, slowing progression of functional loss, habilitation of function never achieved, and striving for excellence in performance. Refer to Chapter 9 for additional discussion.

The established plan of care determines the interventions and the method, or road map, toward the achievement of the agreed-on outcome goals. The therapist, in collaboration with the client, can choose from restrictive and nonrestrictive treatment environments and interventions to best achieve identified goals. The available choices of interventions will depend on the therapist's skill, the level of function and ability of the client to control his or her own neuromuscular system, and treatment tools and strategies that are available in the clinic. Yet freedom within that established environment must exist if learning by the client is to occur. Another way to consider intervention is to refer to it as a clinical road map (Figure 1-7). Within the map, a therapist, through professional education, efficacy of preexisting clinical pathways, and clinical experience can generally identify the most expedient way to guide a client toward the desired outcome. When the specific client enters into this interaction, slight variations off the existing pathway may lead to quicker outcomes. If the client diverges away from the desired end product, it is the therapist's responsibility to guide that individual back into the clinical map. For example, if a therapist and client are working on coming to standing patterns and the client begins to fall, the therapist would need to guide the client back into the desired movement patterns and not allow the fall. In that way the client is working on the identified outcome. Falling as a functional activity should be taught as a different intervention and would be considered part of a different clinical map. The degree to which the therapist needs to control the response of the

client will determine the extent to which the intervention would be considered contrived. Contrived interventions can, in time, lead to functional independence of the client, but as long as the therapist needs to control the environment, functional independence has not been achieved. There are many ways to get to a desired outcome. Involving the client in the goal setting and intervention planning process will lead to the best result. These interactions require trust of the therapist as a guide and teacher. Refer to Chapter 9 and all chapters in Section II for a more thorough discussion of intervention strategies.

Most treatment interventions used for clients with CNS pathology incorporate principles of neuroplasticity, adaptation, motor control, and motor learning in various environmental contexts. Thus, the consideration of the basic science of central and peripheral nervous system function (see Chapter 4) and a behavioral analysis of movement (see Chapter 3) must be included in any conceptual model used as a foundation for the entire diagnostic process.

Also of considerable significance is the client-therapist interaction, which is labeled the *learning environment*. This may be the critical factor in the success or failure of therapeutic interventions. The concept of human movement as a range of observable behaviors, the complexity of the CNS as a control center, and the interactions between the client and therapist within closed and open learning environments form an abstract conceptual triad. Each part of this triad has unique characteristics that have the ability to influence performance and progress in the clinical setting. Together they allow for the client to be viewed as a total human being, allowing the therapist to consider multiple constructs at once so that a client's responses and movement patterns may all be considered and developed simultaneously. In this way, key signs such as movement in body parts distant to the area being treated, pain, or a response of the autonomic nervous system will not be missed. Attention to these responses

may be the answer to attaining goals and successful client-therapist rapport.

Concept of Human Movement as a Range of Observable Behaviors

As researchers continue to unravel the mysteries of brain function and learning, their understanding of how children and adults initially learn or relearn after neurological insult is often explained with new and possibly conflicting theories. Yet behavioral responses observed as functional patterns of movement, whether performed by a child, adolescent, young adult, or older person, are still visually identified by a therapist, family member, or innocent observer as either normal or abnormal.

Human beings exhibit certain movement patterns that may vary in tonal characteristics, amplitude, aspects of the specific movement sequences, and even the sequential nature of development. Yet the range of acceptable behavior does have limitations, and variations beyond those boundaries are recognizable by most people. A 5-year-old child may ask why a little girl walks on her toes with her legs stuck together. If questioned, that same 5-year-old child may have the ability to break down the specific aspects of the movement that seem unacceptable even to that 5-year-old child. From birth a sighted individual observes normal human movement. Because the range of behaviors identified as normal within any functional activity does not vary from individual to individual, human movement patterns are predictable. This concept does provide flexibility in analysis of normal movement and its development. Some children choose creeping as a primary mode of horizontal movement, whereas others may scoot. Both forms of movement are normal for a young child. In both cases each child would have had to develop normal postural function in the head and trunk to carry out the activity in a normal fashion. Thus for the child to develop the specific functional motor behavior, the various components or systems involved in the integrated execution of the act would require modulation in a plan of action. Because the action must be carried out in a variety of environmental contexts, the child would need the opportunity to practice in those contexts, identify errors, self-correct to regulate existing plans, and refine for skill development. Thus each movement has a variety of complex systems interactions, which when summated are expressed by means of the motor neuron pool to striated muscle tissue function. The specifics of that function, whether fine or gross motor control, or full-body or limb-specific movement, still reflect the totality of the interaction of those systems. No matter the age of the individual, the motor response still reflects that interaction, and the behavior can be identified as normal and functional, functional but limited in adaptability, or dysfunctional and abnormal. Because of the simplicity or complexity of various movements and the components necessary to modulate control over various movements, therapists can (1) look at any movement pattern, (2) evaluate its components, (3) identify what is missing, and (4) incorporate treatment strategies that help the client reduce impairments and achieve the desired functional outcome.

One can be confident that no infant will be born, jump out of the womb, walk over to the physician, and shake hands or say “hi” to mom and dad before learning to roll or control posture of the trunk and head. Instead, normal

motor development requires new motor plans that lead to the infant’s ability to achieve functional movement through motor learning. These new motor programs will be modified and reintegrated along with other programs to develop normal motor control in more complex patterns and environments because of neuroplasticity. Each pattern, and the advancement from one pattern to another, requires time and repetition for mastery.

Two important aspects of the clinical problem-solving process emerge when observing motor behavior. First, the evaluation of motor function is based on the interaction of all components of the motor system and the cognitive and affective influences over this motor system, as stated previously. Second, the therapist needs to recognize which aspects of the movement are deficient, absent, distorted, or inappropriate when cross-referenced with the desired outcome (part of the diagnosis-prognosis process). These behaviors, although dependent on many factors, are consistent regardless of age of the client. Some clients may not have had the opportunity to experience the desired skill, whereas others may have lost the skill as a result of changes within the CNS or disuse. In either case, the normal patterns and range of behaviors remain the same. Refer to Chapter 3 for an additional discussion of movement analysis across the life span.

The Complexity of the Central Nervous System as a Control Center

The concept of the CNS as a control center is based on a therapist’s observations and understanding of the sensory-motor performance patterns reflective of that system. This understanding requires an in-depth background in neuroanatomy, neurophysiology, motor control, motor learning, and neuroplasticity and gives the therapist the basis for clinical application and treatment. Understanding the intricacies and complex relationships of these neuromechanisms provides therapists with direction as to when, why, and in what order to use clinical treatment techniques. Motor behaviors emerge based on maturation, potential, and degeneration of the CNS. Each behavior observed, sequenced, and integrated as a treatment protocol should be interpreted according to neurophysiological and neuroanatomical principles as well as the principles of learning and neuroplasticity. As science moves toward a greater understanding of the neuromechanisms by which behaviors occur, therapists will be in a better position to establish efficacy of intervention. Unfortunately, our knowledge of behavior is ahead of our understanding of the intricate mechanisms of the CNS that create it. Thus the future will continue to expand the reliability and validity of therapeutic interventions designed to modify functional movement patterns. First, therapists need to determine what interventions are effective within a clinical environment. Then the efficacy of specific treatment variables can be studied and more clearly identified. The rationale for the use of certain treatment techniques will likely change over time. As our knowledge of the CNS continues to evolve, so will the validation of techniques and approaches used in therapeutic environments. At that point, evidence-based practice will truly be a reality. Chapters 4 and 5 have additional information and references on CNS function. Chapter 9 has an in-depth discussion of intervention options.

Concept of the Learning Environment

The concept of the learning environment is the most abstract and complex of the three concepts in the clinical triad model. For that reason it is by far the most difficult to present in concrete terms. Components of the therapist, the patient, and the clinical environment formulate and maintain this environment.

To comprehend the dynamics of the learning environment and function with optimal success, the clinician must do the following:

- Understand the learning process and provide an environment that promotes learning.
- Investigate the use of sensory input and motor output systems, feed-forward and feedback mechanisms, and cognitive processing as means for higher-order learning.
- Use the principles and theories of motor control, motor learning, and neuroplasticity to facilitate learning and carryover of treatment into real-life environments.
- Obtain knowledge of both the client's and the provider's learning styles. If these learning styles are not compatible, then the clinician is obligated to teach using the client's preferred style.
- Attend to the sensory-motor, cognitive, and affective aspects of each client, regardless of the clinical emphasis at any given time.

At all times there are four distinct components of the learning environment in operation: the internal and external environments of the client, and the internal and external environments of the clinician (Figure 1-8). All four represent interactive components of the learning environment.

The Client

A critical component of the ability to learn is the *client's internal environment*. When a lesion occurs within a body system it affects the entire internal environment of the client both directly and indirectly. If the lesion occurs before initial learning, then habilitation must take place. These clients may possess a genetic predisposition for a specific learning style, even though one has not yet been established. The therapist should test the inexperienced CNS by creating experiences in various contexts that require a variety of types of higher-order processing to discover optimal methods of learning that best suit the CNS of the client. Then the therapist can employ the most effective strategies in treatment. If previous learning has occurred and preferential modes of operating have been established, then the therapist needs to know what those are and whether they have been affected by the neurological insult so that proper rehabilitation can be

instituted.⁸⁴ The use of preferential sensory input modes such as visual compared with verbal or kinesthetic does not mean that other modes are ineffective, nor do all modes function optimally in any given situation.

One way to determine preferential learning styles is by taking a thorough history. Leisure activities and job choices often give clues to learning styles. For example, a client who loved to take car engines apart or build model ships demonstrates a preference for the visual-kinesthetic learning style, whereas a client whose preference for pure enjoyment was sitting in a chair with a novel demonstrates a probable preference toward verbal learning. Again, this does not mean that the clients in the examples mentioned could not selectively use all methods, but it does illustrate the issue of preference. Both the position of the lesion and the preferential learning style can play key roles in matching the learner with a particular treatment environment and identifying potential for recovery of function. For example, if a client has had a massive insult to the left temporal lobe and before the trauma showed poor ability in using the right parieto-occipital lobe, then spatial or verbal strategies may be ineffective in the relearning process. However, a client with the same lesion who had high-level right parieto-occipital function before the insult will probably learn at a much faster rate if visual-kinesthetic strategies are used to promote learning.

The *client's external environment* is the second critical component.⁸⁵ All external stimuli, including noise, lighting, temperature, touch, humidity, and smell, modulate the client's responses. External inputs can invoke either negative or positive influences on internal mechanisms and alter the client's ability to manipulate the world. A therapist should make every effort to be aware of what externally is influencing the client.⁸⁶⁻⁸⁹ It is important to know what is happening to the client both within and outside of the hospital or clinic experience. Any behavioral change displayed by the client, such as a change in mood or attitude, or a change in muscle tone could serve as an indicator to the therapist that an environmental effect may have occurred. A follow-up determination of what may have happened can help the therapist understand the situation, help the client deal with the environmental influences, and allow the therapist to obtain additional professional assistance if needed.

The third critical component is the *internal environment of the clinician*.⁹⁰ The clinician should be aware of personal internal factors that can influence patient responses. Everyone has preferential styles of teaching and learning; yet many of us may be unaware of what they are and how they affect our outlook on life and interactions with other people. A common example of a mismatch of styles is what happens when two people are arguing opposing sides of a political issue. Although both individuals may process the same data, they may have different learning strategies and come up with very different conclusions.

The interplay of learning styles occurs continually in an academic setting. A student who is asked the question "What do you want out of this course?" would probably say, "A good grade." Getting a good grade requires doing well on course requirements, including tests. High-grade test performance usually depends on not only a knowledgeable demonstration of a subject but also the way in which the teacher formulates the question and the teacher's expectation for a response. In a clinical setting, it is important that

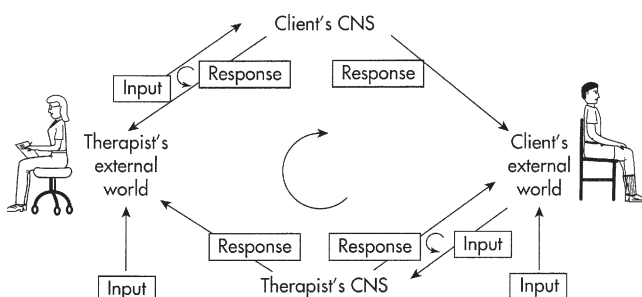

Figure 1-8 ■ Clinical learning environment.

the clinician be aware of the client's response to the practitioner's request.

This external-internal environmental interaction concept brings up another important clinical consideration.⁹¹ As students, most of us probably “clashed” with one or two teachers with whose learning styles we could never identify. As learners we cannot or will not adapt to all learning styles. For that reason there may be some clients who do not respond to our teaching. When that seems evident, a shift of therapists is appropriate for the rehabilitation process to succeed.

The fourth component of the learning environment is the *clinician's external environment*. It is generally expected that personal life should never affect professional work. To accept this assumption, however, may be to deny that emotions affect behavioral patterns (see Chapters 5 and 6). Response patterns can vary without cognitive awareness when an individual is emotionally upset or under stress. For example, suppose that Mr. Smith, who has a hypertonic condition because of a stroke, comes down early for therapy each morning, has a cup of coffee, and chats while you write notes. If one day you are under extreme stress and do not feel like interacting as Mr. Smith rolls his wheelchair into your office, you might say, “Mr. Smith, I'll be with you in a few minutes. Go over to the mat, lock your brakes, pick up the pedals, and we'll transfer when I get there.” Mr. Smith will quickly sense a change in your behavior. Society has taught him that you are a professional and that your personal life does not affect your job. Thus he may draw a logical conclusion that he must have done something to change your behavior. When you go to transfer him you notice he is more hypertonic than usual and ask, “Is something bothering you? You're tighter than usual,” and so goes the interaction. Your external environment altered your internal state and, thus, normal response patterns. In turn, you altered Mr. Smith's external environment, changing his internal balance, and created a change of emotional tone that resulted in increased hypertonicity.^{92,93} If instead of interacting with Mr. Smith as if nothing were wrong, you had informed him you were upset over something unrelated to him, you might have avoided creating a negative environment. Mr. Smith's responses may have been different if you had shared with him the fact that there are days that you are upset and have mood changes. As he accepts your changes as normal, you may have created an opportunity for him to also exhibit a range of behavioral moods. You have also given him an opportunity to offer his assistance to comfort or help you if he so desires. Such behavior encourages interdependence and social interaction and facilitates long-term goals for all rehabilitation clients.

Each client is unique. Therefore it is difficult to analyze the specifics related to each individual's learning environment. However, six basic learning principles have been established that are relevant to both the client and the clinician in any learning environment.⁹⁴⁻⁹⁶ These *six principles of the learning experience* are as follows:

1. Individuals need to be able to solve problems and practice those solutions as motor programs if independence in daily living is desired. This requires the use of intrinsic feedback systems to modulate feed-forward motor plans as well as correct existing plans.
2. The possibility of success must exist in all functional tasks, regardless of the level of challenge to the client.
3. An individual will revert to safer or more familiar motor programs or ways to solve problems and succeed at functional tasks when task demands are new, difficult, or unfamiliar.
4. The learning effect occurs in multiple areas of the CNS simultaneously when teaching and learning are focused within one area of the CNS.
5. Motivation is necessary to drive the individual to try to experience what would be considered unknown. Simultaneously, success at the activity is critical to keep the individual motivated to continue to practice.
6. Clinicians need to be able to analyze an activity as a whole, determine its component parts, and use problem-solving strategies to design effective individualized treatment programs. At the same time, if independence in living skills is an objective, the therapist needs to teach the client those problem-solving strategies rather than teaching the solution to the problem.

Although all six learning principles seem simple, their application within the clinical setting is not always as obvious. *Principles 1 and 2* are intricately linked with the appropriateness and difficulty of tasks presented to clients. If a client is asked to perform a task such as standing, rolling, relaxing, dressing, or maneuvering a wheelchair, a problem has been presented that requires a sequence of acts leading to a solution. To succeed, the client must be able to plan the entire task and modulate all motor control during the sequence of the entire activity. If steps are not mastered, if sequencing is inappropriate or absent, or if motor control systems are not modulated accurately, dependence on the clinician to solve the problem is reinforced. If the clinician can differentiate missing components (impairments) from functioning systems, creating an environment that encourages and allows the CNS to adapt and learn ways to regain that control, it will lead to optimal self-empowerment of the client and will help eliminate disabilities. Error in the ability to intrinsically self-correct during practice is critical for motor learning. Error that always leads to failure does not help the client learn avenues of adaptation. Linked intricately with success is the challenge of the task. The greater the task difficulty or complexity, the greater the challenge and consequently the greater the satisfaction of success.

There is a subtle interplay among degree of difficulty, challenge, and success. Selecting tasks that are age appropriate, clinically relevant, and goal related is a challenge to the therapist. For the patient to be successful, the therapist must be a creative problem solver and knowledgeable about the client's needs, abilities, and goals. If the tasks are too simple or if the client considers them unimportant, boredom will ensue and progress may diminish. If the tasks are too difficult, the client may feel defeated and may turn away from them. In such cases a child tends to withdraw physically, whereas an adult usually avoids the problem. Being late to therapy, having to leave early, needing to go to the bathroom, and scheduling conflicting sessions are all avoidance behaviors that may be linked to inappropriate tasks.

The *third learning principle* describes a behavior inherent in all people: reversal. When confronted by a problem, individuals revert to patterns that produce feelings of comfort and competence when solving the problem. In [Figure 1-9](#), a 2-year-old child is confronted with just such a conflict. The bridge he wants to cross is unstable. The

Figure 1-9 ■ Reverting to more comfortable behavior patterns when confronted with a problem. **A**, Scooting. **B**, Bunny hopping. **C**, Creeping. **D**, Cruising. **E**, Walking.

task goal is to cross the bridge; how that is accomplished is not as relevant as the task specificity. Therefore the child chooses a 6-month-old behavior and thus scoots. On gaining confidence, the child sequences from scooting to four-point bunny hopping, then creeping, on to cruising,

and finally to reciprocal walking. The child's reversal lasted approximately 2 minutes. Although reverting to more familiar or comfortable ways of solving problems is normal, it creates constant frustration in the clinic if it is prolonged. For example, if a client with residual

hemiplegia has spent a week modifying and controlling a hypertonic upper-extremity pattern during a simple task and is now confronted with a more difficult problem, the hypertonia within the limb will most likely return with the added complexity of the task. If another client has successfully worked to obtain the standing position and then is asked to walk, the strong synergistic patterns that had been controlled may return. The pattern or plan for standing is different from that for walking, and the emotional implications of walking are very high. The clinician should anticipate the possibility of the patient returning to a more stereotypical pattern. This possibility must also be explained to the patient. Anticipating that less efficient patterns will usually return as the tasks demanded increase in complexity, the clinician can attempt to modify the unwanted responses and let the patient know that the response is actually normal given the CNS dysfunction, but that movement can be changed and normalized with practice. The key to comprehension of this concept is not the behavior itself; instead, it is the attitude of a therapist toward a new task presented to the client. If the clinician expects the client to be successful, the client will also expect success. If failure occurs, both parties will be disappointed and a potentially negative clinical situation will be created; however, if the client succeeds, both will have expected the result and their attitude will be neither excited nor depressed. On the other hand, a clinician who expects the client to revert to an old behavior can prepare the client. If the client reverts, neither party will be disappointed; but if no reversion occurs, both will be excited, pleased, and encouraged by the higher functional skill. By understanding the concept, the clinician can maintain a very positive clinical environment without the constant negative interference of perceived failure when a client does revert.

The *fourth learning principle* deals with the totality of the client. Whether the area of emphasis is motor performance, emotional balance, or perceptual integration, all areas are affected. Therefore understanding and respect for all areas are important if optimal client function is a primary objective. This does not suggest that therapists should address each aspect of personality; however, integration of the client's physical, mental, and spiritual areas should be a responsibility of the staff. Awareness of possible adverse effects of one learned behavior on other CNS functions can help avoid potential problems. For example, if working on lower extremity patterns creates extreme upper extremity hypertonicity through associated patterns, the clinician is not dealing with the client as a whole.

The unknown creates fear and curiosity for most individuals, and the *fifth learning principle* points out that for most clients the unknown is all encompassing, whatever the degree of prior learning. For a client whose only difficulty is a flaccid upper extremity, functional activities such as toileting, dressing, or eating will be troublesome and unfamiliar. Motivation is a critical factor for success. Maintaining motivation to try while ensuring a high degree of success is an important teaching strategy that tends to encourage present and future learning.

An additional comment regarding clients who lack motivation should be made. If a client chooses to be totally dependent and has no need to become independent, then a therapist will probably fail at whatever task is presented. For

example, Mr. Brown, a 63-year-old bank president with a wife, four children, and 10 grandchildren, survives an operable brain tumor with residual right hemiparesis and minimal cognitive-affective deficits. The client's work history indicates that he was highly success oriented. Unknown to most persons is that for 63 years Mr. Brown desired to be a passive-dependent person, but circumstances never allowed him to manifest those behaviors. With the neurological insult, he is in a position to actualize his needs. Until the client desires to improve, therapy will probably be ineffective; thus, motivating the client becomes critical. This might be accomplished in a variety of ways. Knowing that Mr. Brown values privacy, especially with respect to hygiene, that he thoroughly enjoys dancing and birdwatching in the forest, and that he ascribes importance to being accepted in social situations, such as cocktail parties, helps the therapist create a learning environment that motivates this client toward independence. Being independent in hygiene requires certain combinations of motor actions, including sitting, balance, and transfer skills. Being able to birdwatch deep in an unpopulated forest requires ambulation skills, tolerance of the upright position for extended periods of time, and endurance. Being socially accepted depends to a large extent not only on grooming but on normal movement patterns, especially in the upper extremity and trunk. Creating a therapeutic environment that stresses independence in the three goals identified by the client will simultaneously create further independence in other areas. Whether the client decides to return to banking and other activities in conflict with his personality will need to be addressed later. Another way to motivate Mr. Brown is to place him in an environment in which he is not satisfied, such as a nursing home or his own home with an assistant rather than his wife to help him with his needs. Dissatisfaction with the current external environment will generally motivate an individual to change. Obviously, creating a positive environment for change versus a negative one would be the method of choice.

The *sixth learning principle* has been discussed in earlier sections. To be a successful teacher of motor skills and to assist the client in recovery of function, the clinician should be able to break more complex motor plans and functional tasks into smaller component parts. These parts can then be taught successfully and then integrated back into the whole activity for optimal learning to occur. The therapist should always strive to allow each client to solve movement problems and develop strategies for reaching the outcome goals, rather than producing the desired outcome for or with the patient.

Many additional learning principles from the fields of education, development, and psychology can be used to explain the behavioral responses seen in our clients. It is not expected that all therapists will intuitively or automatically know how to create an environment conducive to helping the patient achieve optimal potential. Yet all can become better at creating a beneficial learning environment by understanding how people learn. The critical importance of being honest and accurate with prognosis and how that will ultimately affect function outcomes, participation in life, and quality of life cannot be overemphasized.⁹⁷

The principles presented in this chapter deliver a strong message: individuals need to solve problems and most want to solve the problem given a chance that the solution will be successful. Unless the task fits the individual's current

capability, adaptation using whatever is available will become the consensus that drives the motor performance through the CNS. Learning is taking place in all aspects of life, and the client must ultimately take responsibility for the means to solve the problem.⁹⁸

THE CLIENT AND PROVIDER RELATIONSHIP

The Client's Role in the Relationship

Active participation in life and in relationships promotes learning. Rogers⁹⁹ defines significant learning as learning that makes a difference and affects all parts of a person. We have spoken of a relationship centered on an individual's health. One of the individuals involved in the relationship (the therapist) has knowledge that is to be imparted to or skills to be practiced by the other. The relationship "works" if the learning environment facilitates exchange between the participants. The concept of equal partners is crucial. The issue and practice of informed consent is not just political or ethical; it is central to client care. Voluntarism has to be practiced by both practitioner and client. Each has a moral obligation to facilitate the process of health care within the moment. Although the Western world of medicine has steadily climbed a path toward excellence in medical technology and clarification of medical diagnosis as seen in WHO's ICD-10,¹⁰⁰ it has not as easily recognized the client's need to assume an equal role in the decision making or for the practitioner to seek the client's help. Consumers are now seeking to play a more active role in their health care. This role has developed out of our scientific understanding of motor learning (see Chapter 4) and the fiscal necessity of decreasing the number of therapeutic visits.

Consumers of health care are becoming aware of the affect of medicine's control over their lives. This awareness has been fueled by the price they are paying for that health care. A recent Surgeon General's report confirms that expenditures for health are increasing. In addition, preventive care assumes major importance in view of the fact that seven out of 10 deaths in the United States today are the result of degenerative diseases, such as heart disease, stroke, and cancer.¹⁰¹ Like other major causes of death, trauma (cited as the most frequent cause of death in persons younger than age 40 years¹⁰²) is increasingly linked to lifestyles.

During their training, individuals in the health care professions internalize values that reinforce the traditional professional attitude alluded to earlier. Many of these values do not support a partnership relationship with the client. Society is beginning to question the traditional role of the health care professional as the knowledge expert; however, professional educational institutions and organizations resist the pressure to change the image. The professions still hold the image of great authority given to them by the public and fostered through increased political activity. This is true for both those professionals dealing with disease and pathology (physicians, nurses, pharmacists) and those dealing with functional movement problems limiting participation in life (OTs, PTs, Speech Language Pathologists).

The major purpose of the patient's relationship with the health care professional is to exchange information useful to both regarding the health care of the client. McNerney³¹ calls health education of the client the missing link in

health care delivery. As the gap grows between technology and the users of that technology, client health education becomes more important than ever.¹⁰³ McNerney³¹ notes that although health care providers are now making efforts to educate their clients, they are doing so with little consistency, enthusiasm, theoretical base, or imagination and often with little coordination with other services. The health care professional continues to receive training and embrace professional organizational membership that places a premium on control of information and control of the decision making. There is and should be a special effort to introduce health education concepts into the basic educational programs of health care professionals. McNerney identified many of the problems three decades ago, and many still exist today.

When patients are given more information about their illnesses and retain the information, they express more satisfaction with their caregivers. A study by Bertakis¹⁰⁴ tested the hypothesis that patients with greater understanding and retention of the information given by the physician would be more satisfied with the physician-patient relationship. The experimental group received feedback and retained 83.5% of the information given to them by the physician. The control group received no feedback and retained 60.5% of the information. Not surprisingly, the experimental group was more satisfied with the physician-patient relationship.

If the client is to be informed and included in the treatment process, client health education will have to go beyond the current styles of information giving. If the client is to assume some of the responsibility for his or her therapy, the therapist will have to facilitate that involvement. The attitude of the therapist toward educating clients about their health could affect his or her ability to facilitate client involvement in the care process.

The more the professional sees himself or herself as the expert, the less likely he or she will be to see the client as capable of responsibility or expertise in the care process. If communication skills and health education were an integral part of medical school and health care professional school curricula, perhaps the health care professionals would temper their assumption of the "expert" professional role. Payton¹⁰⁵ points out that it is the client alone who can ultimately decide whether a goal is worth working for. Careful planning can be influential in helping all providers include the client in the process.

The health care delivery system in the United States has to serve all citizens.¹⁰⁶ That is no easy task. The United States is a society of great pluralism. It is a free society. It is a society that is used to being governed by persuasion, not coercion. Given the variety of economic, political, cultural, and religious forces at work in American society, education of the people with regard to their health care is probably the only method that can work in the long run. The future task of health education will be to "cultivate people's sense of responsibility toward their own health and that of the community." Health education is an effective approach with perhaps the most potential to move us toward a concept of preventive care.

Becker and Maiman¹⁰⁷ discussed Rosenstock's Health Belief model as a framework to account for the individual's decision to use preventive services or engage in preventive

health behavior. Action taken by the individual, according to the model, depends on the individual's perceived susceptibility to the illness, his or her perception of the severity of the illness, the benefits to be gained from taking action, and a "cue" of some sort that triggers action. The cue could be advice from a friend, reading an article about the illness, a television commercial, and so on. In some way, the person is motivated to do something.

Mass media has promoted individuals' education, which may correctly guide or misguide consumers' decision making.^{108,109} This concept was put forward as early as 1976.¹¹⁰ Today the consumer thus has a heightened expectation of the quality of care he or she will receive. Similarly, consumers come to receive medical care because of media education, whereas in the past that level of education was not available.^{111,112} As of today, the media are just beginning to be used by OT and PT professions, in the hope that this media use will educate the public regarding when, where, and how to decide on whether to seek our services. It will be a few years before research can be done to determine if this use of media will assist in educating the public.

Many aspects of today's lifestyles do not reinforce wellness. The obesity seen throughout the industrialized world proves that point.¹¹³⁻¹¹⁵ Yet whether the client takes some responsibility for his or her functional problems and recovery depends a great deal on whether the health care provider gives some to him or her. Today's literature certainly reinforces the need for patient responsibility and active participation in one's own functional recovery.¹¹⁶⁻¹²⁴ This change in responsibility may be caused by third-party payers and the lack of funding versus promotion of a new health care model in which the patient is an active participant, but as long as the change occurs, the world will be better served.

Fink¹²⁵ in 1980, over three decades ago, recognized the importance of the provider-patient relationship. The state of what is referred to as *health* varies for each client and includes both the simple and complex variables of that client's life, from the last nutritional meal to the totality of the client's life event history (see [Figure 1-5](#)). The relationship of the therapist and the client can lead to better use of the health care system by giving responsibility to the consumer.^{126,127} The therapist has an advantage over most other health care practitioners, who see the patient at infrequent intervals and who seldom touch the patient as a PT or an OT does.

The illness or trauma of the client that represents a disintegrating force in his or her life may represent an opportunity for the therapist to grow professionally. The client and the therapist may have different psychological backgrounds, and, although the client's presence is usually related to a medical crisis, the therapist's presence may support the purposes of personal growth, financial gain, prestige, and unconscious gratification in influencing the lives of others through professional skill.¹²⁸

As the consumer becomes more involved, so should the family.¹²⁹ Patients in therapy have always been happier with the family involved.¹³⁰ The therapist must be willing to facilitate the involvement of the family members and help them learn to take responsibility for some of the care and decision making. Most health care professionals are not conditioned to allowing patients and family members to

assume responsibility for their own care; however, better outcomes can be achieved if this is permitted and accepted.

Therapists are caught up in the same problems of the health care system as other health care professionals. Inflation has often caused profit to become a more important motive than human care considerations for setting priorities in our clinics. Research is heavily focused on technical procedures, yet the relationship with patients in the care process is vital. Singleton¹³¹ labeled this phenomenon a paradox in therapy. Despite the commitment to humanistic service on which the profession was founded, the service rendered is often mechanistic.

The educational programs should emphasize whole-patient treatment, increased communication skills, interdisciplinary awareness, and patient-centered care.^{44-46,132} The change in roles described previously requires a professional who demonstrates a potential for the assumption of many roles, responsibilities, and choices along the care pathway. The therapist working with the client with neurological problems must always be ready to respond to triggers anywhere along the pathway from early intervention, midway during a crisis, or later during long-term care, because these triggers signal a need for change. Of equal importance, the path must be well documented to empower the therapist to reflect on current and prognosticated treatment intervention.

The Provider's Role in the Relationship

Gifted therapists are often thought to have intuition. Yet intuitive behavior is based on experience, a thorough knowledge of the area, sensitivity to the total environment, and ability to ask pertinent questions as the therapist evaluates, conceptualizes about, and treats clients (Chapter 5). How these questions are formulated and the answers documented vary among therapists, but the result is the formulation of a unique profile for each client.

Cognitive-perceptual processing by the client will often determine the learning environment to be used, the sequences for treatment, and the estimated time needed for therapeutic intervention. Thus the client is in a position to play an important role with the therapist within the clinical problem-solving process. In that interactive environment, the therapist can ask questions regarding cognitive, affective, and motor domains that will help clarify, document, and guide future decisions regarding empowerment of the client. (See the client profile questions regarding cognitive, affective, and sensorimotor areas in [Boxes 1-1, 1-2, and 1-3](#).) The motor output area is the main system the client uses to express thoughts and feelings and demonstrate independence to family, therapists, and community. This motor area cannot be evaluated effectively by itself while the cognitive-perceptual and the affective-emotional areas are negated. If that rigidity becomes a standard of care, accurate prognosis and selection of appropriate interventions will continue to be inconsistent and lack effectiveness within the clinical environment. No one will question that therapists today need to use reliable and valid examination tools in order to measure efficacy of our interventions. Finding the link between structured examination and intuitive knowledge is a characteristic of master clinicians. Even therapists who intuitively know a patient's problem need to use objective measures today to verify that intuition. Therefore third-party payers can justify

BOX 1-1 ■ COGNITIVE AREA QUESTIONS FOR CLIENT PROFILE

- A. Sensory input: awareness level
 1. What sensory systems are intact, and which have impairments?
 2. Are any sensory systems in conflict with others?
 3. If conflict between systems is present, to which system does the client pay attention?
- B. Perceptual awareness and development
 1. What specific perceptual processing deficits does the client have, and how would that affect motor performance?
 2. Do the perceptual problems relate to input distortion, processing deficits, or both? If input distortion is alleviated, is information processed appropriately?
- C. Preferential higher-order cognitive system
 1. Was or is the individual's primary preferential system verbal, spatial, or kinesthetic?
 2. Is the client's preferential system different from yours? If so, can you work through the client's system?
 3. Is the client's preferential system affected by the clinical problems?
 4. Can the client adequately use nonpreferred systems?
- D. Level of cognition
 1. Is the client functioning on a concrete, abstract, or fragmented level?
 2. Does the client's level of cognition change? If so, when and why?
 3. Is the client realistic? Does the client exercise judgment? If so, when? If not, when and why?
 4. Which inherent systems or outside influences are interfering with or distorting the client's potential? (Systems within the individual and the environment around the client, such as the staff, the family, and the other patients, must be considered.)

BOX 1-2 ■ AFFECTIVE AREA QUESTIONS FOR CLIENT PROFILE

- A. Level of adjustment or stage of adjustment to the health condition
 1. At what level or stage of adjustment is the client with respect to the system problem and ability to participate in functional activities?
 2. At what level of adjustment is the family?
 3. Will the level of adjustment of the client or family affect treatment?
 4. If emotions are affecting treatment, what can be done to eliminate this problem?
- B. Level of emotional control
 1. Can the client exercise impulse control?
 2. When does the degree of emotional or impulse control vary?
 3. How did and does the client respond to stress?
 4. How did and does the client respond to perceived success and failure?
 5. What types of stresses outside of the specific physical system problems are being placed on the client?
- C. Attitude (attitude toward bodily system problems and the functional ability is covered to some degree under level of acceptance, although additional information needs to be gathered)
 1. Before the onset of the bodily system problem, what was the client's attitude toward individuals with cognitive and/or motor system problems, and specifically, those related to his or her primary system problem?
 2. What is the client's attitude toward your professional domain?
 3. What is the family's attitude toward individuals with bodily system limitations and inability to participate in normal life activities, especially those related to its family member?
 4. What is the family's attitude toward your professional domain?
- D. Social adjustment
 1. At what social developmental stage is the client's performance?
 2. Is the social interaction in alignment with cognitive and sensorimotor stages of development?
 3. Are the family's social interactions and expectations at the level of the client's performance?
 4. Is the client's level of social adjustment the same as the rehabilitation team's level of expectation?
 5. Is the client aware of his, her, or others' socially appropriate or inappropriate behavior?

BOX 1-3 ■ SENSORIMOTOR AREA QUESTIONS FOR CLIENT PROFILE

- A. Level of motor performance with respect to performance
 1. Is the client's level of motor performance or sensory and motor integration congruous with the staff's expected performance level?
 2. Is the client's level of motor control integration congruous with the family's expected performance level?
 3. Is the client's level of motor function congruous with his or her expected level of performance and participation?
- B. Functional skills
 1. What functional skills does the client perform in a normal fashion?
 2. What functional skills does the client perform given systems limitations?
 3. What functional skills has the client learned to perform that are reinforcing stereotypical patterns or hindering normal movement and the ability to participate?
 4. What functional skills do the client and family consider of primary importance? Will breaking these down to smaller component skills hinder normal learning?
- C. Abnormal patterns
 1. What patterns are present?
 2. When are these normal and abnormal patterns observed? Do they vary according to spatial positions?
 3. Is there ever a shifting or altering in degree of these abnormal patterns? If so, under what circumstances does this variance occur?
- D. Degree of cortical override
 1. Does the client need to inhibit abnormal output by intentional thought, or does he or she use procedural adjustment through normal feed-forward mechanisms?
 2. What amount of energy is being used to override abnormal output?
 3. Can the client use cognitive systems to control motor output?
 4. What amount of energy are you demanding the client to use when attending to the task? Are you asking the client to fully attend to the specific motoric task, or are you overloading the system to take away some cortical attention?

payment for services while the patient benefits from the intuitive guidance in the clinical decision making by the therapist.

Once the therapist has a clear understanding of the client's strengths and weaknesses, specific clinical problems can be identified and treatment procedures selected that allow flexibility in treatment sessions. Many treatment suggestions for various problems can be found in Chapter 9 and Chapters 11 to 27.

CONCLUSION

In this sixth edition of the textbook, we hope to bring the reader into the clinical practice of the twenty-first century. As the professions continue to evolve in depth and breadth, the future will encapsulate the knowledge, skill, and lessons of the past and the needs and problems of current and immediate health delivery systems while maintaining unique scopes and parameters of practice in an ever-changing environment. The professions must adapt and grow as they embrace change without losing the integrity

and philosophical reasons they came into existence. The only concept that is guaranteed in the future is *change*. Both physical and occupational therapy are dynamic professions with the ability to adapt and evolve to provide the health care service expected and deserved by the consumer. The future is up to every practitioner. The consumer of our services is dependent on our willingness to learn, adapt, and provide a high quality of care at an appropriate cost for the best outcomes. We have done that in the past, are doing it in the present, and will continue doing it in the future.

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 132 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Health and Wellness: The Beginning of the Paradigm

JANET R. BEZNER, PT, PhD

KEY TERMS

paradigm
perceptions
well-being
wellness
whole person

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Define and differentiate the terms *health* and *wellness*.
2. Describe the characteristics of wellness.
3. Compare and contrast illness, prevention, and wellness paradigms.
4. Identify and analyze a variety of wellness measures.
5. Synthesize a wellness approach into neurorehabilitation.

In learning to cope with the often chronic nature of their conditions, individuals with neurological disease, not unlike individuals with health conditions of other systems, learn to rely on their abilities to adapt and compensate for their activity limitations and participation restrictions to regain the ability to participate in life. Although not an uncommon approach to life for any human being, the achievement of health or wellness takes on an increased focus for individuals with chronic health conditions, and it is strongly correlated to the quality of life they achieve. A casual consideration of the terms *health* and *wellness* indicates that they are similar, if not the same, in meaning, a commonly held belief among those without health conditions. This interpretation of the terms becomes problematic, however, in the presence of health conditions. Can an individual with a health condition be well? Can a person without a health condition be ill? The concepts of health and wellness and their associated meanings and measures will be explored in this chapter to provide a perspective for movement specialists that will enhance their ability to promote health and well-being in clients with neurological disease.

DEFINITIONS AND RELATIONSHIPS AMONG TERMS

The classic understanding of the term *health* from a biomedical perspective is “absence of disease.” The antonym of *health*, therefore, is disease. The World Health Organization contributed to the confusion between the terms *health* and *wellness* when in 1948 it defined *health* as “a state of complete physical, mental and social well-being, and not merely the absence of disease or infirmity.”¹ Indeed, there are numerous illustrations of the influence of the mind and spirit on the body and thus the importance, from a public health perspective, of considering more than the physical state of the body when formulating solutions to health problems. However, there is also value in differentiating health from more global concepts such as wellness and quality of life, if for no other reason than to explain the phenomenon that an individual can be diseased and well or can experience a high quality of life while simultaneously living with a chronic

disease. Considering the catastrophic nature of many neurological diseases that compromise physical health, it is even more important to distinguish between health and wellness to recognize and pursue avenues to enhance overall quality of life and well-being.

H. L. Dunn first conceptualized the term *wellness* in 1961 and offered the first definition of the term: “an integrated method of functioning which is oriented toward maximizing the potential of which the individual is capable.”² Since Dunn’s introduction of the term, numerous researchers and educators have attempted to explain wellness by proposing various models and approaches.³⁻¹¹ Although the literature is full of references to and information about wellness, including numerous definitions of the term, a universally accepted definition has failed to emerge. Several conclusions can be drawn, however, from the abundance of literature regarding wellness.

For many people, including the public, health and wellness are synonymous with physical health or physical well-being, which commonly consists of physical activity, efforts to eat nutritiously, and adequate sleep. Research has indicated that when the public is asked to rate their general health, they narrowly focus on their physical health status, choosing not to consider their emotional, social, or spiritual health.¹² Referring to the definition of wellness from Dunn, and consistent with numerous other theorists, it is obvious that wellness, as it is defined, includes more than just physical parameters.

The common themes that emerge from the various models and definitions of wellness suggest that wellness is multidimensional,^{2,4-13} salutogenic or health causing,* and consistent with a systems view of persons and their environments.^{2,15-17} Each of these characteristics will be explored.

First, as a multidimensional construct, wellness is more than simply physical health, as the more common understanding of the term might suggest. Among the dimensions

*References 1, 2, 4, 7, 8, 10, 14.

included in various wellness models are physical, spiritual, intellectual, psychological, social, emotional, occupational, and community or environmental.¹⁸ Adams and colleagues¹⁸ in 1997, toward the aim of devising a wellness measurement tool, proposed six dimensions of wellness on the basis of the strength and quality of the theoretical support in the literature. The six dimensions and their corresponding definitions are shown in Table 2-1.

The second characteristic of wellness is that it has a salutogenic or health-causing focus,¹⁴ in contrast to a pathogenic focus in an illness model. Emphasizing the factors that cause health (e.g., salutogenic) supports Dunn's² original definition, which implied that wellness involves "maximizing the potential of which the individual is capable." In other words, wellness is not just preventing illness or injury or maintaining the status quo; rather, it involves choices and behaviors that emphasize optimal health and well-being beyond the status quo. Thus an individual may or may not be well before pathological conditions and health conditions involve the body and similarly may be well during an acute episode or chronic pathology or health condition whether that chronic problem results in static activity limitations or even progressive participation restrictions.

Third, wellness is consistent with a systems perspective. In systems theory each element of a system is independent and contains its own subelements, in addition to being a subelement of a larger system.^{12,15,16} Furthermore, the elements in a system are reciprocally interrelated, indicating that a disruption of homeostasis at any level of the system affects the entire system and all its subelements.^{15,16} Therefore overall wellness is a reflection of the state of being within each dimension and a result of the interaction among and between the dimensions of wellness. Figure 2-1 illustrates a model of wellness reflecting this concept. Vertical movement in the model occurs between the wellness and illness poles as the magnitude of wellness in each dimension changes. The top of the model represents wellness because it is expanded maximally, whereas the bottom of the model represents illness. Bidirectional horizontal movement occurs within each dimension along the lines extending from the inner circle. As per systems theory, movement in every dimension influences and is influenced by movement in the

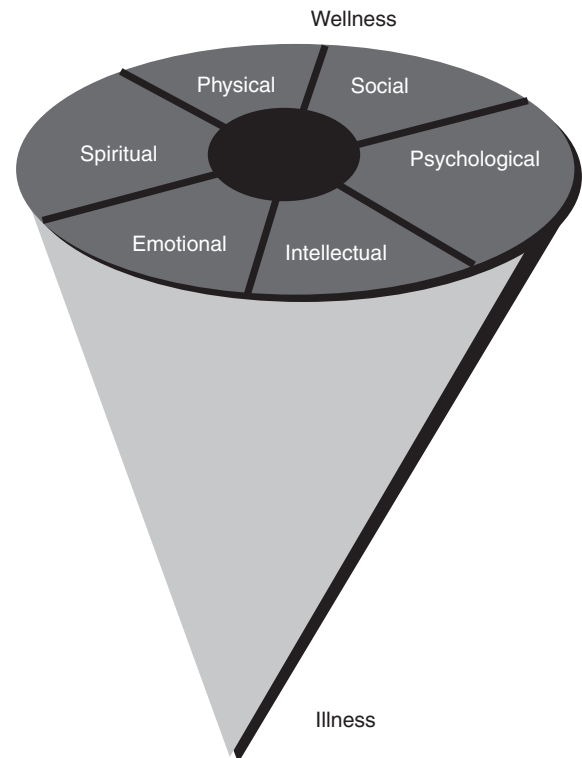

Figure 2-1 ■ The wellness model.

other dimensions.¹⁸ As an example, an individual who has a knee injury and undergoes surgery to repair the anterior cruciate ligament will probably have at least a short-term decrease in physical wellness. Applying systems theory and according to the model, this individual may also have a decrease in other dimensions such as emotional or social wellness in the postoperative period. The overall effect of these changes in these dimensions will be a decrease in overall wellness, which anecdotally we know occurs when patients have an illness or injury.

A term related to wellness, *quality of life*, is also used to indicate the subjective experience of an individual in a larger context beyond just physical health. Quality of life has been defined as "an individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards, and concerns. It is a broad ranging concept affected in a complex way by the person's physical health, psychological state, level of independence, social relationships, and their relationship to salient features of their environment."¹⁹ Parallel to the issues related to the concept of wellness, there is lack of agreement in the literature on the definition of quality of life and its theoretical components,²⁰⁻²³ as well as variation in the use of subjective or objective quality-of-life indicators.²¹ Implied by the World Health Organization definition, and supported by several other authors, quality of life is best conceptualized as a subjective construct that is measured through an examination of a client's perceptions. In other words, quality of life, like wellness, is the subjective experience of health, illness, activity and participation, the environment, social support, and so forth, and it is best measured through an assessment of client perceptions.

TABLE 2-1 ■ DEFINITIONS OF THE DIMENSIONS OF WELLNESS¹⁸

Emotional	The possession of a secure sense of self-identity and a positive sense of self-regard
Intellectual	The perception that one is internally energized by the appropriate amount of intellectually stimulating activity
Physical	Positive perceptions and expectancies of physical health
Psychological	A general perception that one will experience positive outcomes to the events and circumstances of life
Social	The perception that family or friends are available in times of need, and the perception that one is a valued support provider
Spiritual	A positive sense of meaning and purpose in life

A WELLNESS PARADIGM

The ultimate importance of gaining an understanding of health and wellness is to be able to apply it when interacting with patients/clients. In this sense, the goal would be to improve the health and well-being of the client, in addition to improving movement and participation. A comparison of the traditional “illness” paradigm with both “prevention” and “wellness” paradigms will identify ways in which a physical or occupational therapist can incorporate a wellness paradigm into the treatment of a patient with a neurological condition in the context of rehabilitation. The three approaches or paradigms are contrasted in Table 2-2 on six parameters, including the view of human systems, program orientation, dependent variables, client status, intervention focus, and intervention method.

As stated previously, in a wellness paradigm each dimension or part of the system affects and is affected by every other part, resulting in an integrative view of the human system. In contrast, in a traditional illness or medical model, the systems are independent. There are specialties in medicine by body system (e.g., neurology, orthopedics, gynecology), and in many physical and occupational therapy education programs, courses are arranged by body system (e.g., neurology, orthopedics, cardiopulmonary physical dysfunction, psychosocial), as indicators of the independence of the systems. In a prevention approach, there is recognition that the systems interact, or influence one another, but not in the reciprocal fashion characteristic of wellness.

The program orientation of an illness paradigm is the pathology or disease-causing issue, whereas the orientation of a prevention paradigm is normogenic, meaning efforts are aimed at maintaining a normal state or condition (e.g., normal muscle length, tone). Shifting to a wellness paradigm requires a salutogenic or health-causing approach,¹⁴ with a focus on how to achieve greater well-being, health, or quality of life. This shift emphasizes the capabilities and abilities of the individual rather than the limitations and deficits.

The variables of interest in an illness paradigm are clinical variables, such as blood tests, $\dot{V}O_2$ max (maximum volume of oxygen use), and tests of muscle strength. Changes in these variables result in labeling the patient more or less ill. In a prevention paradigm, the variables measured are behavioral—for example, whether the individual smokes, exercises, or wears a helmet. Positive improvement in a

prevention approach typically results in a change in an individual’s behavior. In contrast, the variables measured in a wellness paradigm are perceptual, indicating what the patient/client thinks and feels about herself or himself. Although clinical, physiological, and behavioral variables are useful indicators of bodily wellness and are commonly used to plan individual and community interventions, their utility as wellness measures falls short.²⁴ Clinical and physiological measures assess the status of a single system, most commonly the systems within the physical domain of wellness. It can be argued that behavioral measures are a better reflection of multiple systems because of the importance and influence of motivation and self-efficacy on the adoption of behaviors, but they do not describe the wellness of the mind. On the other hand, perceptual measures, capable of assessing all systems and having been shown to predict effectively a variety of health outcomes,^{18,25-29} can complement the information provided by body-centered measures insofar as they are valid, congruent with wellness conceptualizations, and empirically supportable.²⁴

The influence of perceptions on health and wellness has been demonstrated repeatedly in the literature with a multiplicity of patient/client populations and in a variety of settings. Mossey and Shapiro²⁵ demonstrated more than 25 years ago that self-rated health was the second strongest predictor of mortality in the elderly, after age. Numerous other researchers have replicated these findings in other populations, lending support to the value of perceptions in understanding health and wellness and indicating that how well you *think* you are may be more important than how well you are as measured by clinical tests and measures or the judgment of a health professional. Wilson and Cleary²⁴ argued for the use of perceptions in understanding and explaining quality of life, proposing that health perceptions provide an important link between the biomedical model or clinical/illness paradigm, with its focus on “etiological agents, pathological processes, and biological, physiological, and clinical outcomes,” and the quality-of-life model or social science paradigm, with its focus on “dimensions of functioning and overall well-being”²⁴ (Figure 2-2). Citing studies that have used perceptual measures, including the Mossey and Shapiro²⁵ study, Wilson and Cleary²⁴ state that health perceptions “are among the best predictors of [outcomes from] general medical and mental health services as well as strong predictors of mortality, even after controlling for clinical factors.”²⁴

Shifting to client status in each of the three paradigms, the subject receiving treatment in an illness paradigm is called the *patient*, whereas in a prevention paradigm the subject is a *person-at-risk* because of the focus on risk factors and the maintenance of a state of normalcy. In a wellness paradigm, the client is considered a whole person, to emphasize the multiple systems interacting to produce a state of well-being, and, more important, that a high-functioning or intact physical dimension, although important, is not necessary to achieve a state of well-being or a high quality of life.

Consistent with the client status elements, the focus of intervention in an illness paradigm is on symptoms and in a prevention approach on risk factors. Consistent with a whole-person focus in a wellness approach, the intervention focuses on dispositions. Defined as a prevailing tendency,

TABLE 2-2 ■ THE WELLNESS MATRIX

	ILLNESS	PREVENTION	WELLNESS
View of human systems	Independent	Interactive	Integrative
Program orientation	Pathogenic	Normogenic	Salutogenic
Dependent variables	Clinical	Behavioral	Perceptual
Client status	Patient	Person at risk	Whole person
Intervention focus	Symptoms	Risk factors	Dispositions
Intervention method	Prescription	Lifestyle modification	Values clarification

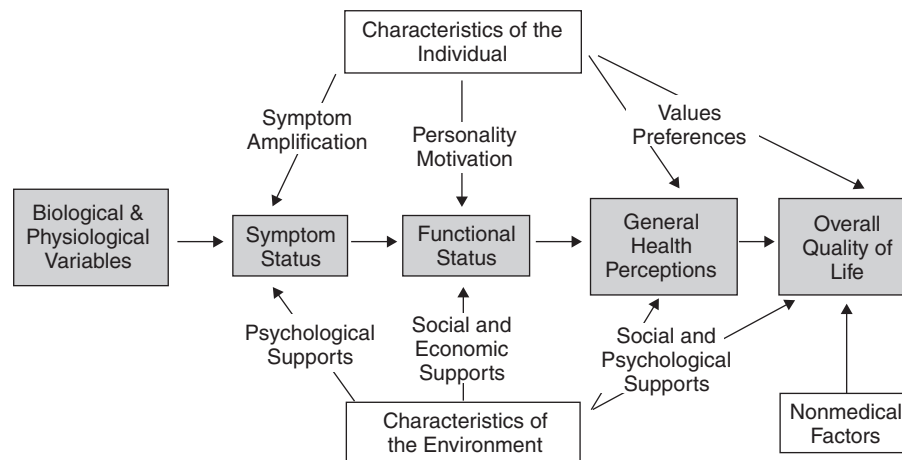

Figure 2-2 ■ Health-related quality-of-life conceptual model. (Modified from Wilson IB, Cleary PD: Linking clinical variables with health-related quality of life. *JAMA* 273:59–65, 1995.)

mood, or inclination or the tendency to act in a certain manner under given circumstances, dispositions produce perceptions, which can be measured to indicate a global or psychosocial assessment of the whole person, given input from all of the systems. Combined with symptom and risk factor assessment, perceptions of the individual provide valuable additional information about a client that can enhance the therapists' ability to intervene and the success of the interventions selected. Table 2-3 lists a few measurement tools that assess client perceptions.

The intervention method used in an illness paradigm is prescriptive. The prescriptive meaning is based on the system affected and symptoms reported. An intervention in

an illness paradigm is prescribed to correct or improve the illness. Given that risk factors are the focus in a prevention paradigm and the aim is to maintain or return the person-at-risk to a normal state, the intervention method that is most appropriate is lifestyle modification in an attempt to change the behavior that is producing the identified risk. The intervention method in a wellness approach is called *values clarification*, and it is consistent with the focus on dispositions and measurement of perceptions. The aim of values clarification is to enhance self-understanding by surfacing the person's perceptions of the situation and its impact on his or her life. When values clarification can precede intervention prescription and lifestyle modification, wellness

TABLE 2-3 ■ SAMPLE ITEMS FROM PERCEPTUAL MEASUREMENT TOOLS

INSTRUMENT	PERCEPTUAL CONSTRUCT	SAMPLE ITEMS (RESPONSES)
Short Form 36 ³²	General health perceptions	“In general, would you say your health is _____?” (excellent, very good, good, fair, or poor) “Compared with 1 year ago, how would you rate your health in general now?” (much better than 1 year ago, somewhat better, about the same, somewhat worse, much worse)
Satisfaction with Life Scale ⁴⁵	Life satisfaction	“In most ways my life is close to my ideal” “I am satisfied with my life” (7-point Likert scale from strongly disagree [1] to strongly agree [7])
Perceived Wellness Survey ²⁸	Perceived wellness	“I am always optimistic about my future” “I avoid activities that require me to concentrate” (6-point Likert scale from very strongly disagree [1] to very strongly agree [6])
NCHS General Well-Being Schedule ⁴⁰	General well-being	“How have you been feeling in general?” (in excellent spirits; in very good spirits; in good spirits mostly; up and down in spirits a lot; in low spirits mostly; in very low spirits) “Has your daily life been full of things that were interesting to you?” (all the time, most of the time, a good bit of the time, some of the time, a little of the time, none of the time)
Philadelphia Geriatric Center Morale Scale ⁴¹	Morale	“Things keep getting worse as I get older” “I am as happy now as when I was younger” (yes, no)
Memorial University of Newfoundland Scale of Happiness ⁴²	Happiness	“In the past months have you been feeling on top of the world?” “As I look back on my life, I am fairly well satisfied” (yes, no, don't know)

will be enhanced because the intervention will be more targeted and considerate of the person rather than the health condition.

MEASUREMENT OF WELLNESS

As a result of the varied way that wellness has been defined and understood, a variety of wellness measures exist. Consistent with the characteristics of wellness described, a wellness measure should reflect the multidimensionality and systems orientation of the concept and have a salutogenic focus. In the literature, as well as in daily practice, clinical, physiological, behavioral, and perceptual indicators are all touted as wellness measures. Clinical measures include serum cholesterol level and blood pressure, physiological indicators include skinfold measurements and maximum oxygen uptake, behavioral measures include smoking status

and physical activity frequency, and perceptual measures include patient/client self-assessment tools such as global indicators of health status (“Compared with other people your age, would you say your health is excellent, good, fair, or poor?”)³⁰ and the Short Form 36 (SF-36) Health Status Questionnaire³¹ (see Table 2-3).

Although some perceptual measures assess only single system status (e.g., psychological well-being, mental well-being), numerous multidimensional perceptual measures exist that can serve as wellness measures. Perceptual constructs that have been used as wellness measures include general health status,³¹ subjective well-being,^{31,32} general well-being,^{33,34} morale,^{35,36} happiness,^{37,38} life satisfaction,³⁹⁻⁴¹ hardiness,^{42,43} and perceived wellness^{18,44,45} (see Table 2-3). Refer to Figure 2-3 for the “Perceived Wellness Survey” used by many professionals to help conceptualize

Perceived Wellness Survey

The following statements are designed to provide information about your wellness perceptions. Please carefully and thoughtfully consider each statement, then select the one response option with which you most agree.

	Very Strongly Disagree	Very Strongly Agree
1. I am always optimistic about my future.	1 2 3 4 5 6	
2. There have been times when I felt inferior to most of the people I knew.	1 2 3 4 5 6	
3. Members of my family come to me for support.	1 2 3 4 5 6	
4. My physical health has restricted me in the past.	1 2 3 4 5 6	
5. I believe there is a real purpose for my life.	1 2 3 4 5 6	
6. I will always seek out activities that challenge me to think and reason.	1 2 3 4 5 6	
7. I rarely count on good things happening to me.	1 2 3 4 5 6	
8. In general, I feel confident about my abilities.	1 2 3 4 5 6	
9. Sometimes I wonder if my family will really be there for me when I am in need.	1 2 3 4 5 6	
10. My body seems to resist physical illness very well.	1 2 3 4 5 6	
11. Life does not hold much future promise for me.	1 2 3 4 5 6	
12. I avoid activities which require me to concentrate.	1 2 3 4 5 6	
13. I always look on the bright side of things.	1 2 3 4 5 6	
14. I sometimes think I am a worthless individual.	1 2 3 4 5 6	
15. My friends know they can always confide in me and ask me for advice.	1 2 3 4 5 6	
16. My physical health is excellent.	1 2 3 4 5 6	
17. Sometimes I don't understand what life is all about.	1 2 3 4 5 6	
18. Generally, I feel pleased with the amount of intellectual stimulation I receive in my daily life.	1 2 3 4 5 6	
19. In the past, I have expected the best.	1 2 3 4 5 6	
20. I am uncertain about my ability to do things well in the future.	1 2 3 4 5 6	
21. My family has been available to support me in the past.	1 2 3 4 5 6	
22. Compared to people I know, my past physical health has been excellent.	1 2 3 4 5 6	
23. I feel a sense of mission about my future.	1 2 3 4 5 6	
24. The amount of information that I process in a typical day is just about right for me (i.e., not too much and not too little).	1 2 3 4 5 6	
25. In the past, I hardly ever expected things to go my way.	1 2 3 4 5 6	
26. I will always be secure with who I am.	1 2 3 4 5 6	
27. In the past, I have not always had friends with whom I could share my joys and sorrows.	1 2 3 4 5 6	
28. I expect to always be physically healthy.	1 2 3 4 5 6	
29. I have felt in the past that my life was meaningless.	1 2 3 4 5 6	
30. In the past, I have generally found intellectual challenges to be vital to my overall well-being.	1 2 3 4 5 6	
31. Things will not work out the way I want them to in the future.	1 2 3 4 5 6	
32. In the past, I have felt sure of myself among strangers.	1 2 3 4 5 6	
33. My friends will be there for me when I need help.	1 2 3 4 5 6	
34. I expect my physical health to get worse.	1 2 3 4 5 6	
35. It seems that my life has always had purpose.	1 2 3 4 5 6	
36. My life has often seemed void of positive mental stimulation.	1 2 3 4 5 6	

Figure 2-3 ■ The Perceived Wellness Survey.¹⁸

the client's perception of her or his wellness. This survey was first published in the *American Journal of Health Promotion* in 1997.¹⁸

Physical therapists assess perceptions as a part of the patient/client history, as recommended in the "Guide to Physical Therapist Practice."⁴⁶ Occupational therapists assess perceptions as part of their focus on human performance and occupation. Some of the kinds of perceptions that can be assessed include perceptions of general health status, social support systems, role and social functioning, self-efficacy, and functional status in self-care and home management activities and work, community, and leisure activities. Although a few of these categories are included in overall wellness, such as general health status and social and role functioning, measuring wellness perceptions specifically can provide additional and more complete information about the patient that both the physical and occupational therapist can use to formulate a plan that can be insightful to the patient/client. Therefore perceptual tools should be used when measuring wellness.

MERGING WELLNESS INTO REHABILITATION

Incorporating wellness into rehabilitation requires that the therapist or provider modify the traditional approach used to treat patients, which involves changing the focus from illness to wellness, being a role model of wellness, incorporating wellness measures into the examination, considering the client within his or her system, and offering services beyond the traditional patient-provider relationship. Establishing a wellness approach also requires that the provider assume the role of a facilitator or partner rather than that of an authority figure.⁴⁷

When a patient is ill, it is often appropriate for the health care provider to act as the expert because the patient has limited ability to provide self-care and is relying on the provider for information and skills to recover and improve. In a wellness paradigm the best approach is to believe that the client knows best in terms of maximizing her or his potential; therefore assuming a partner or facilitator role is more appropriate and will create a relationship in which the client feels empowered to take control. Rather than "making" the client well, the provider can view the client as a whole person within a biopsychosocial context and partner with the client to discover the most appropriate path to achieve wellness. This approach is consistent with a client-centered perspective, in comparison to a biomedical approach in which the emphasis is on impairment and activity limitations.⁴⁸⁻⁵⁰ Recent discussions in the literature by a variety of health care providers suggest there is an important role for a client-centered approach within traditional medical settings.⁴⁸⁻⁵² Client-centered care requires the following:

- Assessment of and consideration for client thoughts, feelings, and expectations
- Education about the client's condition to enhance the client's ability to take responsibility for her or his own well-being
- A shift in professional identity from expert advisor to partner and facilitator
- Excellent communication skills, including the use of language the client can understand and effective listening skills

- Providers who have a high level of confidence in their knowledge and skill to guide clients to optimize their potential (e.g., achieve greater wellness)^{49,50}
- Providers who are role models and who assume the role of facilitator, which will establish a relationship and an environment in which clients can attain greater wellness

It may be most instructive to consider first how a wellness approach could be adopted with clients who are seemingly healthy or without pathology. As experts in movement problems associated with the causes and consequences of pathological conditions, physical and occupational therapists should play a significant role in primary and secondary prevention. Indeed, intervention programs designed by therapists for patients/clients with pathology generally include instruction in preventive behaviors and activities (secondary prevention). Although appropriate and worthwhile, these efforts do not produce the significant outcomes that primary prevention programs might because they are applied after the onset of risk, illness, or injury. Contemporary practice includes a role for the physical and occupational therapist in primary prevention—that is, interacting with clients to promote health and improve wellness *before* they become patients.

Because individuals without overt disease are typically unmotivated to seek professional assistance, consideration must be given to how a provider recruits those without disease. A focus on wellness and health-causing activities is a powerful solution to this dilemma. In a sports or athletic context, this approach would be considered "performance enhancing" and would be marketed to individuals who have goals and ambitions related to improving athletic performance in a specific context (e.g., improving 10K time, increasing cycling distance or speed). In a general wellness context, an appropriate marketing message might be to improve quality of life or productivity, or any subjective measure that a client deems important. The same knowledge and skills therapists use when intervening to prevent injury, delay or prevent the progression of disease, or enhance quality of movement are useful in a primary prevention context in which the goal is to improve quality of life, well-being, and productivity. The difference is the context in which the knowledge and skills are applied. Adopting a wellness paradigm and a client-centered perspective or focus creates an environment surrounding the client-provider relationship that both empowers the client to make meaningful changes and establishes a partnership that is most conducive to change and improvement. The improvement of quality of life or wellness requires a consideration of the client as a whole person, by definition, as discussed previously in this chapter. Using a client-centered, whole-person approach to the design of an intervention program requires a considerably different approach than the traditional, biomedical approach of measuring clinical and behavioral variables to identify impairments and functional loss and creating an intervention aimed at ameliorating the impairment.^{49,50} Suddenly clients are more than their diseases, which sends a much different message and creates a much different relationship between the provider and the client.

Applying this same approach to individuals with chronic health conditions implies that the therapist must attend to more than just impairments and activity limitations and their

causes when designing intervention programs and determining the best approach to adopt with an individual client. It requires consideration of issues such as social support given and received, intellectual curiosity, physical self-esteem, general self-esteem, optimism, and so forth. Recognition of these dimensions of the individual provides a unique

opportunity to keep the client at the focus of the intervention and design interventions in partnership with the client that will stand a greater chance of producing positive, meaningful outcomes.⁴⁹ The following examples attempt to illustrate the adoption and application of a wellness paradigm within neurorehabilitation.

CASE STUDY 2-1 ■ WELLNESS INTERVENTION CONCEPTS IN NEUROREHABILITATION

The client is a 56-year-old poststroke (cerebrovascular accident [CVA]) man who expresses a desire to return to a pre-CVA hobby, fly fishing. In addition to the physical requirements necessary to fly fish, which the therapist would typically assess and then incorporate into the intervention plan for the goal of independence in fly fishing, a wellness approach requires additional considerations. Recognizing the client's desire to fly fish requires the therapist to explore the client's goals and expectations and incorporate them into the intervention plan, as well as to appreciate the role of fly fishing in the achievement of well-being for this client. After the therapist provides education about living after a CVA, the client is aware that fly fishing is a realistic expectation. To understand the biomechanics and physical requirements of fly fishing, the therapist partners with the client to learn the process of fly fishing, thus gaining from the "expertise" of the

client for the purpose of helping the client achieve his goal. The partnership relationship established in this case requires the therapist to be confident that she or he can identify the motor control, motor programming, and perceptual and cognitive aspects of the movement program such as the strength, motion, postural requirements, axial-distal motor relationships for fly fishing, and the client's self-efficacy post-CVA, even though the therapist had never participated in or observed the activity. Throughout the process, excellent communication is required between the therapist and client to ensure that expectations are clear and that understanding is achieved to establish and meet goals. The task of learning how to fly fish may have also required the therapist to go beyond the typical boundaries of traditional care, including challenging reimbursement limitations, to assist the client in his quest for enhanced well-being.

CASE STUDY 2-2

The client is a 25-year-old man with a posttraumatic brain injury who would like to be able to spend more time with his friends. During the discussion about his desires, the therapist, learning that the group plays basketball one or two times per week, inquires about the client's interest in joining the group. The client indicates that he used to play basketball but is concerned about his ability to run and produce the movements necessary to play now. The therapist, in the role of facilitator and partner, assures the client that playing basketball is a

realistic goal and expresses a willingness to assist the client in achieving his goal. To provide the interventions necessary, the therapist must understand the physical requirements of basketball, obtain access to a basket and ball, interact with the client's friends, be open to learning about basketball from the "expertise" of the client, and support and motivate the client. The therapist recognizes that playing basketball with his friends will contribute greatly to the client's overall well-being and is thus a worthwhile goal.

In both cases the therapist functions as the movement specialist, also recognizing, however, the role of movement in the enhancement of emotional and social well-being within a paradigm of overall wellness. The potential contributions this approach can make to the overall quality of life of individuals living with neurological disease are immense and within the scope of practice and abilities of the physical and occupational therapist. Viewing the client within a larger context than the narrowly focused physical dimension provides increased opportunity to have an impact on well-being and quality of life.

KEY TERMS

abnormal movement strategies
 developmental theory
 neuroconstructivism
 nonlinear dynamics
 normal movement strategies
 stages of motor development
 systems theory

OBJECTIVES

After reading this chapter, the student or therapist will be able to:

1. Comprehend the complexity and interlocking nature of human development over a lifetime.
2. Differentiate traditional theories of development from contemporary theories.
3. Analyze the differences among various subsystems within the human organism.
4. Identify elements of physiological changes over a lifetime.
5. Analyze normal movement strategies and identify subsystems responsibility for success of a motor task.
6. Identify normal changes in motor strategies over a lifetime and synthesize differences between normal movement patterns and pathological movement problems across the life cycle.

As physical and occupational therapists assume greater roles in primary care of patients/clients, they recognize the importance of a multifactorial approach. To competently evaluate functional movement across the life span, clinicians must possess knowledge and skills in the development of skilled, refined movement across domains. Only then will therapists be prepared to perform the necessary evaluative and diagnostic testing and effectively develop and implement plans of care aimed at minimizing impairments, maintaining or regaining functional skills, and improving quality of life.

Throughout much of the twentieth century, developmental researchers were heavily focused on skill acquisition from infancy through early childhood.¹⁻³ In the 1970s, as research paradigms directed at motor development and motor learning evolved, it became evident that changes in motor skills were not limited to childhood but occurred throughout the life span. Consequently, the concept of life span development came to incorporate the prenatal period through older adulthood.

During infancy (birth to 1 year) and childhood (1 year to 10 years) acquisition of motor skills coupled with cognitive and perceptual development are the primary foci of developmental researchers and clinicians. As the young child transitions to adolescence (11 to 19 years) and has the opportunity to experience motor behaviors across different environmental contexts, more complex behaviors emerge. Adulthood (20 to 59 years) signals a period when skills are refined and motor behaviors mature. Only through practice and repetition are skills attained and retained. Individuals who continue to use motor learning strategies into late adulthood (60 years through death) often report more successful aging than those who do not engage in such motor skills.⁴

Identifying mechanisms that enable individuals to be successful in acquisition and retention of functional motor

behaviors is critical to examining variables that alter or impair these same behaviors in other individuals. Kandel and colleagues⁵ suggested that “the task of neural science is to understand the mental processes by which we perceive, act, learn, and remember” (p. 3). This view supports the interactive and collaborative nature of intrinsic and extrinsic systems to accomplish motor learning tasks.

Given the interactive nature of different subsystems, it would seem most effective for clinicians to recognize the need for implementing a multidimensional approach when devising intervention programs. To discuss the interactive nature of these issues, this chapter will (1) briefly provide a historical perspective of theories of motor development, (2) discuss domains (cognition, memory, perception, and so on) associated with life span motor development from prenatal development through older adulthood, (3) discuss the impact of various body systems on motor skill acquisition, and (4) describe behavioral changes that may positively or negatively influence motor performance across the life span.

With the focus of this book on neurological rehabilitation, it is imperative to incorporate the complex and interactive nature of the physiological, cognitive, and perceptual systems. Although readers can read about movement development across the life span, it will not integrate into clinical practice until the therapist understands movements of the client and how those movements reflect the summation of systems interacting to allow that individual to express movement, whether that be as a functional task, a written script, or the use of verbal language. Without that link between identified movement and motor control expressing that movement, often the therapist misses critical clues to the analysis of the central nervous system (CNS) of the client and how best to provide an environment that provides the opportunity for that individual to improve functional skills and quality of life. For that reason, figures have been inserted to

help the reader understand the differences among movement patterns across the life span.

THEORIES OF DEVELOPMENT

Development is often portrayed as a series of stages through which an infant progresses, with a fixed order to the sequence.⁶ A developmental theory may be characterized as a systematic statement of principles and generalizations that provides a coherent framework for studying development. Historically, development was thought to be linear, occurring in an invariant sequence and resulting in behavioral changes that are direct reflections of the maturation of anatomical and physiological systems.^{7,8} Development is generally examined in terms of quantitative and qualitative change. Although it is universally accepted that acquisition of developmental skills is not reversible, the underlying principles surrounding the emergence of these behaviors has evolved over the past 50 to 75 years.

Early developmental theorists used neuromaturational models of CNS organization as the framework for conceptualizing development.^{1,2} These researchers provided elaborate descriptions of posture acquisition and a blueprint delineating skill development. Research focused on the emergence of cognitive and affective behaviors and ignored the processes and mechanisms involved in acquiring motor skills.⁹ Several investigators attributed developmental changes to intrinsic variables such as maturation of the CNS, whereas others associated changes with extrinsic variables involving the environment.^{1,2,10,11}

During the 1930s and 1940s, Arnold Gesell and Myrtle McGraw led a cadre of avant-garde researchers exploring the field of infant motor development. Gesell^{1,12} described the normative time frame for when behaviors emerge, and McGraw² examined the underlying mechanisms responsible for the emergence of these behaviors. The underlying premise, the foundation for their elaborate descriptions of motor development, was based on maturational processes in the CNS.

Gesell, a pioneer in developmental research, was a proponent of the theory that nature drives development.¹³ He proposed that growth is a process so complicated and so sensitive that intrinsic factors are solely responsible for influencing development. He used the evolutionary thinking of Darwin and Coghill to explain changes in motor behaviors. Coghill,¹⁴ in his work with salamander embryos, reported that motor behaviors, like swimming, emerge in an orderly sequence as connections of specific neural structures appear. Coghill concluded from his observations of emergence of behaviors in the salamanders that human infant motor behaviors appear in a predictable sequence and at predictable chronological ages.

With Coghill's research as the foundation for his thinking, Gesell embraced the concept of a hierarchical organization of the CNS. He believed that the emergence of motor behaviors was contingent on maturation in the CNS and concluded that only after the emergence of higher-level neural structures would complex motor behaviors appear. Within this constrained theoretical perspective, extrinsic or environmental stimuli, human or otherwise, were thought to have little impact on the appearance of motor behaviors. Gesell concluded that infant development is preprogrammed and linear, emerging at predetermined stages or periods in

time.¹³ Perhaps his greatest contribution to motor development was the conceptualization of milestones as markers to evaluate infant behavior.

Although McGraw was a proponent of ontogenic development as one variable influencing motor development, she did not believe, as Gesell did, that it was the sole determinant.¹⁵ Rather, McGraw attempted to explain the emergence of motor behaviors through environmental influences as well as CNS maturation.² She examined the temporal and qualitative aspects of motor skill acquisition through her study of Jimmy and Johnny,¹⁶ a study of twin brothers in which one twin was provided an exercise program, whereas no intervention was afforded the other twin. She found temporal and qualitative differences in the boys' acquisition of motor skills and attributed differences in acquisition of these behaviors to disparities in practice opportunities.

McGraw believed that the acquisition of the movement (process) is as important as when (chronological time frame) the behavior is acquired (the outcome). She further elaborated that, within the constraints imposed by the developing CNS, a rich and challenging environment can and does facilitate temporal efficiency in acquisition of motor behaviors. And finally, she proposed that practicing motor skills influences emergence of the same behavior.

Sufficient evidence exists to support the premise that although some predetermined processes occur at relatively similar points in development, not all motor behaviors emerge at the same biological, chronological, or psychological age in every individual. Although motor milestones provide information regarding outcome, no information can be derived about the process of attaining motor skills from those specific milestones. Perhaps a more realistic explanation may be that emergence of new skills occurs out of a need to solve specific problems within the environment. Working within this context, it is evident that traditional theories of development and maturation fail to adequately encapsulate the innate variability in human development.^{9,10}

Within the last few decades, researchers have used more current theories of development when designing studies involving infants and young children.¹⁷⁻¹⁹ These investigators examined the process of skill acquisition rather than using traditional methods that assess outcome as a measure of motor development.²⁰

Although early pioneers in developmental research described development as linear, uniform, and sequential, Thelan and Smith²¹ depict development as "messy," "fluid," context-sensitive, and nonlinear. Linear and nonlinear dynamics are derived from mathematics. Linear dynamics is described by the proportional relationship of the initial condition to the outcome, whereas no such proportional relationship exists in nonlinear dynamics. Nonlinearity is used to describe complex systems, in this case biological or more specifically human systems.²² Within these complex systems exists a level of unpredictability, given the interactive and interdependent nature of biological systems.

Thelan and Smith²¹ suggested that, although traditional theories of development support the premise that behaviors emerge in accordance with a relatively fixed temporal sequence, an organism may exhibit "precocial" abilities when the context is altered and the behavior emerges earlier than expected. These authors stated that immature systems exhibit behaviors that are variable and easily disrupted.

Although development of some organisms in a controlled laboratory environment may reflect more traditional perceptions of development, outside, in a more naturalistic environment, development is more likely to be flexible, fluid, and tentative. Thelan and Smith also found that factors most likely to have an impact on performance are the “immediacy of the situation” and the “task at hand” rather than “rules” of the performance. Given this perspective, Thelan and Smith²¹ identified six goals as essential to developmental theory. These goals are as follows:

1. To understand the origins of novelty.
2. To reconcile global regularities with local variability, complexity, and context-specificity.
3. To integrate developmental data at many levels of explanation.
4. To improve a biologically plausible yet non-reductionist account of the development of behavior.
5. To understand how local processes lead to global outcomes.
6. To establish a theoretical basis for generating and interpreting empirical research.²¹ (p. xviii)

Thelan and Smith urged developmental researchers to devise paradigms that attempt to explain development in terms of diversity, flexibility, asynchrony, and “the ability of even young organisms to reorganize their behavior around context and task” (p. 18).²¹

Contemporary theorists inferred that developmental changes are nonlinear and emergent and may be the result of the interactive effects of intrinsic and extrinsic variables. This divergence from traditional thinking compelled avant-garde scholars to propose new theories.^{21,23,24} Investigators described behaviors as complex, interactive, cooperative, and reflects an ability to organize and regroup around task and context, rather than conforming to a rigid structure and rule-driven hierarchy, as many earlier cognitive researchers believed.^{21,24} Contemporary theorists exploit technology to derive a model to explain variability and flexibility in developing, mature, and aging populations.²⁴

GENERAL SYSTEMS THEORY

Systems theory, first described by von Bertalanffy in 1936, was not discussed in great detail until 1948. In 1954 von Bertalanffy and colleagues from three other professions met to discuss systems movement.²⁵ Theorists then applied systems theory to a variety of human and nonhuman systems. As theorists became acquainted with systems theory, they became more receptive to alternate theoretical proposals of growth and development in living organisms.

Systems theory may be applied as a transdisciplinary model examining relationships of structures as a whole.²⁶ “The notion of a system may be seen as simply a more self-conscious and generic term for the dynamic interrelatedness of components”²⁶; von Bertalanffy proposed this theory to more adequately describe biological systems, investigate principles common to all complex organisms, and develop models that can be used to describe them.²⁶

Principles that embody general systems theory include nonsummative wholeness, self-regulation, equifinality, and self-organization.²⁶ Contrary to systems theory in disciplines such as traditional physics, in which systems are said to be *closed*, von Bertalanffy suggested that biological systems are open and modifiable and that changes in the system

are the result of the dynamic interplay among elements of the system.²⁶

Embedded in the general systems theory is nonlinear dynamics, a concept in which behaviors are not described as the sum of their parts. Thus within a nonlinear model, a mathematical model is derived.^{24,27} Characterized within this model is the notion that systems may change in a sudden, discontinuous fashion. During development a small increase or decrease in one parameter leads to changes in the behavior. This abrupt change, identified as a bifurcation, causes the system to move out of its previous state and toward a new state of being.

Throughout development, periods of rapid differentiation or change occur when an organism is most easily altered or modified. These periods were identified by Scott²⁸ as “critical periods.” Physiological systems are most vulnerable during these periods and may be seriously affected by both intrinsic and extrinsic factors acting on the system. These periods occur at different times for different body systems. Understanding systems theory and the concept of critical periods is crucial to all aspects of motor development.

As scientists began to revisit theories of motor development, they discarded some of the traditional theories and embraced contemporary concepts of nonlinear dynamics.^{24,25,27} Proponents of nonlinear dynamics contend that modifications in motor behaviors are the result of dynamic interactions among the musculoskeletal, peripheral and central neuromuscular, cardiovascular and pulmonary, and cognitive and emotional systems.²⁶ These interactive, multidimensional elements are vulnerable to changes in organizational and behavioral abilities (system) over time.^{28,29} Some theorists propose that as skills are acquired and organizational or behavioral changes occur, the system is driven to identify the most efficient and effective strategy to produce motor behavior(s).^{28,29} Yet others purport that variability implies that typical healthy individuals may use a variety of strategies to produce the same behavioral outcome and that variability is an indication of the individuals’ flexibility in responding to unpredictable perturbations.^{24,30} Implicit in nonlinear dynamics is the concept of critical periods in development.^{28,29,31} Investigators suggested that interventions imposed during a critical period may more easily positively or negatively modify the behavior. Recognizing the crucial role systems theory and critical periods play in development is vital to comprehending how developmental skills emerge. The multifactorial nature of nonlinear dynamics illustrates the complexity of development and the difficulty in identifying the appropriate variables that influence motor skill development.

With use of concepts previously described, it is reasonable to expect that a small change in any subsystem may result in a large change in a motor behavior. This is evident in work by Thelan and colleagues examining stepping in infants 8 weeks of age.^{29,31-34} They reported that introducing a small change in one element of the system, identified as a small weight applied to an infant’s leg, resulted in the infant being unable to step. The authors deduced that small changes in one subsystem, in this case the musculoskeletal system, may result in a change in the outcome. This lends support to the hypothesis that modifying one aspect of a multicomponent system, especially during a critical

period, may cause the system to evolve into an entirely new behavior.

Periods of rapid differentiation, although often observed during early life, have also been observed across the life span. Changes in anthropometric measures, such as weight gain during pregnancy, influence coordination between limbs and cause emergence of a different gait pattern. Changes in one system, in this case the endocrine system, result in increased ligamentous laxity at the pelvis and also contribute to gait alterations.

Menopause may be another critical period. During menopause, decreases in hormone production are thought to lead to osteoporosis and cardiac disease.³⁵ Examples described previously provide evidence across the life span that the dynamic interplay within a system and among systems may significantly influence emergence and disappearance of behaviors.

Although research in the beginning of the twentieth century was heavily focused on development of the very young, studies during the latter part of the century were directed toward research on aging. Technological advances in medicine have dramatically increased life expectancies. During the twentieth century, the number of individuals in the United States older than 65 years old grew from 3 million to 35 million.³⁶ Perhaps the most significant statistic is that the oldest old grew from 100,000 in 1900 to 4.2 million in 2000.³⁶ By 2011 the Baby Boomer generation will begin turning 65 years old, and the number of older individuals will increase sharply between 2010 and 2030.³⁶ By 2030, Americans over the age of 65 years will represent nearly 20% of the population, and by 2050 the number of individuals over the age of 85 years could grow to 21 million.³⁶ Given this incredible demographic transformation and that current policymakers are, in large part, the generation directly affected by these statistics, a significant paradigm shift in funded research has evolved over the past quarter century. “As such, aging and death are inseparable partners to growth and development”³⁷ (p. 32). Recognizing that a critical mass of Americans are entering older adulthood, terminology that operationally defines and is then applied consistently when referring to the aging population or an individual is imperative.

Biological and Chronological Age

Age can be described in terms of chronological age and biological age.³⁸ Chronological age is the period of time that a person has been alive, beginning at birth. In infants it is measured in days, weeks, or months, whereas in adults it is expressed in terms of years and at times decades.

Although chronological age is measured in terms of temporal sequencing, biological age is related more to functioning and physiological aging of organ systems.³⁹ For example, a triathlete may have biologically younger cardiovascular and pulmonary systems than same-age peers who do not perform high-level aerobic activities. Another example might be a child who underwent precocious puberty. Precocious puberty, identified as puberty earlier than 8 years of age in girls and 9.5 years in boys, results in acceleration in a biological system before same-chronological-age peers.⁴⁰ Physiological changes include elevated hormonal levels, which would then stimulate development of breast tissue and early menstruation in girls. Changes in the musculoskeletal

system include early closure of the epiphyseal plates, resulting in significantly smaller stature. Conversely, these young women’s reproductive cycles are significantly skewed. Women would also have menopause and aging issues associated with hormonal changes earlier than other women of the same chronological age. Although no consistent method has been established for measuring biological age, there is general agreement that a wide variability of biological aging exists and that a number of factors contribute to accelerated or decelerated biological aging.

Aging

“Aging refers to the time-sequential deterioration that occurs in most animals including weakness, increased susceptibility to disease and adverse environmental conditions, loss of mobility and agility, and age-related physiological changes” (p. 9).⁴¹ Although Goldsmith’s description of aging is typically viewed as an inevitable fact of life, there is scientific evidence and theoretical support for the idea that age-related changes will eventually be more medically treatable than previously thought.^{38,41,42}

Scientists are hesitant to attribute a decline in functional movement in older adults to a decline in physiological systems or to diminished opportunities for practice or conditioning.⁴ Rowe and Kahn reported that “with advancing age the relative contribution of genetic factors decreases and [of] the nongenetic factors increases” (p. 446).⁴ Age-related factors that are modifiable may be used to identify individuals who may or may not age successfully. For instance, lifestyle choices, including diet, physical activity, and other health habits, and behavioral and social factors have a potent effect and accelerate or decelerate aging. Evidence to support this was initially derived from a 10-year study conducted by Rowe and Kahn.⁴³ The authors identified three critical factors that contribute to aging successfully: avoidance and absence of disease, maintaining cognitive and physical functioning, and “sustained engagement in life.”⁴³ Recently researchers suggested that Rowe and Kahn’s classification of successful aging is too restrictive and may lead to classifying individuals with relatively minor health problems as unhealthy. McLaughlin and colleagues⁴⁴ suggested that a critical variable in defining successful aging is first identifying what the goal is for measuring successful aging. Only then can researchers determine how best to define and measure successful aging. Although controversy exists regarding defining successful aging, factors that contribute to successful aging hinge on higher levels of physical activity, increased social interactions, and positive perception of health, as well as no smoking, chronic diseases (arthritis, diabetes), or impaired cognition.^{45,46} Consequently, developing healthy behaviors early in life may be critical to maintaining good health and may play a significant role in successful aging. Factors associated with aging are generally identified as either age related or age dependent. Age-dependent changes within organ systems are observed in individuals at a similar age, whereas age-related changes may be accelerated or decelerated in same-age individuals on the basis of intrinsic or extrinsic factors related to lifestyle. Just as variables associated with lifestyle (extrinsic factors) influence aging, genetics (intrinsic factors) also play a significant role. From a genetic perspective, structural and functional changes are generally thought to be a consequence of aging and are

therefore predictable and consistent across physiological systems. Variables thought to influence the genetic potential for longevity include environmental factors such as toxins, radiation, and oxygen free radicals. Free radicals are highly reactive molecules produced as cells turn food and oxygen into energy.⁴⁷ In summary, the use of biological age rather than chronological age may be a more accurate reflection of an individual's true age.

Theories of Aging

Throughout the twentieth century, the average life expectancy of individuals living in the United States increased. The second half of the twentieth century signaled a shift in the focus of human development research, from infant and child development to older adult development.

Scientists view aging as a progressive accumulation of changes over time that increases the probability of disease and death.⁴⁸ Given that portrayal of aging, researchers have proposed myriad hypotheses regarding aging. Aging theories evolved because there is no single factor or mechanism responsible for physiological aging.³⁸ Biological aging theories, similar to developmental theories, are attributed to complex, underlying mechanisms.^{38,41,42,49} Although theorists attempt to classify aging theories, these theories are rarely mutually exclusive. Some theories were formulated around control of physiological functioning, others around cellular changes, and still others around genetic causes.

Neuroendocrine theory is based on the premise that hormones play a significant role in aging.^{42,49} Hormones are vital to repairing and regulating bodily functions. Hormone production decreases significantly during aging and limits the body's ability to repair and regulate itself as effectively. Although hormonal decline is one plausible explanation for age-related changes, it does not account for all changes. Harman⁵⁰ proposed the free radical theory on the basis of his investigations that examined the effects of radioactive materials on human tissue.⁵⁰

Harman reported that when human tissue is exposed to radiation, a byproduct is formed. He identified the byproduct, an unstable compound, as a free radical. Over time, human tissue with free radicals showed evidence of biological defects consistent with accelerated aging. Harman postulated that accumulation of free radicals in human tissue may also occur as a part of the normal aging process. This became known as the free radical theory of aging.⁵⁰⁻⁵²

Free radicals are highly reactive molecules that damage proteins, lipids, and deoxyribonucleic acid (DNA). In some instances the free radicals combine with enzymes and turn into water and a harmless form of oxygen that moves harmlessly through the cells.⁵¹ In other instances the oxygen binds with intrinsic or extrinsic sources that influence the aging process.

Scientists have suggested several different ways that free radicals influence aging through intrinsic and extrinsic mechanisms.^{51,52} An example of an intrinsic mechanism would be chronic infections that extend phagocytic activity and expose tissues to oxidants, creating cumulative oxidative changes in collagen and elastin. Extrinsic sources of free radicals include environmental toxins—for example, industrial waste and cigarette smoke.

Human exposure to intrinsic and extrinsic free radicals causes large numbers of reactive oxygen molecules to interact with DNA, leading to mutations thought to be the cause of a variety of diseases, including cancer, atherosclerosis, amyloidosis, age-related immune deficiency, senile dementia, and hypertension. Although some scientists suggest that aging has many factors that can accelerate or decelerate the process, other scientists suggest a much simpler, preprogrammed theory, known as the Hayflick limit.^{38,51-53}

Hayflick and Moorhead^{53,54} proposed that there is a finite number of times that a normal cell is capable of dividing. Current thinking is that cells are capable of dividing up to 50 times. Cell division is recognized as one way in which cells age and, after attaining the maximum number of divisions, finally die.

The factor thought to limit a cell's ability to divide infinitely is the presence of telomeres. Telomeres are minute units at the end of the DNA chain.⁵³ Each time a cell divides a small amount of the telomere is used in the process. Eventually, when cells have exhausted the supply of telomeres available, the cell is unable to divide and cell death ensues.

Telomerase, a substance that can lengthen telomeres, is available in human cells. Typically, telomerase is switched off in all cells except the reproductive cells. The availability of telomerase in reproductive cells allows for many more divisions than previously observed in the Hayflick limit. In addition to the presence of telomerase in reproductive cells, scientists have also discovered that telomerase remains active in cancer cells. Both reproductive and cancer cells divide well beyond the 50-division limit. Consequently, scientists are now working toward activating telomerase in all cells to slow or stop aging. If scientists are successful in activating telomerase in other cells, it may stimulate skin cell regrowth for burn patients and cure diseases that result from failure of aging cells to divide, as in macular degeneration or Hutchinson-Guilford progeria syndrome.^{55,56} The downside of this is that scientists may have a difficult time controlling the telomerase and in fact may see more uncontrolled cell growth—cancer—one of the greatest threats to prolonged existence.

Although many aging theories are directed at mechanisms that negatively influence aging, other theories are focused on factors that have a positive impact on aging processes. One such process is the caloric restriction theory.^{50,52,53,57} Liang and colleagues,⁵⁷ with use of several genetic mouse models, investigated the impact of dietary control on the life span. The authors reported that the mice did, in fact, have their life spans extended when their dietary intake was controlled. Although these findings are potentially significant, given the small sample size and model examined, these data were not generalizable to all species. The researchers suggested that these preliminary data provide a foundation for scientists to examine whether dietary control will extend the life span in humans as it did in the mouse models.

Although a large body of literature exists examining the underlying mechanisms associated with aging, it seems inconceivable that any one mechanism is responsible for age-related changes. More likely is that aging may be attributed to multiple factors, including lifestyle choices, in combination with the physiological and environmental factors.⁵⁸

Garilov and Gavrilova⁵⁸ conducted an exhaustive review of aging theories and concluded that additional research is necessary to further elaborate and validate existing aging theories and dispel unlikely theories.

In summary, scientists are unsure how much of the decline in motor behaviors in older adults is attributable to true decline in physiological systems, how much is attributable to expected decline, how much to a decreased ability to perform skilled behaviors under variable conditions, and how much to decreased practice or conditioning.⁵⁹⁻⁶² This suggests that physical or occupational therapy intervention may provide older adults with strategies to positively influence successful aging rather than being applied only after a negative outcome of aging is realized or a neurological insult has occurred.

The exogenous and endogenous variables of aging are thought to be interrelated and provide an expansive description of the deleterious changes at the cellular, organ, and system level that accompany both aging and many age-associated diseases. The accumulation of damage is in DNA, proteins, membranes, and organelles, as well as the formation of insoluble protein aggregates. Many organ systems, such as the cardiovascular system, the brain, and the eye, are not programmed for indefinite survival. Consequently, the inability to maintain the integrity of tissues and organs is the end result of the multidimensional aspect of aging.

PHYSIOLOGICAL CHANGES IN BODY SYSTEMS ACROSS THE LIFE SPAN

Organ systems undergo critical physiological changes across the life span. These alterations are observed most often during periods of rapid differentiation. Applying concepts of dynamic systems theory to life span development may help to explain how small changes in biologic systems have a significant impact on the individual as a whole.

Examining interactions among variables within different body systems may provide insight into when one system may play a greater or lesser role in acquisition, retention, or deterioration of functional motor behaviors. The next section will examine how different systems develop and their contribution to functional movement.

Musculoskeletal System

Structural and functional adaptations in the musculoskeletal system are evident across the life span. The musculoskeletal system provides a structural framework for the body to move and serves as protection for the internal organs.

Skeletal muscle tissue first appears during the fifth week of embryonic development and continues to develop into adulthood.^{53,63} During this early period of embryonic development, the differentiation of musculoskeletal system is rapid: during the fifth week of embryonic life the limb buds appear, by the seventh week muscle tissue is present in the limbs, and limb movements emerge as early as the eighth week of prenatal life.^{40,64,65}

Whereas many of the structural aspects of the musculoskeletal system are formed prenatally, muscle and bone continue to grow into adulthood. Motor skill acquisition involves considerable variability among young children from age 5 months through 3 years. During this time, the rate of growth of muscle tissue is reportedly two times faster than that of bone.⁶⁶

Structural and functional differences in the musculoskeletal system of a child versus an adult are attributed to the presence and predominance of muscle fiber types. For example, infant muscles are composed predominantly of type I (slow-twitch) fibers, whereas adult muscles contain types I and II (fast-twitch) fibers. Behaviorally, infant movements are characterized predominantly by postural movements. The capacity to produce a greater repertoire of movements, including rapid or ballistic movements, emerges later in development.

Distinct differences also exist in temporal differentiation of the muscular systems of males and females of the same chronological age. Through adolescence, boys show evidence of a significantly greater increase in fiber size compared with girls.⁶⁷ In addition, differences exist in the age at which the number of muscle fibers dramatically increases. Girls reportedly have a steady increase in the muscle fibers from 3.5 to 10 years of age. In contrast, boys have two periods of rapid differentiation in the number of muscle fibers. The first period occurs from birth until 2 years of age and the second from ages 10 to 16 years.⁶⁷ Although the pace slows considerably, muscle fiber development continues in men and women well into middle adulthood.

Age-related changes evident in the musculoskeletal system include decreased fiber size, loss of muscle mass, denervation of muscle fibers, decline of total muscle fiber number, and decreased quantity of fast-twitch fibers.⁶⁸⁻⁷⁰ Muscle mass decreases beginning at around age 50 years, and by age 80 years up to 40% of muscle mass has been lost.⁷¹ Muscle force production likewise decreases at a rate of about 30% between 60 and 90 years of age. Additional musculoskeletal changes documented in older adults include decreased tensile strength in bone, reduced joint flexibility, and limited speed of movement. Decreased muscle mass in a person older than 60 years may be attributed to decreased size, fewer type II muscle fibers, and an increase in fat infiltration into the muscle tissue.^{72,73} Clinically these factors manifest as reduced muscle force production during high-velocity movements.

Currently, scientists are examining the premise that, as an individual ages, muscular changes are more likely attributable to decreased motor activity levels and are age related rather than being solely age dependent.^{69,72} Acknowledging that investigators had previously found that muscle power deteriorates more quickly with age, scientists set out to measure training effects in older adults.^{61,74} These investigators concluded that with training older adults were capable of improving strength, power, and endurance.

The skeletal system, similar to the muscular system, experiences periods of growth, stability, and degeneration. The immature skeletal system is composed primarily of preosseous cartilage and physes (growth plates).⁷⁵ More simply, bone in infants and young children is flexible, porous (lower mineral count), and strong with a thick periosteum.^{75,76} Given these properties of immature bone, a child is less likely to have a fracture because the periosteum is strong and consequently the bones absorb more energy before the break point is reached. In addition, if a fracture does occur, healing is usually quicker because callus is formed faster and in greater amounts in children than in adults.

A primary difference between the child's and the adult's skeletal system is the presence of the growth plate complex

in children. Whereas primary ossification occurs prenatally, secondary ossification is not complete until the child reaches skeletal maturity, generally at age 14 years in girls and 16 years in boys.^{76,77}

Even after bones have attained their full length, they continue to grow on the surface. This is termed *appositional growth* and continues throughout most of life. During childhood and adolescence, new bone growth exceeds bone resorption and bone density increases. Until age 30 years, bone density increases in most individuals, and bone growth and reabsorption remain stable through middle adulthood. Later in adulthood, resorption exceeds new bone growth and bone density declines.⁷⁸

Women exhibit more loss of bone mass than men do.⁷⁹ Decreased bone density in women is generally attributed to differences in the types and levels of hormones present. Although the difference is most significant during menopause, premenopausal women still lose bone density at a higher rate than their male peers do.

Osteopenia is the presence of a less-than-normal amount of bone and, if not treated, may result in osteoporosis. Progressive loss of bone density, observed into older adulthood, is commonly identified as osteoporosis. Osteoporosis is more common in women than in men and is a major cause of fractures and postural changes in both sexes.⁸⁰

Overall, much of the growth in the musculoskeletal system is related to demands placed on the system. Intrinsic and extrinsic forces imposed on the musculoskeletal systems of typically and atypically developing children may lead to structural and functional differences in their respective skeletal structures. Consequently, temporal sequencing, acquisition, and characteristics of motor behaviors emerge differently in typically and atypically developing children. Similarly, age-related changes in older adulthood may be accelerated in direct proportion to decreased levels of activity.⁸¹ Older adults who maintain more active lifestyles and place greater physical demands on their musculoskeletal systems are more likely to have an improved bone density and muscle mass than their peers who are not as active.⁸²

Sarcopenia, the age-related loss of muscle mass, affects strength, power, and functional independence in older adults.^{72,82} Although these changes are observed in many older adults, the degree of the muscular changes varies.⁷⁰ Researchers examining sarcopenia in older adults reported that men are affected more by sarcopenia than women are.^{72,83} In fact, men with sarcopenia manifest four times the rate of activity limitations than do men with a normal muscle mass. Changes in the cross-sectional area of muscles directly affect the force production of a given muscle; consequently, as the cross-section of a muscle diminishes, its ability to produce force decreases. As an individual ages the number and size of the muscle fibers decrease, resulting in a reduction in strength.⁸⁰ Although this is true in all muscles, the impact is greater on muscles of the lower extremities than in those of the upper extremities.⁷²

Although strength is critical to musculoskeletal function, flexibility is equally as important. Flexibility incorporates joint motion and the extensibility of the tissues that cross the joint. The degree of flexibility changes across the life span as a direct result of aging and activity level.¹⁰ Changes in flexibility are evident throughout life: limited at birth,

increasing until the individual approaches adolescence, and then gradually decreasing. Exceptions may be seen in athletes, dancers, and other individuals involved in activities that incorporate flexibility training. Loss of flexibility as a consequence of age may have a negative impact on functional independence in older adults. Flexibility is thought to be directly proportional to the amount, frequency, and variability of motor activities performed. As activity increases, so does flexibility. Conversely, as individuals exhibit decreased levels of motor activity, often associated with age, flexibility decreases.⁷⁸

By age 70 years, flexibility is thought to have decreased by 25% to 30%.⁷⁰ Although this was purported to be age dependent, it may be more likely that it is age related.⁶⁹ Regularly performing exercise directed toward improving strength and flexibility can reverse the effects of inactivity for most individuals, even those older than 90 years of age.^{69,81}

Although it may take longer for older individuals to regain strength or flexibility than a young adult or child, musculoskeletal tissue is modifiable throughout life. Modifying the strength and flexibility of an older adult requires that other bodily systems be capable of modifying performance levels to meet the increased needs of the musculoskeletal system.

As scientists continue to examine functional changes across different systems as a consequence of age, physical and occupational therapists must educate individuals regarding the importance of embracing a physically active lifestyle and methods to enhance quality of life at each stage in an individual's life (see Chapter 2). Although all systems contribute to an individual's health and wellness across the life span, the cardiovascular and pulmonary systems play a key role (see Chapter 30).

Cardiovascular and Pulmonary Systems

The cardiovascular system is composed of the heart, lungs, and associated vascular complex. It is responsible for pumping blood through the coronary, pulmonary, cerebral, and systemic circulations, with the goal of perfusing all bodily tissues for the delivery of oxygen and vital nutrients and picking up waste products for elimination. The pulmonary system is responsible for oxygen transport, gas exchange, and removal of airborne pollutants that may enter during respiration (see Chapter 30).

The interdependent nature of the cardiovascular and pulmonary systems is evident in the fact that, each minute, all of the body's blood travels through the lungs before being returned to the left side of the heart for ejection into the systemic circulation.⁸⁴ Because of this relationship, changes in heart function can dramatically affect lung function, and vice versa. In addition, these two systems are connected as part of a larger closed pressure-volume loop through the peripheral circulatory structures. Likewise, any alteration in the function of the peripheral vessels will affect both the heart and lungs, and vice versa.

The function and homeostasis of the cardiovascular, pulmonary, and peripheral vascular systems are influenced by both internal and external forces.⁸⁴ Internal mechanisms of control are based on the autonomic nervous system, the relative health of the anatomic structures involved, the growth and development of the structures, and the behavioral and emotional adaptations of a particular individual.

All those internal mechanisms are subject to changes with growth and development, aging, and the unique life experiences of an individual. Growth and development primarily affect the physics of the system by altering volumes, lengths, smooth and myocardial muscular tension, and physiological capacitance within the system to support the growing body. Numerous effects of aging have an impact on the adaptability of the system. Behavioral and emotional responses influence both autonomic and volitional cardiovascular and pulmonary reactions to stress. External forces include movement environment and activity level, which alter the gravitational forces on the closed pressure-volume system. An increased activity level causes exercise stress, which requires an altered demand for oxygen and nutrients to the structures providing the work. Finally, emotional stress needs to be considered as an external factor. Behavioral responses to stress can affect functional movement and cause maladaptive coping mechanisms on any or all systems. As with anything, the age, cognitive status, and relative health of an individual will dictate the potential success of these endeavors.

Because oxygen transport and exchange are the primary requirements for sustaining life, efforts toward maximizing the efficiency of the cardiovascular and pulmonary systems represent a fundamental component of therapeutic practice. It is critical that no matter where a patient falls in the life span, strategies for screening, prevention, and rehabilitation of the cardiovascular and pulmonary systems be incorporated into a comprehensive plan to promote optimal mobility and independence.⁸⁵ It is essential for therapists to keep in mind that all interventions have a direct or indirect impact on these systems and that it is their responsibility to monitor and manage those responses to maintain safety.

A detailed understanding of the anatomy of the heart, lungs, and vessels, as well as the physiology and interrelationship of the organs involved, is essential to the practice of both physical and occupational therapy. Refer to Chapter 30 for additional information. For pediatric therapists, the added knowledge of normal growth and development of these structures is critical.

From weeks 3 to 8 of fetal life, the cardiac structures are formed.^{63,64,86} All other structures of the cardiovascular system are fully developed and functional shortly after birth. Although the left and right ventricles are of similar size at birth, by 2 months of age the muscle wall of the left ventricle is thicker than that of the right ventricle.⁸⁷ This is attributable to the fact that the left ventricle is responsible for pumping blood to the whole body, requiring a higher internal pressure and contractile force, whereas the right ventricle is responsible for pumping blood only to the lungs, a relatively low-pressure function in a healthy individual.

It bears mentioning that the heart's function begets structure. Therefore if function becomes impaired, the structure is likely to adaptively change. For example, if the resistance in the vascular system from the right ventricle to the lungs becomes increased, the right ventricle must pump harder, with a greater volume of blood, to overcome the resistance.⁸⁸ Over time, this will increase the size of the ventricular walls because the myocardium is muscular tissue that is as equally capable of hypertrophy as skeletal muscle tissue.

Structurally, the heart doubles in size by year 1, and its size increases fourfold by year 5. Many of the changes associated with size are complete by the time the child has reached maturity. Recall that cardiac output (CO) is equal to stroke volume times heart rate. As the size of the heart increases (increasing the volume capacity for each stroke), the heartbeat decreases and the blood pressure increases.⁸⁹ Heart rate in a newborn infant is generally 120 to 200 beats per minute (bpm), 80 bpm by 6 years of age, and 70 bpm by 10 years of age.^{87,90} Systolic blood pressure (defined as maximal pressure on the artery during left ventricular contraction or systole) is 40 to 75 mm Hg at birth and increases to 95 mm Hg by 5 years of age.⁸⁷ Blood pressure continues to rise into adolescence. The capacity to maintain exercise for longer periods and greater intensities increases through early childhood. Although cardiovascular disease is generally associated with adults, children as young as 5 years of age may show signs of or be at risk for cardiovascular disease if they do not engage in regular aerobic activity.^{87,91}

Development of the pulmonary system occurs late in prenatal and early postnatal life.⁹⁰ As the lungs increase in size, tripling in weight during year 1, the capacity and efficiency increase while the respiratory rate decreases.⁹⁰ Although the vital capacity of a 5-year-old child is 20% of an adult's, this is not usually a limiting factor during exercise.⁸⁹ Overall, aerobic capacity increases during childhood and is slightly higher in boys than in girls. The overall work capacity of children increases most dramatically from 6 through 12 years of age.⁸⁹ Peak oxygen consumption is achieved early in adulthood and changes in direct relation to activity levels. Lungs of an average adult at rest take in about 250 mL of oxygen every minute and excrete about 200 mL of carbon dioxide.⁹²

As activity decreases in older adulthood, so do the structural and functional capacities of the cardiovascular and pulmonary systems. Many of these changes are a result of decreased elasticity of the tissues, decreased efficiency of the structures, and decreased ability to increase workload. CO decreases approximately 0.7% per year after age 20 years so that by age 75 years the CO is 3.5 L/min, down from 5 L/min at age 20 years.⁹² Functional changes include a decrease in the overall maximum heart rate from 200+ bpm through young adulthood to 170 bpm by age 65 years.⁸⁷ Older adults have less elastic vessels, and resistance to the blood volume increases. Consequently, older adults reach peak CO at lower levels than do younger individuals. These cardiovascular changes may be compounded by inactivity, resulting in decreased capacity to perform activities that raise metabolic demands and increase the requirement for oxygen transport.⁹³ The impact of these normal aging responses, however, can be reduced through structured aerobic and anaerobic activities. Conversely, physiological performance of the cardiovascular and pulmonary systems improves in response to growth and development.

Throughout life, performance of motor activities and activities of daily living (ADLs) is highly dependent on the integrity of an individual's cardiopulmonary and cardiovascular systems. Introduction of aerobic activities during early childhood has implications for improved health and wellness across the life span. Although aging has a negative

impact on performance and efficiency of the cardiovascular and pulmonary systems, aerobic exercise has a positive impact on these systems. Changes in the cardiovascular and pulmonary systems have a significant impact on other systems and consequently on overall body function. Information from these systems, including blood pressure and oxygen saturation rates, is communicated through the nervous system. The nervous system, in turn, regulates responses of the cardiovascular and pulmonary systems through the autonomic nervous system.

Neurological System

The nervous system encompasses the CNS and the peripheral nervous system (PNS). The CNS includes the brain and spinal cord, and it is responsible for all bodily functions. The PNS includes both the autonomic and the somatic nerves and is responsible for transporting impulses to and from the CNS.⁵ The capacity for humans to produce behaviors far beyond those of other animals is directly related to the complex abilities of the CNS and interneuronal communications.

Over the past two decades, technological advances have enabled neuroscientists to dramatically improve their understanding of the molecular changes in the nervous system over time.⁹⁴ Development of the CNS is coordinated through intrinsic influences involving the temporal and spatial coordination of synaptic connections with genetic processes, along with extrinsic or environmental factors. Initially, development of the CNS is dependent on precise connections formed between specific types of nerve cells and begins with the recruitment of cells that form the neural plate, which gives rise to the neural tube, and then differentiation of regions of the brain begins.^{5,95} Changes in the nervous system are predicated on critical periods, or times when different regions of the brain are sensitive to change, and occur across the life span.^{5,28}

Each region of the brain is thought to undergo critical or sensitive periods at different ages. One of the most critical periods in development of the CNS occurs from birth through 1 year of age. During this period, when the system is most vulnerable to change, intrinsic and extrinsic variables may influence the nervous system structurally and functionally.

Differentiation of cells in the nervous system begins during the embryonic period and continues throughout adulthood.^{5,94} Development of the nervous system during embryonic life involves the overproduction of glial cells and neurons that, after they are no longer useful, die. Additional developmental changes noted in the nervous system include increased myelination within the brain and an increase in neuronal size.⁶³ Much of the growth may be attributed to these changes in the nervous system and may account for the development of the infant's brain, which increases to one half the size of the adult brain during the first year of life. Neural development, particularly in the cerebral cortex, documented early in development may emerge out of environmental demands and the need to solve problems (tasks). Consequently, experiences can alter neural networks, and more complex experiences lead to increasing complexity of the neural structures.⁹⁶ Whereas researchers long supported the premise that decline of the nervous system begins generally after age 30 years, more recent studies indicate that

adults, even older adults, can form new neural connections and grow new neurons as an outgrowth of learning and training.^{94,97} Before the work of Eriksson and colleagues, researchers and clinicians believed that structural changes in older adults, such as decreased numbers of corticospinal fibers, intracortical inhibition, and neuronal degradation in centers in the CNS, particularly the cerebellum and basal ganglia, were inevitable.⁹⁸ In contrast, findings from a study conducted by Draganski and colleagues⁹⁹ challenged traditional constructs that the only possible changes in the adult human brain were the result of negative changes caused by aging or pathology. Instead these researchers suggested that a direct relationship existed between learning a novel task, juggling, and structural changes in the gray matter. The authors caution that these structural changes were task specific and limited to the training period. Reexamination of magnetic resonance imaging (MRI) scans, after 3 months of no training, demonstrated that subjects no longer displayed the same structural changes as during juggler training.

Loss of neurons in the centers controlling sensory information, long-term memory, abstract reasoning, and coordination of sensorimotor information negatively affects function. For some individuals this may not have significant implications. For others, CNS changes create serious functional losses. Alterations in the CNS, including altered neural control and decreased efficiency in temporal sequencing of muscle synergies, may play a role in postural instability and impaired sensation. Together these changes can result in falls.⁶⁸

Although the CNS, similar to other bodily systems, may have the capacity to compensate for some age-related changes, the degree of compensation may be modulated by the complexity of the task and continuation of "practice" over time. Although some investigators have reported that neuromuscular systems in older adults may not be as flexible as systems in younger adults, new studies examining changes in mature and aging systems are still in the early stages. Neuromuscular systems in older adults may not be as capable of rapidly reorganizing muscle synergies to produce variable functional responses.⁹⁸ The researchers did say that this may be related not solely to the aging neurological system but to other factors including experience, cardiovascular and musculoskeletal fitness, and current level of functional independence. Other scientists suggested an alternative view that repetition of motor activities may stimulate new growth in dendrites located proximal to neurons previously lost.⁶⁸ The authors were quick to add that, although the pathways or connections may be activated, this may or may not result in improved functional ability. Implicit in performance of many functional activities is cognition. If changes in cognition coexist with changes in other systems, it may be difficult to accurately interpret the underlying causes.

Cognitive System

Cognition may be defined as awareness, perception, reasoning, and judgment.¹⁰⁰ Cognitive development involves processes of perception, action, attention, problem solving, memory, and mental imagery. Action, from the perspective of physical or occupational therapy, may be referred to as *functional movement(s)* and incorporates all the processes described previously to successfully perform a specific task.

Jean Piaget, one of the most recognized scientists in developmental psychology of the twentieth century, was particularly intrigued with how biological systems affect what individuals “know.”^{100,101} He observed interactions among children of different ages and hypothesized that younger children’s thought processes were different from those of older children as evidenced through the differences in responses between them to the same questions.

Piaget proposed that cognitive development moved in a linear, stagelike progression, each stage of which involves radically different schemes.¹⁰¹ He suggested four stages of cognitive development, identified as sensorimotor state (infancy), preoperational (toddler and early childhood), concrete operational (childhood and early adolescence), and formal operational (adolescence and adulthood).¹⁰⁰ He proposed that (1) sensorimotor behaviors stimulate cognitive development and (2) problem solving as a measure of cognition enables infants and young children to identify and modify motor behaviors.

Piaget’s theory of cognitive development focused around how humans adapt within the environment and how these adaptations or behaviors are controlled.¹⁰¹ He postulated that behavioral control is mediated through schemas or plans, generated centrally. These schemas provide a representation of the world in an effort to formulate an action plan. At birth, infants’ earliest schemas are organized around reflexive behaviors that are modified as the infant adapts to the affordances and constraints of the environment.

Piaget suggested that adaptations occur through two processes: assimilation and accommodation.¹⁰¹ He defines *assimilation* as a process of altering the environment around cognitive structures. An example of assimilation is when an infant, initially breast-fed, is transitioned to bottle feeding. *Accommodation* refers to changes of the cognitive structures to meet changing demands of the environment. Accommodation may be involved when an infant transitions from nutritive sucking (breast or bottle) to nonnutritive sucking (pacifier).

Much of Piaget’s work was based on descriptive case studies. Although some aspects of his theory were supported by subsequent studies, other aspects of his work have not been shown to have empirical evidence. The inconsistencies of research findings examining Piaget’s stages of development may be indicative of the dynamic and nonlinear nature of development and, more specifically, cognition.

Rather than postulating that infants are reflexive beings with little or no volitional movements early on, it may be more appropriate to view infants as competent beings with volitional and complex behaviors present at birth.¹⁰² Brazelton reported that a newborn infant turns toward the mother’s voice rather than toward an unfamiliar voice. In addition, research conducted by Meltzoff and Moore¹⁰³ provides evidence supporting the complex nature of infant behavior. They found that infants as young as 2 to 3 weeks of age can imitate facial gestures performed by adults. Their work was supported by subsequent studies performed by independent investigators using different procedures and in different environments.¹⁰⁴ These findings, contrary to Piaget’s proposal that infants were not capable of imitative behaviors until 1 year of age, provided scientists with a new perspective on infant behavior.

Contemporary researchers approach developmental theory from a dynamic and nonlinear model.^{21,95,96,105} Over the past 10 years, advances in technology (e.g., diagnostic imaging, functional magnetic resonance imaging [fMRI], magnetoencephalography [MEG], event-related potentials [ERPs]) have dramatically improved the ability to document change within the developing brain.⁹⁵ These technological advances coupled with developmental paradigm shifts and computer modeling have led developmentalists to propose new theoretical frameworks to explain cognitive development. One model, called *neuroconstructivism*, incorporates intrinsic constraints and abilities of the CNS at the most basic cellular level with extrinsic influences involving environmental experiences and interactions.^{95,96} Fundamental to the neuroconstructivist theory is the principle of context dependence, in which representations emerge in direct response to the structural changes in the cognitive system. Embedded within neuroconstructivism is the concept of the infant as interactive, in contrast to more traditional developmentalists’ perception of the infant as passive. Experiences that individual infants engage in vary through processes involving competition and cooperation. The processes employed during development may result in differing pathways or trajectories of development through which the outcome or behavior is realized. Despite the variability in the individual developmental trajectories, the behavioral outcome is often similar.

This model is purportedly applicable to typical and atypical development as well as mature and aging systems. In contrast, whereas the processes and interactions among multiple interactive constraints (biological and environmental) may be similar in typical and atypically developing systems, the constraints may differ. Hence, the outcome or emergent behavior may be different.

Current theories lend support to the concept that the cognitive system integrates multimodal input to process, interpret, store, and retrieve information as a mechanism for information processing and problem solving.¹⁰⁰ Changes in cognition, defined as relatively permanent changes in behavior, cannot be measured directly but rather must be inferred from changes observed across multiple systems.

As the ability of infants to act on the environment develops, their ability to accurately detect and process relevant information becomes more efficient, lending support to the interdependence of the motor, cognitive, and perceptual systems.

Information processing, defined as the ability to understand human thinking, is a critical factor that must be examined within the cognitive system. Initially, infants and young children cannot recognize relevant cues or chunk information for storage. As children’s developing systems become more adept at integrating information from multiple systems and more efficient at processing information, they begin to process relevant information more effectively. Consequently, infants and young children may not use or interpret information as efficiently as older children.

The integrative nature of movement, cognition, and perception is evident in developmental psychology literature.¹⁰⁶ Given that these domains are interrelated, one area cannot be examined in isolation of other interrelated systems. Acquisition of motor skills is the primary mechanism for evaluating cognition and perception in prelinguistic

children. In addition, as individuals grow older, changes in any system may influence functional movement. Finally, when examining functional movements, therapists must always consider the individual's cognitive and perceptual abilities.

As higher-level cognitive processing skills become apparent, the child can accurately identify relevant cues, filter irrelevant cues, and process information more efficiently. One such higher-level cognitive processing skill is executive functioning. Adolescence signals a period during which executive functioning begins to mature.¹⁰⁷ This period may be characterized as critical in CNS development. During this critical period, production of mature, adult-like decisions requires selective attention and increased integration of information via the prefrontal cortex. During the maturation process, adolescents may exhibit inconsistent decision making, resulting in less-than-optimal outcomes. By young adulthood, as the individual approaches maturity, optimal executive decision making becomes more consistent.

Human systems are continuously pelted with sensory information through some or all of the sensory modalities. At any one time much more sensory information is available than can possibly be processed. Consequently, the individual must learn to select information relevant to the task and chunk the information for processing.

Another example of the multidimensional processes involved in higher-order tasks such as functional movement is found in a study conducted by Hazlett and Woldorff.¹⁰⁸ They proposed that implicit in motor tasks are concepts of cognition including attention, perception, and information processes. This multimethodological approach examined (1) the influence of attention on sensory and perceptual processing, (2) the executive control of attention by higher centers of the brain, and (3) the processes underlying multi-sensory integration and the mechanisms by which attention interacts with such integration processes.¹⁰⁸

Throughout the life span, physical growth and development of many systems have an impact on the acquisition and performance of motor skills. Changes in one system and the interactive effects on all other systems can lead to deleterious changes in motor performance as a whole.

A new paradigm that embraces the concept that memory and cognition do not deteriorate as part of normal aging is a topic of discussion in scientific literature.¹⁰⁹ This perspective was proposed after Gould and colleagues¹⁰⁹ conducted a study that found that adult primates continue to develop new brain cells throughout life. The addition of new neocortical neurons throughout adulthood provides a continuum of neurons of different ages that may form a basis for marking the temporal dimension of memory. These late-generated neurons play an important role in learning and memory of older adults.

Changes in cognitive function are often revealed during tasks that require processing and retrieval of cognitive or motor memory. Consequences of aging include slowed information processing and increased time necessary to perform motor skills. Even though learning may take more time in older adults, once a behavior is learned, retention is similar to that of younger individuals. Of significance for older adults is delayed performance of long-standing tasks such as driving a car, which may have serious consequences

for the driver, passengers, or others in the immediate vicinity of the vehicle. Delays in processing and task execution pose risks to the older adult or individuals with CNS deficits and may affect the individual's level of independence and quality of life.¹¹⁰

Although older adults experience deterioration in the processing and retrieval of information, the extent of the decline is unpredictable. Cognitive deficits most frequently observed in older adults include word retrieval, recall, dual-task execution, and activities involving rapid processing or working memory.

Memory

Memory can be broken down to three types: working, declarative, and procedural. Working memory, short-term memory, is the equivalent of the RAM of a computer.¹⁰⁰ This is the mechanism that enables a child who does not appear to be attending to what the parent is saying to repeat what the parent has just said. Given the temporary nature of this memory, no space in the hippocampus or amygdala is required. Working memory may in fact be more of a cortical phenomenon. Declarative memory is what is typically envisioned when we think of intermediate or long-term memory. Declarative memory is the area where long-term information about everything an individual has ever learned or information acquired is stored, including facts, figures, and names.¹⁰⁰ An example of declarative memory is a second-grade teacher recalling the name of a student she had in her class 15 years previously. Declarative memory is analogous to the hard drive in the computer. The third type of memory is procedural memory. Procedural memory involves all motor activities, actions, habits, or skills that are learned through repetition in motor practice.¹⁰⁰ Examples of procedural memory include walking, playing an instrument, and driving a car.

Rovee-Collier and colleagues¹¹¹⁻¹¹³ have conducted numerous studies related to memory retention in prelinguistic children. Evidence exists to support the premise that infants as young as 2 to 3 months of age are capable of identifying relevant cues and chunking this information for later retrieval. One caveat is that retrieval of such information is possible only when the specifics of the behavior are retained. Infant memories are tightly linked to the specific information related to the task, environment, and stimulus. Consequently, a slight change in any of these three components may result in an inability to retrieve information from infant memory. Retention of information is directly proportional to the infant's age. As an infant grows older, the period for which information is retained increases.

As children grow older, they develop more effective and efficient strategies to retain information. During adolescence the brain enters a plastic period, particularly in the frontal lobes. Neuronal connections that control sleeping and eating habits, regulate motor behavior, and modulate impulses, decision making, memory, and other high-level cognitive functions change significantly during adolescence. Given the plasticity of the adolescent's brain, it is highly probable that environmental stimuli influence intrinsic changes in the adolescent's CNS.

Across the life span, some aspects of cognition seem to be impaired or changed before others. One area most susceptible to age-associated changes is the prefrontal cortex.

This particular area of the brain is where information critical to executive function, attention, and working memory is stored.¹¹⁴ Although memory is one component of cognition that is generally acknowledged to deteriorate as an individual moves toward older adulthood, not all aspects of memory are affected at the same time or in the same way.

Episodic memory is reportedly the first to be impaired, then working memory (short-term memory).¹¹⁴ Implicit memory and semantic memory remain intact for a much longer period of time. Little information is available about procedural memory, memory of how to perform tasks. Researchers have suggested that an older adult's declarative memory is also affected by normal and neuropathological aging.^{42,114} These investigators suggested that although older adults with deterioration in declarative memory are able to perform tasks, the individual is unable to retain information and consequently unable to learn tasks.⁴² Many factors negatively or positively influence memory, including the nature of encoding or processing that information, such as the source of the material or time of day material is presented.¹¹⁴

Although evidence exists that many aspects of memory decline with age, recent evidence supports the premise that variables other than encoding and retrieving information may have a significant impact on memory and remembering in older adults.^{115,116} Researchers at the University of Kuopio examined memory in older persons and focused on neuropsychological processes as a method for evaluating memory and other functions of the frontal lobe.¹¹⁶ The investigators reported that elderly subjects with subsequent degradation of the frontal lobe had memory loss. These researchers suggested that some aspects of memory loss could be staved off through memory-sharpening activities and games, limitation of alcohol consumption, and participation in activities designed to retain details of skills and tasks. Similar to these findings are the conclusions of May and colleagues,¹¹⁵ who examined the role of emotion in memory tasks for older adults. They reported that older adults seem to be motivated to remember information that is emotionally relevant and meaningful. These findings lend support to yet another system, the emotive system, which could add vital information to an older adult's memory and task performance.

Emotional System

Although current literature does examine the emotional development of children,¹¹⁷⁻¹²⁵ the normal emotional development of adults over a life span remains a mystery. Zinck and Newen¹²⁶ proposed a classification of emotion that might provide a clearer understanding of responses within and between individuals and factors that affect emotion. The authors characterized emotion into four categories based on when the emotions appear developmentally. Emotion is characterized as a means of communicating state, expectations, and reactions of an individual.¹²⁶ Emotions are "interpersonal/interactive" behaviors that enable the individual to communicate to the world. The four categories are pre-emotions, basic emotions, primary cognitive emotions, and secondary cognitive emotions. Pre-emotions and basic emotions function as basic mental representations, whereas primary cognitive and secondary cognitive emotions are categorized as cognitive attitudes.

Pre-emotions are characterized as innate behaviors, present at birth, nonspecific, nonintentional, and used for communication to others about the state of the infant.¹²⁶ Pre-emotions are identified as comfort and distress. These responses may be positive or negative responses depending on the situations. Pre-emotions are the most fundamental sensations followed by basic emotions.

Basic emotions and developmental timing of basic emotions include joy at 2 to 3 months, anger at 3 to 4 months, sadness at 3 to 7 months, and fear at 7 to 9 months. These emotions are said to emerge in the absence of conscious processing of stimuli. These responses are shared by other mammals, and do not involve complex cognitive processing. These behaviors lead to faster and more stereotypic responses.¹²⁶

Primary cognitive emotions are characterized as basic emotions with more specificity, in addition to a cognitive component. Primary cognitive emotions are highly dependent on the individual's cognitive development as well as cultural variations and socialization.

Secondary cognitive emotions are depicted as complex constructs that involve social relations, with consideration for expectations of the future. Consequently, secondary cognitive emotions are highly dependent on personal experiences and culture. The authors provide an example of how one situation—high performance in academics—would be perceived by different cultures. Whereas a child from one culture might receive praise for and exhibit pride in high academic performance, a child from another culture could have such performance deemphasized and display shame. In addition to cognition, secondary cognitive emotions incorporate social constructs of family, culture, previous experiences, and environment in formulating complex responses. These responses are cumulative, using previous experiences to render new responses.

Typically, emotional "development" emerges in childhood. Examination of emotion in adults often involves a retrospective analysis of the behavior over a specified period of time. Although the focus of the research may be directed toward emotion, memory cannot be disentangled from the emotion. With regard to aging in older adults, researchers generally have reported that emotions—in particular, negative emotions—diminish later in life. Some researchers have suggested that diminished negative emotions may be attributed to decreased functioning in the amygdala.¹²⁷ Still other investigators have suggested that, rather, a decline in the functioning of the amygdala and decreased ability to recall negative experiences may be attributed to the socioemotional selectivity theory (SST).¹²⁸ The SST involves prioritization of memories and which temporal boundaries play a role in prioritization. Specifically, older adults do not perceive negative emotions as a priority; hence older adults are more likely to process positive emotions than negative.

A literature search of "normal emotional development across the life span" was limited in scope and volume.¹²⁹ Problems in normal emotional development can be identified throughout medical literature, but again the emphasis is on children and adulthood emotional problems stemming from either pathological conditions or environmental conditions during childhood.¹³⁰⁻¹³⁵ Within the literature, the reader can find discussions of emotional intelligence in adults and how emotional skills such as empathy or cultural sensitivity might

be taught.¹³⁶⁻¹⁴² Specific aspects of an emotion or mood change and how that might assist or hinder an individual within a psychosocial environment can be located,¹⁴³⁻¹⁴⁶ but the integration of the entire emotional system and its normal changes throughout life still eludes researchers. Future research directed toward aging and emotion has potential to broaden the theoretical perspective by examining emotional experiences in an ecological context.¹⁴⁷ In addition, identifying, measuring, and analyzing variables that appear to make a difference in social and professional success will be future scholars' dissertation studies.¹⁴⁸ (See Chapter 5 on the limbic system and its influence on motor control and Chapter 9 on psychosocial adaptation and adjustment for additional information.)

Language

Consistent with all areas of development, acquisition of language, receptive and expressive, is measured quantitatively and qualitatively. Critical to the acquisition of receptive and expressive language is sensory, cognitive, perceptual, and motor development in the infant and child. Researchers have found evidence that language development emerges through nonverbal gestures or "signs"¹⁴⁹⁻¹⁵³ and is evident as early as 6 months of age.^{152,153} As the number of nonverbal gestures increases, verbal communication reportedly emerges earlier than in infants who do not use nonverbal gestures.^{150,152,153} "Gesture thus serves as a signal that a child will soon be ready to begin producing multi-word sentences."¹⁵⁴ Having a large number of gestures at 18 months of age positively affects later language development and is the foundation for later linguistic abilities.¹⁵¹

Imitation, such as "mama" or "dada," is often the first form of verbal communication, progressing to spontaneous single-word utterances. Infants produce their first spoken single-word utterances as early as 12 to 15 months of age.¹⁵⁵ During this time the child's brain is undergoing rapid differentiation in Broca's area; at the same time, motoric ability to communicate verbally is emerging. Consequently it is evident that intrinsic (neurodevelopmental) constraints and extrinsic (environmental) factors affect the emergence of receptive and expressive language. Investigators examining utterances in children and adults reported that utterances produced by children do not approximate those of adults until 14 years of age.^{156,157} Recently researchers reported that, consistent with findings of earlier investigators, articulatory movement speed increases from birth to adulthood.¹⁵⁷ Throughout childhood, as language acquisition emerges, children become more sophisticated in communicating and more fully integrate information from intrinsic and extrinsic sources to produce more complex utterances.¹⁵⁵

Maner and colleagues¹⁵⁶ reported that children exhibited increased variability when a five-word sentence was embedded in longer sentences than when the child spoke only the five-word sentence. These findings led the investigators to infer that a relationship existed between language processing and movement in young children.¹⁵⁸ In addition, adults reportedly modified the five-word sentence when it was embedded in the longer sentence, but 5-year-olds did not modify the utterance. Sadagopan and Smith¹⁵⁹ replicated the work of Maner and colleagues¹⁵⁶ and found that children aged 5 to 16 years exhibited more variability when the five-word sentence was embedded in a more complex sentence

compared with when the five-word sentence was spoken in isolation. Young adults (21 to 22 years old) reportedly did not exhibit this same variability. In addition, investigators reported that the duration of the simple and complex utterances differed between children and adults. Unlike the youngest children (5 and 7 years), duration of the utterances decreased in adults. This finding provided evidence for the investigators' theory that adults altered or shortened the complex utterances, given the shorter duration taken to utter the complex sentence. Whereas earlier researchers reported that both adults and children decrease their rate of speech during complex sentences,¹⁶⁰ more recently investigators suggested that adults may increase their rate of speech production. Sadagopan and Smith¹⁵⁹ reported that although both children and adults slow the rate of speech production, children exhibited a much slower rate than adults in producing complex sentences. Hence investigators concluded that whereas adults' rate of speech production did explain some of the difference in utterance duration for the simple and complex sentences, it did not fully explain the differences. This led investigators to suggest that differences in utterance duration may be attributed to both faster rate of speech and altered or shortened complex sentences containing the simple five-word phrase.

The dynamic nature of language is grounded in the constructs of dynamical systems theory involving intrinsic and extrinsic mechanisms. These mechanisms evolve over time and are highly sensitive to changes within and between systems.

Perceptual System

As researchers continue to examine the interactive and interdependent roles of body systems, the perceptual system must not be omitted. Perception, yet another process important to performance of functional movements, involves acquisition, interpretation, selection, and organization of sensory information. Perception is the very essence of the interaction between organism and environment. Every movement gives rise to perceptual information and in turn guides the organism to adapt movements accordingly.^{10,161}

Initially perception revolves around the infant's visual exploration of people, objects, and environmental activities. Infants are capable, at birth, of visually exploring their environment, people, and objects.¹⁰¹ Investigators have suggested that infants use information acquired through visual exploration to develop new methods of exploring and discovering cues about the environment such as depth, distance, surface definition, and dimensionality of objects.¹⁶²

A second phase of perceptual exploration emerges as an infant's exploratory behaviors transition to functional movements such as reaching and kicking. Through these exploratory behaviors emerge additional mechanisms for acquiring information about the environment.^{6,161} Throughout development, active exploration enhances perceptual information through each new encounter and enables the infant to recognize distinctive features and similar characteristics that allow the infant to differentiate between objects. The information generated from exploration provides new input to many subsystems, in particular the sensory, motor, and cognitive systems that enable the individual to gain new knowledge about the environment and the action.

Development of the infant's perceptual system is dependent on acquiring new information about the affordances of the task that may influence performance of the action. As the infant develops the capacity for independent mobility, the expanse of the environment increases, as do the opportunities to integrate prior knowledge with newly acquired information to discover uncharted surroundings. This again supports the interactive and interdependent nature of systems throughout development. As maturation progresses, infants develop the ability to evaluate information acquired from various systems and to make decisions about the optimal strategy for successfully navigating over or around a surface. With maturation, successful navigation of new environments depends on opportunities for exploration that may involve other processes in addition to motor processes. An example of this may be seen in a person trying to locate a building in an unfamiliar city. Adults typically use maps as a visual representation of the surroundings that allow them to find the location. Infants and young children are most accurate in locating desired targets through active exploration. This allows the child to acquire spatial information critical to locating the destination at a future time.

If perception is the process of integrating and organizing intrinsic and extrinsic input, then changes in sensory systems as a consequence of aging are certain to affect perception.¹⁶³ The visual perceptual processing system is most often identified as altered in older adults. Specifically, researchers have reported that although older adults are capable of discriminating between variation in depth perception in a manner similar to that of younger adults, they are less able to discriminate between three-dimensional shapes of objects.¹⁶⁴ Clearly the perceptual system is closely associated with many other body systems, and therefore age-related or age-associated structural and functional changes in associated systems will affect the perceptual system.

In addition, May and colleagues¹¹⁵ found that older adults placed less emphasis on perceptual aspects of an event than they did on the emotional components when encoding information. They suggested that older adults may find emotional information to be more meaningful than perceptual information and may retain more elaborate, detailed processing of emotional data than perceptual information.

Although there is no conclusive evidence regarding age-related changes in perception, evidence may be emerging that supports age-associated or individual differences.¹⁶⁵ Nonetheless, the role of perception in aging should continue to be investigated and should not be underestimated or minimized until such time as adequate evidence exists.

MOTOR DEVELOPMENT

Movement is the primary mechanism by which prelinguistic children communicate with their environment. That said, it is no wonder that development of motor skills is greatest during the first 2 years of life. Motor development may be defined as the acquisition, refinement, and integration of biomechanical principles of movement in an effort to achieve a motor behavior that is proficient.¹¹

Early developmental researchers referred to infants as *reactive*, inferring that, early on, infants are responsive to stimuli rather than capable of initiating functional movements. Young infants were characterized as “reflexive” beings producing stereotypic primitive and postural responses to

stimuli. Emergence of these reflexive motor behaviors was based on traditional models of CNS organization and motor development theories. Traditional theories of human development emerged from animal models and studies involving spontaneously aborted fetuses.^{14,166} Traditionally, sucking and stepping behaviors were examples of developmental reflexes. By definition, a reflex is a consistent response to a consistent stimulus. By use of traditional models of CNS organization, developmental reflexes, present at birth, become integrated as higher centers assume control over lower centers and then volitional movements begin to emerge.

Over the past two to three decades, advances in technology have enabled scientists to gain more insight into fetal and infant motor abilities. More recently, research has generated evidence that behaviors emerge out of a need to solve a problem in the environment rather than solely as a result of maturation in the CNS.¹⁶⁷ Given this evidence supporting the premise that newborn infants are capable of producing complex volitional movements, previous views of the infant as passive and “reflexive” are no longer accurate. In addition, continuing to refer to early infant motor behaviors as “reflexes” may also not accurately reflect the behavior. A reflex is defined as a consistent response given in response to a consistent stimulus. Perhaps use of the term *innate motor behaviors* to reflect behaviors that are present at birth may be more appropriate. See Figure 3-1, A to C, for a visual explanation of how the complexity of the stepping reaction of a newborn infant and the learned programming for upright posture and balance, including biomechanical range and force production, will lead to the integration of stepping in standing. Similarly, as an individual ages, loss of some of the postural power, effectiveness of balance reactions, and fear can create a potentially dangerous environment for an elderly person (Figure 3-1, D to E). Likewise, an individual with an abnormal or inefficient stepping pattern (Figure 3-1, F) should automatically stand out to a therapist analyzing movement dysfunction. If a clinician does not have a clear picture in his or her mind of the movement pattern desired, then easily or quickly identifying the system or subsystem motor impairments seen in a client's movement dysfunction may be outside a therapist's analytical repertoire.

Contemporary research refutes the assertion that infants are reactive organisms.^{95,96} In contrast, contemporary studies purport that infants are competent and capable of producing complex interactive behaviors at birth.^{101,168} Additional support for the complex nature of a newborn infant is evident in the infant's ability to discriminate and turn toward his or her mother's voice rather than toward the voice of an adult with whom the infant is unfamiliar.

Evidence from studies examining motor development indicate that motor behaviors do not always emerge in a linear and predictable sequence, nor do all individuals achieve the same skills at the same chronological age.^{8,168} Rather, emergence of motor behaviors in an alternate sequence may be attributed to the intrinsic and extrinsic constraints that contribute to motor development in a nonlinear fashion and is not necessarily indicative of atypical development. Figure 3-2, A is an example of a child who had a very large head at birth. His head circumference was in the

Figure 3-1 ■ Development and integration of stepping, upright vertical posture, and vertical balance reaction: **A**, automatic stepping in a newborn infant; **B**, early cruising or side-stepping using multiple points of support; **C**, early bipedal independent stepping; **D**, 90-year-old client stepping; **E**, 78-year-old client with falling problems; **F**, abnormal stepping after traumatic brain injury.

99.9th percentile and remained so for the first 3 years of his life. His Apgar score at birth was 10, or normal. He was slow in rolling over and coming to sit and spent much of his time playing with his hands and feet and visually exploring the environment. [Figure 3-2, B and C](#) illustrate that his focus was on fine motor development throughout his first year, especially when he was placed in a vertical position. He loved to play catch when placed in a sitting position and accurately trajectoryed the ball toward a partner when playing by age 1 year. His early gross motor development was within the normal range but below the mean. He started independently walking at age 14 months and began running on the same day. [Figure 3-2, D through F](#) illustrate that once he gained control over the heavy weight of his head, he quickly caught up in gross motor skill. And, like any

child, he has taken full advantage of his environment to play and learn.

Motor performance, measured both qualitatively and quantitatively, is highly dependent on the task, the environment, and the individual. Changes in motor performance emerge in accordance with age-dependent changes, within different systems, and with respect to environmental affordances and constraints. As skills emerge in speech, language, and cognition, other previously achieved skills may “regress.” In reality, acquisition of a new skill requires more attention than the previously attained skills; consequently, the infant or child’s attention is divided between the tasks. Lindenberger and colleagues¹⁶⁹⁻¹⁷¹ conducted studies investigating life span changes in resource allocation during multitask activities. The researchers found that for young

Figure 3-2 ■ Head size can affect when a child initiates independent movement activities and whether he develops gross or fine motor skills. **A**, A 2-month-old being fed (note large head). **B**, Child at 5 months old placed in sitting has overcome delayed head control in vertical. **C**, By 9 months old, the child has gained normal head control as well as fine motor skills. **D**, Head control in horizontal crawling. **E**, Child running at 2 years of age. **F**, Normal head control on slide. By 1 year of age, head size is no longer a variable.

children certain tasks require more attention, and attempting to perform such a task in conjunction with a task requiring less attention causes deterioration in performance of both tasks. Hence, deterioration of a previously attained skill is more likely a result of attentional demands of young children performing high-attention tasks rather than a true “regression” of the skill (see Chapter 1, Figure 1-9, p. 18). This progression is illustrated by a child confronted with a new environment, who will seem as if he or she has regressed in motor performance while confronting and solving a task-specific challenge—for example, crossing over a suspension bridge that moves from side to side, is compliant to body weight, and creates a perceptual challenge from the visual surround. Once the child understands the task, his attention is directed toward developing effective strategies to solve a problem and successfully perform the motor behavior of crossing the bridge. Stability or consistency in performing a skilled movement is achieved by self-organization through practice and repetition.²¹ Performance of skilled movements, such as those observed in athletes, is measured not only on the consistency in performing the task but also on the skilled performance of the task under variable conditions.²¹ Conversely, decreased frequency in performing a motor skill as an effect of age may result in a less rich repertoire of normal variability and may be a contributing factor to a decline in motor skills.³⁰ Just as motor skills emerge from a multifactorial interweaving of maturation and experience, deterioration in motor performance may be attributable to alterations in various systems that occur as part of the aging process. Emergence

of motor behaviors is never the same for any two individuals, nor does decline in functional motor behaviors follow the same time line. Figure 3-3 illustrates how standing patterns will change with practice, be maintained as long as practice continues, become extremely efficient within a specific environmental context, or become deficient after CNS injury.

Prenatal (0 to 40 Weeks' Gestation) Development

Motor behaviors emerge early in embryonic life. By the tenth week of fetal life the variety of observed movements increases, as does the frequency of the movements. Complex movements are present by gestational age (GA) 12 weeks, and goal-directed movements may be seen as early as GA 13 weeks. Facial movements, including sucking, swallowing, and yawning, are evident in the second and third trimesters. The fetal activity level increases so that by week 14 GA, periods of quiet (no activity) are only 5 to 6 minutes in duration. Investigators have documented 15 fetal movements visible by 15 weeks of age.¹⁷² After initial observation of a motor behavior, it remains part of the fetal repertoire. Pooh and Ogura's¹⁷² research lends support to the premise that before delivery fetuses are in fact capable of producing complex motor behaviors.

The dynamic nature of birth and the associated change from the intrauterine to the extrauterine environment alter the production of movements previously observed in fetal life.⁶⁵ As the newborn infant adapts to the forces in the extrauterine environment, motor behaviors emerge. These

Figure 3-3 ■ Standing as a functional activity will become procedural with practice and be maintained over a lifetime as long as impairments do not preclude practice or injury to the central nervous system (CNS): **A**, early standing; **B**, relaxed standing as adults; **C**, standing on uneven surfaces; **D**, procedural standing during a functional activity; **E**, advanced skill in standing as ballet dancer; **F**, maintained functional standing in healthy 83-year-old elderly couple; **G**, elderly man developing verticality impairment; **H**, subtle abnormal standing after head injury; and **I**, multiple subsystem problems in standing after CNS injury.

complex behaviors lend additional evidence to the premise that at birth infants are competent beings.

The extrauterine environment poses many challenges for the newborn infant. Consequently, fetal behaviors observed by ultrasonography may not be evident postnatally until the infant learns to adapt to the new environment by modifying movements to accommodate to the new forces imposed by gravity. Newborn infants must learn to use new strategies to generate functional motor behaviors, given the different environmental constraints.

Infancy (Birth to 12 Months)

As alluded to earlier, newborn infants possess a rich array of motor behaviors. During the first year of life, motor behaviors are the primary mechanism for learning. Every movement is a new and unique opportunity to gain knowledge about the environment. During each movement, new information is gathered in an effort to solve environmental problems, and as a result this motor planning fosters cognitive development. Similarly, each movement provides feedback that intrinsically enables the infant to modify movements in accordance with changes in the environment, the skill, or growth parameters.¹⁷³ This interdependence between perception and motor behaviors allows one domain to facilitate acquisition of skills in the other domain in a reciprocal fashion.

Given the capabilities of a newborn infant, many behaviors previously identified as reflexes are in fact functional motor behaviors that the infant is capable of modifying. Evidence that one such behavior, sucking, is not a reflex was supported by studies examining sucking rates when stimuli were varied.^{174,175} Researchers reported that the sucking response varied depending on the level of hunger or environmental stimuli. In addition, when the stimulus is introduced after feeding, after the infant is satiated, the stimulus may produce no response or a diminished response, thus refuting the idea that sucking is reflexive.

Consequently, rather than refer to these behaviors as *developmental reflexes*, it seems more accurate to refer to such motor behaviors, evident at birth, as *innate motor behaviors*. Innate motor behaviors are, in essence, functional behaviors present at birth that are modifiable given alterations in feedback from intrinsic or extrinsic mechanisms.

Additional evidence exists to refute the concept that other motor behaviors are reflexes. Stepping is one such behavior. Thelan and Fisher^{18,32,33} conducted a series of experiments examining the stepping reflex in young infants. Early developmentalists hypothesized that stepping reflexes, present at birth, became integrated and then later emerged as a volitionally controlled movement. Thelan and Fisher^{18,33} found that when one variable, weight, was altered, infants mimicked “integration” or emergence of the behavior. Young infants who were stepping had weights added to their lower extremities, to simulate weight gain over the first few months. These infants stopped stepping. Similarly, infants who did not step were submersed in chest deep water, simulating less weight in the lower extremities, and stepping appeared. Obviously, the presence and absence of this behavior was mediated by weight gain in the lower extremities and not by CNS control as early developmental researchers had postulated. Consequently, upright mobility emerges when the infant is able to garner the force production in the

lower extremities to modulate stepping. This is just one example of the significance of one system on another and the interdependent nature of body systems. Recognizing the interdependence of systems may provide one explanation for the presence or absence of motor behaviors at any given time. These concepts have been transferred into the therapeutic practice environment when working with individuals who cannot generate enough force to produce the movement given the body size or cannot produce the postural stability to reinforce the stepping pattern or one of a variety of other motor components that support normal upright stepping or walking. (See Chapter 4 for theories of motor control and learning, Chapter 8 for therapeutic approaches to assist a client with learning or relearning motor control, and Chapter 37, which introduces emerging practices to bridge the gap between normal human movement development and technologies.)

At birth, an infant is capable of turning toward the sound of her or his mother’s voice and visually focusing on objects 8 to 12 inches from the face.¹⁰¹ These behaviors are apparent when the infant’s head is supported, given that at birth the newborn infant does not have the neck strength to maintain head control against gravity. Similarly, auditory and visual stimuli continue to bombard the infant and challenge the motor system, fostering the need to attain head control.

Infant motor behaviors during the first 3 months of life are focused on acquisition of head control in all planes of movement. Once the infant has achieved head control in the supine and prone positions, the complexity of the tasks increases exponentially on the basis of the new challenges and stimuli presented to the infant. For example, while in the prone position an infant may reach for an object out of reach and then roll to attain the desired object. Improvements in visual acuity enable an infant to visually track people and objects at greater distances while challenging the infant to seek out the stimuli.

By age 3 to 4 months, as the infant is able to maintain head control in the upright position for longer periods, coordinated eye-hand activities begin to emerge. Acquisition of manipulative skills involves perception and lends support for the coupling of developing cognitive, sensory, and motor systems.^{23,161} Bushnell and Boudreau⁶ added that if the infant is unable to achieve a motor skill and this skill is coupled with a sensory or cognitive task, that task may not be attained. Bushnell and Boudreau’s⁶ research focused on the role of motor development in achieving skills in other domains.

Reaching is one such task that the researchers suggest may serve to promote skills in cognitive and sensory domains. Initial reaching activities enable the infant to gain information relevant to depth perception, and coupling this information then allows the infant to modulate parameters associated with reaching. For example, the infant must learn to vary the distance moved and force necessary to attain an object given a series of opportunities. Infant grasping and reaching may initially seem inefficient, but with practice under varying situations efficiency and accuracy improve across multiple domains with varying rates. Figure 3-4 illustrates both the error that provides feedback and the success during complex movement patterns after practice.

As infants develop an upright sitting posture, they use their upper extremities for support. Sitting, a functional motor

Figure 3-4 ■ Reaching activity. **A**, Error in reaching leads to learning, and **B**, reaching becomes accurate during a complex motor task.

behavior, is tightly linked to the performance of most ADLs and occupational and leisure-time activities. [Figure 3-5](#) depicts development of functional sitting over a lifetime. A delay in attaining independent sitting may directly affect upper extremity control, alter attainment of skills in other domains, and ultimately affect an individual's level of functional independence.

As upright trunk posture is attained and independent sitting emerges, usually by 6 months of age, and infants then begin to explore using their manipulative skills. Manipulative skills are composed of reaching and grasping behaviors. Upper-extremity interlimb coordination bimanual and unimanual tasks include retrieving objects (placed within reach); holding two objects, one in each hand; using two hands to hold an object (bottle); and holding a toy in one hand while retrieving another object with the free hand.¹⁷⁶

During the second half of year 1, the infant is focused on mobility, initially prone (rolling, crawling), then creeping on

all fours, and then upright (cruising and ambulation). Adolph and Berger²³ reported that as coordination of upper- and lower-extremity movements with trunk control emerges and infants begin upright mobility, they spend up to 50% of their day performing balance- and mobility-based activities, varying the surface, distance, and other parameters each time the task is performed ([Figure 3-6](#)). On the basis of research conducted with infants acquiring independent mobility, Adolph and Berger²³ estimate that an infant walks up to 29 football fields each day.

Acquisition of independent mobility is complicated by new manipulative skills, as discussed by Corbetta and Thelan.¹⁷⁶ They found that while infants are achieving independent mobility, their manipulative skills are highly variable and vacillate between bimanual and unimanual tasks depending on the nature of other tasks with which the infant is involved. Infants may revert to performing bimanual activities, with upper extremities coupled and movements synchronized, during early acquisition of independent mobility, signaling the presence of multiple tasks requiring attention. Unimanual control signals uncoupling of the upper extremities and asynchronous manipulation in young children.

Analyzing the early development of a child is often done at specific times over the first year, such as at birth, 2 months, 6 months, and 9 months. As important as understanding and analyzing a complex phase of development such as 3 months is analyzing the changes in motor control and learning of a specific motor function over a period of time. The development of head control is a good example of how the nervous system adapts and learns given different environmental restraints over a period of time. The complexity and integration of movement patterns involved in a child gaining functional control over the head in all spatial environments can be delineated into many components. Each component can then become a variable in determining how and if a child has or will develop a specific movement pattern such as head control (see [Figure 3-2](#)).

Early Childhood (1 Year to 5 Years)

Whereas the first year of life is characterized by periods of rapid physical growth and acquisition of motor skills, the second year signals a slower rate of growth, refinement of current skills, and acquisition of new motor skills.¹⁷⁷ Concurrently the toddler experiences rapid differentiation in other domains including cognition, speech, and social-emotional domains.

At the onset of the second year of life, independent ambulation becomes refined as other forms of mobility wane. Dynamic balance in an upright bipedal posture evolves as the infant develops more mature gait characteristics. Modification of parameters indicative of a more mature gait include narrowing of the base of support, decreased co-contraction in the lower extremities, and improved intralimb coordination, as well as learning to modulate displacement and velocity.²³ As gait matures and toddlers have more opportunity to explore their environment, more challenges appear. Attempts to solve these problems and challenges result in the appearance of more complex motor behaviors that include running, climbing, and jumping. Toddlers find particular pleasure in throwing, kicking, and catching balls. In addition, toddlers assert their independence through such activities as propelling themselves with riding toys.

Figure 3-5 ■ Development and maintenance of functional sitting. **A**, Early support sitting during first year. **B**, Independent sitting during play. **C**, Functional sitting in adolescents while studying. **D**, Adults sitting without support while eating. **E**, Sitting as part of a social interaction of an adult group. **F**, Functional changes in sitting in the elderly. **G**, Loss of adequate sitting programs after closed head injury.

Toddlers continue to explore and assert independence through activities involving bimanual and unimanual tasks. Challenges to fine motor skills of toddlers involve manipulating functional objects (large buttons, eating utensils, crayons, door knobs, and blocks; opening and closing jars to retrieve

small objects [cereal, raisins]). Achieving these tasks enables the toddler to perform rudimentary aspects of ADLs such as eating and dressing and adds another degree of independence. [Figure 3-7](#) illustrates development of ambulatory skill over a lifetime.

Figure 3-6 ■ Emergence of upright mobility: **A**, quadruped in preparation for quadrupedal creeping, **B**, moving from quadruped into standing, and **C**, moving in vertical.

Preschool-age children pedal a tricycle and use a narrow base of support to walk along a balance beam. By age 3 years most children ascend stairs using alternating feet and by 4 years most descend stairs alternately. **Figure 3-8** shows a preschooler descending stairs. The gait pattern matures with

reciprocal arm swing and a heel-to-toe gait pattern. Early in the preschool period, children mimic a “true” run and have difficulty efficiently controlling all aspects of the behavior. Finally, receipt and propulsion of balls of all shapes and sizes improve qualitatively.

Figure 3-7 ■ Functional ambulation over the life span. **A**, Early independent walking. **B**, Two young adults walking on sand. **C**, Three adults of different body sizes, each walking independently. **D**, Hiking with backpacks requires motor adaptations. **E**, Elderly man walking with visual guidance instead of visual anticipation, creating potential functional impairments.

Figure 3-8 ■ Child descending stairs successfully: **A**, attention on stepping down and **B**, success at the task.

Fine motor skills expand significantly during the preschool period. The environmental demands of preschool and day care preparation for entering primary grades are the driving force behind acquisition of many manipulative behaviors. Most children begin to cut with scissors, copy circles or crosses, use a crayon to trace a circle, match colors, and often demonstrate hand preference. Although maturity certainly plays a role in skill performance, the efficiency with which skills are performed is also influenced by genetics, affordances and constraints of the environment, practice, and intrinsic motivation.

Childhood (5 to 10 Years)

Childhood is characterized as a period when children begin their formalized education, usually in a structured environment separate from their families. Consequently, a new set of dynamics comes into play. Children take on new roles with peers and adults outside of the family. During this period of social-emotional change, other systems also undergo changes.

Motor skills that children display during this period include galloping, hopping on one foot for up to 10 hops (hopscotch), jumping rope, kicking a ball with improved control (soccer), and bouncing a large ball (basketball). Often these skills emerge while playing with peers during directed (physical education or community-based team sports) and nondirected (recess) periods. Mobility, balance, and fine motor skills improve dramatically. Girls and boys exhibit similar abilities in speed up to age 7 years but by age 8 years boys begin to outperform girls.¹⁷⁷

During childhood, manipulative skills increase exponentially. **Figure 3-9**, **A** through **E**, shows the amazing skill developed between birth and age 4 years. Manipulative skills assume a predominant role as part of the academic experience, requiring high levels of practice and opportunities for refinement of the skills. Hand preference is confirmed by this age. As components of independence, many of the manipulative skills achieved are directly related to self-care activities. Skills that improve dramatically include dressing, including fastening and unfastening clothing; tying shoes; using an implement for writing (coloring and handwriting); and successfully manipulating utensils not only to eat, but to socially interact while eating. As children approach preadolescence (9 to 12 years of age), manipulative skills improve dramatically. Children produce cursive handwriting and complex drawings.

Perceptual development often improves significantly, often in direct relationship to the demands of the tasks along with practice, feedback, and motivation.¹⁷⁷ Visual-perceptual systems are nearing maturity and allow children to participate in sophisticated activities such as archery, baseball, dance, and swimming. **Figure 3-10** helps bring to light complex skill development during a lifetime. That skill development may begin with a fun team sport activity and lead to a lifetime of professional accomplishment.

The musculoskeletal system enters a period when muscle growth is rapidly increased, accounting for a large percentage of the weight gained during this period.¹⁷⁷ Constraints and affordances of the musculoskeletal system along with demands of the tasks and environment are highly interactive and influential in skilled activities. Children are generally flexible because muscle and ligamentous structures are not firmly attached to bones. Although this allows for flexibility, it also poses risks for musculoskeletal injury. Care should be taken when participation in high-level athletic activities is a consideration.

Qualitative changes in coordination, balance, speed, and strength improve while existing motor skills become more refined and controlled, more efficient, and more complex.¹⁷⁷ Qualitative improvements of motor skills may be attributed to an asynchronous growth in children's limbs in relation to the trunk. Consequently, better leverage is attained. Motor skills strongly influence social domains as boys and girls begin to perform in organized sports teams in school and the community. Competition within sports becomes a powerful force in motivating children to practice motor skills or directing children away from organized sports. Children with poorly developed motor skills, as a result of either genetics or opportunity, may be excluded from team activities and experience social isolation.¹⁷⁷ Similarly, a child may have the genetic potential to become a master in an area that uses a specific motor task, but if he or she is never introduced

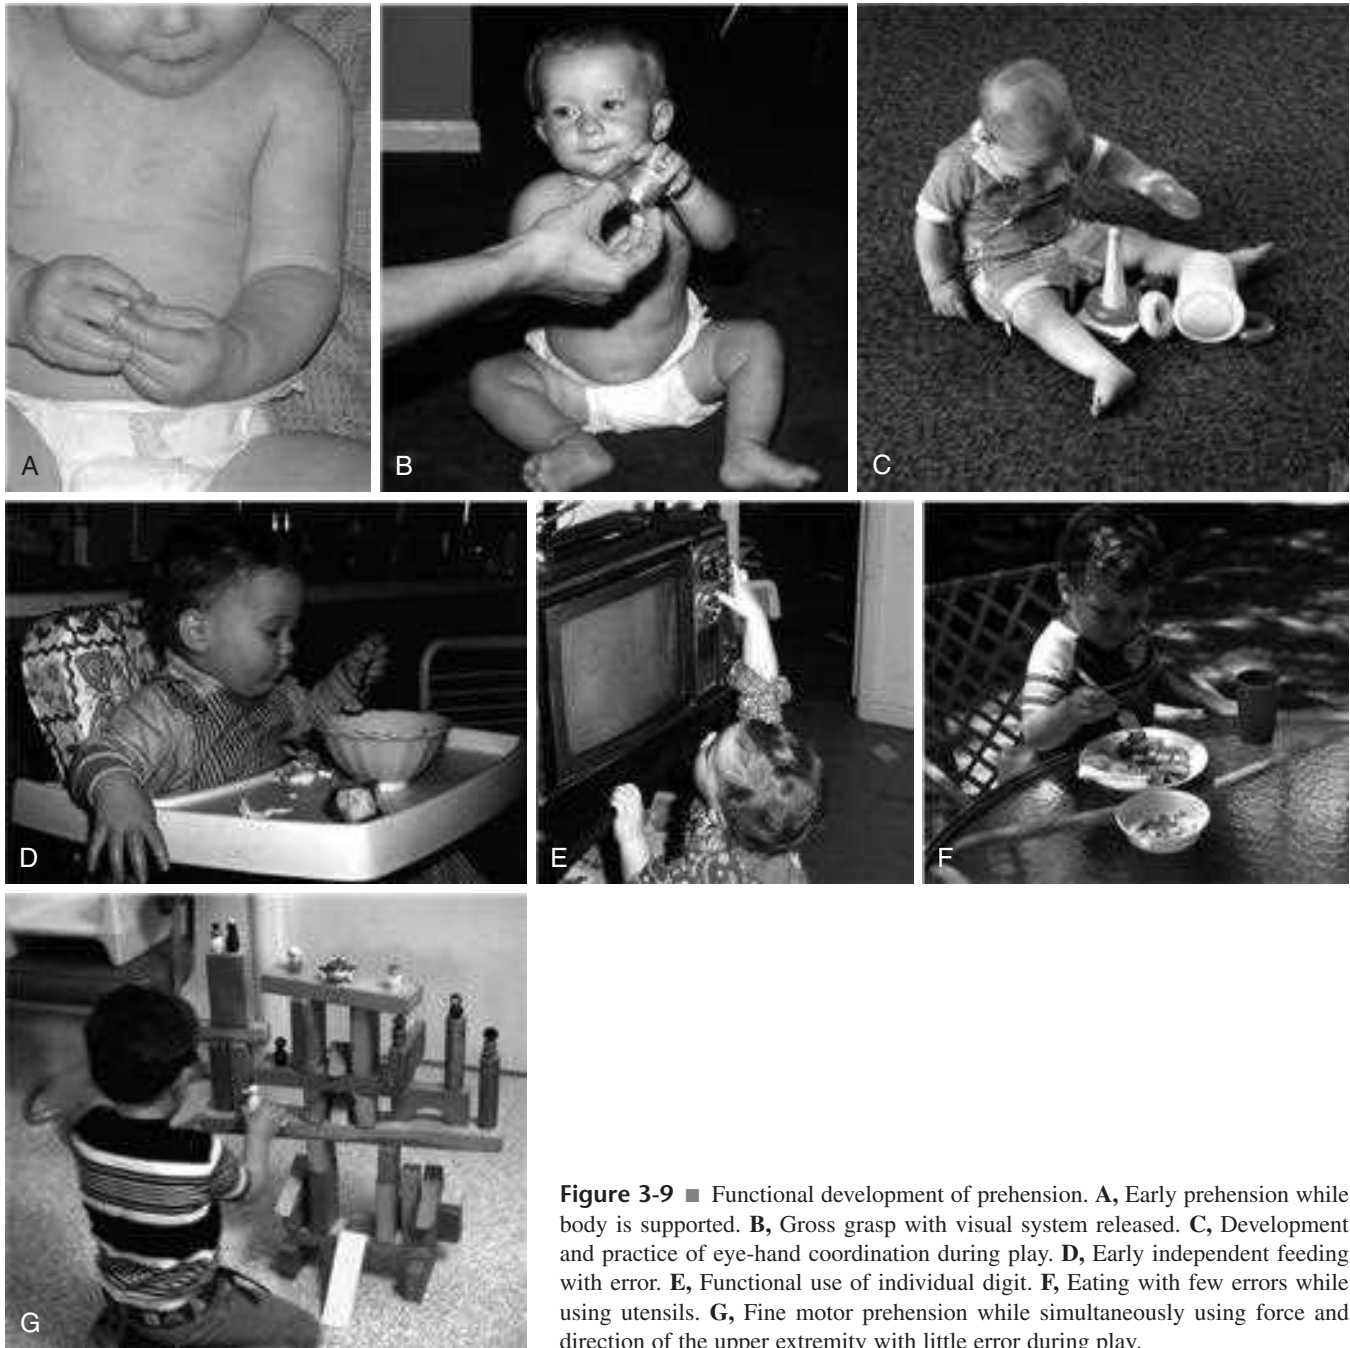

Figure 3-9 ■ Functional development of prehension. **A**, Early prehension while body is supported. **B**, Gross grasp with visual system released. **C**, Development and practice of eye-hand coordination during play. **D**, Early independent feeding with error. **E**, Functional use of individual digit. **F**, Eating with few errors while using utensils. **G**, Fine motor prehension while simultaneously using force and direction of the upper extremity with little error during play.

to the specific environment, such as playing a piano, and the motor skill is never actualized.

Adolescence (11 to 19 Years)

Early adolescence signifies a period characterized by improved quantitative performance and qualitative changes in skills along with physical growth (size and strength).¹¹ By age 12 years, reaction times closely resemble those of the mature adult. Although skills involving balance, coordination, and eye-hand coordination also continue to improve with respect to perceptual development and information processing, the rate is not as dramatic. Elite athletes, in contrast, often continue to show steady improvement in qualitative and quantitative skill performance well into adulthood.

During later adolescence, when periods of physical growth have stabilized, motor skills acquired previously continue to develop in speed, distance, accuracy, and power. Many adolescents are involved in competitive sports. However, few exhibit performance levels identified with elite athletes. Those athletes that do reach this high level of skill often have a genetic predisposition, environmental affordances, adequate opportunities for high-level practice and performance, and strong motivation. More often, adolescents performing in competitive sports will find this is their avocation rather than their vocation (see [Figure 3-10](#)).

Manipulative skills of adolescents resemble those of adults. Greater dexterity of the fingers for more complex tasks including art, sewing, crafts, knitting, wood carving,

Figure 3-10 ■ Complex skill development. **A**, Child participating in a team sport. **B**, Adult demonstrating advanced skill development as a professional baseball player.

and musical performance enables adolescents to perform these motor tasks with greater precision and proficiency.

Adulthood (20 to 39 Years)

Motor performance is relatively consistent in adulthood. Skillful performance of movements may be characterized not only through consistency, but also through the infinite ways in which the skill is performed. Hence, change is gen-

erally focused on leisure activities or elite athletic competition. Leisure activities of many adults involve exercise of some form. Maintaining a healthy lifestyle through exercise and fitness is one method for staving off effects of aging and degenerative diseases. Although many adults participate in exercise for health and wellness (refer to Chapter 2 for additional information), others who do not routinely exercise are at risk for obesity and associated health problems. Often some of the physical activity expressed through the motor system is an example of parent-child bonds and creates a fun environment for play. When a task-specific activity is selected and challenged by family members, the motivation to perform becomes high. In Figure 3-11, A, the observer might think that all three individuals are performing similarly with similar strategies. In reality, single-leg stance increases in difficulty as the base of support decreases and the body size changes. Note that the smallest individual has the smallest foot and the largest base of support in proportion to his body size. The adolescent is not as tall as his father, but his foot size is significantly larger, which (1) increases his base of support, (2) gives him less input proportional to his foot size or representation on the somatosensory cortex, and (3) gives him higher degrees of freedom when shifting his weight, which can either increase or decrease the task difficulty depending on practice. Figure 3-11, B shows the way both taller individuals use strategies to initially assume the upright stance position while the smaller child attained the single leg stance by stepping from a table. Body height, weight, and amount of practice all are variables that will help determine outcome. All three individuals achieve success, although the specific motor patterns and strategies used to succeed may be different. In Figure 3-11, C, a child with severe sensory organization problems would not be able to solve the challenge presented in Figure 3-11, A, because he cannot even begin to stand independently on a large, stable surface. Again, therapists need to be able to match the motor program impairments causing the child with learning disabilities to fail at the task and identify what programs are needed or expressed in the success of all three individuals in Figure 3-11, A.

The peak of muscular strength occurs at 25 to 30 years of age in both men and women. After that period, muscle strength decreases as result of a reduction in the number and size of the muscle fibers.¹⁷⁸ Loss is related to genetic factors, nutritional intake, exercise regimen, and daily activities.

Middle Adulthood (40 to 59 Years)

Changes associated with aging have been identified in the neuromuscular, musculoskeletal, and cardiovascular and pulmonary systems. These age-associated changes can greatly affect motor performance, although the degree is highly variable. Between 30 and 70 years of age, strength loss is moderate, with about 10% to 20% of total strength lost, for most activities—insignificant and undetectable by the individual.^{68,179} Participating in regularly scheduled exercise regimens that emphasize aerobic and strengthening activities may reduce effects associated with aging. Furthermore, developing muscle mass and competence in motor skills early in life may have long-term positive effects on adult skills and reduce the risk of disability and frailty later in life.¹⁸⁰

Figure 3-11 ■ A complex task performed by individuals with different foot size and body composition. **A**, Three individuals of differing age, body composition, and experience successfully performing the same task. **B**, The strategy used by the adolescent and adult to find verticality. **C**, A child with learning difficulties failing at independent one-legged stance.

Older Adulthood (60+ Years)

Age-related changes may be attributed to alteration in perception, compensations in the neural mechanisms, and changes between and within the different systems involved in motor skill performance.¹⁸¹ Integrated effects may include slowing in movement production and increased activation of agonist-antagonist muscle groups. An example of agonist-antagonist activation is during dynamic balance activities.¹⁸² After age 70 years, most individuals incur losses in muscle strength of up to 30% over the next 10 years. Overall, the loss of muscle strength through adulthood may

be as much as 40% to 50% by the time an individual reaches 80 years of age.⁶⁵ The percentage decline is inversely related to the demand by the individual for repetition of the movements. For example, repetitive movements, such as playing tennis daily, running, playing golf, or downhill skiing, may significantly decrease the percentage of loss of strength compared with individuals who do not participate in such activities.

Although some effects are age associated and may be reduced with regular exercise and increased motor activity, not all are modifiable. Willardson⁸² reported that older

adults who maintain more active lifestyles are more likely to have a more favorable outcome than are peers who were not as active. Findings by Voelcker-Rehage and Willimczik⁹⁷ supported the findings of Willardson⁸² in regard to older adults and lifestyle. In addition, Voelcker-Rehage and Willimczik⁹⁷ found that older adults aged 60 to 69 years were able to acquire and refine a novel task (juggling) at a level comparable to children 10 to 14 years old and adults 30 to 59 years old. Only young adults aged 15 to 29 years performed at a higher skill level. Furthermore, adults older than age 70 years were found to have limitations in their ability to learn the novel motor skill. Moreover, as individuals age, they generally have a decreased ability to produce force, and they tend to coactivate agonist-antagonist muscles.¹⁸³ The researchers suggested that older adults may coactivate agonist-antagonist muscles as a strategy to (1) modulate movement variability and (2) maintain accuracy in movement. The investigators also reported that older adults' coactivation strategy compromised the subjects' ability to rapidly accelerate their limbs in exchange for improved accuracy of control.

In addition, information processing appears to be slowed in older adults.¹⁸¹ Motor times have also been found to be delayed in older adults, particularly when a higher-level force is required.

Temporal coupling also appears to be altered in older adults.¹⁸¹ Perhaps as individuals age, they are less able to modulate timing of muscles during contraction and relaxation phases and are more likely to coactivate agonist-antagonist muscles. The outcome behaviors are typified by poorly coordinated motor activities and increased time to produce adequate muscle force to elicit the behavior.

In addition to reduced efficiency in movement production, variability in performance of motor skills also increases with age. Although small changes in individual systems may not have a significant effect on functional movements, the compounding effects of changes in several systems may have serious implications for older adults and place them at increased risk for falls and injuries.⁵⁸ Figure 3-12, A and B are examples of movement dysfunctions seen within an elderly population. These alterations are limiting the individual's ability to respond to a given motor task. As individuals age, there can be a large number of potential alterations in the body systems that limit CNS and musculoskeletal options when the individual tries to accomplish a motor activity. These limitations can place individuals at high risk of failure of any one motor task. The greatest fear within this group is not death; it is falling, and as a result losing independence. Prevention, as discussed in Chapter 2, will be more and more important as the world's population of elderly individuals enlarges on a yearly basis.

Thirty percent of all community-dwelling elderly persons fall at least once each year.^{179,184} Factors contributing to falls include intrinsic and extrinsic variables.¹⁸⁵⁻¹⁸⁷ Intrinsic alterations in the older adult have implications for performance of motor skills and potential for falls. Risks associated with falls increase with age and when functions of the neuromuscular, musculoskeletal, cardiovascular and pulmonary, and sensory systems deteriorate. This deterioration of covariant factors and not age itself is more closely related

Figure 3-12 ■ As individuals age, more sedentary lifestyles, pre-existing long-term health issues such as chronic obstructive pulmonary disease or chronic back pain, and a decrease in environmental challenges can lead to a higher risk of falls. **A**, Woman with chronic back problems leading to a fixed trunk. **B**, Man with chronic obstructive pulmonary disease and a fixed flexed posture resulting from inactivity.

to health and wellness and end-of-life age.¹⁸⁸ Another critical variable that is closely associated with motor decline in the aging is the individual's social interactions and participation in life.¹⁸⁹ Research has yet to determine whether a decrease in motor performance results from a decrease in participation in life.

Researchers have examined manipulative skills in older adults and reported changes in muscle performance and flexibility.^{56,190,191} These changes resulted in decreased hand function associated with impaired performance of ADLs.

STRATEGIES FOR FOSTERING ACQUISITION AND RETENTION OF MOTOR BEHAVIORS ACROSS THE LIFE SPAN

Movements occur out of a need to solve problems in the environment. Solving these problems is not dependent on any one system but rather is a collaborative effort of multiple systems. The clinician is responsible for examining the patient's performance by evaluating the underlying conditions and the strategies that the individual may use to modify a behavior. Figure 3-13, A to F, presents an example of individuals standing up from a chair. The first panels (Figure 3-13, A and B) show a child whose feet are not on the surface because the child's legs are not long enough. No matter the variance of the task, the child was motivated to succeed. The second individual (Figure 3-13, C and D), an elderly man, has lost the ability to shift his weight forward over his feet and thus is rising posterior on his heels, which will require anterior flexor power to prevent him from falling backward. The third individual (Figure 3-13, E and F) has residual motor problems after a stroke. She has been taught to come to stand over her less-involved leg versus centering her base of support between her two feet. The specific way an individual learns, maintains, and relearns a specific motor task as a functional activity will vary, but the important principle will be to empower the individual to succeed with fluid, dynamic motor pattern options. Therapists need to visualize movement and place the movement pattern of the individual on top of that image. The specific motor impairments will then become obvious and treatment options will be generated. Examination is vital to this process, although it often occurs in an environment far removed from the client's natural surroundings.

Through acquisition of motor skills, individuals of all ages are afforded the opportunity to meet the environmental demands imposed by work, play, family, or personal activities. Refer to Figure 3-13 as an example of common motor activities used at work, play, and home. Motor skill acquisition, retention, and decline are influenced by constraints or affordances that affect opportunities for practice in an environment that challenge and drives the individual to perform optimally. The client's investment in achieving a successful outcome can help foster persistence in reaching the desired outcome.

Practice, the primary method for acquisition and retention of motor tasks, is exciting for very young children because each attempt is a new opportunity to achieve the outcome and reach a new level of independence. In contrast, practice in adolescent and adult populations may not be seen in the same light but rather as tedious and boring. Instead, physical and occupational therapists have the responsibility to challenge

the cognitive, affective, motor, perceptual, sensory, and physiological systems through client-selected activities. Activities directed toward the age and needs of the individual, such as interactive dance mats for adolescent clients or ballroom dancing for the older adult, may provide the motivation necessary to practice the task a sufficient number of times to achieve the desired outcome. Figure 3-14, A to H show age-appropriate challenges to individuals. The activity used with a child may be inappropriate for use with an adult, although a similar motor behavior may be the desired outcome. If the individual identifies the activity, he will be more motivated and more likely to practice a desired skill. Carryover from a clinical setting to a home or environmental setting is critical when looking at movement function over a life span.

Strategies used to achieve desired motor outcomes may include a variety of feedback mechanisms to correct errors and identify more efficient strategies to attain the motor skill. Embracing the concept of enablement rather than disablement may also serve to motivate the client because individual abilities are acknowledged and promoted while strategies are used for acquisition or relearning of motor skills. The needs of adolescent and adult clients are unique and differ significantly from those of the young infant or child.

Opportunities for exploration that engage the infant or young child are the primary motivation for movement. Although motor activities serve as the primary focus, engaging the infant or child provides stimulation that promotes development across multiple domains (e.g., cognition, social, communication). Environmentally challenging activities place demands on the child that maintain a level of curiosity or motivation and encourage persistence in attaining a motor skill that is successful and efficient. As the child matures, play-based activities shift the focus, depending on the expected outcomes. Overall, play is the primary mechanism that children use to mimic adult-like behaviors. Finally, children and adults use play or leisure activities as a means of promoting skill acquisition and proficiency across all developmental domains.

Development of Head Control as an Example of Movement Development across the Life Span and Its Impact on Quality of Life

When analyzing the development of head control by viewing movement of a young child over the first few years, it becomes clear that the motor control of the head in all spatial positions is very complex, requiring the integration of a variety of movement patterns. The infant needs to develop both the flexors that bend the head forward as well as the flexors that tuck the chin. These flexor patterns will be integrated into diagonal movements in order to roll over from supine to prone. A neck-righting program orients the body to the head when the head is initially moving. Although the neck-righting program is present at birth, it will take the child a couple of months to gain the power necessary to independently flex and rotate the head against gravity with the body following the head in order to roll over. As the flexor power improves, it will be integrated into patterns of coactivation with postural extensors. The extensor movements of the head include (1) extension from a flexion position through hyperextension and/or rotation of the head in

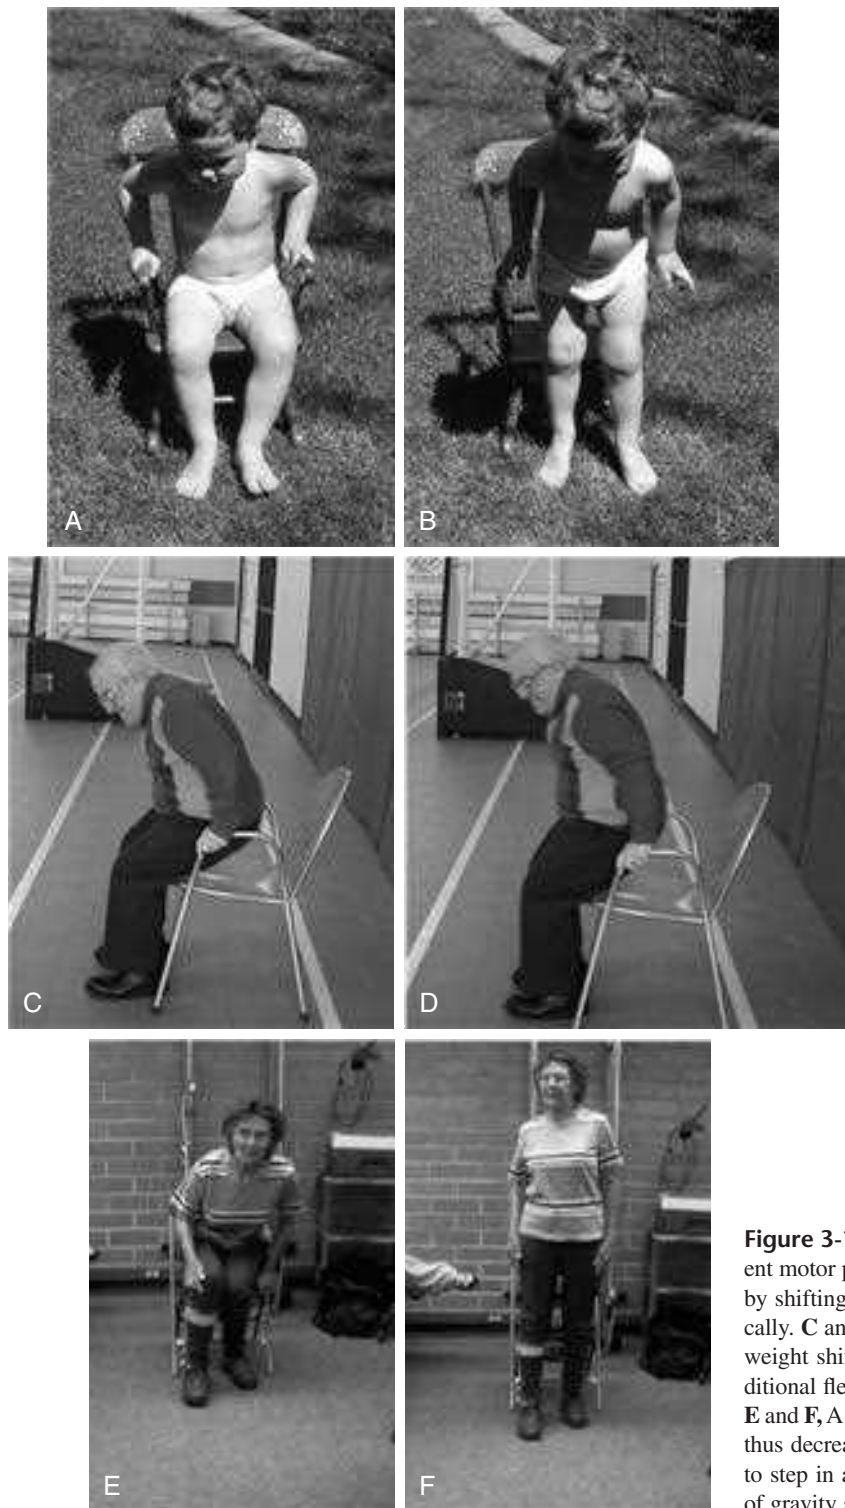

Figure 3-13 ■ Three individuals coming to stand using different motor patterns. **A and B**, A child rising to stand from a chair by shifting his weight over his base of support and rising vertically. **C and D**, An elderly man rising to stand without adequate weight shifting forward over his base of support, requiring additional flexor power to prevent falling backward into the chair. **E and F**, A woman after a stroke rising over her less involved leg, thus decreasing her symmetrical weight distribution and ability to step in any direction with either foot as a response to center of gravity shifting outside her base of support.

all spatial planes, and (2) postural extension, holding and/or stabilizing each vertebra within the spinal column. These postural programs help coactivate the flexors and postural extensors simultaneously to stabilize the head in space. There are a variety of motor programs that assist in gaining this control of the head. Head-righting reactions, using the semicircular canals, are programmed to right the head, or bring it to face vertical, no matter where the head is in space.

The righting programs need the underlying power to produce the force necessary to right the head. The heavier the head, whether in weight of the cranium or its positioning against gravity, the harder it is to right the head to vertical. Thus it could be hypothesized that if the head were in a vertical position or vertical in reference to gravity, it would be easier to control the head in space. The force production would be nominal compared with the force production

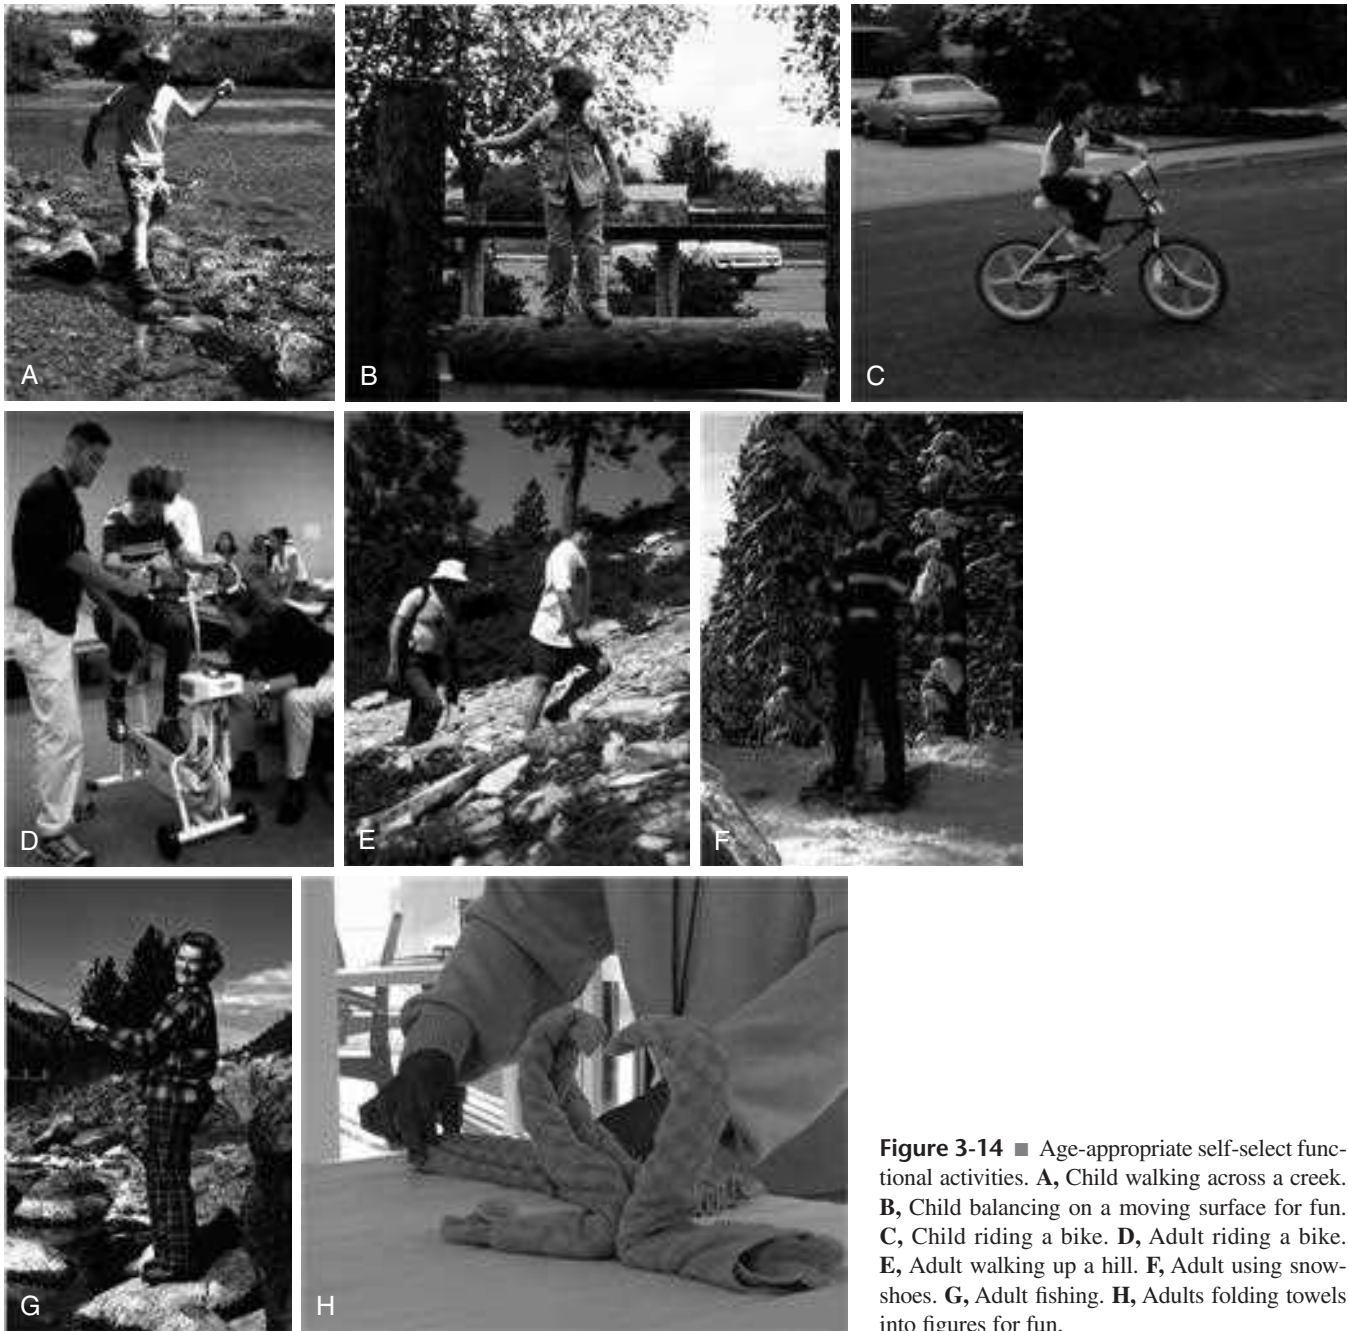

Figure 3-14 ■ Age-appropriate self-select functional activities. **A**, Child walking across a creek. **B**, Child balancing on a moving surface for fun. **C**, Child riding a bike. **D**, Adult riding a bike. **E**, Adult walking up a hill. **F**, Adult using snowshoes. **G**, Adult fishing. **H**, Adults folding towels into figures for fun.

needed when bringing the head up from horizontal or just holding it against gravity when horizontal. There are motor programs triggering extensor tone due to the position of the otoliths in the inner ear. The degree of tone will depend upon whether the head is horizontal in supine, vertical, or in between. This response has been labeled the *tonic labyrinthine reaction* (TLR). The TLR is strongest in the supine position because of the optimal pull of the otoliths by gravity. When an individual is supine, the tactile input from pressure to the surface of the skin increases extensor tone. Thus, in the supine position the tactile input and the information from the hair cells of the otoliths are activating the motor pool of the extensors and simultaneously decrease the motor pool of the flexors. These systems decrease the ability of the

motor control system to generate flexor tone in supine. When the child is placed prone, the skin sensitivity decreases extensor tone.

Flexor Control

Figure 3-15, *A* through *F*, illustrates the patterns of a healthy 4-week-old when being pulled to sit and returned to the floor. Initially the child has difficulty flexing his head when trying to pull the head into flexion from the supine position because of both the extensor tactile system and the labyrinthine mechanism, which inhibit the flexors while facilitating the extensor muscles. This can be seen in **Figure 3-15**, *A* through *C*. This lack of adequate flexor control would be considered normal for the child's age but also defined as a head lag

Figure 3-15 ■ A 1-month-old child being pulled to sit from supine and lowered back down. **A**, Starting position in supine. **B**, Pulled toward vertical, maximal resistance from gravity, inadequate response to stretch by neck flexors. **C**, Position of ears and otoliths inhibits flexors; thus inadequate head righting is still seen. **D**, Child in vertical, weight through hips, quick stretch to head in all directions facilitates head control. **E**, Child lowered back toward horizontal continues to have adequate head control. **F**, Maximal stretch from gravity; child still retains adequate neck flexion.

(Figure 3-15, A through C). As the child approaches vertical, his weight is shifted down through his buttocks and over his base of support. At that point the head control kicks in (Figure 3-15, D and E). This motor control of the head in vertical incorporates both postural extensors and flexors while optimizing the use of optic and labyrinthine righting and stretch to both flexors and extensors muscle groups (Figure 3-15, D). The child is able to maintain better control of head and neck flexors when lowered back down to supine (Figure 3-15, E and F). This ability to control the head while transitioning from sitting to supine illustrates the fan swing principle: once the flexor program is elicited in the vertical position, it can maintain head control for a longer period of time and through more degrees of motion as the head movement progresses from vertical to horizontal.

Over the next month the child will develop flexor control in space by using head righting, muscle strength, and facilitation of the nervous system to keep the head and eyes oriented toward an object as the head travels through space. Motor control over flexor patterns becomes more flexible, and the power needed to perform tasks increases. Figure 3-16, A through C, demonstrates the pull to sit pattern in a healthy 3-month-old infant. She not only has learned to dampen the influence of the TLR in the supine position and the skin's influence on the extensor motor pool, but also has learned that by flexing most of her body parts (flexion facilitates flexion) she will gain additional flexor control of the head

when pulled from supine (Figure 3-16, A). This flexion continues as the child goes through midrange (Figure 3-16, B) and continues as the child approaches vertical (Figure 3-16, C). Unfortunately, the child does not have the integrated motor control over flexion and extension or the balance reactions in sitting to extend the legs as she approaches vertical. This movement is a prerequisite for gaining control of long sitting in vertical. These new motor movements will become the foundation for balance reactions in vertical sitting.

A month later the child's nervous system integrates the flexor patterns into smooth movement through 90 degrees of motion from supine to sitting (Figure 3-17, A through C). The child also demonstrates a more integrated response to being lowered backward from vertical (Figure 3-17, D). Yet the child's motor system has not developed the rotatory aspects or control of the diagonal flexor patterns as shown in Figure 3-17, E. These rotatory patterns will develop as the child practices rotation in rolling and then incorporates that rotation when coming to sit in a partial rotation pattern.

The child will not be able to independently initiate motor control over the adult pattern of coming to a sitting position for at least 3 to 5 years but certainly should gain that control by age 6 (Figure 3-18). As the child's age increases, the movement patterns become more complex, and additional motor programs are learned and integrated. This aspect of head control will be maintained and integrated in movement patterns as the individual explores the environment.

Figure 3-16 ■ A 3-month-old healthy child pulled to sit. **A**, Initial stretch in horizontal pulls in neck flexion along with flexion of the hips and knee. **B**, Adequate neck flexion persists as child looks at therapist while being pulled to sit: midrange. **C**, Transitioning to vertical; less stress on neck flexors, yet flexion persists in lower extremities.

Figure 3-17 ■ Pull to sit in 4 month-old-healthy child. **A**, Child looks as therapist places finger to the child's head—recognized tactile stimulus, relaxed supine. **B**, Child pulled to sit, neck tucked and hips flexed. **C**, In vertical, child relaxes hip flexors in order to have sitting balance. **D**, Child lowered toward supine maintains neck and trunk control. **E**, Rotation added into lowering to supine pattern; neck response is inadequate.

Extensor Control

As the child develops flexion, the child also needs to develop the extensor control of the head. There are two extensor component patterns used by the CNS to control extension. The first pattern is controlling extension of the head from a totally flexed position (as if an individual were looking down at his shoes) to a hyperextension position (as if an

individual in a standing position were looking up at the stars). This pattern has a large range of motion, and the power needed will change depending on the head's position in space, in relation to gravity, as well as the weight of the head itself. The second pattern is considered “postural” and requires the small muscles of the neck and the shoulder and trunk to hold each vertebra in relation to the vertebra above

Figure 3-18 ■ Normal 6-year-old using adult independent coming-to-sit pattern.

and the vertebrae below. This is the boney support encompassing the spinal cord. Similarly, in the upper cervical region as the flexor and extensor patterns work together in a coactivation pattern, chin tucking occurs. This pattern allows the head to remain stable in space, keeping the eyes and the ears horizontal to the surroundings, a key component for perceptual learning. This movement pattern is often called *optic and labyrinthine righting of the head* because both the eyes and the ears provide stimuli to trigger this motor response.

Assessment of Head Control

Most individuals analyze the development of postural control by evaluating the extensor aspect of head control in the prone position. But the prone position is not the first position in which a child begins to achieve independent head control. **Figure 3-19**, A through C, illustrates a newborn (2 days old) extending both the long extensors (**Figure 3-19**, A and B) as well as moving into the postural extensor pattern component when tucking the chin (**Figure 3-19**, C). While prone the newborn child has very little independent control over extension and can just clear the airways (**Figure 3-20**). This same limitation is not present when the child is in a supported vertical position. After a week the extensor patterns in the vertical position have already become more functional and demonstrate better motor control and greater power.

Figure 3-21, A through C, shows the same child at 1 week of age while supported in a vertical position. **Figure 3-21**, C is a beautiful example of the postural pattern one expects to see consistently later in the child's development. Obviously, he is practicing these movements every time he is vertical and given these limited degrees of freedom. Looking at the same child at 1 month of age (**Figure 3-22**), the integration of these postural movements is continuing down his entire spine. This does not mean he can hold this pattern for an extended period of time but does illustrate his ability to move with control into a total postural extension pattern and hold it at least briefly. On the same day and about 15 minutes later, the child (**Figure 3-23**) was placed prone on the floor, clearly demonstrating that he has not developed the necessary power to control his head or upper trunk for postural extension in the prone position. Although he is more relaxed prone at 1 month than at birth (see **Figure 3-20**) and can lift and turn his head in both directions, it will still be 1 or 2 additional months before he can extend his head and trunk enough to prop on his elbows. It will take more time to roll from prone to supine.

While the cervical and upper thoracic muscles are developing postural power, they need to learn to hold the head in space against gravity for longer periods of time. Postural function requires coordination and coactivation of the short extensors of the neck and the neck flexors—especially the sternocleidomastoid, hyoid, and scalene muscles—in order to tuck the chin and balance the head in space. These movement patterns play a key role in stabilization of the head in order to move the head in and out of vertical space. The motor control system uses both righting and balance reactions in order to gain full head and neck control of vertical space. The movements become more and more complex, modifying and integrating various additional motor programs in order to have greater flexibility to control and move the head. These patterns give the eyes and ears the visual and auditory orientation needed to process consistent external environmental information. **Figure 3-24** illustrates an individual after head injury who has lost his automatic righting of the head in vertical. He has the ability to bring his head to vertical by hyperextension of the neck but does not do so automatically. This hyperextension pattern dramatically changes the motor patterns of head, neck, and trunk control which will affect his upright behaviors including balance, gait, feeding, and social interactions.

Figure 3-19 ■ Newborn neck extension in supported vertical position. **A**, Newborn lacks postural extension of trunk and head. **B**, Newborn initiates neck extension, showing that patterns exist. **C**, Newborn moves into postural extension of upper cervical region.

Figure 3-20 ■ When placed prone, the newborn has excessive flexion.

Application of the Development of Head Control to Rehabilitation

The reason the patterns of head extension in vertical have been presented is to illustrate that motor control progresses from vertical to horizontal and then from horizontal to vertical. Therapists think of the prone position as the first position in which the child develops extensor control because it is the first position in which an observer sees independent selection of extensor movement. However, extensor control begins when an individual passively brings a young baby to sitting or standing. The baby learns to control the head with small movements that displace the center of gravity. Understanding this stage of head control may be a critical component of working with a neurologically impaired youngster or an adult.

Analysis between Normal and Impaired Motor Function

Differentiating normal age-related reactions of any movement impairment is the responsibility of a movement specialist. For example, differentiating the movement of a normal child who has a lag in head control (see [Figure 3-15, B](#) and [C](#)) from the movement of a child who does not demonstrate any head control ([Figure 3-25, A](#) through [E](#)) should guide the therapist in a decision about where to begin treatment. It is an unrealistic expectation for the child in [Figure 3-25](#) to gain

flexor head control by starting at supine. After the child has been pulled to sit, flexor power production is beyond the control of the child's motor system. Once the child is vertical, the influence of gravity on the weight of the head has decreased. The vertical position also inhibits any influence of the otoliths when supine. The upright position helps to facilitate the labyrinthine and optic righting of the head. [Figure 3-25, D](#) and [E](#) demonstrates how the tone within the neck and shoulder girdle changes once the head attains a vertical position. A therapist should not only see a change to more normal tonal patterns but also observe relaxation of the facial muscles—closure of the mouth and a more functional position of the eyes in space for visual processing.

Movement demonstrates the ease or difficulty the motor system is experiencing while trying to complete an activity. The activity analyzed may be a basic pattern such as head control or a complex one as seen in [Figure 3-3, E](#). Differentiating between the movements in [Figure 3-15, A](#) and [Figure 3-25, A](#) should guide the clinician in establishing realistic prognoses. The first child, with practice and CNS maturity, should automatically develop head control, whereas the second child has gone beyond his age-appropriate movement delays and has abnormal responses to the stretch stimuli.

Similar analysis can be made when looking at the extensor component of head control. The vertical position that optimizes extension is kneeling or standing because compression down through the joints and spine facilitates extension. Using kneeling or standing may pull in too much extension, especially if it results in hyperextension. In that case sitting may be appropriate even though it may facilitate flexion. When kneeling or standing, if inadequate extension still exists, then adding additional compression (see [Chapter 9, p. 207](#)) down through the head or shoulder girdle may help. Using an apparatus that takes away some of the weight of the head or trunk reduces the demand on the nervous system and may help the individual regain postural neck, shoulder girdle, and upper trunk control (see [Chapter 9, p. 232](#)). As the individual begins to demonstrate that control, the therapist can slowly take away the assistance with the expectations that the individual will gain independence in that activity.

As the individual ages, changes in the control of the head can lead to new problems. [Figure 3-12, B](#), is an example of a man who has a fixed flexed posture. If the flexed posture is permanent, treatment alternatives must take into consideration

Figure 3-21 ■ Child 7 days old in vertical extension. **A**, Child eliciting active neck and trunk extension in vertical at 7 days. **B**, Child does not have adequate righting of the head in vertical at 7 days but is responding. **C**, Child pulls into postural extension of the neck and trunk, allowing for binocular vision at 7 days.

Figure 3-22 ■ A 1-month-old child, when supported in a vertical position, shows postural extension of the neck and trunk while looking at his mother.

Figure 3-23 ■ Same child when placed prone, 15 minutes after Figure 3-22 was taken. This child demonstrates that when prone he still has a flexor bias and has little adequate postural extension in this position.

the impact this posturing will have on all ADLs. As stated earlier, any patient can exhibit a range of problems in head control. How those movement impairments present themselves and which treatment alternatives a therapist might select will depend on the clinician's ability to analyze normal movement and create an optimal environment for patients to engage and practice those patterns.

Clinical Example

Cervical torticollis in a child is an imbalance in rotation of the neck and muscle groups secondary to position of the fetus in utero. Cervical torticollis in adults is a focal dystonia or an imbalance of excitation and inhibition of the neck muscles. These patients have impaired integrative balance responses. Standard medical intervention is botulinum toxin injections followed by physical therapy focusing on range of motion and strengthening exercise. The emphasis needs

Figure 3-24 ■ An individual who sustained a closed head injury with residual lack of postural neck extension has poor head control in vertical.

to be on restoring and progressing head control from vertical to supine—that is, trying to help the neck muscles to retrain a stable condition in the vertical position by using a collar for support. Compression down through the cervical and thoracic spine can facilitate flexors, extensors, and rotator muscles. Then, as in the infant, with arms fixed on a stable support surface, slowly let the patient move out of vertical toward horizontal, moving only as far as head control is maintained, which may be as limited as 10 to 20 degrees. Repeat this activity many times in order for this activity to become procedural. Patients can hold onto some stable support object at home in order to practice. The challenge for both the therapist and the patient is to retrain head control in order for the individual to be able to participate in life.

Summary

Normal development of head control has been highlighted because so many clinicians become frustrated with clients who do not have adequate head control. The examples of the development of head control serve as a foundation for every movement pattern that people use, whether stationary or in motion. The process used to analyze the development of head control can be used to analyze all movement patterns, whether the movement problem is caused by a bodily system (biomechanical, cardiopulmonary, CNS or another system problem) or by some environmental factor.

SUMMARY

Clinicians must focus best practice toward successful client management geared toward promotion of function and prevention of chronic illness or disability for the youngest of the young to the oldest of the old. As practitioners, we must embrace tenets central to the *Healthy People 2020* project. Physical and occupational therapists serve as role models for individuals of all ages and educate diverse groups of individuals about the multifaceted, interactive systems involved in the acquisition, retention, and deterioration of motor

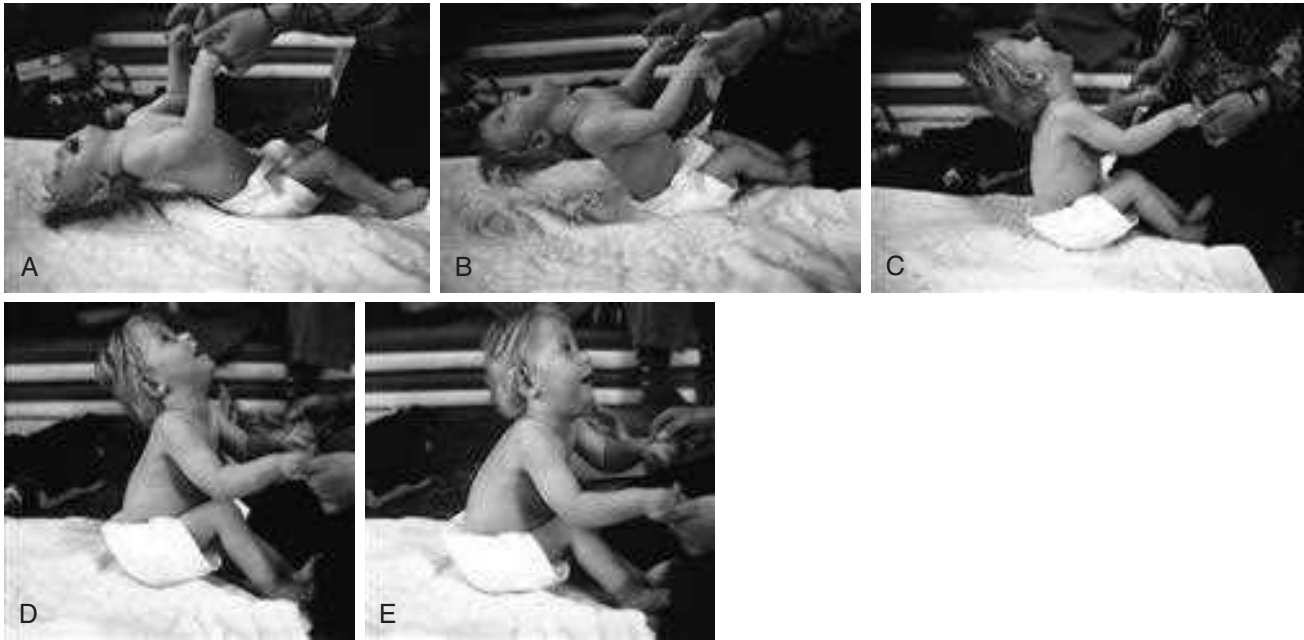

Figure 3-25 ■ Child 2½ years old with cerebral palsy being pulled to sit, and muscle action facilitated once vertical. **A**, Initial pull toward sit; no response to stretch of neck flexors. **B**, Continued pull toward vertical, head at end range of neck extension. **C**, Trunk in vertical but neck remains in horizontal; no flexor response. **D**, Child pulled beyond vertical as trunk extensors begin to activate from stretch and mouth closure is beginning. **E**, Therapist facilitates head into vertical as mouth continues to relax and close and eyes are looking at a target.

behaviors. Recognizing internal and external constraints or affordances that influence motor behaviors enables the clinician to devise a plan of care and the scientist to design a study targeting the needs of the whole person. Analyzing, understanding, and visually recognizing movement patterns that are efficient, fluid, and goal oriented and that vary across the life span are the first steps or prerequisites to evaluating abnormal movement patterns that do not fall within a normal parameter. **Figure 3-26**, A to G, shows an example of rolling, a basic movement strategy controlled by the child midway through the first year of life that can become an extremely challenging activity after a CNS insult. Differentiating between components of a normal movement and deviations that prohibit normal movement falls into the clinical expertise of occupational and physical therapists (see Chapter 9, **Figure 9-1**, p. 199) Without the knowledge of normal movement, analysis of the causation of abnormal movement would be difficult if not impossible. This chapter has been written to help the reader understand normal movement across the life span. It is the first step, and in sighted individuals the analysis begins as soon as visual images are recorded in the visual cortex.

Scientists acknowledge that development is characterized as nonlinear, emergent, and dynamic, rather than sequential, predictable, and stagelike. Dynamic systems theory, although it does have certain limitations, provides a better explanation for development than do neuromaturational theories. The emphasis or responsibility does not lie with any one system but varies across different systems as a consequence of age, genetics, or experience.¹⁰⁴ That said, future studies directed at examining human movement and optimal variability through nonlinear dynamics may provide new perspectives in motor development and control.

Human behavior is by nature complex. As such, no one system or skill develops in isolation but rather emerges from a complex interaction among multiple systems. Complex behaviors are evident beginning in utero and continuing throughout life. No one theory explains the development of complex motor behaviors, and none encompass the essence of interindividual and intraindividual variability in aging. Aspects of various theories provide evidence that an integrative perspective is a more accurate reflection of aging. As theorized earlier, lifestyle choices and other modifiable behaviors have potent effects on aging. Interventions designed to provide older adults with strategies to positively influence successful aging, rather than being sought after a negative outcome of aging is realized, may improve the quality of life. Optimal quality of life is what all individuals hope to obtain, whether learning to reach a cracker, climbing the highest mountain, or playing a game of bridge. Maintaining that quality before the end of life, no matter the age, is often based on movement function. The client, whenever possible, should determine identification of the specific function. Identification of the necessary steps to get from existing skill to desired skill is the role of a movement specialist, whether that therapist is dealing with preventive care or postinsult care.

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 191 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Figure 3-26 ■ Rolling—an activity achieved within the first year. **A**, Child beginning rolling in supine position. **B**, Child semiprone with trunk rotation. **C**, Child brings arm through to become symmetrical while proceeding toward prone position. **D**, Child prone with postural extension. **E**, Adult with traumatic brain injury; first try at rolling toward prone position from supine. **F**, Adult's second try at rolling, changing programming. **G**, Once prone, he is stuck, unable to extend.

CHAPTER 4

Contemporary Issues and Theories of Motor Control, Motor Learning, and Neuroplasticity

MARGARET L. ROLLER, PT, MS, DPT, ROLANDO T. LAZARO, PT, PhD, DPT, GCS,
NANCY N. BYL, PT, MPH, PhD, FAPTA, and DARCY A. UMPHRED, PT, PhD, FAPTA

KEY TERMS

motor control theory
motor learning
neuroplasticity

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify the evolution of motor control theories and discuss the utility of current theory in clinical practice.
2. Identify body structures and functions that contribute to the control of human posture and movement.
3. Relate the cognitive, associative, and autonomous stages of motor learning to behavior and skill performance.
4. Describe the variety of practice conditions that may be used to enhance motor learning within a practice session.
5. Apply motor learning variables related to person, task, and environment within the therapeutic setting.
6. Discuss neuroplasticity theories that explain how the nervous system adapts to demands placed on learning and performance.
7. Discuss the relationship among motor control, motor learning, and neuroplasticity in the production of functional movement behaviors.

The production and control of human movement is a process that varies from a simple reflex loop to a complex network of neural patterns that communicate throughout the central nervous system (CNS) and peripheral nervous system (PNS). Neural networks and motor pattern generators develop as the fetus develops in utero and are active before birth. These simple patterns become building blocks for more skillful, complex, goal-directed motor patterns as a person develops throughout life. New motor patterns are learned through movement, interactions with rich sensory environments, and challenging experiences that drive a person to solve problems. Personal desires and goals of the individual shape the process of learning new motor skills at all stages of life. If a condition exists or develops, or if an event occurs that damages the nervous system and prevents normal transmission, processing, and perception of information in the PNS and CNS, movement control becomes abnormal, slow, labored, uncoordinated, or weak, or movement may not be produced at all. The damaged nervous system is able to repair itself, change, and adapt to some extent by means of nerve regeneration and neuroplasticity. However, when nerve cells die and neural connections are not viable, alternative pathways within the nervous system exist to take the place of the normal process and provide some means of meeting the movement goal—whether it is to walk, use an arm to eat, or make a facial expression. This process of change, healing, or motor learning depends on many factors including inherent elements of the individual such as age, the extent of tissue damage, and other physiological and cognitive processes, as well as external factors such as interactions with sensory and motor system challenges, and

goal-directed practice of meaningful, functional motor skills.

This chapter introduces the reader to basic concepts of motor control, motor learning, and neuroplasticity. Figures and tables are provided within each section to emphasize and summarize concepts. A patient case example is used to illustrate concepts in this chapter as they apply to the evaluation and management of people with neurological conditions. This chapter provides a foundation for chapters in Section II: Rehabilitation Management of Clients with Neurological System Pathology, and acts as a foundation for interacting with and treating patients in any clinical setting.

MOTOR CONTROL

Motor control is defined as “the systematic transmission of nerve impulses from the motor cortex to motor units, resulting in coordinated contractions of muscles.”¹

This definition describes motor control in the simplest terms—as a top-down direction of action through the nervous system. In reality, the process of controlling movement begins before the plan is executed, and ends after the muscles have contracted. The essential details of a movement plan must be determined by the individual before the actual execution of the plan. The nervous system actively adjusts muscle force, timing, and tone before the muscles begin to contract, continues to make adjustments throughout the motor action, and compares movement performance with the goal and neural code (directions) of the initial motor plan. This extension of the definition takes into account that the body *accesses sensory information* from the environment, *perceives* the situation and *chooses a movement plan* that it

believes to be the appropriate plan to meet the outcome goal of the task that the person is attempting to complete, *coordinates this plan* within the CNS, and finally *executes* the plan through motor neurons in the brain stem and spinal cord to communicate with muscles in postural and limb synergies, plus muscles in the head and neck that are timed to fire in a specific manner. The movement that is produced supplies *sensory feedback* to the CNS to allow the person to (1) modify the plan during performance, (2) know whether the goal of the task has been achieved, and (3) store the information for future performance of the same task-goal combination. Repeated performance of the same movement plan tends to create a preferred pattern that becomes more automatic in nature and less variable in performance. If this movement pattern is designed and executed well, then it is determined that the person has developed a skill. If this pattern is incorrect and does not efficiently accomplish the movement goal, then it is considered abnormal.

Theories and Models of Motor Control

We begin this section with a summary and historical perspective of motor control theories (Table 4-1). The control of human movement has been described in many different ways. The production of reflexive, automatic, adaptive, and voluntary movements and the performance of efficient, coordinated, goal-directed movement patterns involve multiple body systems (input, output, and central processing) and multiple levels within the nervous system. Each model of motor control that is discussed in this section has both merit and disadvantage in its ability to supply a comprehensive picture of motor behavior. These theories serve as a basis for

predicting motor responses during patient examination and treatment. They help explain motor skill performance, potential, constraints, limitations, and deficits. They allow the clinician to (1) identify problems in motor performance, (2) develop treatment strategies to help clients remediate performance problems, and (3) evaluate the effectiveness of intervention strategies employed in the clinic. Selecting and using an appropriate model of motor control is important for the analysis and treatment of clients with dysfunctions of posture and movement. As long as the environment and task demands affect changes in the CNS and the individual has the desire to learn, the adaptable nervous system will continue to learn, modify, and adapt motor plans throughout life.

Motor Programs and Central Pattern Generators

A motor program (MP) is a learned behavioral pattern defined as a neural network that can produce rhythmic output patterns with or without sensory input or central control.² MPs are sets of movement commands, or “rules,” that define the details of skilled motor actions. An MP defines the specific muscles that are needed, the order of muscle activation, and the force, timing, sequence, and duration of muscle contractions. MPs help control the degrees of freedom of interacting body structures, and the number of ways each individual component acts. A generalized motor program (GMP) defines a pattern of movement, rather than every individual aspect of a movement. GMPs allow for the adjustment, flexibility, and adaptation of movement features according to environmental demands. The existence of MPs and GMPs is a generally accepted concept; however, hard evidence that an MP or a GMP exists has yet to

TABLE 4-1 ■ THEORIES OF MOTOR CONTROL

MOTOR CONTROL THEORY	AUTHOR AND DATE	PREMISE
Reflex Theory	Sherrington 1906 ²⁴⁴	Movement is controlled by stimulus-response. Reflexes are combined into actions that create behavior.
Hierarchical Theories	Adams 1971 ²⁴⁵	Cortical centers control movement in a top-down manner throughout the nervous system. Closed-loop mode: sensory feedback is needed and used to control the movement. Open-loop mode: movements are preprogrammed and no feedback is used.
Dynamical Systems Theory	Bernstein 1967 ¹⁰ Turvey 1977 ²⁴⁶ Kelso and Tuller 1984 ²⁴⁷ Thelen 1987 ²⁴⁸	Movement emerges to control degrees of freedom. Patterns of movements self-organize within the characteristics of environmental conditions and the existing body systems of the individual. Functional synergies are developed naturally through practice and experience and help solve the problem of coordinating multiple muscles and joint movements at once.
Motor Program Theory	Schmidt 1976 ²⁴⁹	Adaptive, flexible motor programs (MPs) and generalized motor programs (GMPs) exist to control actions that have common characteristics.
Ecological Theories	Gibson and Pick 2000 ²⁵⁰	The person, the task, and the environment interact to influence motor behavior and learning. The interaction of the person with any given environment provides perceptual information used to control movement. The motivation to solve problems to accomplish a desired movement task goal facilitates learning.
Systems Model	Shumway-Cook 2007 ³⁵	Multiple body systems overlap to activate synergies for the production of movements that are organized around functional goals. Considers interaction of the person with the environment.

be found. Advancements in brain imaging techniques may substantiate this theory in the future.^{2,3}

In contrast to MPs, a central pattern generator (CPG) is a genetically predetermined movement pattern.⁴ CPGs exist as neural networks within the CNS and have the capability of producing rhythmic, patterned outputs resembling normal movement. These movements have the capability of occurring without sensory feedback inputs or descending motor inputs. Two characteristic signs of CPGs are that they result in the repetition of movements in a rhythmic manner and that the system returns to its starting condition when the process ceases.⁵ Both MPs and CPGs contribute to the development, refinement, production, and recovery of motor control throughout life.

The Person, the Task, and the Environment: An Ecological Model for Motor Control

Motor control evolves so that people can cope with the environment around them. A person must focus on detecting information in the immediate environment (perception) that is determined to be necessary for performance of the task and achievement of the desired outcome goal. The individual is an active observer and explorer of the environment, which allows the development of multiple ways in which to accomplish (choose and execute) any given task. The individual analyzes a particular sensory environment and chooses the most suitable and efficient way to complete the task. The *person* consists of all functional and dysfunctional body structures and functions that exist and interact with one another. The *task* is the goal-directed behavior, challenge, or problem to be solved. The *environment* consists of everything outside of the body that exists, or is perceived to exist, in the external world. All three of these motor control constructs (person, task, environment) are dynamic and variable, and they interact with one another during learning and production of a goal-directed, effective motor plan.

Body Structures and Functions that Contribute to the Control of Human Posture and Movement

Keen observation of motor output quality during the performance of functional movement patterns helps the therapist determine activity limitations and begin to hypothesize impairments within sensory, motor, musculoskeletal, cardio-pulmonary, and other body systems. The following section presents and defines some of these key factors, including sensory input systems, motor output systems, and structures and functions involved in the integration of information in the CNS.

Role of Sensory Information in Motor Control

Sensory receptors from somatosensory (exteroceptors and proprioceptors), visual, and vestibular systems and taste, smell, and hearing fire in response to interaction with the external environment and to movement created by the body. Information about these various modalities is transmitted along afferent peripheral nerves to cells in the spinal cord and brain stem of the CNS. All sensory tracts, with the exception of smell, then synapse in respective sensory nuclei of the thalamus, which acts as a filter and relays this information to the appropriate lobe of the cerebral cortex (e.g., somatosensory to parietal lobe, visual to occipital lobe,

vestibular, hearing, and taste to temporal lobe). Sensory information is first received and perceived, then associated with other sensory modalities and memory in the association cortex. Once multiple sensory inputs are associated with one another, the person is then able to *perceive* the body, its posture and movement, the environment and its challenges, and the interaction and position of the body with objects within the environment. The person uses this perceptual information to create an internal representation of the body (internal model) and to choose a movement program, driven by motivation and desire, to meet a final outcome goal. Although the sensory input and motor output systems operate differently, they are inseparable in function within the healthy nervous system. Agility, dexterity, and the ability to produce movement plans that are adaptable to environmental demands reflect the accuracy, flexibility, and plasticity of the sensory-motor system.

The CNS uses sensory information in a variety of ways to regulate posture and movement. Before movement is initiated, information about the position of the body in space, body parts in relation to one another, and environmental conditions is obtained from multiple sensory systems. Special senses of vision, vestibular inputs that respond to gravity and movement, and visual-vestibular interactions supply additional information necessary for static and dynamic balance and postural control as well as visual tracking. Auditory information is integrated with other sensory inputs and plays an important role in the timing of motor responses with environmental signals, reaction time, response latency, and comprehension of spoken word. This information is integrated and used in the selection and execution of the movement strategy. During movement performance, the cerebellum and other neural centers use feedback to compare the actual motor behavior with the intended motor plan. If the actual and intended motor behaviors do not match, an error signal is produced and alterations in the motor behavior are triggered. In some instances, the control system anticipates and makes corrective changes before the detection of the error signal. This anticipatory correction is termed *feed-forward control*. Changing one's gait path while walking in a busy shopping mall to avoid a collision is an example of how visual information about the location of people and objects can be used in a feed-forward manner.

Another role of sensory information is to revise the reference of correctness (central representation) of the MP before it is executed again. For example, a young child standing on a balance beam with the feet close together falls off of the beam. An error signal occurs because of the mismatch between the intended motor behavior and the actual motor result. If the child knows that the feet were too close together when the fall occurred, then the child will space the feet farther apart on the next trial. The information about what happened, falling or not falling, is used in planning movement strategies for balancing on any narrow object such as a balance beam, log, or wall in the future.

Sensory information is necessary during the acquisition phase of learning a new motor skill and is useful for controlling movements during the execution of the motor plan.⁶⁻⁸ However, sensory information is not always necessary when performing well-learned motor behaviors in a stable and familiar context.^{6,7} Rothwell and colleagues⁷ studied a man with severe sensory neuropathy in the upper extremity. He could write sentences with his eyes closed and drive a car

with a manual transmission without watching the gear shift. He did, however, have difficulty with fine motor tasks such as buttoning his shirt and using a knife and fork to eat when denied visual information. The importance of sensory information must be weighed by the individual, unconsciously filtering and choosing appropriate and accurate sensory inputs to use to meet the movement goal.

Sensory experiences and learning alter sensory representations, or cortical “maps,” in the primary somatosensory, visual, and auditory areas of the brain. Training, as well as use and disuse of sensory information, has the potential to drive long-term structural changes in the CNS, including the formation, removal, and remodeling of synapses and dendritic connections in the cortex. This process of cortical plasticity is complex and involves multiple cellular and synaptic mechanisms.⁹ Plasticity in the nervous system is discussed further in the third section of this chapter.

Choice of Motor Pattern and the Control of Voluntary Movement

A choice of body movement is made based on the person’s perception of the environment, his or her relationship to objects within it, and a goal to be met. The person chooses from a collection of plans that have been developed and refined over his or her lifetime. If a movement plan does not exist, a similar plan is chosen and modified to meet the needs of the task. Once the plan has been chosen it is customized by the CNS with what are determined to be the correct actions to execute given the perceived situation and goal of the individual.

Coordination

The movement plan is customized by communications among the frontal lobes, basal ganglia, and cerebellum, with functional connections through the brain stem and thalamus. During this process specific details of the plan are determined. Postural tone, coactivation, and timing of trunk muscle firing are set for proximal stability, balance, and postural control. Force, timing, and tone of limb synergies are set to allow for smooth, coordinated movements that are accurate in direction of trajectory, order, and sequence. The balance between agonist and antagonist muscle activity is determined so that fine distal movements are precise and skilled. This process is complicated by the number of possible combinations of musculoskeletal elements. The CNS must solve this “degrees of freedom” problem so that rapid execution of the goal-directed movement can proceed and reliably meet the desired outcome.¹⁰ Once these movement details are complete the motor plan is executed by the primary motor area in the precentral gyrus of the frontal lobe.

Execution

Pyramidal cells in the corticospinal and corticobulbar tracts *execute* the voluntary motor plan. Neural impulses travel down these central efferent systems and communicate with motor neurons in the brain stem and spinal cord. The corticobulbar tract communicates with brain stem motor nuclei to control muscles of facial expression, mouth and tongue for speaking and eating, larynx and pharynx for voice and swallow, voluntary eye movements for visual tracking and saccades, and muscles of the upper trapezius for shoulder girdle elevation. The corticospinal tract communicates with

motor neurons in the spinal cord. The ventral corticospinal tract system communicates primarily with proximal muscle groups to provide the appropriate amount of activation to stabilize the trunk and limb girdles, thus allowing for dexterous distal limb movements. The lateral corticospinal tract system communicates primarily with muscles of the arms and legs—firing alpha motor neurons in coordinated synergy patterns with appropriate activity in agonist and antagonist muscles so that movements are smooth and precise. Other motor nuclei in the brain stem are programmed to fire just before corticospinal tract activity in order to supply postural tone. These include lateral and medial vestibular spinal tracts, reticulospinal tract, and rubrospinal tract systems. Adequate and balanced muscle tone of flexors and extensors in the trunk and limbs occurs automatically, without the need for conscious control. These brain stem nuclei have tonic firing rates that are modulated up or down to effectively provide more or less muscle tone in body areas depending on stimulation from gravity, limbic system activity, external perturbations, or other neuronal activity.

Adaptation

Adaptation is the process of using sensory inputs from multiple systems to adapt motor plans, decrease performance errors, and predict or estimate consequences of movement choices. The goal of adaptation is the production of consistently effective and efficient skilled motor actions. When all possible body systems and environmental conditions are considered in the motor control process, it is easy to understand why there is often a mismatch between the movement plan that is chosen and how it is actually executed. Errors in movements occur and cause problems that the nervous system must solve in order to deliver effective, efficient, accurate plans that meet the task goal. To solve this problem the CNS creates an internal representation of the body and the surrounding world. This acts as a model that can be adapted and changed in the presence of varying environmental demands. It allows for the ability to predict and estimate the differences between similar situations. This ability is learned by practicing various task configurations in real-life environments. Without experience, accurate movement patterns that consistently meet desired task goals are difficult to achieve.¹¹

Anticipatory Control

Anticipatory control of posture and postural adjustments stabilizes the body by minimizing displacement of the center of gravity. Anticipatory control involves motor plans that are programmed to act in advance of movement. A comparison between incoming sensory information and knowledge of prior movement successes and failures enables the system to choose the appropriate course of action.³

Flexibility

A person should have enough flexibility in performance to vary the details of a simple or complex motor plan to meet the challenge presented by any given environmental context. This is a beneficial characteristic of motor control. When considering postural control, for example, a person will typically display a random sway pattern during standing that may ensure continuous, dynamic sensory inputs to multiple sensory systems.¹² The person is constantly adjusting

posture and position to meet the demand of standing upright (earth vertical), as well as to seek information from the environment. Rhythmic, oscillating, or stereotypical sway patterns that are unidirectional in nature are not considered flexible and are not as readily adaptable to changes in the environment. Lack of flexibility or randomness in postural sway may actually render the person at greater risk for loss of balance and falls.

Control of Voluntary Movement

Table 4-2 shows the body system processes involved in motor control, their actions, and the body structures included. The following section explains these processes in more detail.

Role of the Cerebellum

The primary roles of the cerebellum are to maintain posture and balance during static and dynamic tasks and to coordinate movements before execution and during performance. The cerebellum processes multiple neural signals from (1) motor areas of the cerebral cortex for motor planning, (2) sensory tract systems (dorsal spinal cerebellar tract, ventral spinal cerebellar tract) from muscle and joint receptors for proprioceptive and kinesthetic sense information resulting from movement performance, and (3) vestibular system information for the regulation of upright control and balance at rest and during movements. It compares motor plan signals driven by the cortex with what is received from muscles and joints in the periphery and makes necessary adjustments and adaptations to achieve the intended coordinated movement sequence. Movements that are frequently repeated “instructions” are stored in the cerebellum as procedural memory traces. This increases the efficiency of its role in coordinating movement. The cerebellum also plays a role in function of the reticular activating system (RAS). The RAS network exists in the brain stem tegmentum and consists of a network of nerve cells that maintain consciousness in humans and help people focus attention and block out distractions that may affect motor performance. Damage to

the cerebellum, its tract systems, or its structure creates problems of movement coordination, not execution or choice of which program to run. The cerebellum also plays a role in language, attention, and mental imagery functions that are not considered to take place in motor areas of the cerebral cortex (see Table 4-2).

The cerebellum plays four important roles in motor control¹³:

1. *Feed-forward processing*: The cerebellum receives neural signals, processes them in a sequential order, and sends information out, providing a rapid response to any incoming information. It is not designed to act like the cerebral cortex and does not have the capability of generating self-sustaining neural patterns.
2. *Divergence and convergence*: The cerebellum receives a great number of inputs from multiple body structures, processes this information extensively through a structured internal network, and sends the results out through a limited number of output cells.
3. *Modularity*: The cerebellum is functionally divided into independent modules—hundreds to thousands—all with different inputs and outputs. Each module appears to function independently, although they each share neurons with the inferior olives, Purkinje cells, mossy and parallel fibers, and deep cerebellar nuclei.
4. *Plasticity*: Synapses within the cerebellar system (between parallel fibers and Purkinje cells, and synapses between mossy fibers and deep nuclear cells) are susceptible to modification of their output strength. The influence of input on nuclear cells is adjustable, which gives great flexibility to adjust and fine-tune the relationship between cerebellar inputs and outputs.

Role of the Basal Ganglia

The basal ganglia are a collection of nuclei located in the forebrain and midbrain and consisting of the globus pallidus, putamen, caudate nucleus, substantia nigra, and subthalamic nuclei. It has primary functions in motor control and motor learning. It plays a role in deciding which motor plan

TABLE 4-2 ■ COMPONENTS OF MOTOR CONTROL: BODY SYSTEM PROCESSES INVOLVED IN MOTOR CONTROL, THEIR ACTIONS, AND THE BODY STRUCTURES INCLUDED

PROCESS	ACTION	BODY STRUCTURES INVOLVED
Sensation	Sensory information, feedback from exteroceptors and proprioceptors	Peripheral afferent neurons, brain stem, cerebellum, thalamus, sensory receiving areas in the parietal, occipital, and temporal lobes
Perception	Combining, comparing, and filtering sensory inputs	Brain stem, thalamus, sensory association areas in the parietal, occipital, visual, and temporal lobes
Choice of movement plan	Use of the perceptual map to access the appropriate motor plan	Association areas, frontal lobe, basal ganglia
Coordination	Determining the details of the plan including force, timing, tone, direction, and extent of the movement of postural and limb synergies and actions	Frontal lobe, basal ganglia, cerebellum, thalamus
Execution	Execution of the motor plan	Corticospinal and corticobulbar tract systems, brain stem motor nuclei, and alpha and gamma motor neurons
Adaptation	Compare movement with the motor plan and adjust the plan during performance	Spinal neural networks, cerebellum

or behavior to execute at any given time. It has connections to the limbic system and is therefore believed to be involved in “reward learning.” It plays a key role in eye movements through midbrain connections with the superior colliculus and helps to regulate postural tone as a basis for the control of body positions, preparedness, and central set. Refer to Chapter 20 for additional information on the basal ganglia.

Information Processing

The processing of information through the sensory input, motor output, and central integrative structures occurs by various methods to produce movement behaviors. These methods allow us to deal with the temporal and spatial components necessary for coordinated motor output and allow us to anticipate so that a response pattern may be prepared in advance. *Serial processing* is a specific, sequential order of processing of information (Figure 4-1) through various centers. Information proceeds lockstep through each center. *Parallel processing* is processing of information that can be used for more than one activity by more than one center simultaneously or nearly simultaneously. A third and more flexible type of processing of information is *parallel-distributed processing*.¹⁴ This type of processing combines the best attributes of serial and parallel processing. When the situation demands serial processing, this type of activity occurs. At other times parallel processing is the mode of choice. For optimal processing of intrinsic and extrinsic sensory information by various regions of the brain, a combination of both serial and parallel processing is the most efficient mode. The type of processing depends on the constraints of the situation. For example, maintaining balance after an unexpected external perturbation requires rapid processing, whereas learning to voluntarily shift the center of gravity to the limits of stability requires a different combination of processing modes.

In summary, information processing reinforces and refines motor patterns. It allows the organism to initiate compensatory strategies if an ineffective motor pattern is selected or if an unexpected perturbation occurs. And, most important, information processing facilitates motor learning.

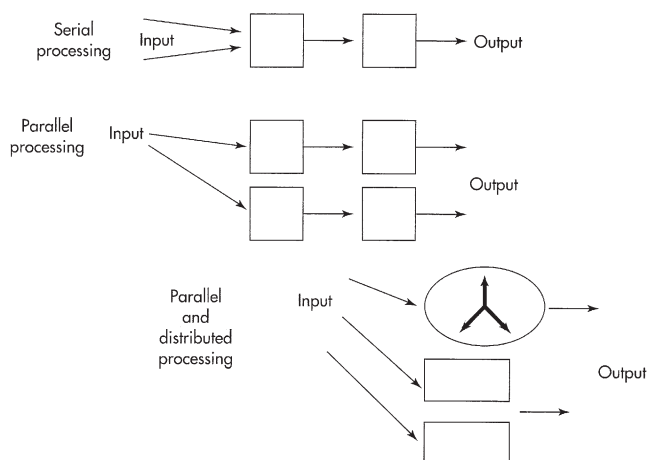

Figure 4-1 ■ Methods of information processing.

Movement Patterns Arising from Self-Organizing Subsystems

Coordinated movement patterns are developed and refined via dynamic interaction among body systems and subsystems in response to internal and external constraints. Movement patterns used to accomplish a goal are contextually appropriate and arise as an emergent property of subsystem interaction. Several principles relate to self-organizing systems: reciprocity, distributed function, consensus, and emergent properties.¹⁵

Reciprocity implies information flow between two or more neural networks. These networks can represent specific brain centers, for example, the cerebellum and basal ganglia (Figure 4-2). Alternatively, the neural networks can be interacting neuronal clusters located within a single center, for example, the basal ganglia. One model to demonstrate reciprocity is the basal ganglia regulation of motor behavior through direct and indirect pathways to cortical areas. The more direct pathway from the putamen to the globus pallidus internal segment provides net inhibitory effects. The more indirect pathway from the putamen through the globus pallidus external segment and subthalamic nucleus provides a net excitatory effect on the globus pallidus internal segment. Alteration of the balance between these pathways is postulated to produce motor dysfunction.^{16,17} An abnormally decreased outflow from the basal ganglia is postulated to produce involuntary motor patterns, which produce excessive motion such as chorea, hemiballism, or nonintentional tremor. Alternatively, an abnormally increased outflow from the basal ganglia is postulated to produce a paucity of motions, as seen in the rigidity observed in individuals with Parkinson disease (see Chapter 20).

Distributed function presupposes that a single center or neural network has more than one function. The concept also implies that several centers share the same function. For example, a center may serve as the coordinating unit of an activity in one task and may serve as a pattern generator or oscillator to maintain the activity in another task. An advantage of distributing function among groups of neurons or centers is to provide centers with overlapping or redundant functions. Neuroscientists believe such redundancy is a safety feature. If a neuronal lesion occurs, other centers can

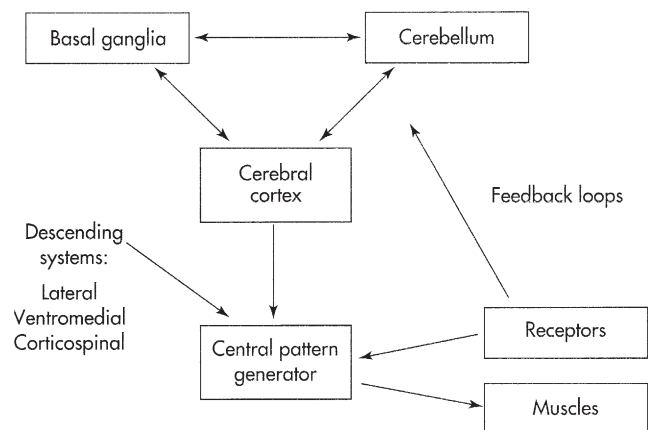

Figure 4-2 ■ Systems model of motor control.

assume critical functional roles, thereby producing recovery from CNS dysfunction.¹⁸⁻²²

Consensus implies that motor behavior occurs when a majority of brain centers or regions reach a critical threshold to produce activation. Also, through consensus extraneous information or information that does not require immediate attention is filtered. If, however, a novel stimulus enters the system, it carries more weight and receives immediate attention. A novel stimulus may be new to the system, may reflect a potentially harmful situation, or may result from the conflict of multiple inputs.

Emergent properties may be understood by the adage “the whole is greater than the sum of its parts.” This concept implies that brain *centers*, not a single brain center, work together to produce movement. An example of the emergent properties concept is continuous repetitive activity (oscillation). In Figure 4-3, A, a hierarchy is represented by three neurons arranged in tandem. The last neuron ends on a responder. If a single stimulus activates this network, a single response occurs. What is the response if the neurons are arranged so that the third neuron sends a collateral branch to the first neuron in addition to the ending on the responder? In this case (Figure 4-3, B), a single stimulus activates neuron No. 1, which in turn activates neurons No. 2 and No. 3, causing a response as well as reactivating neuron No. 1. This neuronal arrangement produces a series of responses rather than a single response. This process is also termed *endogenous activity*.

Another example of an emergent property is the production of motor behavior. Rather than having every MP stored in the brain, an abstract representation of the intended goal is stored. At the time of motor performance, various brain centers use the present sensory information, combined with past memory of the task, to develop the appropriate motor strategy. This concept negates a hardwired MP concept. If MPs were hardwired and if an MP existed for every movement ever performed, the brain would need a huge storage capacity and would lack the adaptability necessary for complex function.

A. A single response per stimulus

B. Emergent property: more than one response

Key:

N = neuron

$S+t_0$ = start time

$R+t$ = response 1; response 2, etc.

Figure 4-3 ■ Emergent property.

Controlling the Degrees of Freedom

Combinations of muscle and joint action permit a large number of degrees of freedom that contribute to movement. A system with a large number of degrees of freedom is called a *high-dimensional system*. For a contextually appropriate movement to occur, the number of degrees of freedom needs to be constrained. Bernstein¹⁰ suggested that the number of degrees of freedom could be reduced by muscles working in synergies, that is, coupling muscles and joints of a limb to produce functional patterns of movement. The functional unit of motor behavior is then a *synergy*. Synergies help to reduce the degrees of freedom, transforming a high-dimensional system into a low-dimensional system. For example, a step is considered to be a functional synergy pattern for the lower extremity. Linking together stepping synergies with the functional synergies of other limbs creates locomotion (interlimb coordination).

Functional synergy implies that muscles are activated in an appropriate sequence and with appropriate force, timing, and directional components. These components can be represented as fixed or “relative” ratios, and the control comes from input given to the cerebellum from higher centers in the brain and the peripheral or spinal system and from prior learning (see Chapter 21).^{20,22,23} The relative parameters are also termed *control parameters*. Scaling control parameters leads to a change in motor behavior to accomplish the task. For example, writing your name on the blackboard exemplifies scaling force, timing, and amplitude. Scaling is the proportional increase or decrease of the parameter to produce the intended motor activity.

Coordinated movement is defined as an orderly sequence of muscle activity in a single functional synergy or the orderly sequence of functional synergies with appropriate scaling of activation parameters necessary to produce the intended motor behavior. Uncoordinated movement can occur at the level of the scaling of control parameters in one functional synergy or inappropriate coupling of functional synergies. The control parameter of duration will be used to illustrate scaling. If muscle A is active for 10% of the duration of the motor activity and muscle B is active 50% of the time, the fixed ratio of A/B is 1:5. If the movement is performed slowly, the relative time for the entire movement increases. Fixed ratios also increase proportionally. Writing your name on a blackboard very small or very large yields the same results—your name.

Timing of muscle on/off activation for antagonistic muscles such as biceps and triceps, or hamstrings and quadriceps, needs to be accurate for coordination and control of movement patterns. If one muscle group demonstrates a delayed onset or maintains a longer duration of activity, overlapping with triceps “on” time, the movement will appear uncoordinated. Patients with neurological dysfunction often demonstrate alterations in the timing of muscle activity within functional synergies and in coupling functional synergies to produce movement.^{24,25} These functional movement synergies are not hardwired but represent emergent properties. They are flexible and adaptable to meet the challenges of the task and the environmental constraints.

Finite Number of Movement Strategies

The concept of *emergent properties* could conceivably imply an unlimited number of movement strategies available to perform a particular task. However, limiting the degrees of

freedom decreases the number of strategies available for selection. In addition, constraints imposed by the internal environment (e.g., musculoskeletal system, cardiovascular system, metabolic activity, cognition) and external environment (e.g., support surface, obstacles, lighting) limit the number of movement strategies. Horak and Nashner²⁶ observed that a finite number of balance strategies were used by individuals in response to externally applied linear perturbations on a force plate system. With use of a life span approach, VanSant²⁷ identified a limited number of movement patterns for the upper limb, head-trunk, and lower limb for the task of rising from supine to standing.

The combination of these strategies produces the necessary variability in motor behavior. Although an individual has a preferred or modal profile, the healthy person with an intact neuromuscular system can combine strategies in various body regions to produce different movement patterns that also accomplish the task. Persons with neurological deficits may be unable to produce a successful, efficient movement pattern because of their inability to combine strategies or adapt a strategy for a given environmental change (e.g., differing chair height for sit-to-stand transitions).

Variability of Movements Implies Normalcy

A key to the assessment and treatment of individuals with neurological dysfunction lies in variability of movement and in the notion that variability is a sign of normalcy, and stereotypical behavior is a sign of dysfunction.

Age, activity level, the environment, constraints of a goal, and neuropathological conditions affect the selection of patterns available for use during movement tasks. When change occurs in one or more of the neural subsystems, a new movement pattern emerges. The element that causes change is called a *control parameter*. For example, an increase in the speed of walking occurs until a critical speed and degree of hip extension are reached, thereby switching the movement pattern to a run. When the speed of the run is decreased, there is a shift back to the preferred movement pattern of walking. A control parameter shifts the individual into a different pattern of motor behavior.

This concept underlies theories of development and learning. Development and learning can be viewed as moving the system from a stable state to a more unstable state. When the control variable is removed, the system moves back to the early, more stable state. As the control variable continues to push the system, the individual spends more time in the new state and less time in the earlier state until the individual spends most of the time in the new state. When this occurs, the new state becomes the preferred state. Moving or shifting to the new, preferred state does not obviate the ability of the individual to use the earlier state of motor behavior. Therefore new movement patterns take place when critical changes occur in the system because of a control parameter but do not eliminate older, less-preferred patterns of movement.

Motivation to accomplish a task in spite of functional limitations and neuropathological conditions can also shift the individual's CNS to select different patterns of motor behavior. The musculoskeletal system, by nature of the architecture of the joints and muscle attachments, can be a constraint on the movement pattern. An individual with a

functional contracture may be limited in the ability to bend a joint only into a desired range, thereby decreasing the movement repertoire available to the individual. Such a constraint produces adaptive motor behavior. Dorsiflexion of the foot needs to meet a critical degree of toe clearance during gait. If there is a range of motion limitation in dorsiflexion, then biomechanical constraints imposed on the nervous system will produce adaptive motor behaviors (e.g., toe clearance during gait). Changes in motor patterns during the task of rising from supine to standing are observed when healthy individuals wear an orthosis to limit dorsiflexion.²⁸ The inability to easily open and close the hand with rotation may lead to adaptations that require the shoulder musculature to place the hand in a more functional position. This adaptation uses axial and trunk muscles and will limit the use of that limb in both fine and gross motor performance. Refer to Chapter 23.

Preferred, nonobligatory movement patterns that are stable yet flexible enough to meet ever-changing environmental conditions are considered *attractor states*. Individuals can choose from a variety of movement patterns to accomplish a given task. For example, older adults may choose from a variety of fall-prevention movement patterns when faced with the risk of falling. The choice of motor plan may be negatively influenced by age-related declines in the sensory input systems or a fear of falling. For example, when performing the Multi-Directional Reach Test,²⁹ an older adult may choose to reach forward, backward (lean), or laterally without shifting the center of gravity toward the limits of stability. This person has the capability of performing a different reaching pattern if asked, but prefers a more stable pattern.

Obligatory and stereotypical movement patterns suggest that the individual does not have the capability of adapting to new situations or cannot use different movement patterns to accomplish a given task. This inability may be a result of internal constraints that are functional or pathophysiological. The patient who has had a stroke has CNS constraints that limit the number of different movement patterns that can emerge from the self-organizing system. With recovery, the patient may be able to select and use additional movement strategies. Cognition and the capability to learn may also limit the number of movement patterns available to the individual and the ability of the person to select and use new or different movement patterns.

Obligatory and stereotypical movement patterns also arise from external constraints imposed on the organism. Consider the external constraints placed on a concert violin player. These external constraints include, for example, the length of the bow and the position of the violin. Repetitive movement patterns leading to cumulative trauma disorder in healthy individuals can lead to muscular and neurological changes.³⁰⁻³³ Over time, changes in dystonic posturing and changes in the somatosensory cortex have been observed. Although one hypothesis considers that the focal dystonia results from sensory integrative problems, the observable result is a stereotypical motor problem.

To review, the nervous system responds to a variety of internal and external constraints to develop and execute motor behavior that is efficient to accomplish a specific task. Efficiency can be examined in terms of metabolic cost to the individual, type of movement pattern used, preferred or

habitual movement (habit) used by the individual, and time to complete the task. The term *attractor state* is used in dynamical systems theory to describe the preferred pattern or habitual movement.

Individuals with neurological deficits may have limited repertoires of movement strategies available. Patients experiment with various motor patterns in order to learn the most efficient, energy-conscious motor strategy to accomplish the task. Therapists can plan interventions that help to facilitate refinement of the task to match the patient's capability, allowing the task to be completed using a variety of movement strategies rather than limited stereotypical strategies, leading to an increase in function.

Errors in Motor Control

When the actual motor behavior does not match the intended motor plan, an error in motor control is detected by the CNS. Common examples of errors in motor control are loss of balance; inappropriate scaling of force, timing, or directional control; and inability to ignore unreliable sensory information, resulting in sensory conflict. Any one or combination of these errors may be the cause of a fall or error in performance accuracy.

Errors also occur when unexpected factors disrupt the execution of the program. For example, when the surface is unreliable (sand, unstable, moving), this will force the individual to adapt motor responses to meet the demand of the environment. Switching between closed environments (more stable) and open environments (more unpredictable) will challenge the individual to adapt motor responses. When an individual steps off of a moving sidewalk, a disruption in walking occurs. The first few steps are not smooth because the person needs to switch movement strategies from one incorporating a moving support surface to one incorporating a stationary support surface.

Errors occur in the perception of sensory information, in selection of the appropriate MP, in selection of the appropriate variable parameters, or in the response execution. Patients with neurological deficits may demonstrate a combination of these errors. Therefore an assessment of motor deficits in clients includes analysis of these types of errors. If a therapist observes a motor control problem, there is no guarantee that the central problem arises from within the motor system. Somatosensory problems can drive motor dysfunction; cognitive and emotional problems express themselves through motor output. Thus it is up to the movement specialist to differentiate the cause of the problem through valid and reliable examination tools (see Chapter 8). Once the cause of the motor problem has been identified, selection of interventions should lead to more outcomes.

All individuals, both healthy and those with CNS dysfunction, make errors in motor programming. These errors are assessed by the CNS and are stored in past memory of the experience. Errors in motor programming are extremely useful in learning. Learning can be viewed as decreasing the mismatch between the intended and actual motor behavior. This mismatch is a measure of the error; therefore a decrease in the degree of the error is indicative of learning. Errors, then, are an important part of the rehabilitation process. However, this does not mean that the therapist allows the client to practice errors over and over. The ability of the patient to detect an error and correct it to produce appropriate and

efficient motor behavior is one key to recovery and an important consideration when intervention strategies are developed. This will be discussed further in the next section of this chapter.

Motor Control Section Summary

Motor control theories have been developed and have evolved over many years as our understanding of nervous system structure and function has become more advanced. The control of posture and movement is a complex process that involves many structures and levels within the human body. It requires accurate sensory inputs, coordinated motor outputs, and central integrative processes to produce skillful, goal-directed patterns of movement that achieve desired movement goals. We must integrate and filter multiple sensory inputs from both the internal environment of the body and the external world around us to determine position in space and choose the appropriate motor plan to accomplish a given task. We combine individual biomechanical and muscle segments of the body into complex movement synergies to deal with the infinite "degrees of freedom" available during the production of voluntary movement. Well learned motor plans are stored and retrieved and modified to allow for flexibility and variety of movement patterns and postures. When the PNS or CNS is damaged and the control of movement is impaired, new, modified, or substitute motor plans can be generated to accomplish goal-directed behaviors, remain adaptable to changing environments, and produce variable movement patterns. The process of learning new motor plans and refining existing behaviors by driving neuroplastic changes in the nervous system is discussed in the next sections of this chapter. The control of posture and balance is also discussed in Chapter 22.

MOTOR LEARNING

Therapeutic interventions that are focused on restoring functional skills to individuals with various forms of neurological problems have been part of the scope of practice of physical therapists (PTs) and occupational therapists (OTs) since the beginning of both professions. These two professions have emerged with a complementary background to examine, evaluate, determine a prognosis, and implement interventions that empower clients to regain functional control of activities of daily living (ADLs) (e.g., getting out of bed, bathing, walking, and eating, as well as working, playing, and socially interacting) and resume active participation in life after neurological insult. These two professions specialize in the analysis of movement and possess knowledge of the scientific background to understand why the movement is occurring, what strengths and limitations exist within body systems to produce that movement, and how different therapeutic interventions can facilitate or enhance functional movement strategies that remediate dysfunction and ultimately carry over into improved performance of daily activities and participation in life of an individual. PTs and OTs are also knowledgeable about diseases of body systems (neurological, musculoskeletal, integumentary, cardiopulmonary, and integumentary systems) and how the existence or progression of these pathological states affects motor performance and quality of life. Consideration and training of individuals who give assistance and support needed to help clients maintain functional skills during

transitional disease states is also a component of practice and of treating the client in a holistic manner.

It is therefore important for clinicians to understand how individuals learn or relearn motor tasks and how learning of motor skills can best be achieved to optimize outcomes.

Motor learning results in a permanent change in the performance of a skill because of experience or practice.³⁴ The end result of motor learning is the acquisition of a new movement, or the reacquisition and/or modification of movement.³⁵ The patient must be able to prepare and carry out a particular learned movement³⁶ in a manner that is efficient (optimal movement with the least amount of time, energy, and effort),³⁷ consistent (same movement over repeated trials),³⁸ and transferrable (ability to perform movement under different environments and conditions) to be considered to have learned a skill.

Long-term learning of a particular motor task allows the patient to use this particular skill to optimize function. This type of learning is expressed in declarative and procedural memory. Declarative or explicit memory is expressed by conscious recall of facts or knowledge. An example of this could be the patient verbally stating the steps needed when going up the stairs with the use of crutches. This is opposed to procedural (or nondeclarative) learning, in which movement is performed without conscious thought (e.g., riding a bike or rollerblading). The interplay of conscious (cognitive and emotional) and unconscious memory affects ultimate learning and may decrease the time needed to learn or relearn a functional movement and its use in everyday activity.

The ability of an individual to have learned a motor skill is measured indirectly by testing the ability of a patient to perform a particular task or activity both over time and in different environmental contexts (performance). The testing must be done over a period of time to determine long-term learning and minimize the temporary effects of practice. In *retention tests*, the patient performs the task under the

same conditions in which the task was practiced. This type of test evaluates the patient's ability to learn the task. This is in contrast to *transfer tests*, in which the patient performs the activity under different conditions from those in which the skill was practiced. This evaluates the ability of the patient to use a previously learned motor skill to solve a different motor problem.

Motor skills can be categorized as discrete, continuous, or serial. Discrete motor skills pertain to tasks that have a specific start and finish. Tasks that are repetitive are classified as *continuous* motor skills. Serial skills involve several discrete tasks connected in a particular sequence that rapidly progress from one part to the next.³⁷ The category of a particular motor skill is a major factor in making clinical decisions regarding the person-, task-, and environment-related variables that affect motor learning. This is discussed later in the chapter.

An Illustration of Motor Learning Principles

Motor learning is the product of an intricate balance between the feed-forward and feedback sensorimotor systems and the complex central processor—the brain—for the end result of acquiring and refining motor skills. People go through distinct phases when they learn new motor skills.

Observe the sequential activities of the child walking off the park bench in [Figure 4-4](#), A through C. A clear understanding of this relationship of walking and falling is established. In frame A, the child is running a feed-forward program for walking. The cerebellum is procedurally responsible for modulating appropriate motor control over the activity and will correct or modify the program of walking when necessary to attain the directed goal. Unfortunately, a simple correction of walking is not adequate for the environment presented in frame B. The cerebellum has no prior knowledge of the feedback presented in this second frame and thus is still running a feed-forward program for stance on the

Figure 4-4 ■ A, Experiencing the unknown. B, Identifying the problem. C, Solving the problem.

left leg and swing on the right leg. The cerebellum and somatosensory cortices are processing a massive amount of mismatched information from the proprioceptive, vestibular, and visual receptors. In addition, the dopamine receptors are activated during the goal-driven behaviors, creating a balance of inhibition and excitation. Once the executive or higher cognitive system recognizes that the body is falling (which has been experienced from falling off a chair or bed), a shift in motor control focus from walking to falling must take place. To prepare for falling, the somatosensory system must generate a sensory plan and then relay that plan to the motor system through the sensorimotor feedback loops. The frontal lobe will tell the basal ganglia and the cerebellum to brace and prepare for impact. The basal ganglia are responsible for initiating the new program, and the cerebellum carries out the procedure, as observed in Figure 4-4, C. The child succeeds at the task and receives positive peripheral and central feedback in the process. It is possible that this experience has created a new procedural program that in time will be verbally labeled “jumping.” The entire process of the initial motor learning takes 1 to 2 seconds. Because of the child’s motivation and interest (see Chapter 5), the program is practiced for the next 30 to 45 minutes. This is the initial acquisition phase and helps the nervous system store the MP to be used for the rest of the child’s life. If this program is to become a procedural skill, practice must continue within similar environments and conditions. Ultimately the errors will be reduced and the skill will be refined. Finally, with practice, the program will enter the retention phase as a high-level skill. The skill can be modified in terms of force, timing, sequencing, and speed and is transferrable to different settings. This ongoing modification and improvement are the hallmarks of true procedural learning. Modifications within the program will be a function of the plasticity that occurs within the CNS throughout life as the child ages and changes body size and distribution. Similar plasticity and the ability to change, modify, and reprogram motor plans will be demanded by individuals who age with chronic sensorimotor limitations. Unfortunately, in many of these individuals, the CNS is not capable of producing and accommodating change, which creates new challenges as they age with long-term movement dysfunctions (see Chapters 27, 32, and 35).

Stages of Motor Learning

Several authors have developed models to describe the stages of motor learning. These models are presented in Table 4-3. Regardless of the model, it is widely accepted

TABLE 4-3 ■ STAGES OF MOTOR LEARNING—THREE MODELS

MOTOR LEARNING MODEL	STAGE ONE	STAGE TWO	STAGE THREE
Fitts and Posner (1967) ³⁹	Cognitive	Associative	Autonomous
Bernstein (1967) ¹⁰	Novice	Advanced	Expert
Gentile (1998) ⁴⁶	Acquire the plan	Develop consistency and adaptability	

that the process of learning a motor task occurs in stages. During the initial stages of learning a motor skill, the intent of the learner is to understand the task. To be able to develop this understanding requires a high level of concentration and cognitive processing. In the middle and later stages, the individual learns to refine the movement, improve efficiency and coordination, and perform the skill within different environmental contexts. The later stages are characterized by automaticity and a decreased level of attention needed for successful completion of the task. It is important to emphasize early that because the activities performed by a learner during each stage of learning will be different, the role of the clinician, the types of learning activities, and the clinical environment must also be different.

The learning model described by Fitts and Posner³⁹ consists of a continuous progression through three stages: cognitive, associative, and autonomous.

A learner functions in the *cognitive stage* at the beginning of the learning process. The person is highly focused on the task, is attentive to all that it demands, and develops an understanding of what is expected and involved in performance of the skill. Many errors are made in performance; questions are asked; cues, instructions, and guidance are given by the clinician; and demonstrations are found to be helpful in this phase of learning. Performance outcomes are variable and inconsistent, but the improvements achieved can be profound.

During the *associative stage* the learner refines movement strategies, detects errors and problem solves independent of therapist feedback, and is becoming more efficient and reliable at achieving the task goal. The length of time spent in this phase tends to be dependent on the complexity of the task. The ability to associate existing environmental inputs with motor plans for improved timing, accuracy, and coordination of activities to accomplish a task goal is improved. Although variability in performance decreases, the client continues to explore solutions to best solve a movement problem.

Focused practice with repetition over time leads to the automatic performance of motor skills in the *autonomous stage* of learning. The individual is in control of the learned movement plan and is able to use it with little cognitive attention while involved in other activities. Skills are performed with preferred, appropriate, and flexible speed, amplitude, direction, timing, and force. Consistency of performance is a hallmark of this phase, as is the ability to detect and self-correct performance errors. Individuals who do not have the cognitive skill to remember the learning can go through a much longer repetitive practice schedule to learn the motor skill, but there will be very little carryover into other functional movements or activities.⁴⁰⁻⁴²

In summary, the overall process of the stages of motor learning as introduced by Fitts and Posner³⁹ suggests that first a basic understanding of a task be established, along with a motor pattern. Practice of the task then leads to problem solving and a decrease in the degrees of freedom during performance, resulting in improved coordination and accuracy. As the learner continues to practice and solves the motor task problem in different ways and with different physical and environmental constraints, the movement plan becomes more flexible and adaptable to a wide range of task demands.

Bernstein¹⁰ presented a more biomechanical perspective as he addressed the problem of degrees of freedom during motor learning. He also broke the motor learning process down into three stages: novice, advanced, and expert. He proposed that these three stages are necessary to allow a learner to reduce the large number of degrees of freedom that are inherent in the musculoskeletal system, including structure and function of muscles, tendons, joints. He proposed that as a person learns a new motor skill, he or she gains coordination and control over the multiple interacting variables that exist in the human body to master the target skill.

The *novice stage* is defined by the coupling of movement parameters—degrees of freedom—into synergies. During this stage some joints and movements may be “frozen” or restrained to allow successful completion of the task. An example of this is posturally holding the head, neck, and trunk rigid while learning to walk on a narrow surface.

The *advanced stage* is achieved by combining body parts to act as a functional unit, further reducing the degrees of freedom while allowing better interaction and consideration for environmental factors. He considers that motor plans must be adapted to the dynamic environmental conditions in which the task must be performed. In this stage the learner explores many movement solutions, reduces some degrees of freedom, develops more variable movement patterns, and learns to select appropriate strategies to accomplish a given task. This stage of motor learning is accomplished through practice and experience in performing a task in various environments. To achieve this stage the learner progressively releases some couplings, allowing more degrees of freedom, greater speed and amplitude of movement, and less constraints on the action. Performance of the task becomes more efficient, is less taxing on the individual, and is executed with decreased cognitive effort. Variability of performance becomes an indicator that a level of independence in the activation of component body parts during a given task has indeed been achieved.

In Bernstein’s *expert stage*, degrees of freedom are now released and reorganized to allow the body to react to all of the internal and external mechanisms that may act on it at any given time. At the same time, enhanced coactivation of proximal structures is learned and used to allow for greater force, speed, and dexterity of limb movements.⁴³

Gentile presented a two-stage model of motor learning.^{44,45} She considered motor learning from the goal of the learner and strongly considered how environmental conditions influence performance and learning.

Stage one requires the client to problem solve strategies to get the idea of a movement and establish a motor pattern that will successfully meet the demands of the task. As with the models presented previously, this process demands conscious attention to the components of the task and environmental variables to formulate a “map” or framework of the movement pattern. Once this framework is established, the client has a mechanism for performing the task; however, errors and inconsistency in performance accuracy are often present.⁴⁶

During *stage two* the client attains improved consistency of performance and the ability to adapt the movement pattern to demands of specific physical and environmental situations. Greater economy of movement is achieved, and less

cognitive and physical effort is expended to reach the task goal. Practice in appropriately challenging conditions leads to consistent, efficient, correct execution while maintaining adaptive flexibility within the motor plan, allowing the client to react quickly to changing conditions of the task.

The three motor learning theories just presented simplify a complex process into simple stages to give a broad picture of the development of skilled movement performance. Each theory can be used to assist the therapist in the process of teaching and facilitating long-term learning or relearning of motor skills before and after insult to the nervous system. The ultimate goal of motor learning is the permanent acquisition of adaptable movement plans that are efficient, require little cognitive effort, and produce consistent and accurate movement outcomes.

Variables that Affect Motor Learning

The ecological model (constraints theory) of motor control and learning states that motor learning involves the person, the task, and the environment.⁴⁷ For a purposeful and functional movement to occur, the *individual* must generate movement to successfully meet the *task* at hand, as well as the demands of the *environment* where the task must be performed. For motor learning to be successful, several variables related to each of these three constructs must be taken into account.

Variables Related to the Individual

The clinician must first differentiate general motor performance factors that are under the control of the individual’s cognitive and emotional systems and those that are controlled by the motor system itself. These concepts are presented in Figure 4-5. There are many cognitive factors such as arousal, attention, and memory, as well as cortical pathways related to declarative or executive learning, that have specific influences over behaviors that are observed after neurological insult.^{48,49} Other factors such as limbic connections to cortical pathways affected by motivation, fear and belief, and emotional stability and instability also dramatically affect motor performance and declarative learning. Some of these factors may also limit activity and participation. Therapists need to learn how to discriminate among motor output, somatosensory input, cortical processing, and limbic emotional state problems and identify how the latter two systems affect motor output. With that differentiation,

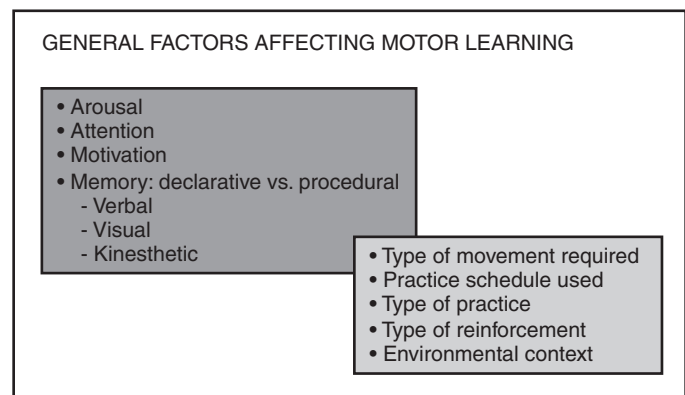

Figure 4-5 ■ Concepts affecting motor learning.

clinicians should also be able to separate specific motor system deficits from motor control problems arising from dysfunction within other areas of the CNS. Last, the patient's fitness level; current limitations in strength, endurance, power, and range of motion; or pain level may also influence learning.^{35,50-55}

Variables Related to the Task

The two major variables related to the task itself that must be considered when facilitating motor learning include practice of the task and feedback related to task performance.

Practice. Practice is defined as “repeated performance in order to acquire a “skill.”⁵⁶ As the definition implies, several repetitions of the task are usually required to be able to achieve skillful performance of a task. With other variables being constant, more practice results in more learning.³⁵ To be effective, these repetitions must involve a process of problem solving rather than just repetition of the activity.⁵⁷ The therapist can manipulate several variables related to practice to optimize motor learning of an individual with a movement dysfunction secondary to a neurological insult.

Practice Conditions. The term *practice conditions* refers to the manner in which the task or exercise is repeated with respect to rest periods, the amount of exercise, and the sequence in which these tasks or exercises are performed.

According to apportionment of practice in relation to rest periods, massed tasks or exercises can be classified as *massed practice* or *distributed practice*. Massed practice is when the rest period is much shorter in relation to the amount of time the task or exercise is practiced.⁵⁸ This is contrasted against distributed practice, in which the time between practice sets is equal to or greater than the amount of time devoted to practicing a particular task or activity, such that the rest period is spread out throughout the practice.⁵⁹ In terms of neurological physical therapy practice, it is important to consider the effect of physical and mental fatigue when training. For example, physical fatigue sets in during massed practice of a particular balance exercise activity in standing and may cause a patient to fall. Moreover, individuals who are cognitively impaired may not respond positively to sustained activity that requires considerable concentration and therefore might fail in the performance of the skill. On the other hand, to be functional and useful in daily life, certain activities have to be performed without significant amounts of rest periods. For example, taking significant rest breaks when ambulating for even a short distance limits an individual's ability to use walking in a functional manner. Sometimes a patient needs more rest periods in the initial stages of learning a skill to compensate for impairments in muscular endurance or cardiopulmonary function, with the intent of decreasing these rest periods to achieve skill performance that reflect how that activity is used in real-life situations. Therefore therapists should consider the skill demands and the desired results when choosing one practice type versus another.⁵⁹

Complete tasks or activities can usually be divided into smaller subcomponents. The way those subcomponents are practiced relative to the entire task or activity can also be manipulated to optimize motor learning. To practice the entire task or parts of the task, whole learning, pure-part learning, progressive-part learning, or whole-part learning may be used. Figure 4-6 summarizes these concepts.

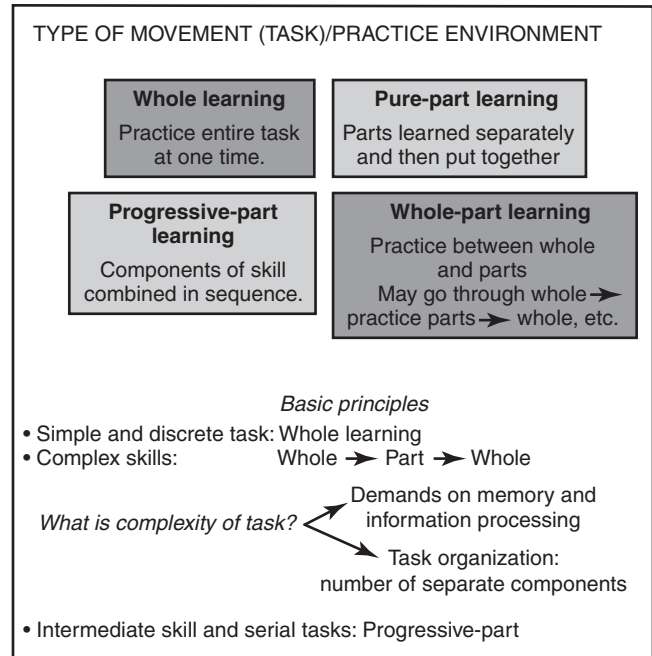

Figure 4-6 ■ Type of movement (task) and practice environment.

Whole learning suggests that the learner practice the entire movement as one activity. Asking a person to stand up incorporates the entire activity of coming to stand from sitting. Simple movements such as rolling, coming to sit, coming to stand, and walking might best be taught as a whole activity as long as the individual has all the component parts to practice the whole.

In pure-part learning the therapist introduces one part first, then this part is practiced by the learner before another new part is introduced and practiced. Each part is critical to the whole movement, but which one is learned first does not matter. Learning a tennis serve is an excellent example of an activity that can be taught as a pure-part. Learning to toss the ball vertically to a specific spot in space is a very different and a separate part from swinging the tennis racket as part of the serve. Learning to squeeze the toothpaste onto the brush is a very different movement strategy from brushing the teeth.

Progressive-part learning is used when the sequence of the learning and the component parts need to be programmed in a specific order. Line dancing is an activity taught using progressive parts. Individuals with sequencing deficits often need to be taught using progressive parts or the individual will mix up the ordering of parts during an activity. Therapists see this in the clinical arena when an individual stands up from a wheelchair and then tries to pick up the foot pedals and lock the brakes. Given that problem, that patient needs to practice progressive part learning by first locking the brake, then picking up the foot pedals and finally standing. If the activity is not practiced using progressive-part learning, the patient will have little consistency in how the parts are put together, thereby placing that individual at high risk of failing at the functional task.

Whole-part learning can be used when the skill or activity can be practiced between the whole and the parts. In the clinical environment, a common application of this concept

is *whole to part to whole learning*.⁶⁰ First the therapist has the client try the whole activity, such as coming to stand or reaching out to turn the door handle. Next, the therapist has the client practice a component part. Finally the whole activity is practiced as a functional pattern. In this way therapists work on the functional activity, then work on correcting the impairment or limitation, such as power production, range, or balance, and then go back to the functional activity in order to incorporate the part learning into the whole. An example might be asking a patient to first stand up from a chair. As he tries to stand he generates too much power, holds his breath, and cannot repeat the activity more than once. The therapist decides to practice a component part by first assisting the patient to a relaxed standing posture, then having him eccentrically begin to sit into a partial squat, and then having him return to standing. As the patient practices, he will increase the range of lengthening and eventually will sit and return to stand. Once that is accomplished, he will continue to practice sit to stand to sit to stand as a whole activity.

According to the sequence in which component tasks are practiced, blocked or random practice may be used. In *blocked practice* the patient first practices a single task over and over before moving to the next task. On the other hand, in *random practice*, the component tasks are practiced without any particular sequence. The contextual interference effect explains the difference in motor performance found when comparing these two types of practice. Studies have shown performance may be enhanced by using blocked practice; however, learning is not enhanced by using this type of practice. Random practice has been shown to enhance learning because this type of practice forces the learners to come up with a motor solution each time a task is performed.^{61,62}

Feedback. The use of feedback is another important variable related to motor learning. Feedback is defined as the use of sensory information—visual, auditory, or somatosensory—to improve performance, retention, or transfer of a

task. Internal feedback pertains to sensory information that the patient receives that can be used to improve performance of that particular task or activity in the future. The therapist provides extrinsic or augmented feedback with the intent of improving learning of the task. In people with neurological dysfunctions, extrinsic feedback is important because the patient's intrinsic feedback system may be impaired or absent.

Extrinsic feedback can further be classified as knowledge of performance (KP) or knowledge of results (KR). KP is given concurrently while the task is being performed and can therefore also be called *concurrent feedback*. Feedback given concurrently, especially during the critical portions of the task, allows the patient to successfully perform the activity.

KR pertains to feedback given at the conclusion of the task (therefore also called *terminal feedback*) and provides the patient information about the success of his or her actions with respect to the activity. KR can be classified as faded, delayed, or summary. In faded feedback the therapist provides more information in the beginning stages of learning of the skill and slowly withdraws that information as the patient demonstrates improvement in the performance of the task. With delayed feedback, information is given to the patient when a period of time has elapsed after the task has been completed. The intent of this pause between the termination of task and feedback is to give the patient some time to process the activity and generate possible solutions to the difficulties encountered in the previous performance of the task. In contrast, summary feedback is provided after the patient has performed several trials of a particular task without receiving feedback. Previous studies showed that subjects who were given more frequent feedback performed better during the task acquisition stage of learning but worse on retention tests compared with those who received summary feedback.^{63,64}

Additional concepts related to long-term learning are presented in Figure 4-7.

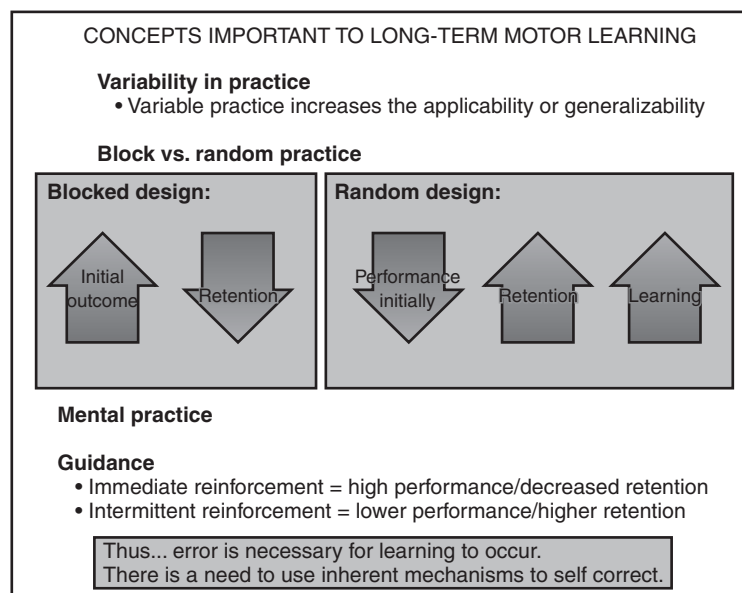

Figure 4-7 ■ Concepts important to long-term learning.

Variables Related to the Environment

Therapists can alter the environmental conditions to optimize motor learning. Gentile^{44,45} described the manipulation of the environment in which a task is performed to make an activity more appropriate for what the patient is able to do. A *closed environment* is stationary; it allows the patient to practice the skill in a predictable manner, with minimal distractions from the environment. On the other hand, an *open environment* is one that is in motion or unpredictable. In patients with neurological dysfunctions, clinicians may decide to have a patient practice a skill in a closed environment to allow the patient to plan the movement in advance and to perform the movement with minimal distractions or challenges. An example of this would be performing gait training in a quiet and empty therapy gym. As the patient improves, it may be important to practice this activity in an open environment to provide a real-world application of a task. Going back to the previous example, the therapist may have the patient ambulate in an open environment such as a busy gym with crowds and noise, a crowded cafeteria, or a moving walkway.

If prior procedural learning has occurred, then creating an environment that allows the program to run in the least restrictive environment should lead to the most efficient outcome in the shortest time.^{51,52} If a patient needs to learn a new program, such as walking with a stereotypical extension pattern, then goal-directed, attended practice with guided feedback is necessary. It may be easier to bring back an old ambulatory pattern by creating an environment to elicit that program than to teach a client to use a new inefficient movement program.⁵³⁻⁵⁵

A therapist must identify what MPs are available and under what conditions. This allows the therapist to (1) determine whether deficits are present, (2) anticipate problems in performance, and (3) match existing programs with functional activities during training. Similarly, knowing available MPs and the component body systems necessary to run those programs aids the therapist in the selection of intervention procedures.

If the client has permanent damage to either the basal ganglia or the cerebellum, then retaining the memory of new MPs may be difficult and substitution approaches may become necessary. Through evaluation the clinician needs to determine whether anatomical disease or a pathological condition is actually causing procedural learning problems and whether identifying and teaching a substitution pattern or teaching the patient to compensate with an old pattern will allow the individual to succeed at the task. However, therapists should never forget that the plasticity of the CNS can promote significant recovery and adaptation through the performance of attended, goal-directed, repetitive behavior.^{65,66}

Providing an appropriate level of challenge to the learner optimizes motor learning. The clinician must learn to expertly manipulate the environment to best facilitate learning. A task that is too difficult for the client will result in persistent failure of performance, frustration, and lack of learning, and the only option will be to compensate through available patterns of movement that limit function. An activity that is too easy and routinely results in 100% success also does not result in learning because the learner becomes bored and no longer attends to the learning. The most beneficial level of challenge for training will create some errors in

performance, require the client to solve problems to meet the demands presented, and allow a level of success that inspires continued motivation to practice and achieve a higher standard of skill.

Systems Interactions: Motor Responses Represent Consensus of Central Nervous System Components

Motor behavior reflects not only motor programming but also the interaction of cognitive, affective, and somatosensory variables. Without a motor system, neither the cognitive nor the emotional systems have a way to express and communicate inner thoughts to the world. The cognitive and emotional systems can positively or negatively affect motor responses. The significance of the somatosensory or perceptual-cognitive cortical system must be emphasized. The somatosensory association areas play a critical role in the ideational and constructional aspects of the MP itself. When there are deficits within this system, clients will often demonstrate significant distortions in motor control even without a specific motor impairment. An example of this problem might be an individual who had a stroke and developed a “pusher syndrome.” The motor behavior shown by this client would be pushing off vertical generally in a lateral or posterolateral direction.⁶⁷ Physically correcting the client’s posture to vertical or asking the patient to self-correct will not eliminate the original behavior. Pusher syndrome does not stem from a motor problem but rather from a perceptual problem of verticality from thalamic nuclei radiating false information to the somatosensory cortices. Although a therapist might want to augment intervention by trying to push the patient to vertical, the patient will resist that movement pattern. Functional training becomes frustrating to both the patient and the therapist because the impairment does not fall within the motor system itself. Reliance on the use of vision and environmental cues might be the best intervention strategy for this type of problem because the impairment is within the sensory processing centers.⁶⁸ Asking the patient to find midline and reach across midline, then acknowledging success, along with a lack of falling help the somatosensory system to relearn and thus begin to inherently correct to vertical. Verbalizing to the patient that you (the therapist) acknowledge that she or he feels as if she or he is falling when placed in the vertical position demonstrates to the client that you have accepted the patient and his or her perceptions. Simultaneously maintaining tactile contact to prevent the patient from falling effectively lets the limbic system relax and reduces its need to trigger motor reactions. This example creates conflict between the cognitive system’s information from the thalamus and motor system feedback. The thalamus is saying vertical is “X,” and the motor system is saying “if X then I am falling.” When the goal is not to fall, then the cognitive system will generally override the thalamic information and learn to accept a new concept of vertical. Taking all these variables into the treatment environment optimizes the potential that the patient will self-correct during a functional activity such as reaching with weight shift.

If a patient’s insult falls within the limbic or emotional system, then motor behavior could also be affected. The motor dysfunction will be different from the dysfunction reflecting damage either in the sensory cortices or associated

with information sent to them. For years it has been common knowledge that individuals who are depressed will demonstrate motor signs of withdrawal (e.g., flexion). If the posture of flexion was created by a chemical response related to depression, then somatosensory retraining would have a limited effect on behavior. Similarly, functional training may initially modify the impairments, but without changes within the limbic system itself no permanent change will be achieved. Instead, augmenting the input to alter the emotional system and then reinforcing self-control could create the best potential outcome.

For many clinical problems, functional retraining of the motor system through attended, sequenced, repetitive practice could lead to greater functional gains, although the body system impairment(s) may never be eliminated. That is, muscle strengthening and programming coactivation to enable joint stability could restore client independence. Given the complexity of impairments and function in a patient with a neurological insult, a therapist may need to use all three types of intervention procedures to affect all areas of the CNS simultaneously. The decision of which intervention is most appropriate or which should be emphasized falls within the professional judgment of the clinician. There is no easy recipe to decide which intervention is best for all people. It is the problem-solving skills of the therapist and one's keen analysis of movement function and dysfunction that lead to the best solution. Obviously, patient involvement and desired outcomes are also critical components leading to this decision.

PRINCIPLES OF NEUROPLASTICITY: IMPLICATIONS FOR NEUROREHABILITATION Rehabilitation, Research, and Practice

Rehabilitation is the process of maximizing functional learning. The integration of basic neuroscience into clinical practice is critical for guiding the questioning of researchers and maximizing the recovery of patients. The 1990s were referred to as the “Decade of the Brain.” For the last 20 years, researchers have made enormous advances in understanding the adaptability of the CNS. Because of this revolution, clinicians must focus on recovery rather than compensation. There is sufficient evidence that the CNS not only develops and matures during adolescence, but also recovers from serious disease and injury and maintains sensory, motor, and cognitive competency through spontaneous healing, appropriate medical management, physical exercise, balanced nutrition, and learning. Across the life span, individuals can maximize independence and quality of life by taking advantage of learning from enriched environments, task-specific training, and attended, progressive, goal-oriented, repetitive behaviors. In addition, the nervous system can adapt negatively to repetitive and abnormal patterns of movement based on structural anomalies, pain, abnormal biomechanics, or bad habits (see the section on [motor learning](#) in this chapter).

The paradigm shift in rehabilitative intervention strategies based on neuroplasticity has just begun. Basic science researchers cannot ignore the impact of their findings on the health and function of the consumer. Clinical researchers must collaborate in clinical studies to determine the impact

of basic science findings with patients.⁶⁹⁻⁷¹ Clinicians cannot simply provide the same, familiar treatment of yesterday because it is comfortable and easy and requires minimal effort. Physical therapy professionals must be dynamic, enthusiastic, evidence-based and committed to lifelong learning, ready to accept the challenge and unique opportunity to work with other members of the health care team to translate neuroscience to practice. Failure to translate basic science findings into clinical practice will significantly impair the potential for patient recovery.

During the last 45 years, three large conferences⁷²⁻⁷⁴ focused on these issues in neuroscience. In 1966 the Northwestern University Special Therapeutic Exercise Project (NUSTEP) conference in Chicago, Illinois, brought researchers, basic scientists, educators, and master clinicians together for 6 weeks to identify commonalities in approaches to interventions and to integrate basic science into those commonalities. A huge shift from specific philosophies to a bodily systems model occurred in 1990 at Norman, Oklahoma, the site of the Second Special Therapeutic Exercise Project conference (II STEP). During the next 15 years, concepts of motor learning and motor control were beginning to affect the methodology and intervention philosophies of both occupational and physical therapy. Simultaneously, newer approaches such as locomotion training with partial weight bearing on a treadmill,^{75,76} task-specific training,^{77,78} constraint-induced movement training,^{79,80} neuroprotective effect of exercise,⁸¹ mental and physical practice,^{82,83} patient-centered therapy,⁸⁴⁻⁸⁶ and sensorimotor training⁸⁷ were frequently seen in peer-reviewed literature. The third STEP conference, Summer Institute on Translating Evidence into Practice (III STEP), occurred in July 2005 in Salt Lake City, Utah. At this conference, unique clinical models for intervention were embraced that will direct professional education for decades. Changes in practice over the next 15 years will lead to embracing many older intervention techniques with current evidence-based practice.

Four primary conclusions were summarized from the III STEP conference: (1) client-centered, empowerment models needed to be the platform for all neurorehabilitation and postdisease models of care; (2) evidence-based practice needs to start with the documentation of clinical effectiveness based on reliable and valid measurement tools followed by efficacy studies; (3) a strong link is needed among basic science, clinical science, and disease-specific motor dysfunction research to develop the best patient management environments; and (4) movement science belongs to a broad community that requires integration of the goals, cultural beliefs, ethnic values, emotional understanding, and scientific knowledge of many individuals, including but not limited to health care providers (physicians, PTs and OTs, psychologists), clinical research practitioners, basic science researchers, educators, clients, families, and employers.

There are a variety of challenges to implementing effective, neuroscience-based interventions. The first is the patient. Patient-centered therapy is critical for effective therapeutic outcomes. The patient can be both the obstacle to successful recovery^{88,89} and the critical link to success.^{90,91} To achieve optimum neural adaptation, the patient must be engaged in attended, goal-directed, novel, progressive

behaviors. There is no measurable neural adaptation with passive movements or passive stimuli. For a change in neural response to be achieved, the stimulus needs to be novel or a surprise and the individual has to attend to the stimulus, make a decision about what to do, and receive some feedback regarding the appropriateness or accuracy of the outcome.⁹² This progressive decision making has to be done repetitively and progressed in difficulty over time. These behaviors may be difficult to achieve when a person is depressed, feels hopeless, lacks motivation or cognition, or has emotional instability or there is neglect of one or more parts of the body.

Another obstacle to bringing scientific evidence into practice is the barrier created by living in a society in which the economics of health care rather than the science or the patient benefits drive the delivery of services (see Chapter 10). When a physician or a therapist recommends a new approach to intervention, the third-party payer may deny payment for service because it is “experimental.” Furthermore, third-party payers may deny the opportunity to apply findings from animal studies to human subjects. Another example of constraint from the third-party payer is the timing of intervention. Despite the evidence that the CNS can be modified under conditions of goal-oriented, repetitive, task-relevant behaviors even years poststroke, insurance companies deny coverage of service late in the recovery process. The insurance company may interpret “medically necessary services” as the services provided during the first 30 days postinjury, the time after a cerebrovascular accident when the greatest spontaneous recovery occurs. Furthermore, even though neural adaptation research confirms that enriched environmental conditions and sensory inputs can facilitate both greater and continued recovery, the insurance company may claim that the services⁹³⁻⁹⁵ are simply for maintenance. Thus, as the science of neuroplasticity continues to develop, it is critical to improve the interface among the scientist, the practitioner, the patient, and the third-party payer. Clinicians and researchers must regularly inform third-party payers about current research evidence.

Integration of Sensory Information in Motor Control

Understanding neural adaptation must include attention to sensory as well as motor systems. In virtually all higher-order perceptual processes, the brain must correlate sensory input with motor output to assess the body’s interaction with the environment accurately. A problem in the somatic motor system affects the motor output system. Both systems are independently adaptive, but functional neural adaptation involves the interaction of both sensory and motor processing.

The sensory system provides an internal representation of both the inside and outside worlds to guide the movements that make up our behavioral repertoire. These movements are controlled by the motor systems of the brain and the spinal cord. Our perceptual skills are a reflection of the capabilities of the sensory systems to detect, analyze, and estimate the significance of physical stimuli. (See the section on augmented therapeutic intervention in Chapter 9 for a detailed discussion of each sensory system.) Our agility and dexterity represent a reflection of the capabilities of the motor systems

to plan, coordinate, and execute movements. The task of the motor systems in controlling movement is the reverse of the task of sensory systems in generating an internal representation. Perception is the end product of sensory processing, whereas an internal representation (an image of the desired movement) is the beginning of motor processing.

Sensory psychophysics looks at the attributes of a stimulus: its quality, intensity, location, and duration. Motor psychophysics considers the organization of action, the intensity of the contraction, the recruitment of distinct populations of motor neurons, the accuracy of the movements, the coordination of the movements, and the speed of movement. In both the sensory and motor systems, the complexity of behaviors depends on the multiplicity of modalities available. In sensation, there are the distinct modalities of pain, temperature, light touch, deep touch, vibration, and stretch, whereas in the motor system can be found the modalities of reflex responses, rhythmic motor patterns within and between limbs, automatic and adaptive motor responses, and voluntary fine and gross movements.⁹⁶⁻¹¹⁶ Although all motor movements require integration of sensory information for motor learning, once motor control is attained the system can run on very little feedback. The relationship of incoming sensory information is particularly complex in voluntary motor movements that constantly adapt to environmental variance. For voluntary motor movements, the motor system requires contraction and relaxation of muscles, recruitment of appropriate muscles and their synergies, appropriate timing and sequencing of muscle contraction and relaxation, the distribution of the body mass, and appropriate postural adjustments. As stated, once an MP is learned, it does not take the same amount of sensory information to run the program in a feed-forward manner within the motor system as long as the information to the cerebellum is able to run and adjust all aspects of the program. (See Chapter 21 and the section on motor control in this chapter.) To learn new programs, the CNS must go through the process of receipt of sensory input, perceptual processing, communication with the frontal lobes, and relays to basal ganglia and cerebellum, followed by intentional, goal-directed execution of the motor plan.

Within each movement, there must be adjustments to compensate for the inertia of the limbs and the mechanical arrangement of the muscles, bones, and joints both before and during movement to ensure and maintain accuracy. The control systems for voluntary movement include (1) the continuous flow of sensory information about the environment, position, and orientation of the body and limbs and the degree of contraction of the muscles; (2) the spinal cord; (3) the descending systems of the brain stem; and (4) the pathways of the motor areas of the cerebral cortex, cerebellum, and basal ganglia. Each level of control is based on the sensory information that is relevant for the functions it controls. This information is provided by feedback, feed-forward, and adaptive mechanisms. These control systems are organized both hierarchically and in parallel. These systems also control activation of sensations and motor movements as well as inhibition (e.g., globus pallidus). Furthermore, some parts of the brain are needed for new learning (e.g., cerebellum) and others for maintained learning (e.g., globus pallidus, hippocampus). The hierarchical but

interactive organization permits lower levels to generate reflexes without involving higher centers, whereas the parallel system allows the brain to process the flow of discrete types of sensory information to produce discrete types of movements.^{117,118}

Ultimately, the control of graded fine motor movements involves the sensory organ of the muscle, the muscle spindle, which contains the specialized elements that sense muscle length and the velocity or changes in spindle length. In conjunction with the tendon organ, which senses muscle tension, the muscle spindle provides the CNS with continuous information on the mechanical state of the muscle. Ultimately the firing of the muscle spindles depends on both muscle length and the level of gamma motor activation of the intrafusal fibers. Similarly, joint proprioceptors relay both closed and open chain input and mobility (range) information from within the joint structures to the CNS. This illustrates the close relationship between sensory and motor processing and the integral relationship between the two.¹¹⁹

Foundation for the Study of Neuroplasticity

The principal models for studying cortical plasticity have been based on the representations of hand skin and hand movements in the New World owl monkey (*Aotus*) and the squirrel monkey (*Saimiri*). These primate models have been chosen because their central sulci usually do not extend into the hand representational zone in the anterior parietal (S1) or posterior frontal (M1) cortical fields. In other primates the sulci are deep and interfere with accurate mapping. Albeit there are differences in hand use among primates, in all of the primates the hand has the largest topographical representation for the actual size of the extremity, the detail of this representation is distinct, and the hand has the greatest potential for skilled movements and sensory discrimination. However, the findings from studies of this cortical area are applicable across the different cortices as well as the other cornerstones of the brain such as the thalamus, basal ganglia, brain stem, and cerebellum.^{120,121} See Figure 4-8 to identify specific anatomical locations and their respective classifications.

To understand neural adaptation and to be able to apply the principles to practice, it is necessary to objectively measure the changes. Positive changes in neural structure can be measured by using a variety of imaging techniques (e.g., magnetic resonance imaging [MRI], functional MRI [fMRI], magnetoencephalography, magnetic source imaging [MSI]). The types of outcomes that can be expected electrophysiologically and functionally are summarized in Table 4-4. At this time, imaging techniques are applied primarily for research purposes or to rule out other pathology. The specific type of intervention to address the principles of neuroplasticity may vary, but the outcomes must be clearly documented.

Principles of Neural Adaptation

To achieve maximum neural adaptation, there are some basic principles to follow (Box 4-1). Learning is the key to neural adaptation. Plasticity is the mechanism for encoding, the changing of behaviors, and both implicit and explicit learning. During neural adaptation, the fundamental questions are as follows: As we learn, how does the brain change its representations of inputs and actions? What is the nature of the processes that control the progressive elaboration of performance abilities? In different individuals, what are the sources of variance for emergence of improved performance? What changes in cortical plasticity facilitate the development of “automatic” motor behaviors? Why are some behaviors hard

TABLE 4-4 ■ NEUROPROTECTIVE MOTOR ENRICHMENT FACTORS AFFECTING OUTCOMES

	NEGATIVE PLASTICITY	POSITIVE PLASTICITY
Stimulation	Disuse, unskilled	Intensive, skilled
Quality of sensory input	Noisy, nonspecific	Appropriate, specific
Modulation	Not challenging	High stakes, novel, challenging
Outcome	Negative behaviors	Positive behaviors

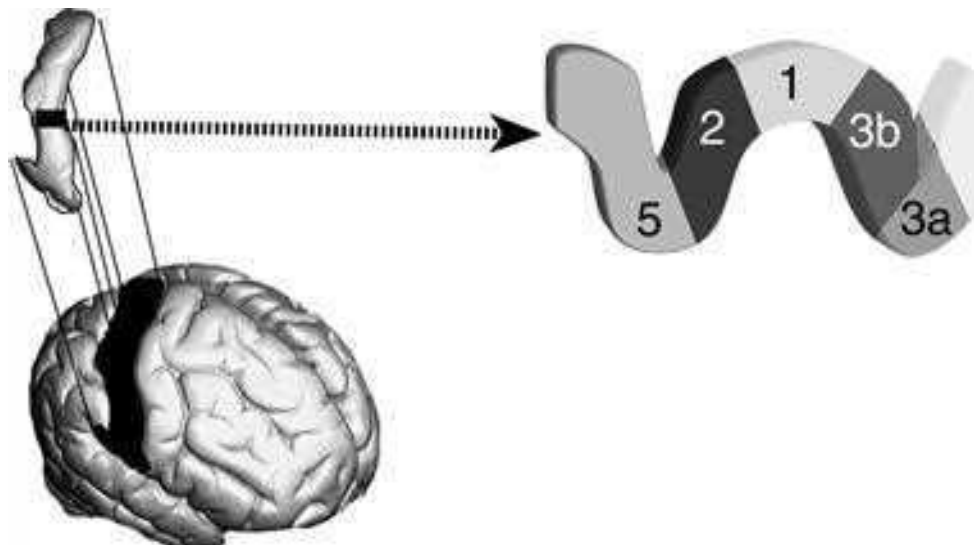

Figure 4-8 ■ Classification and anatomical locations of cortical map.

to change? What limits plasticity processes? What are the critical elements of brain circuitry, genes, synapses, neural chemistry, neuronal networks, and neural connections for restoration of lost function? What guidelines need to be followed to drive the greatest change in brain structure and function? How do spontaneous compensatory behavioral

strategies contribute to or interfere with restoring lost neuronal function? How does the unaffected side contribute to or interfere with neuroplastic changes and restoration of function? Does damage to the brain alter the neuronal response to learning (e.g., cascade of cellular activity for healing altered circuitry, new neural connections)?

BOX 4-1 ■ NEUROPLASTICITY PRINCIPLES TRANSLATED TO GUIDE CLINICAL PRACTICE

BASIC PRINCIPLES

Translating basic science to clinical practice is a challenge over time. There is no exact protocol. Learning activities need to be adapted and matched to the abilities, goals, and objectives of each individual. Based on research evidence, the following principles can help guide training:

1. *Use it or lose it*—Stay active and keep challenging learning. Failure to regularly engage specific and general brain functions can lead to functional degradation.
2. *Use it and improve it*—Engaging in training behaviors that drive specific brain functions can lead to an enhancement of the function.
3. *Be specific*—The training experience must match the desired outcome; the nature of neural plasticity is dictated by the nature of the training.
4. *Repetition is essential*—Learning requires repetition progressed in difficulty and spaced over time.
5. *Intensity matters*—Plasticity changes require a sufficient training intensity to ensure durability of pathways.
6. *Salience is important*—The training must be salient and match the outcome behavior desired and the goals of the individual.
7. *Age must be addressed*—Training-induced plasticity occurs most readily in a young brain, but neural adaptation continues across the life span with learning-based training. With aging, greater efforts at variety, integration, and discovery may be needed.
8. *Transference*—Plasticity in response to one training experience can also enhance acquisition of similar behaviors and adaptation in other experiences and other parts of the body.
9. *Interference*—Plastic changes after one training experience may interfere with the acquisition of changes in similar systems.
10. *Patient expectation*—Patient expectation can facilitate the outcomes of training; patients who expect to get better can enhance their learning.
11. *Reward or feedback*—Feedback allows modification of training behaviors, correcting errors and improving accuracy of learning.
12. *Environment*—Enrich the environment by simply noticing everything in the environment, expanding the environment to include new opportunities and interacting with others.
13. *Fun*—Learning is greatest when it is associated with discovery and fun.
14. *Helping others*—Maintaining the fitness of the brain is best when individuals look beyond themselves to help and involve others.

INTEGRATE THE PRINCIPLES OF NEURAL ADAPTATION INTO NEUROREHABILITATION

When embarking on a rehabilitation program with someone, match the principles of neuroplasticity to interactions with the patient, the family, the health care team, and the job, emphasizing the importance of the following:

1. Thinking positively about health and recovery; expect to get better
2. Setting clear goals and objectives for retraining
3. Encouraging the family to be involved in the retraining activities.
4. Creating learning activities that are attended-goal directed, repetitive, progressed in difficulty, increased in variety and depth, spaced over time, rewarded, and complemented with feedback on accuracy
5. Linking activities temporally (in time) and spatially but progressively sequenced; making the stimulus strength adequate for detection and appropriate to avoid abnormal behaviors
6. Integrating training behaviors into meaningful functional activities
7. Making training activities age appropriate
8. Integrating training activities across multiple sensory modalities appropriate for desired outputs
9. Performing training activities in different postural orientations and different environments, which facilitate the best performance
10. Matching training behaviors with progression of healing and recovery as well as development
11. Strengthening positive responses with meaningful rewards
12. Making it difficult to use the unaffected side (e.g., wearing a glove)
13. Avoiding activities that stimulate repetition of abnormal movements
14. Maintaining high levels of attention and cognitive function within the context of all daily activities; avoiding habitual unattended behaviors
15. Maintaining self-esteem
16. Avoiding an egocentric focus; thinking about how to help and be involved with others
17. Being fit, thinking “tall,” and challenging balance by interacting in new unstable environments

RESEARCH VALIDATED OUTCOMES FOLLOWING CENTRAL NERVOUS SYSTEM TRAINING

With thoughtful, attentive regular physical exercise, integrated learning-based activities, daily learning, and specific

BOX 4-1 ■ NEUROPLASTICITY PRINCIPLES TRANSLATED TO GUIDE CLINICAL PRACTICE—cont'd

practice to improve skills, there is scientific evidence confirming the following positive outcomes:

1. Strengthened and elaborated neuronal interconnections
2. Improved health and vigor of nerve cell populations (including neurotransmitters, nerve brain growth factors, dopamine)
3. Increased physical size of brain centers and a slowing down of shrinkage and atrophy of the brain with aging and disuse
4. Increased accuracy of neuronal processing
5. Improved strength of associative memory processes and the capacity for the brain to remember what is seen, heard, felt, or learned
6. Faster brain processing and more reliable connections to improve sharpness and completeness of how our brain represents and records information
7. Improved coordination of neuronal activities across brain subsystems
8. Improved abilities to broaden and control our attention, shift attention, and take in more information with better acuity
9. Improved integration in vision, listening, feeling, and awareness of joint and trunk position in space
10. Improved ability to suppress noise and distractions to stay on track
11. Improved security of mobility and more reliable postural reactions to protect from falling in familiar and stable as well as unfamiliar and unstable environments
12. Reactivation of long underpracticed skills that support independent mental and physical actions (e.g., riding a bike, skipping, throwing and catching balls, playing an instrument)
13. Restoration of fluency, self-confidence, liveliness, and happiness
14. Increased longevity
15. Increased blood flow and oxygen to the heart and nervous system
16. Physical exercise combined with attended learning-based exercise for decreased risk of heart disease, cancer, metabolic failure, and Alzheimer disease
2. Growth in the number of neuron populations excited with progressively greater specificity in the neuronal representations, and stronger temporal coordination
3. Strengthening of neural connections (synapses) following important behavioral inputs
4. Increased oxygenation
5. Decreased atrophy of the brain
6. Shortening of the time between the stimulus and neuronal activation (latency)
7. Modification of the amplitude of neuronal firing
8. Improvement in the ability to turn off neurons once fired
9. Increased ability to inhibit unwanted neuronal firing in response to an input
10. Shortened integration time between processing inputs and production of outputs
11. Specialization of representational firing in response to familiar inputs
12. Improved temporal sequencing of firing following familiar inputs
13. Increased myelination
14. Increased complexity of dendrites and change in number and complexity of synapses
15. Increased consistency of response (e.g., density of neuronal responses)
16. Improved selective excitation
17. Increased specificity of neuronal response
18. Increased salience of the response
19. Change in cortical (and noncortical) topography
20. Increased area of representation
21. Smaller receptive fields
22. Increased density of receptive fields
23. Improved precision and order of receptive fields

METHODS OF MEASURING NEURAL ADAPTATION**Neurophysiological and Neuroanatomical Outcomes**

Neurophysiological and neuroanatomical changes can be measured in the central nervous system (CNS) with learning. Measurements have been made with a variety of techniques (e.g., neurophysiological mapping after craniotomies, electroencephalography, magnetic source imaging [MSI], functional magnetic resonance imaging [fMRI], electromyography, cortical response mapping with positron emission tomography, and spectroscopy with the potential for neurochemical analysis of neurotransmitters, growth hormones, inhibitors, corticosteroids). With learning it is possible to measure the following:

1. Achievement of specialized cortical representations of behaviorally important inputs

Clinical Documentation of Outcomes after Learning-Based Training

Basic science and clinical research studies report positive correlations between functional outcomes and neural adaptation. With timely prevention, appropriate management of acute insults to the CNS, spontaneous recovery, and thoughtful attention to activities of daily living (ADLs) and task practice, disabling CNS problems can be minimized. Furthermore, early treatment after CNS injury or onset of disease may prevent more extensive damage to the brain. Learning activities may not only be neuroprotective but also drive more complete recovery of function. Changes in neural adaptation can be measured clinically in terms of improvement in function including the following:

1. Fine and gross motor coordination
2. Sensory discrimination
3. Balance and postural control
4. Reaction time
5. Accuracy of movements
6. Rhythm and timing of movements
7. Memory storage, organization, and retrieval
8. Alertness and attention

BOX 4-1 ■ NEUROPLASTICITY PRINCIPLES TRANSLATED TO GUIDE CLINICAL PRACTICE—cont'd

9. Sequencing
10. Logic, complexity, and sophistication of problem solving
11. Language skills (verbal and nonverbal)
12. Interpersonal communication
13. Positive sense of well-being
14. Insight
15. Self-confidence
16. Self-image
17. Signal/noise detection; able to make finer distinctions
18. Ability to “chunk” information for memory and use
19. Learning skills including faster learning
20. Achievement of developmental milestones
21. Appropriate sensitivity of the nervous system (e.g., reduction in hyperactivity and sensory defensiveness)
22. Ability to perform a skill from memory
23. Flexible behaviors; variability in task performance
24. Flexibility for experience-based learning

PRACTICAL SUGGESTIONS FOR MAINTAINING PHYSICAL AND BRAIN HEALTH ACROSS THE LIFE SPAN^{35,128}

Make living a learning experience by creating goal-directed activities that require attention and can be progressed in difficulty or variety over time. Where possible, provide conditions where feedback about performance is received. Try to maintain variability in activities and vary the environments for performing the same and different tasks. Take some risks by changing activities that are familiar and comfortable. Walk around on unstable surfaces as well as familiar surfaces with the eyes closed to challenge balance and postural reactions. Assume different positions to perform common tasks. More specifically:

1. Integrate low intensity to moderate physical exercise into the day, balanced with healthy eating, good hydration, and stress management.
2. Stop all negative learning behaviors; minimize or eliminate bad habits.
3. Be actively engaged at the cutting edge of all activities; minimize habitual behaviors.
4. Improve skills; progressively practice to perform each task better and use mistakes to guide practice.
5. Improve language listening skills and expand the words and the language used.
6. Be a lifelong learner; take classes, go to lectures, listen to audio books, and discuss what was learned with others.
7. Engage in conversational listening (review what is remembered about a conversation right after the conversation ends).

8. Keep hobbies alive; mix life with work and play.
9. Consider learning to play a musical instrument (e.g., take lessons, practice and carefully listen while playing).
10. Sing along with music; sing out loud in the car (loud, clearly, and slowly), and consider joining a choir to share the joy of singing with others.
11. Take time and opportunities to dance; consider taking some lessons.
12. Volunteer in the community to interact with others.
13. Wear a hearing aid if one has been prescribed; wear glasses if they are needed.
14. Improve everyday activities by learning something new or by challenging observation and recall skills: have a puzzle out and add pieces, or have challenging crossword puzzles to work on.
15. Play games that require fine motor skills (e.g., shuffling cards, Ping-Pong, bowling, tennis).
16. After walking to the store, reconstruct all of the things that were seen on the way and at the store and what was accomplished.
17. When waiting for scheduled appointments, review the details of the environment; examine what has changed since the last visit.
18. Before going to social gatherings, try to remember the names of the people who are expected to be there; afterward, review who was there by name.
19. When idle or waiting, instead of sitting, walk around and mentally review items in the environment, organize these items, review tasks that need to be done (including steps required), play a game.
20. Find different ways to get to common places; evaluate which way is fastest, easiest, most interesting, most fun.
21. Constantly read and listen to the news, attend lectures, listen to or watch educational programs.
22. When with others, especially with children or grandchildren, play progressive or problem-solving games (e.g., Boggle, chess, card games, checkers).
23. Look beyond the self; think what you can do to make others happy.
24. Avoid stress; instead enjoy life and share joy with others.
25. Take a walk or ride a bike every day.
26. Find something fun to do every day.

Data from Byl N, Merzenich MM, Cheung S, et al: A primate model for studying focal dystonia and repetitive strain injury: effects on the primary somatosensory cortex, *Phys Ther* 77:269-284, 1997; Kleim J, Jones TA: Principles of experience-dependent neural plasticity: implications for rehabilitation after brain damage. *J Speech Lang Hear Res* 51(1):S225-S239, 2008; and Merzenich M: *The brain revolution* (in press), 2010.

The most informative studies on neuroplasticity are those specifically directed toward defining the changes induced by learning. One approach has been to document the patterns of distributed neural response representation of specific inputs before and after learning. In particular, neuronal responses have been measured in the primary auditory, somatosensory, and motor cortices in animals. These animal studies have been paired with behavioral studies in humans. Both the animal and the human studies provide strong evidence documenting the ability of the brain to functionally self-organize. This capacity for change occurs not only during development but also in adulthood, specifically after learning-based activities. The basic processes for neural adaptation are discussed in the following paragraphs.

1. *Neural circuits must be actively engaged in learning-based activities if degradation and atrophy are to be prevented.*

We know that if infants are deprived of sensory and motor experiences during development, the brain does not develop normally. For example, without exposure to light, there is a reduction in the number of neurons in the visual cortex.¹²² Similarly, if infants are not exposed to sound, there is a reduction in the neurons in the auditory cortex.¹²³ Even in adults, when neural circuits are not used over an extended period of time, they begin to degrade, and the unused area of the brain is allocated to serve another part of the body.¹²⁴ Similarly, if task performance is practiced, then the topography expands and becomes more detailed, as might occur in someone who is blind and reads Braille.¹²⁵ It is also interesting to note that although a person is blind, the visual cortical areas may become active when the individual is reading Braille.¹²⁶ Similarly a person who is deaf may demonstrate activation of the auditory cortex when visual stimuli are presented.

2. *With learning, the distributed cortical representations of inputs and brain actions “specialize” in their representations of behaviorally important inputs and actions in skill learning.*

There seems to be a minimal level of repetitive practice needed to acquire a new skill that will be maintained over time. In fact, this may lead to specialization or change in the underlying neurophysiological processing.¹²⁷⁻¹²⁹ This specialization develops in response to selective cortical neuron responses specialized to demands of sensory, perceptual, cognitive, and motor skill learning.¹³⁰⁻¹³³ This adaptation has been clearly documented in animal studies. For example, if an animal is trained to make progressively finer distinctions about specific sensory stimuli, then cortical neurons come to represent those stimuli in a progressively more specific and progressively “amplified” manner.

3. *There are important behavioral conditions that must be met in the learning phase of plasticity.*

- a. If behaviorally important stimuli repeatedly excite cortical neuron populations, the neurons will progressively grow in number.
- b. Repetitive, behaviorally important stimuli processed in skill learning lead to progressively greater specificity in the spectral (spatial) and temporal dimensions.

4. *The growing numbers of selectively responding neurons discharge with progressively stronger temporal coordination (distributed synchronicity).*

Through the course of progressive skill learning, a more refined basis for processing stimuli and generating actions critical to skilled tasks is enabled by the multidimensional

changes in cortical responses. Consequently, specific aspects of these changes in distributed neuronal response are highly correlated with learning-based improvements in perception, motor control, and cognition.¹³⁴⁻¹³⁷ In these processes the brain is not simply changing to record and store content, but the cerebral cortex is also selectively refining its processing capacities to fit each task at hand by adjusting its spectral or spatial and temporal filters. Ultimately it establishes its own general processing capabilities. This “learning to learn” determines the facility with which specific classes of information can be stored, associated, and manipulated. These powerful self-shaping processes of the forebrain machinery are operating not only on a large scale during development but also during experience-based management of externally and internally generated information in adults. This self-shaping with experience allows the development of hierarchical organization of perception, cognition, motor, and executive management skills.

5. *In learning, selection of behaviorally important inputs is a product of strengthening input coincidence-based connections (synapses).*

The process of coincidence-based input co-selection leads to changes in cortical representation. Coincident, temporally and spatially related events that fire together are strengthened together. In skill learning, this principle of concurrent input co-selection results from repetitive practice that includes the following:

- a. A progressive amplification of cell numbers engaged by repetitive inputs.¹³⁶⁻¹³⁸
- b. An increase in the temporal coordination of distributed neuronal discharges evoked by successive events to mark features of behaviorally important inputs is a consequence of a progressive increase in positive coupling between nearly simultaneously engaged neurons within cortical networks.^{136,139}
- c. A progressively more specific “selection” of all input features that collectively represent behaviorally important inputs, expressed moment by moment in time.^{138,139} Thus skill learning results in mapping temporal neighbors in representational networks at adjacent spatial locations when they regularly occur successively in time.^{65,140,141} Changes in activation patterns, dendritic growth, synapses, and neuronal activities may also be observed.

The basis of the functional creation of the detailed, representational cortical maps converting temporal to spatial representations is related to the Hebbian change principle.¹⁴² The Hebbian plasticity principle applies to the development of interconnections between excitatory and inhibitory inputs within the cortical pyramidal neurons and their connections to extrinsic inputs and outputs. On the basis of the Hebbian principle, the operation of coincidence-based synaptic plasticity in cortical networks results in the formation, strengthening, and continuous recruitment of neurons within neuronal “assemblies” that “cooperatively” represent behaviorally important stimuli.

6. *Plasticity is constrained by anatomical sources and convergent-divergent spreads of inputs.* Every cortical field has the following:

- a. Specific extrinsic and intrinsic input sources
- b. Dimensions of anatomical divergence and convergence of its inputs, limiting dynamic combination Hebbian input co-selection capacities^{143,144}

Anatomical input sources and limited projection overlap both to enable change by establishing input-selection repertoires and to determine the limits for change. There are relatively strict anatomical constraints at the “lower” system levels, where only spatially (spectrally) limited input coincidence-based combined outcomes are possible. In the “higher” system hierarchies, anatomical projection topographies are more powerful, with neurons and neuronal assemblies developing that respond to complex combinations of features of real-world objects, events, and actions.

7. *Plasticity is constrained by the time constants governing coincident input co-selection and by the time structures and potentially achievable coherence of extrinsic and intrinsic cortical input sources.*

To effectively drive representational changes with coincident input-dependent Hebbian mechanisms, temporally coordinated inputs are prerequisite, given the short durations (milliseconds to tens of milliseconds) of the time constants that govern synaptic plasticity in the adaptive cortical machinery (see reference 145 for review). Consistently uncorrelated or low-discharge-rate inputs induce negative changes in synaptic effectiveness. In addition, stimuli occurring repetitively simultaneously can also degrade the representation. These negative effects also contribute importantly to the learning-driven “election” of behaviorally important inputs.

8. *Cortical field-specific differences in input sources, distributions, and time-structured inputs create different representational structures.*

a. There are significant differences in the activity from afferent inputs from the retina, skin, or cochlea generated in a relatively strictly topographically wired V1 (area 17), S1 proper (area 3b), or A1 (area 43) compared with the inferotemporal visual, insular somatosensory, dorso-temporal auditory, or prefrontal cortical areas that receive highly diffuse inputs (see Figure 4-8). In the former cases, heavy schedules of repetitive, temporally coherent inputs are delivered from powerful, redundant projections from relatively strictly topographically organized thalamic nuclei and lower-level, associated cortical areas. Whereas neighboring neurons can share some response properties, neurons or clusters of neurons respond selectively to learned inputs. These neurons are distributed widely across cortical areas and share less information with neighboring neurons. In the “lower” levels, afferent input projections from any given source are greatly dispersed. Highly repetitive inputs are uncommon, inputs from multiple diffuse cortical sources are more common as well as more varied, and complex input combinations are in play. These differences in input schedules, spreads, and combinations presumably largely account for the dramatic differences in the patterns of representation of behaviorally important stimuli at “lower” and “higher” levels.¹⁴⁶

b. Despite these differences in representational organization across the cortex, the cortex does progressively differentiate cortical cells to accomplish specific operational tasks. There is a serial progression of differentiation to allow the development of functional organization that allows an individual to progressively master more and more elaborated and

differentiated perceptual, cognitive, monitoring, and executive skills.

c. The sources of inputs and their field-specific spreads and boundary limits, the distributions of modulatory inputs differentiated by cortical layers in different cortical regions, the basic elements and their basic interconnections in the cortical processing machine, and crucial aspects of input combination and processing at subcortical levels are inherited (see reference 147 for review). Although these inherited aspects of sensory, motor, and cortical processing circuit development constrain the potential learning-based modification of processing within each cortical area, representation changes can occur as a result of environmental interaction and purposeful behavioral practice.

9. *Temporal dimensions of behaviorally important inputs also influence representational “specialization.”* In at least four ways, the cortex refines its representations of the temporal aspects of behaviorally important inputs during learning.

a. First,

1) The cortex generates more synchronous representations of sequenced and coincident associative input perturbations or events, not only recording their identities but also marking their occurrences (for examples, see references 132, 136, 139, and 148 to 151). These changes in representation appear to be primarily achieved through increases in positive coupling strengths between interconnected neurons participating in stimulus- or action-specific neuronal cell assemblies.^{132,150,152-171} The strength of the interconnectedness increases representational salience as a result of downstream neurons being excited as a direct function of the degree of temporal synchronization of their inputs.

2) Increasing the power of the outputs of a cortical area drives downstream plasticity. Hebbian plasticity mechanisms operating within downstream cortical (or other) targets also have relatively short time constants. The greater the synchronicity of inputs, the more powerfully those change mechanisms are engaged. The strength of the interconnections also helps protect against noise. For example, by simple information abstraction and coding, the distributed neuronal representation of the “signal” (a temporally coordinated, distributed neuronal response pattern representing the input or action) is converted at the entry levels in the cortex into a form that is not as easily degraded or altered by “noise.” The strength of the interconnectedness also confers robustness of complex signal representation for spatially or spectrally incomplete or degraded inputs.

b. Second,

1) The cortex can select specific inputs through learning to exaggerate the representation of specific input time structures. Conditioning a monkey or a rat with stimuli that have a consistent, specific temporal modulation rate or interstimulus time, for example, results in a selective exaggeration of the responses of neurons at that rate or time separation. In effect, the cortex “specializes” for expected

relatively higher-speed or relatively lower-speed signal event reception.

- 2) Both electrophysiological recording studies and theoretical studies suggest that cortical networks richly encode the temporal interval as a simple consequence of cortical network dynamics.^{172,173}

It is hypothesized that the cortex accomplishes time interval and duration selectivity in learning by positively changing synaptic connection strengths for input circuits that can respond with recovery times and circuit delays that match behaviorally important modulation frequency periods, intervals, or durations. However, studies on including excessive, rapid, repetitive fine motor movements can sometimes lead to serious degradation in representation if the adjacent digits are driven nearly simultaneous in time. This may be associated with negative learning and a loss of motor control.¹⁷⁴

c. Third,

- 1) The cortex links representations of immediately successive inputs that are presented in a learning context.
- 2) As a result of Hebbian plasticity, it establishes overlapping and neighboring relationships between immediately successive parts of rapidly changing inputs yet retains its individualized, distinct cortical representation.^{65,175}

d. Fourth,

- 1) The cortex generates stimulus sequence-specific (“combination-sensitive”) responses, with neuronal responses selectively modulated by the prior application of stimuli in the learned sequence of temporally separated events.
- 2) These “associative” or “combination-sensitive” responses have been correlated with evidence of strengthened interconnections between cortical cell assemblies representing successive event elements separated by hundreds of milliseconds to seconds in time.^{176,177} The mechanisms of origin of these effects have not yet been established.

10. *The integration time (“processing time”) in the cortex is itself subject to powerful learning-based plasticity.*

- a. Cortical networks engage both excitatory and inhibitory neurons by strong input perturbations. Within a given processing “channel,” cortical pyramidal cells cannot be effectively reexcited by a following perturbation for tens to hundreds of milliseconds. These integration “times” are primarily dictated by the time for recovery from inhibition, which ordinarily dominates poststimulus excitability. This “integration time,” “processing time,” or “recovery time” is commonly measured by deriving a “modulation transfer function,” which defines the ability of cortical neurons to respond to identical successive stimuli within cortical “processing channels.” For example, these “integration” times normally range from about 15 to about 200 ms in the primary auditory receiving areas.¹⁷⁸⁻¹⁸⁰ Progressively longer processing times are recorded at higher system levels (e.g., in the auditory cortex, they are approximately a syllable in length, 200 to 500 ms in duration) in the “belt cortex” surrounding the primary auditory cortex.¹⁸¹

- b. These time constants govern—and limit—the cortex’s ability to “chunk” (i.e., to separately represent by distributed, coordinated discharge) successive events within its processing channels. Both neurophysiological studies in animals and behavioral training studies in human adults and children have shown that the time constants governing event-by-event complex signal representation are highly plastic. With intensive training in the right form, cortical “processing times” reflected by the ability to accurately and separately process events occurring at different input rates can be dramatically shortened or lengthened.¹⁸²⁻¹⁸⁵

11. *Plasticity processes are competitive.*

- a. If two spatially or spectrally different inputs are consistently delivered nonsimultaneously to the cortex, cortical networks generate input-selective cell assemblies for each input and actively segregate them from one another.^{139,184,186-188} Boundaries between such inputs grow to be sharp and are substantially intensity independent. Computational models of Hebbian network behaviors indicate that this sharp segregation of nonidentical, temporally separated inputs is accomplished as a result of a wider distribution of inhibitory instead of excitatory responses in the emerging, competing cortical cell assemblies that represent them.
- b. This Hebbian network cell assembly formation and competition appear to account for how the cortex creates sharply sorted representations of the fingers in the primary somatosensory cortex.^{140,189} The Hebbian network probably accounts for how the cortex creates sharply sorted representations of native aural language-specific phonemes in lower-level auditory cortical areas in the auditory and speech processing system of humans. If inputs are delivered in a constant and stereotyped way from a limited region of the skin or cochlea in a learning context, that skin surface or cochlear sector is an evident competitive “winner.”^{136,190} By Hebbian plasticity, the cortical networks will co-select that specific combination of inputs and represent it within a competitively growing Hebbian cell assembly. The competitive strength of that cooperative cell assembly will grow progressively because more and more neurons are excited by behaviorally important stimuli with increasingly coordinated discharges. That means that neurons outside of this cooperative group have greater numbers of more coordinated outputs contributing to their later competitive recruitment. Through progressive functional remodeling, the cortex clusters and competitively sorts information across sharp boundaries dictated by the spectrotemporal statistics of its inputs. If it receives information on a heavy schedule that sets up competition for a limited input set, it will sort competitive inputs into a correspondingly small number of largely discontinuous response regions.^{191,192}
- c. Competitive outcomes are, again, cortical level dependent. The cortex links events that occur in different competitive groups if they are consistently excited synchronously in time. At the same time, competitively formed groups of neurons come to be synchronously linked in their representations of different parts of the complex stimulus and collectively represent

successive complex features of the vocalization through the coordinated activities of many groups.

- d. Neurons within the two levels of the cortex surrounding A1 (see Figure 4-8) have greater spectral input convergence and longer integration times that enable their facile combination of information representing different spectrotemporal details. Their information extraction is greatly facilitated by the learning-based linkages of cooperative groups that deliver behaviorally important inputs in a highly salient, temporally coordinated form to these fields. With their progressively greater space and time constants, still higher-level areas organize competitive cell assemblies that represent still more complex spectral and serial-event combinations. Note that these organizational changes apply over a large cortical scale. In skill learning over a limited period of training, participating neuronal members of such assemblies can easily be increased by many hundredfold, even within a primary sensory area such as S1, area 3b, or A1.^{136,139,174,184,193}
 - e. In extensive training in complex signal recognition, more than 10% of neurons within temporal cortical areas can come to respond highly selectively to a specific, normally rare, complex training stimulus. The distributed cell assemblies representing those specific complex inputs involve tens or hundreds of millions of neurons and are achieved by enduring effectiveness changes in many billions of synapses.
12. *Learning is modulated as a function of behavioral state.*
 - a. At “lower” levels of the cortex, changes are generated only in attended behaviors.^{137,138,146,193-195} Trial-by-trial change magnitudes are a function of the importance of the input to the animal as signaled by the level of attention, the cognitive values of behavioral rewards or punishments, and internal judgments of practice trial precision or error based on the relative success or failure of achieving a target goal or expectation. Little or no enduring change is induced when a well-learned “automatic” behavior is performed from memory without attention. It is also interesting to note that at some levels within the cortex, activity changes can be induced even in nonattending subjects under conditions in which “priming” effects of nonattended reception of information can be demonstrated.
 - b. The modulation of progressive learning is also achieved by the activation of powerful reward systems releasing the neurotransmitters norepinephrine and dopamine (among others) through widespread projections to the cerebral cortex. Norepinephrine plays a particularly important role in modulating learning-induced changes in the cortex.^{148,184,195}
 - c. The cortex is a “learning machine.” During the learning of a new skill, neurotransmitters are released trial by trial with application of a behaviorally important stimulus or behavioral rewards. If the skill can be mastered and thereafter replayed from memory, its performance can be generated without attention (habituation). Habituation results in a profound attenuation of the modulation signals from these neurotransmitter sources; plasticity is no longer positively enabled in cortical networks.
 13. *Top-down influences constrain cortical representational plasticity.*

Attentional control flexibly defines an enabling “window” for change in learning.¹⁸² Progressive learning generates progressively more strongly represented goals, expectations, and feedback^{196,197} across all representational systems that are undergoing change and to modulatory control systems weighing performance success and error. Strong intermodal behavioral and representational effects have also been recorded in experiments that might be interpreted as shaping expectations.^{198,199} These shaping expectations would be similar to those observed in a human subject using multisensory inputs such as auditory, visual, and somesthetic information to create integrated phonological representations, to create fine motor movement trajectory patterns that underlie precise hand control, or to make a vocal production.

 14. *The scale of plasticity in progressive skill learning is massive.*
 - a. Cortical representational plasticity must be viewed as arising from multiple-level systems that are broadly engaged in learning, perceiving, remembering, thinking, and acting. Any behaviorally important input (or consistent internally generated activity) engages many cortical areas. Repetitive training drives all cortical areas to change.^{131,144,200} Different aspects of any acquired skill are contributed from field-specific changes in the multiple cortical areas that are remodeled in its learning.
 - b. In this kind of continuously evolving representational machine, perceptual constancy cannot be accounted for by locationally constant brain representations; relational representational principles must be invoked to account for it.^{131,201} Moreover, representational changes must obviously be coordinated level to level. It should also be understood that plastic changes are also induced extracortically. Although it is believed that learning at the cortical level is usually predominant, plasticity induced by learning within many extracortical structures significantly contributes to learning-induced changes that are expressed within the cortex.
 15. *Enduring cortical plasticity changes appear to be accounted for by local changes in neural anatomy.*

Changes in synapse turnover, synapse number, synaptic active zones, dendritic spines, and the elaboration of terminal dendrites have been demonstrated to occur in a behaviorally engaged cortical zone.^{144,202-207} Through many changes in local structural detail, the learning brain is continuously physically remodeling its processing machinery, not only across the course of child development but also after behavioral training in an adult who has had a neural insult.
 16. *Cortical plasticity processes in child development represent progressive, multiple-staged skill learning.*
 - a. There are two remarkable achievements of brain plasticity in child development. The first is the progressive shaping of the processing to handle the accurate, high-speed reception of the rapidly changing streams of information that flow into the brain. In the cerebral cortex, shaping appears to begin most powerfully within the primary receiving areas of the cortex. With early myelination, the main gateways for information into the cortex are receiving strongly coherent inputs from subcortical nuclei, and they can quickly organize their local networks on the basis of coincident input co-selection (Hebbian) plasticity

mechanisms. The self-organization of the cortical processing machinery spreads outward from these primary receiving areas over time to ultimately refine the basic processing machinery of all the cortex. The second great achievement, which is strongly dependent on the first, is the efficient storage of massive content compendia in richly associated forms.

- b. During development, the brain accomplishes its functional self-organization through a long parallel series of small steps. At each step, the brain masters a series of elementary processing skills and establishes reliable information repertoires that enable the accomplishment of subsequent skills. Second- and higher-order skills can be viewed as both elaborations of more basic mastered skills and the creation of new skills dependent on combined second- and higher-order processing. That hierarchical processing is enabled by greater cortical anatomical spreads, by more complexly convergent anatomical sources of inputs, and by longer integration (processing, recovery) times at progressively higher cortical system levels. This hierarchical but integrating processing allows for progressively more complex combinations of information integrated over progressively longer time epochs as one ascends across cortical processing hierarchies.
- c. As the cortical machinery functionally evolves and consequently physically “matures” through childhood developmental stages, information repertoires are represented in progressively more salient forms (i.e., with more powerful distributed response coordination). Growing agreement directly controls the power of emerging information repertoires for driving the next level of elaborative and combinatorial changes. It is hypothesized that saliency enables the maturation of the myelination of projection tracts delivering outputs from functionally refined cortical areas. More mature myelination of output projections also contributes to the power of this newly organized activity to drive strong, downstream plastic change through the operation of Hebbian plasticity processes.
- d. As each elaboration of skill is practiced, in a learning phase, neuromodulatory transmitters enable change in the cortical machinery. The cortex functionally and physically adapts to generate the neurological representations of the skill in progressively more selective, predictable, and statistically reliable forms. Ultimately, the performance of the skill concurs with the brain’s own accumulated, learning-derived “expectations.” The skill can then be performed from memory, without attention. With this consolidation of the remembered skill and information repertoire, the modulatory nuclei enable no further change in the cortical machinery. The learning machine, the cerebral cortex, moves on to the next elaboration. In this way the cortex constructs highly specialized processing machinery that can progressively produce great towers of automatically performable behaviors and great progressively maturing hierarchies of information-processing machinery that can achieve progressively more powerful complex signal representations, retrievals, and associations. With this machinery in a mature and thereby efficiently operating form, there is a remarkable capacity for

reception, storage, and analysis of diverse and complexly associated information.

- e. The flexible, self-adjusting capacity for refinement of the processing capabilities of the nervous system confers the ability of our species to represent complex language structures. This self-adjusting capacity also allows humans to develop high-speed reading abilities; remarkably varied complex modern-era motor abilities; and abstract logic structures characteristic of a mathematician, software engineer, or philosopher. This nervous system refinement also creates elaborate, idiosyncratic, experience-based behavioral abilities in all of us.

Neuroplasticity and Learning

How Are Learning Sequences Controlled? What Constrains Learning Progressions? Perhaps the most important basis of control of learning progressions is representational consolidation. Through specialization, the trained cortex creates progressively more specific and more salient distributed representations of behaviorally important inputs. Growing representational salience increases the power of a cortical area to effectively drive change wherever outputs from this evolving cortical processing machinery are distributed (e.g., in “higher system levels distributed and coordinated [synchronized] responses” more powerfully drive downstream Hebbian-based plasticity changes).

A second powerful basis for sequenced learning is progressive myelination. At the time of birth, only the core “primary” extrinsic information entry zones (A1, S1, V1) in the cortex are heavily myelinated.^{208,209} Across childhood, connections to and interconnections between cortical areas are progressively myelinated, proceeding from these core areas out to progressively “higher” system levels. Myelination in the posterior parietal, anterior, and inferior temporal and prefrontal cortical areas is not “mature” in the human forebrain until 8 to 20 years of age. Even in the mature state, it is far less developed at the “highest” processing levels.

Myelination controls the conduction times and therefore the temporal dispersions of input sources to and within cortical areas. Poor myelination at “higher” levels in the young brain is associated with temporally diffuse inputs. They cannot generate reliable representational constructs of an adult quality because they do not as effectively engage input-coincidence-based Hebbian plasticity mechanisms. That ensures, in effect, that plasticity is not enabled for complex combinatorial processing until “lower” level input repertoires are consolidated (i.e., become stable, statistically reliable forms).

Although myelination is thought to be genetically programmed, some scientists hypothesize that myelination in the CNS is also controlled by emerging temporal response coherence and is achieved through temporally coordinated signaling from the multiple branches of oligodendrocytes that terminate on different projection axons in central tracts and networks. It has been argued that central myelination is positively and negatively activity dependent and that distributed synchronization may contribute to positive change.²¹⁰ If the hypothesis that coherent activity controls myelination proves to be true, then the emerging temporal correlation of distributed representations of behaviorally important stimuli

is generated level by level. This is done by changes in coupling in local cortical networks in the developing cortex. It would also directly drive changes in myelination for the outputs of that cortical area. These two events in turn would enable the generation of reliable and salient representational constructs at that higher level. By this kind of progression, skill learning is hypothesized to directly control progressive functional and physical brain development through the course of child development. This is accomplished both by refining (“maturing”) local interconnections through response dynamics of information processing machinery at successive cortical levels and by coordinated refinement (“maturing”) of the critical information transmission pathways that interconnect different processing levels.

Another constraint in the development of neural adaptation may be the development of mature sleeping patterns, especially within the first year of life.²¹¹ Sleep both enables the strengthening of learning-based plastic changes and resets the learning machinery by “erasing” temporary unreinforced and unrewarded input-generated changes produced over the preceding waking period.²¹²⁻²¹⁴ The dramatic shift in the percentage of time spent in rapid-eye-movement sleep is consistent with a strong early bias toward noise removal in an immature and poorly functionally unorganized brain. Sleep patterns change dramatically in the older child, in parallel with a strong increase in the daily schedule of closely attended, rewarded, and goal-oriented behaviors. This research will need to be explored in greater detail when these data are related to patients with CNS damage. This population often has poor breathing habits and capabilities that lead to decreased oxygenation and often broken sleep cycles. How much either impairment, breakdown, or the interaction of the two diminishes neuroplasticity has yet to be determined.

Top-down modulation controlling attentional windows and learned predictions (expectations and behavioral goals) must all be constructed by learning. Delays in goal development could also create an important constraint for the progression of early learning. In the very young brain, prediction and error-estimation processes would be weakened because stored higher-level information repertoires are ill formed and statistically unreliable. As the brain matures, stored information progressively more strongly and reliably enables top-down attentional and predictive controls, progressively providing a stronger basis for success and error signaling for modulatory control nuclei and progressively enabling top-down syntactic feedback to increase representational reliability.

Attention, reward and punishment, accuracy of achievement of goals, and error feedback gate learning through a modulatory control system are critical for learning. The modulatory control systems that enable learning are also plastic, with their process of maturation providing constraint or facilitation for progressive learning. These subcortical nuclei are signaled by complex information feedback from the cortex itself. The salience and specificity of that feedback information grow over time. The ability to provide accurate error judging or goal-achievement signaling must grow progressively. The nucleus basalis, nucleus accumbens, ventral tegmentum, and locus coeruleus must undergo their own functional self-organization on the basis of Hebbian plasticity principles to achieve

“mature” modulatory selectivity and power. The progressive maturation of the modulatory control system occurs naturally with development or training. This system can provide another important constraint on skill development progression and regulation of axial or trunk postural and balance control and fine motor coordination.

What Facilitates the Development of Permanent “Automatic” Motor Behaviors? The creation and maintenance of cortical representations are functions of the animal’s or human’s level of attention at a task. Cortical representational plasticity in skill acquisition is self-limiting. Because the behavior comes to be more “automatic,” it is less closely attended, and representational changes induced in the cortex fade and ultimately disappear or reverse (unlearning effects).^{215,216} The element of behavioral performance that enables maintenance of the behavior with minimum involvement of the cortical learning machinery is probably stereotypical movement sequence repetition. As a movement behavior is practiced, an effective, highly statistically predictable movement sequence is adopted that enables the storage of the learned behavior in a permanent form that requires only minimal or no behavioral attention. If behavioral performance declines or behavioral or brain conditions change to render a task more difficult, attention to the behavior will again need to increase, producing an invigorated cortical response to the new learning challenge.

By this view, the cerebral cortex is clearly a learning machine. William James²¹⁷ was the first to point out that the great practical advantage for a self-organizing cortex was the development of what he called “habits.” When a skill is overlearned, it will engage pathways that are so reliable that they can be followed without attention.

Why are some habits retained and others lost? Can sensorimotor learning be sustained when the adaptive representations of the learned behavior “fade” in the cerebral cortex? These areas have not been well researched. However, there are several possibilities. Habits could come to be represented in an enduring form extracortically. The cortex could modify processing in the spinal cord, the basal ganglia, the red nucleus, or the cerebellum. For example, the learning of manual skills requires a motor cortex, but overlearned motor skills may not be significantly reduced by the induction of a wide area 4 lesion.

Another possibility is that behaviorally induced cortical changes endure in a highly efficient representational form that can sustain the representation of its key features on the cortex itself, engaging only limited distributed populations of cortical neurons to represent the behavior with high fidelity. Thus, recall of past learning may take less time to restructure than to reformat entirely new learning, whether it be a cognitive or motor task. The fact that a monkey improves discriminative abilities or movement performance after modifying the cortical neuron response with heavily practiced behaviors supports this alternative. However, many behaviors, such as musical performance, require constant, attended practice at a highly cognitive level to maintain both the representational changes and the performance. It also appears that continued learning with heavily practiced behaviors may be neuroprotective with aging, maintaining function despite loss of cortical neurons as a natural part of aging.

SUMMARY

Over the years, learning has been tied to critical periods of development, with the assumption that if a particular skill or behavior was not learned during the critical period, the opportunity to acquire that skill was lost. In addition, after this critical period of development, aging was associated with inevitable deterioration of brain and neurophysiological function. However, today there is substantial evidence that the brain is an incredibly specialized representational machine that can adapt to meet the specific inputs that engage it. The beauty of the brain is that it not only self-organizes but stores the contents of its learning to create a foundation that increases in depth and breadth and makes predictions on even novel inputs to facilitate acute and efficient operations. The earlier the exposure to multisensory stimuli, the easier it is for the competitive neuronal processes to adapt and to make extensive connections. With growing neuronal specificity and salience, more powerful predictions are continued until there is greater learning and mastery.

Among the important findings of the twentieth century was the validation that the brain is a learning machine that operates throughout life. The aging process can take a toll on the ability to store information and may reduce both the complexity of the information that is processed and the individual's ability to remember. But if an individual is conscious of good hydration, balanced nutrition, physical exercise, and regularly goal-directed progressive learning, CNS pathways of representation and prediction can not only be preserved but also continue to adapt. These activities can also slow the aging process. Thus it is possible to drive improvement in function in individuals with abnormalities related to development, disease, injury, or aging. Learning is not necessarily specifically staged, but rather represents complex abilities developed mostly from systems interaction and integration. Therapists must develop the ability to determine what inputs are reliable and salient to effectively create functional and physical brain maturation, adaptation, and learning. In the face of different types of challenges (structural, emotional, pathological), clinicians must develop more effective strategies that can be used to facilitate neural adaptation, learning, substitution, and representational changes that will allow meaningful maintenance and improvement in function despite anatomical or physiological variances in structure. Although strong behavioral events can be associated with measurable neural adaptability, new, more permanent neural connections and synapses must be strengthened with repetition and increased complexity. Clients with CNS disorders may have damaged certain areas of the brain, which may not recover; however, with learning-based activities it is possible to reorganize the brain, stimulate neurons from adjacent areas, establish new synapses and dendritic pathways,²¹⁸ and activate neurons in the contralateral, uninjured parts of the brain.²¹⁹⁻²²⁵ Creating the best environment to learn a skill may initially need to be contrived, with limitations controlled externally by the therapist's hands or clinical arena. In time, those limitations must be eliminated and variability within the natural environment reintroduced to achieve true learning and ultimate neuroplasticity.

The elements of neuroscience research on neural adaptation have been summarized into 14 principles to guide rehabilitation programs designed to facilitate experience-dependent plasticity.^{96,226,227} These principles, outlined in **Box 4-1**, are similar to those suggested by Nudo¹²⁹ as well as Kleim and Jones¹²⁸ and Byl and colleagues.²²⁸ Although these principles are particularly

relevant to patients with a head injury or stroke, they are also relevant for aging adults,²²⁹⁻²³³ and those with neurodegenerative disease. These principles are not meant to be exhaustive or mutually exclusive but to highlight the principles of experience-dependent plasticity. However, they can serve as a reference for therapists who are designing creative intervention programs based on the translation of basic science to clinical practice and to help organize the extensive research on neuroplasticity.

These principles can be applied across a broad range of exercises—not just “brain exercises” to improve cognition and intellect, but also physical exercise. For example, we know that brain derivative neural factor (BDNF) is necessary for learning. BDNF decreases with aging and is severely reduced in animals with dementia. However, BDNF can be increased with moderate and aerobic exercise.^{234,235} Furthermore, it is clear that timing of enrichment (e.g., mental stimulation, physical exercise, sensory and motor training) is important, not only during development but across the life span. Initiating an exercise program too early (e.g., in less than 24 hours acute post neural injury) may be associated with an exaggeration of cellular injury.²³⁶ However, waiting too long to intervene can limit the efficacy of the learning-based training experience.²³⁷ It also appears that the efficacy of learning-based training may be enhanced with cortical stimulation,²³⁸ repetitive transcranial magnetic stimulation (TMS),²³⁹ and imagery. It is critical to create a positive foundation to maximize learning (e.g., good hydration to maximize blood flow and oxygenation of tissues, adequate nutrition to energize the body, and aerobic activity to increase endorphins and BDNF, as well as positive expectations of getting better [limbic system]). Rehabilitation specialists must not only translate basic neuroscience into practice but participate in clinical research, serve as advocates for patients, ensure access to appropriate rehabilitative services, and be politically active in health care reform.

To ensure maximum neural adaptation, rehabilitation programs must include strong, carefully outlined home programs. Therapists must educate patients and their families about the principles of neuroplasticity to empower them to create progressive learning activities at home and in the community. Patients should revisit health care team members to facilitate ongoing learning. Patients must become their own best therapist, consistently motivating themselves to learn something new, perform attended behavioral activities, observe and integrate new information from their environment, have fun, stay engaged with family, friends, and community and avoid habitual stereotypical behaviors. Learning should be an excuse to travel to new places and learn new skills. Every day should include a new learning experience. Learning and aerobic exercise may not only be neuroprotective but could be critical for slowing down the natural neurodegenerative aspects of aging. Computer gaming, new technology, and robotics can be integrated to expand daily learning-based activities at home (see Chapter 38).

The maximum attainment of skilled performance cannot necessarily be determined. The original injury can be used only as an estimate of the damage with some indicators for prognosis and recovery. The rest of the success of rehabilitation and restoration of function will reside with the motivation and commitment of the individual. How that motivation and commitment are initially established and continually reinforced is based on the patient, the therapist's interactive skills and emotional bond (see Chapter 5),

CASE STUDY 4-1 ■ PERSON WITH PARKINSON DISEASE

People with Parkinson disease develop an array of deficits in motor control that interfere with multiple ADLs and can eventually degrade quality of life. When motor control deficits are evaluated in this population, the severity of the disease, the activity level of the person, and the medication schedule are important considerations. Following are several motor control deficits that are evident in this disease.

Motor control impairments of rigid tone and bradykinesia create alterations in stride length, speed, and step frequency in the gait pattern of persons with Parkinson disease. The person may demonstrate a gait pattern characterized by decreased amplitude of leg movement, duration of the gait cycle, trunk rotation, and arm swing. Difficulty initiating gait, or “freezing,” is an observable motor control problem, and small shuffling steps and a festinating gait pattern are also common.²⁴⁰ Impaired righting and balance reactions can contribute to gait instability. When the demands on gait velocity and frequency are altered, metabolic cost increases and the ability of the individual to safely complete the functional movement with appropriate coordination of postural and motor control is challenged.

A practical outcome measure that can be used to capture the effect of these motor deficits on functional mobility is the Timed Up-and-Go Test (TUG). This quick test can be used to capture the time it takes for a person to initiate sit to stand, transition from sit to stand, walk 3 meters, turn around, walk back, turn, and sit down. During the performance of these sequential movement patterns the clinician can observe gait deviations, postural abnormalities, movement amplitude, and safety awareness. Episodes and duration of “freezing,” or failed initiation, can be accounted for, and the number of steps to turn 180 degrees can be documented.²⁴¹ The overall time to complete the test can supply the clinician with objective data related to fall risk.

Overshooting or undershooting the 3-meter line before turning may be demonstrated. Although clients with Parkinson disease are able to prepare the motor strategy and use advance information, the primary problem is slow onset of execution of movement; therefore changing motor patterns (e.g., switching from walking to turning) can be quite difficult.

To illustrate the multiple motor control deficits, imagine a patient performing the TUG.²⁴² The person may have difficulty accelerating to walk and decelerating to turn around and may have difficulty decelerating when approaching the chair and sitting down. Postural instability may be observed during transfers and turning, and a loss of balance in the backward direction without the activation of an automatic stepping response may occur. The motor control deficits exhibited in the patient with Parkinson disease are numerous and intertwined and their severity is influenced by the progression of the disease. As mentioned earlier, the client cannot appropriately control the increase and decrease in the rate of force

production, which is evident in the acceleration and deceleration phases of the movement. If the rate of force production is altered; amplitude of force production may also be affected.

The person may have a decreased ability to predict and prepare the motor pattern for turning before the actual turn. There appears to be a slow initiation of the turning task. This phenomenon could be caused by an inability to sequence the motor behavior as a whole. Several researchers have observed that the person completes one movement before starting the next movement in the sequence rather than executing a smooth, continuing movement pattern.²⁵ Another reason for the decrease in the ability to perform this task smoothly is the patient’s dependence on visual feedback. Relying more heavily on visual feedback to accomplish a task slows the movement.

The movement deficits observed may also be a result of the inability to effectively coordinate movements such as those observed between postural and motile components of the task. Postural strategies may be classified on a continuum that includes postural preparations, postural adaptations, and postural reactions.²⁴³ The person with Parkinson disease may not predict and make appropriate postural adjustments before the movement and may have deficits in adaptive and reactive postural responses (e.g., righting and equilibrium reactions, and adapting to environmental demands). In the case of the TUG, movement and balance strategies are assessed when the client stands up and sits down. If the client does not use a controlled descent into the chair but rather falls backward, what are the possible causes for the sudden descent? The client’s goal may be to land in the chair, but the preferred pattern may be to fall into the chair. The individual may not be able to predict the time and force needed to activate the muscles for a smooth descent, the individual may be deconditioned and not have the strength or endurance to perform a smooth descent, or the individual may not have the balance strategies required to perform this maneuver.

The client with Parkinson disease is one example of a client with a neurological condition that affects motor output and control. Regardless of the diagnosis, all aspects of motor control need to be examined and activity-based tests must be conducted to determine how the impairments interact to affect the execution of functional tasks. A few key deficits in gross and fine motor control and postural control were examined in this example. It is not within the scope of this section to present all the motor and postural control deficits but to highlight the complexity of patients with neurological pathology. Accurate identification of motor control problems in clients assists the therapist and the client in the development of realistic functional goals and effective intervention programs (see Section II for recommendations regarding specific diseases or pathological conditions and their related body system impairments and activity-based functional limitations).

and the family and other support systems surrounding the client (see Chapter 6).

Acknowledgment

All the present authors and the editors would like to thank both Roberta Newton, PT, PhD, and Sharon Gorman, PT, DPTSc, GCS for their commitment to this text’s evolution, as well as to the delivery of best practices to the elderly population.

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 250 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

CHAPTER 5

The Limbic System: Influence over Motor Control and Learning

DARCY A. UMPHRED, PT, PhD, FAPTA, MARCIA HALL THOMPSON, PT, DPT, DSc,
and THERESE MARIE WEST, PhD, MT-BC, FAMI

KEY TERMS

amygdala
declarative memory
emotional behavior
F²ARV (fear and frustration, anger, rage, violence/
withdrawal) continuum
general adaptation syndrome (GAS)
hippocampus
hypothalamus
limbic network
motor learning
MOVE (motivation or memory, olfaction, visceral,
autonomic nervous system, emotional)

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Understand the complexity of the limbic network and the influence of the limbic network on behavioral and functional responses.
2. Describe the behavioral responses directly influenced by the limbic network.
3. Describe the structures of the limbic network.
4. Describe the interaction between the limbic network and body systems responsible for behavioral responses.
5. Differentiate between limbic-driven motor control responses and frontal, cerebellar, and basal ganglia motor regulation.
6. Differentiate between declarative and procedural learning.
7. Identify signs of both positive and negative limbic network influence on a client's observable behavior and functional responses.
8. Describe appropriate treatment interventions or program modifications for both the limbic high and limbic low client.
9. Understand the influence of the therapist over the limbic network and behavioral and functional responses, and effectively integrate limbic network treatment techniques into current treatment models.

Since the publication of the fifth edition of this book, the limbic network has emerged as a key component of central nervous system (CNS) function, becoming one of the most researched areas of the CNS when analyzing behavior, learning, emotions, and their influence on activities and participation. In the past, review of the literature on the limbic network was limited to investigating potential interactions of other systems with nuclei within the limbic network. This is no longer the case, as neuroscience research has helped to identify the critical nature of behaviors controlled or influenced by the limbic network. Based on research at a cellular level,¹⁻³ a consciousness level,⁴⁻⁷ a bodily systems level,⁸⁻¹⁰ and a quantum level¹¹⁻¹³ it is now clear that the motor system is just one of the many systems affected by the complex limbic network.¹⁴⁻²¹

Although far from yielding a complete understanding, this research and knowledge are increasing daily and force today's therapist not only to recognize limbic behavior but also to develop an understanding of how involvement of the limbic network will positively and negatively affect each patient. Therapists can no longer think of motor control and motor learning as controlled exclusively by an anatomically unique motor system, nor can we understand movement using motor control or motor learning principles alone. Therapists must consider how emotions may influence selection of health care services and how the limbic network strongly influences treatment participation and outcomes, such as motivation and cooperation, responsibility

for and compliance with home programs, levels of functional activity, and empowerment over treatment planning and life activities.

Obviously, the human organism is a complex totality made up of many interlocking parts. The medical system has traditionally divided the body into systems and has forgotten that each specific system is co-dependent on many other systems for function. Today the medical profession is rediscovering the importance of how the systems interact with and influence one another.^{22,23} It is very important that movement specialists do not fall into the same trap as medicine in the past and look at movement from only a biomechanical, muscular, neurological, cardiopulmonary, or integumentary system perspective. They must consider the interaction among systems and their subsystems within an individual. For example, the motor system is a system in and of itself. But cognitive impairment and limbic network involvement can lead to tremendous errors in motor responses even when the motor system is intact. In our clients with CNS dysfunction, impairments exist in the motor and limbic network and in cognition, thus creating the potential for a complex set of behavioral responses to internal or external environmental influences.

Again, the totality of these problems is like interlocking pieces of a complicated puzzle. The therapist learner must always maintain clear visualization of the entire puzzle (the client and all his or her systems) while analyzing any one piece or component system. The process of unraveling the

multisystem “puzzle” and adding new pieces of learning is the journey a therapist learner begins in school and can continue throughout his or her career. This is one example of the limbic network’s influence in our own work as therapists. The decision to continue on a learning journey is driven by desire to learn and answer questions regarding the unknown. The emotions felt by the therapist learner in pursuit of mastery and the ability to have the intellectual memory of the learning are also limbic functions. These behavioral responses play an important role in all our lives and in the lives and recovery of our patients/clients, as we will continue to investigate in this chapter.

A patient example of these interactions can be found in a case description of a middle-aged woman admitted to the intensive care unit (ICU) with multiple pelvic fractures and diagnosed with severe internal bleeding, kidney failure, pneumonia, pulmonary emboli, and severe clotting in the lower extremities. The physician took her husband aside to let him know that she was going to die, to which her husband replied, “I understand. Juggling one system problem is easy, juggling two systems takes a little practice, and three-system involvement may challenge the best medical skill. She is presenting four or five body system failures and you are sure no one can juggle that many problems.” The doctor said yes and the patient’s husband then said, “Please keep juggling and don’t worry about me, because if you do, I would then be one more ball to juggle.” And it did seem that every time the doctors got a handle on a body system problem, another system would fail. She required services from an endocrinologist, infection control specialists, interventional radiologists, a pulmonologist, a hematologist, a vascular surgeon, an internal medicine specialist, a urologist, and a nephrologist. Each specialist shared his or her limited experience with a complex clinical problem like this and that there was nothing in the literature to help his or her respective understanding. After 2½ months in the ICU, the woman survived. The physician who had foretold her death met again with the patient and her family. He stated, “How are you still alive? I know what we did medically, but that was not enough to keep you alive.” And he was right. No model within each respective field could account for her recovery. However, the piece not considered within her medical management was the beliefs and spiritual strength of the patient and her family, a positive limbic network influence on the function of each failing body systems. This concept of limbic influence will be further discussed in the third section of this chapter.

So why has this chapter been positioned so prominently within a textbook on basic neurological rehabilitation? In many curricula the limbic network is discussed only in a basic science course of neuroanatomy and neurophysiology. In others, the limbic role in declarative memory and emotional responses is presented as part of a discussion on memory or cognitive function within a psychology course. Yet today’s curricula do stress and accept “motivation and attention” by the patient as key factors in neuroplasticity and motor learning. Similarly, discussions about the negative effects of “fear of falling” on balance and function in the elderly population are stressed. Both components are controlled by the limbic network, yet the science behind how the system works is often not

presented as a critical element in a student’s education or background for identifying the rationale for behavioral responses. This chapter has been written to provide the reader with the realization that without an understanding of limbic interactions and modulations over motor expression, patient outcomes will always be variable even with consistent and accepted interventions. Similarly, the reliability and validity of measurements of motor performance will always be in question and often inconsistent. And, given the limitations in today’s health care delivery models, stresses, and the growing dependence on home programs, without a keen awareness of the limbic responses of both the patient and the provider, a therapist will have little guarantee of the best possible functional outcome for patients.

For the student learner, the first section of the chapter is a discussion of limbic behavior and how to begin to differentiate true motor responses from those entangled in limbic interactions. For the therapist learner desiring ongoing clinical mastery, the second section delves into the anatomy and physiology of the limbic network, the biology of learning and memory, neurochemistry, and neuroplasticity. The third section discusses the immediate relevance to both the student and practicing clinician—how can we apply our understanding of the limbic network to our patient assessments, treatment, and interactions? In other words, how might it change what we do “come Monday morning”? And finally, in the last section, current advances and future research possibilities in the role of the limbic network are explored.

The concept of patient/client-centered therapy has evolved to become an important aspect of health care delivery.²⁴⁻³⁴ The desire to improve or regain function can be self-motivated, but very often it is instilled through the clinician to the patient that his or her best interests and unique goals are the focus of the health care team. This belief is based on trust, hope, and attainable steps toward desired and realistic goals. Patients know that their desires, interests, and needs as unique and valued members of society are considered. They first believe and then recognize that they are persons with specific problems and desired outcomes. Although they may have specific medical diagnoses, be placed on clinical pathways, administered drugs, and sent off to the next facility in a couple of days, patients need to feel that they, as individuals, have not lost all individuality and that someone cares. That need is a feeling of security and safety that bonds a patient to a therapist along the journey of learning.³⁵⁻³⁷

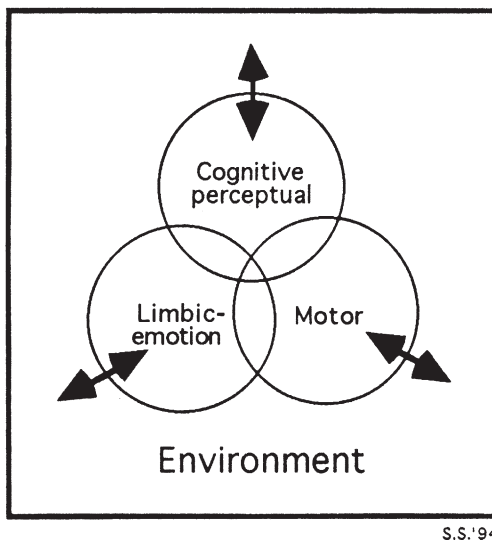

Before understanding and becoming compassionate regarding the needs of other people, such as patients with signs and symptoms of neurological problems, therapists need to understand their own limbic network and how it affects others who might interact with them.³⁸⁻⁴³ Because both occupational and physical therapy professions have evolved to using enablement models and systems interactions to explain movement responses of their respective client populations, separating limbic from true motor or cognitive impairments will help guide the clinician toward intervention strategies that will lead to the quickest and most effective outcomes.

The complexity of the limbic anatomy, physiology, and neurochemistry baffles the minds of basic science doctoral

students. The changes in understanding of cellular metabolism, membrane potentials, and the new mysteries of cell communication and memory perplex the world of science and neuroscience.⁴⁴⁻⁴⁷ How this microcosm relates to the macroworld and how the external environments influence not only consciousness but all levels of CNS function are slowly unraveling but still remain mysteries. Yet a therapist deals with the limbic network of clients on a moment-to-moment functional level throughout the day. Figure 5-1 illustrates the interlocking co-dependency of all major CNS components with the environment. At no time does any system stand in isolation. Thus from a clinical perspective the therapist should always maintain focus on the whole environment and all major interactive components within it, while directing attention to any specific component. How the feedback (internal and external) to the patient's CNS changes the neurochemistry and membrane potential, triggers memory, creates new pathways, or elicits other potential responses is not the responsibility of the clinician or therapist. The responsibility of the clinician is accurate documentation of changes and consistency of those changes toward desired patient outcomes. The professions that focus on movement science are interacting more closely with the neurosciences and other biological sciences and many related professions to unravel many of these mysteries and create better assessment and intervention procedures for future patients.

The primary purpose of this chapter is to discuss the influence of the limbic network on motor learning, motor performance, neuroplasticity, and functional independence in life activities. If a person is fearful or apprehensive, motor performance and the ability to learn either a motor skill or intellectual information will be very different⁴⁸⁻⁵⁵ from that of an individual who feels safe, is given respect, and becomes part of the decision-making process and thus functions inherently with control.^{52,56-61}

An individual will naturally have feelings of loss and reservations or fears about the unknown future after injury to any part of the body, but especially the CNS (see Chapter 6).

S.S.'94

Figure 5-1 ■ Interlocking co-dependency of all major central nervous system components.

Yet that individual needs to be willing to experience the unknown to learn and adapt. The willingness, drive, and adaptability of that individual will affect the optimal plasticity of the CNS.⁶² The limbic network is a key player that drives and motivates that individual. The lack of awareness of that variable or its effect on patient performance will ultimately lead to questions and doubts about the effectiveness and efficacy of both assessment and intervention results. Similarly, if this system is overwhelmed either internally or externally, it will dramatically affect neuroplasticity and motor learning as well as cognitive, syntactical learning (see Chapter 4). At the conclusion of this chapter it is hoped that therapists will comprehend why there is a need to learn to modulate or neutralize the limbic network so that patients can functionally control movement and experience cognitive learning. Then therapists need to reintroduce emotions into the activity and allow the patient to once again experience movement and cognitive success during various levels of emotional demands and environments. This change in the emotional environment will create novelty of the task. This novelty is a critical motivator for learning and will drive neuroplasticity.⁶³⁻⁶⁵

THE FUNCTIONAL RELATIONSHIP OF THE LIMBIC NETWORK TO CLINICAL PERFORMANCE

The Limbic Network's Role in Motor Control, Memory, and Learning

It is not easy to find a generally accepted definition of the "limbic network or complex," its boundaries, and the components that should be included. Mesulam⁶⁶ likens this to a fifth-century BCE philosopher's quotation, "the nature of God is like a circle of which the center is everywhere and the circumference is nowhere." Brodal⁶⁷ suggests that functional separation of brain regions becomes less clear as we discover the interrelatedness through continuing research. He sees the limbic network reaching out and encompassing the entire brain and all its functional components and sees no purpose in defining such subdivision. Although the anatomical descriptions of the limbic network may vary from author to author, the functional significance of this system is widely acknowledged in defining human behavior and behavioral neurology.⁶⁸

Brooks⁶⁹ divides the brain into the limbic brain and the nonlimbic sensorimotor brain. He also defines the two limbic and nonlimbic systems functionally, not anatomically, because their anatomical separation according to function is almost impossible and task specific (Figure 5-2). The sensorimotor portion is involved in perception of nonlimbic somatosensory sensations and motor performance. Brooks defines the limbic brain component as primitive and essential for survival, sensing the "need" to act. The limbic brain is also responsible for memory and the ability to select what to learn from each experience, either positive or negative. Thus the overall purpose of the limbic network is to initiate need-directed motor activity for survival, based on experience. The limbic network therefore initiates and can send neurons up to the frontal lobe or down to the brainstem and thus regulates motor output.

Kandel and colleagues⁵⁶ state that functional behavior requires three major systems: the sensory, the motor, and the motivational or limbic systems. When a seemingly simple

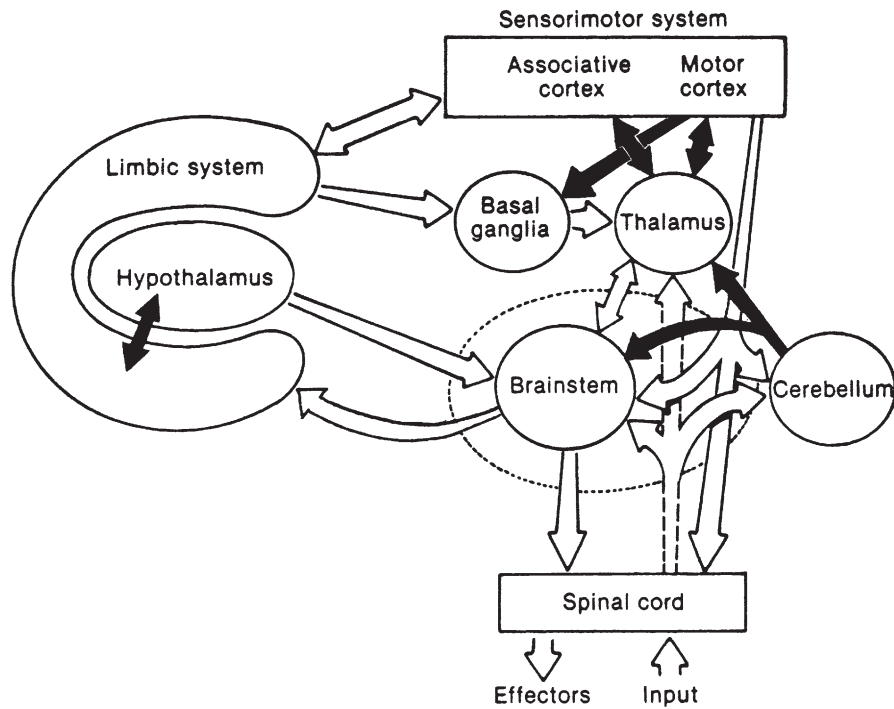

Figure 5-2 ■ Divisions and interconnections between the limbic and nonlimbic cortices (sensory and motor areas).

action, such as swinging a golf club, is analyzed, the sensory system is recruited for visual, tactile, and proprioceptive input to guide the motor systems for precise, coordinated muscle recruitment and postural control. The motivational (limbic) system does the following: (1) provides intentional drive for the movement initiation, (2) integrates the total

motor input, and (3) modifies motor expression accordingly, influencing both the autonomic and the somatic sensorimotor systems. It thereby plays a role in controlling the skeletal muscles through input to the frontal lobe and brain stem and the smooth muscles and glands through the hypothalamus, which lies at the “heart” of the limbic network (Figure 5-3).

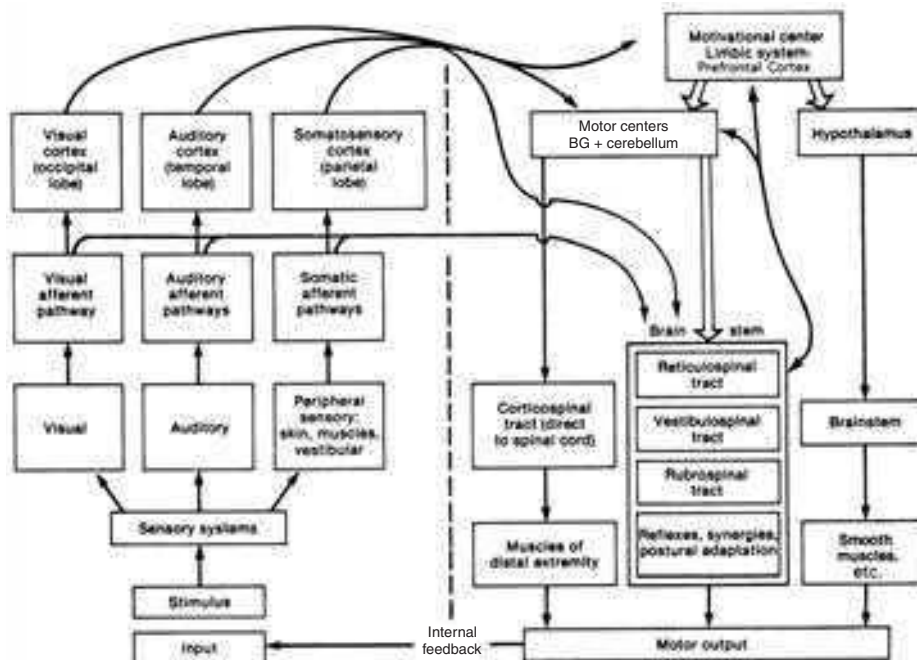

Figure 5-3 ■ Motivational system’s influence over the sensorimotor and autonomic nervous systems. (Adapted from Kandel ER, Schwartz JH, Jessell TM: *Principles of neural science*, ed 4, New York, 2000, McGraw-Hill.)

Noback and co-workers⁷⁰ state that the limbic network is involved with many of the expressions that make us human; namely, emotions, behaviors, and feeling states. That humanness also has individuality. Our unique memory storage, our variable responses to different environmental contexts, and our control or lack thereof over our emotional sensitivity to environmental stimuli all play roles in molding each one of us. Because of this uniqueness, each therapist and each client need to be accepted for their own individuality.

Broca⁷¹ first conceptualized the anatomical regions of the limbic lobe as forming a ring around the brain stem. Today, neuroanatomists do not differentiate an anatomical lobe as limbic, but rather refer to a complex system that encompasses cortical, diencephalon, and brain stem structures.⁵⁶ This description is less precise and encompasses but is not limited to the orbitofrontal and prefrontal cortex, hippocampus, parahippocampal gyrus, cingulate gyrus, dentate gyrus, amygdaloid body, septal area, hypothalamus, and some nuclei of the thalamus.^{56,72-76} Anatomists stress the importance of looking at the interrelated structures and segments or loops within the complex limbic region.^{77,78}

These multiple nuclei and interlinking circuits play crucial roles in behavioral and emotional changes^{77,79,80} and declarative memory.⁷⁹⁻⁹⁶ The loss of any link can affect the outcome activity of the whole circuit. Thus damage to any area of the brain can potentially cause malfunctions in any or all other areas, and the entire circuit may need reorganization to restore function.

Researchers do not ascribe a specific single function to CNS formations but see each as part of a system participating to various degrees in the multitude of behavioral responses (see Chapters 3 and 4 for additional information). Therefore the loss of any part of higher centers or the limbic network may not be clearly definable functionally, and the return of function is not always easy to predict.

Recovery of function after injury may involve mechanisms that allow reorganizing of the structure and function of cortical, subcortical, and spinal circuits. In very young infants, areas within opposite hemispheres may “take over” function, whereas in more mature brains reorganization of existing systems seems to be the current accepted hypothesis within the expanding knowledge of neuroplasticity.⁹⁷⁻¹⁰⁰ For complex behavior, such as in motor functioning requiring many steps, the limbic network, cortex, hypothalamus, basal ganglia, and brain stem work as an integrated unit, with any damaged area causing the whole system to initially malfunction. Without change or encouragement of appropriate external and internal environmental changes that will create neuroplasticity, the initial malfunction can become permanent.¹⁰¹ The timing for optimal neuroplasticity has not yet been established. The medical use of drugs to alter cellular activity and plasticity after CNS damage has become a huge pharmaceutical research area (see Chapter 36). Early as well as later drug therapy may encourage neuroplasticity.¹⁰²⁻¹⁰⁸ The same questions must be asked about early instead of later rehabilitation intervention, as well as the limbic influence over the motor system. A loss of function or a change in behavior cannot necessarily be localized as to the underlying cause. A lesion in one area may cause secondary dysfunction of a different area that is not actually damaged.

The complexity of the limbic network and its associative influence over both the motor control system and cortical structures are enormous. A therapist dealing with a client with motor control or cognitive learning problems needs to understand how the limbic network affects behavioral responses. The knowledge base focuses not only on the client’s deficits but also on the integrative function of the therapist. This understanding should lead to a greater awareness of the clinical environment and the factors within the environment that cause change. Without this knowledge of how to differentiate systems, objective measurements of motor performance or cognitive abilities may be inconsistent without any explanation. Similarly, with excessive limbic activity, clients’ ability to store and retrieve either declarative or procedural learning may be negatively affected, thus limiting the patients’ ability to benefit from traditional interventions and from potentially regaining their respective highest quality of life.

The Limbic Network’s Influence on Behavior: Its Relevance to the Therapeutic Environment **Levels of Behavioral Hierarchies: Where Does the Limbic Network Belong?**

Strub and Black¹⁰⁹ view behavior as occurring on distinct interrelated levels that represent behavioral hierarchies. Starting at level 1, a state of alertness to the internal and external environment must be maintained for motor or mental activity to occur. The brain stem reticular activating system brings about this state of general arousal by relaying in an ascending pathway to the thalamus, the limbic network, and the cerebral cortex. To proceed from a state of general arousal to one of “selective attention” requires the communication of information to and from the cortex, the thalamus, and the limbic network and its modulation over the brain stem and spinal pattern generators.^{56,110}

Level 2 of this hierarchy lies in the domain of the hypothalamus and its closely associated limbic structures. This level deals with subconscious drives and innate instincts. The survival-oriented drives of hunger, thirst, temperature regulation, and survival of the species (reproduction) and the steps necessary for drive reduction are processed here, as well as learning and memory. Most of these activities relate to limbic functioning. If an individual or patient is in a perceived survival mode, little long-term learning regarding either cognition or motor programming will occur. Thus, making the patient feel safe is initially a critical role for the therapist. This approach may require placing the therapist’s hands on the patient initially to take away any possibility of falling. The therapist would first deal with the emotional aspect of the patient’s environment and then shift to the motor learning and control component, in which the patient is empowered to practice and self-correct within the program she or he can control.

On level 3 only cerebral cortical areas are activated. This level deals with abstract conceptualization of verbal or quantitative entities. It is at this level that the somatosensory and frontal motor cortices work together to perceptually and procedurally develop motor programs. The prefrontal areas of the frontal lobe can influence the development of these motor programs, thus again illustrating the limbic influence over the motor system.^{111,112}

Level 4 behavior is concerned with the expression of social aspects of behavior, personality, and lifestyle. Again, the limbic network and its relationship to the frontal lobe are vital. The shift to the World Health Organization International Classification of Functioning, Disability and Health (WHO-ICF) model, which reflects patient-centered therapy, has actualized the critical importance of this level of human behavior.^{24,28,31,113,114}

The interaction of all four levels leads to the integrative and adaptable behavior seen in the human. Our ability to become alert and protectively react is balanced by our previous learning, whether it is cognitive-perceptive, social, or affective. Adaptability to rapid changes in the physical environment, in lifestyles, and in personal relationships results from the interrelationships or complex neurocircuitry of the human brain. When insult occurs at any one level within these behavioral hierarchies, all levels may be affected.

As Western medicine is unraveling the mysteries behind the neurochemistry of the limbic network^{58,115-117} and alternative medicine is establishing effectiveness and efficacy for various interventions and philosophies (see Chapter 39), a fifth level of limbic function may become the link between the hard science of today and the unexplained mysteries. Those medical mysteries would be defined as unexplained yet identified events that have either been forgotten or been hidden from the world by those scientists—mysteries such as why some people heal from terminal illnesses spontaneously, various others heal in ways not accepted by traditional medicine,^{60,118} and still others just die without any known disease or pathological condition.¹¹⁹⁻¹²² One critical component everyone identifies as part of that unexplained healing is a belief by the client that he or she will heal. That belief has a strong emotional component,¹²⁰ and that may be the fifth level of limbic function. How conscious intent drives hypothalamic autoimmune function is being unraveled scientifically, and clinicians often observe these changes in their patients. Through observation it becomes apparent that clients who believe they will get better often do, and those who believe they will not generally do not. Whether belief comes from a religious, spiritual, or hard science paradigm, that belief drives behavior, and that drive has a large limbic component.

The Limbic Network MOVES Us

Moore¹²³ eloquently describes the limbic network as the area of the brain that moves us. The word *MOVE* can be used as a mnemonic for the functions of the limbic network.

Limbic Network Function.

Memory and motivation: drive

Memory: attention and retrieval, declarative learning

Motivation: desire to learn, try, or benefit from the external environment

Olfaction (especially in infants)

Only sensory system that does not have to go through the thalamus as a second-order synapse in the sensory pathway before it gets to the cerebral cortex

Visceral (drives: thirst, hunger, and temperature regulation; endocrine functions)

Sympathetic and parasympathetic reactions

Hypothalamic regulation over autoimmune system

Peripheral autonomic nervous system (ANS) responses that reflect limbic function

Emotion: feelings and attitude

Self-concept and worth

Emotional body image

Tonal responses of motor system affected by limbic descending pathways

Attitude, social skills, opinions

As seen in this outline, the *M* (memory, motivation) depicts the drive component of the limbic network. Before learning, an individual must be motivated to learn, to try to succeed at the task, to solve the problem, or to benefit from the environment. Without motivation the brain will not orient itself to the problem and learn. Motivation drives both our cortical structures to develop higher cognitive associations and the motor system to develop procedures or motor programs that will enable us to perform movement with the least energy expenditure and the most efficient patterns available. Once motivated, the individual must be able to pay attention and process the sequential and simultaneous nature of the component parts to be learned, as well as the whole. Thus there is an interlocking dependence among somatosensory mapping of the functional skills¹²⁴ (cognitive), attention (limbic) necessary for any type of learning, and the sequential, multiple, and simultaneous programming of functional movement (motor). The limbic amygdala and hippocampal structures and their intricate circuitries play a key role in the declarative aspect of memory.¹²⁵⁻¹²⁸ Once this syntactical, intellectual memory is learned and taken out of short-term memory by passing through limbic nuclei, the information is stored in cortical areas and can be retrieved at a later time without limbic involvement.¹²⁹

The *O* refers to olfaction, or the incoming sense of smell, which exerts a strong influence on alertness and drive. This is clearly illustrated by the billions of dollars spent annually on perfumes, deodorants, mouthwashes, and soap as well as scents used in stores to increase customers' desires to purchase. This input tract can be used effectively by therapists who have clients with CNS lesions such as internal capsule and thalamic involvement. The olfactory system synapses within the olfactory bulb and then with the limbic structures and then may go directly to the cerebral cortex without synapsing in the thalamus. Although collaterals do project to the thalamus, unlike all other sensory information, olfaction does not need to use the thalamus as a necessary relay center to access the cortical structures, although many collaterals also project there.^{56,130} Other senses may not be reaching the cortical levels, and the client may have a sensory-deprived environment. Olfactory sensations, which enter the limbic network, may be used to calm or arouse the client. The specific olfactory input may determine whether the person remains calm or emotionally aroused.^{131,132} Pleasant odors would be preferable to most people. With the limbic network's influence on tone production through brain stem modulation, this is one reason aromatherapy causes relaxation and is used by many massage therapists.

A comatose, seemingly nonresponsive client may respond to or be highly sensitive to odor.¹³³ The therapist needs to be acutely aware of the responses of these patients because these responses may be autonomic instead of somatomotor and may be reflected in a higher heart rate or an increase in blood pressure. Using noxious stimuli to try to "wake up" a patient in a vegetative state has the possibility of causing negative arousal, fear, withdrawal, or anxiety and an increase in base

tone within the motor generators.¹³² Using this type of input places the patient at level 2 in a “protective state of survival.” Using a pleasant and personal desirable smell will more likely place a client at level 2 “safety.” The former can lead to strong emotions such as anger, whereas the latter often leads to bonding and motivation to learn. Research has shown that retrieval processing and retrieval of memory have a distinctive emotionality when they are linked to odor-evoked memories.¹³⁴⁻¹³⁶

The *V* represents visceral or autonomic drives. As noted earlier, the hypothalamus is nestled within the limbic network. Thus, regulation of sympathetic and parasympathetic reactions, both of the internal organ systems and the periphery, reflects continuing limbic activity. Obviously, drives such as thirst, hunger, temperature regulation, and sexuality are controlled by this system. Clients demonstrating total lack of inhibitory control over eating or drinking or manifesting very unstable body temperature regulation may be exhibiting signs of hypothalamic-pituitary involvement or direct pathways from hypothalamus to midbrain structures.⁵⁶ Today, this interaction of the hypothalamus with motor neurons that change or support movement has clearly been established.¹³⁷

Less obvious autonomic responses that may reflect limbic imbalances often go unnoticed by therapists. When the stress of an activity is becoming overwhelming to a client, she or he may react with severe sweating of the palms or an increase in dysreflexic activity in the mouth rather than with heightened motor activity. A therapist must continually monitor this aspect of the client’s response behaviors to ascertain that the behaviors observed reflect motor control and not limbic influences over that motor system.

If the sensory input to the client is excessive whether through internal or external feedback, the limbic network may go into an alert, protective mode and will not function at the optimal level, and learning will diminish. The client may withdraw physically or mentally, lose focus or attention, decrease motivation, and become frustrated or even angry. The overload on the reticular system may be the reason for the shutdown of the limbic network and not the limbic network itself. Both are part of the same neuroloop circuitry. All these behaviors may be expressed within the hypothalamic-autonomic system as motor output, no matter where in the loop the dysfunction occurs. Having a functional understanding of the neuroanatomy and their relationships with each other helps therapists unravel some of the mysteries patients present after CNS insult.^{138,139} The evaluation of this system seems even more critical when a client’s motor control system is locked, with no volitional movement present. Therapists often try to increase motor activity through sensory input; however, they must cautiously avoid indiscriminately bombarding the sensory systems. The limbic network may demonstrate overload while at the same time the spinal motor generators reflect inadequate activation. How a therapist might assess this overload would be to closely monitor the ANS’s responses such as blood pressure, heart rate, internal temperature, and sweating versus observing or measuring muscle tone. Although the somatosensory system and the ANS are different, they are intricately connected. The concept of massively bombarding one system while ignoring the other does not make sense in any learning paradigm, especially from a systems

model in which consensus creates the observed behavior. To illustrate this concept, think of an orchestra leader conducting a symphony. It would make no sense for the conductor to ask the string section to play louder if half the brass section got sick. Instead, the conductor would need to quiet the string section and all other sections to allow the brass component to be heard.

E relates to emotions, the feelings, attitudes, and beliefs that are unique to that individual. These beliefs include psychosocial attitudes and prejudices, ethnic upbringing, cultural experiences, religious convictions, and concepts of spirituality.¹²⁰ All these aspects of emotions link especially to the amygdaloid complex of the limbic network and orbitofrontal activity within the frontal lobe.¹⁴⁰⁻¹⁴² This is a primary emotional center, and it regulates not only our self-concept but our attitudes and opinions toward our external environment and the people within it.

To appreciate the sensory system’s influential interaction with the limbic network directly, the reader need only look at the literature on music and how it interacts with emotions.^{143,144} Most people can give examples of instances where music has elicited immediate and compelling emotional responses of various types. Pleasant and unpleasant musical stimuli have been found to increase or decrease limbic activity and influence both cognitive and motor responses. Although the neurological mechanisms are not yet well understood, the limbic network seems to be implicated in both “positive” and “negative” emotions in response to musical stimuli.¹⁴⁵⁻¹⁴⁸ The clinical implications are huge. Excessive noise, loudspeaker announcements, piped in music, and all the therapists’ voices can affect the CNS of a client. These responses can be highly emotional, cause changes in visceral behavior, and affect striated motor expression. Level of musical consonance or dissonance is just one element of the auditory stimulus that is subjectively experienced by the listener as pleasant or unpleasant. The implications are not only that listening to music affects limbic emotional states but that the influence may direct the hypothalamus in regulation of blood flow within the CNS have also been shown.¹⁴⁸ With music or sound being just one input system, the therapist must realize that sensory influence from smell, taste, touch, proprioception, and vestibular and organ system dysfunction can lead to potential limbic involvement in all aspects of CNS function and directly affect the emotional stability of the patient.

Another very important concept linked to the emotional system is the emotional aspect of body image or the concept of SELF. For example, assume that one morning I look in the mirror and say, “The poor world, I will not subject it to me today.” I then go back to bed and eat nothing for the rest of the day. The next day I get up and look in the same mirror and say, “What a change, I look trim and beautiful. Look out world, here I come!” In reality, my physical body has not been altered drastically, if at all, but my attitude toward that body has changed. That is, the emotional component of my body image has perceptually changed.

A second self-concept deals with my attitude about my worth or value to society and the world and my role within it.¹⁴⁹ Again, this attitude can change with mood, but more often it seems to change with experience. This aspect of client-therapist interaction can be critical to the success of a therapeutic environment. The two following examples

illustrate this point, with the focus of bringing perceived roles into the therapeutic setting:

Your client is Mrs. S., a 72-year-old woman with a left cerebrovascular accident (CVA). She comes from a low socioeconomic background and was a housekeeper for 40 years for a wealthy family of high social standing. When addressing you (the therapist), she always says “yes, ma’am” or “no, ma’am” and does just what is asked, no more and no less. It may be very hard to empower this client to assume responsibility for self-direction in the therapeutic setting. Her perceived role in life may not be to take responsibility or authority within a setting that may, from her perception, have high social status, such as a medical facility. She also may feel that she does not have the right or the power to assume such responsibilities. Success in the therapeutic setting may be based more on changing her attitudes than on her potential to relearn motor control. That is, the concept of empowerment may play a crucial role in regaining independent functional skill and control over her environment.^{24,28,31,150-153}

Your client is a 24-year-old lumberjack who sustained a closed-head injury during a fall at work. It is now 1 month since his accident, and he is alert, verbal, and angry and has moderate to severe motor control problems. During your initial treatment you note that he responds very well to handling. He seems to flow with your movement, and with your assistance is able to practice a much higher level of motor control within a narrow biomechanical window; although at times he needs your assistance, you release that control whenever possible to empower him to control his body. At the end of therapy he sits back in his chair with much better residual motor function. Then he turns to you (the female therapist) and instead of saying, “That was great,” he says, “You witch, I hate you.” The inconsistency between how his body responded to your handling and his attitude toward you as a person may seem baffling until you realize that he has always perceived himself as a dominant male. Similarly, he perceives women as weak, to be protected, and in need of control. If his attitude toward you cannot be changed to see you in a generic professional role, he will most likely not benefit as much from your clinical skills and guidance as a teacher. Before the accident the patient may have suppressed that verbal response but not tone and body language. After a traumatic brain injury affecting the orbitofrontal system, the inhibition of the behavioral response itself may be lost, further embarrassing the patient emotionally.

Preconceived attitudes, social behaviors, and opinions have been learned by filtering the input through the limbic network. If new attitudes and behaviors need to be learned after a neurological insult, the status of the amygdaloid pathways seems crucial. Damage to these limbic structures may prevent learning¹⁵⁴; thus, socially maladaptive behavior may persist, making the individual less likely to adapt to the social environment. It is often harder to change learned social behaviors than any other type of learning.¹⁵⁵⁻¹⁵⁸ Because our feelings, attitudes, values, and beliefs drive our behaviors through both attention and motor responses, the emotional aspect of the limbic network

has great impact on our learning and motor control. If a patient is not motivated and places little value on a motor output, then complacency results and little learning will occur.¹⁵⁹⁻¹⁶¹ On the other hand, if a therapist places an extremely high value on a motor output as a pure expression of motor control without interlocking that control with the patient’s limbic influence, the behavioral response may lead to inconsistency, lack of compliance, and thus lack of motor learning and carryover.¹⁵⁹ Similarly, it can cause extreme stress, which even the general public knows causes disease.¹⁶²

Motivation and Reward. Moore¹²³ considers motivation and memory as part of the MOVE system. Esch and Stefano¹⁶³ link motivation with reward and help, illustrating how the limbic network learns through repetition and reward. They state that the concept of motivation includes drive and satiation, goal-directed behavior, and incentive. They recognize that these behaviors maintain homeostasis and ensure the survival of the individual and the species. Although the frontal lobe region appears to play an important role in self-control and execution activities, these functions seem to require a close interlocking neuronetwork between cognitive representation within the frontal regions and motivational control provided by limbic and subcortical structures.^{140,164} An important aspect of motivated behavior is linked to patient- and family-centered therapy.* “The most powerful force in rehabilitation is motivation.”¹⁶⁷ These words are strong and reflect the importance of the limbic network in rehabilitation.

Motivated behavior is geared toward reinforcement and reward, which are based on both internal and external feedback systems. Repeated experience of reinforcement and reward leads to learning, changed expectancy, changed behavior, and maintained performance.¹⁶⁸ Emotional learning, which certainly involves the limbic network, is very hard to unlearn once the behavior has been reinforced over and over.^{169,170} For that reason, motor behavior that is strongly linked to a negative emotional response might be a very difficult behavior to unlearn. For example, a patient who is willing to stand up and practice transfers just to get the therapist off his back is eliciting a movement sequence that is based on frustration or anger. When that same patient gets home and his spouse asks him to perform the same motor behavior, he may not be able to be successful. The spouse may say, “The therapist said you could.” The patient may respond, “I never did like him!” Thus repetition of motor performance with either the feeling of emotional neutrality or the feeling of success (positive reinforcement) is a critical element in the therapeutic setting. Consistently making the motor task more difficult just when the client feels ready to succeed will tend to decrease positive reinforcement or reward, lessen the client’s motivation to try, and decrease the probability of true independence once the patient leaves the clinical setting. When pressure is placed on therapists to produce changes quickly, repetition and thus long-term learning are often jeopardized, which may have a dramatic effect on the quality of the client’s life and the long-term treatment effects once he or she leaves the medical facility. Motor control theory (see Chapter 4) coincides with limbic

*References 24, 27, 28, 31, 34, 135, 150, 165, 166.

research regarding reinforcement. Inherent feedback within a variety of environmental contexts allowing for error with correction leads to greater retention.¹⁷¹ Repetition or the opportunity to practice a task (motor or cognitive) in which the individual desires to succeed will lead to long-term learning.¹⁷² Without practice or motivation the chance of successful motor learning is minimal to nonexistent.

Positive emotional states may create a limbic environment in which the therapist can link reward and pleasure associations to new motor sequences. Although it is well known that appropriate selections of music can stimulate states of highly pleasant positive affects and physical relaxation, the neurological mechanisms for these effects are not well understood. In an early study by Goldstein^{173a} subjects reported pleasant physical sensations of tingling or “thrills” in response to music listening. After subjects were injected with naloxone, which blocks opiate receptors, thrill scores and tingling sensations were attenuated in some subjects. Although responses to music are highly individualized and this study has not been replicated, it suggests that endorphins may be released under certain music listening conditions that elicit pleasant physical sensations. In a positron emission tomography (PET) study of cerebral blood flow (CBF) changes measured during highly pleasurable “shivers or chills” in response to subject-selected music, Blood and colleagues¹⁴⁷ found that as the intensity of the chills increased, CBF increases occurred in the left ventral striatum, dorsomedial midbrain, bilateral insula, right orbitofrontal cortex, thalamus, anterior cingulate cortex, supplementary motor area, and bilateral cerebellum. As the intensity of chills increased, significant CBF decreases were also observed in the right amygdala, left hippocampus and amygdala, and ventral medial prefrontal cortex. The increases found in brain structures associated with reward or pleasant emotions and decreases in areas associated with negative emotional states suggest that music (1) must be carefully selected according to individual preferences and responses, in order to reliably elicit such highly pleasurable experiences as “shivers down the spine” and (2) might be used therapeutically to positively affect limbic activity.

Other studies provide additional support for the notion that music may activate limbic and paralimbic areas associated with reward or pleasurable emotions. Brown and colleagues¹⁴⁵ conducted a PET study of 10 nonmusicians who listened passively to unfamiliar music, which they later reported had elicited strongly pleasant feelings. Unlike previous studies of music, emotion, and limbic activity, this research design called for subjects to listen passively without engaging in any task such as evaluating affective components during the music. The authors noted that the music stimuli used was musically complex and strongly liked by the subjects. When the CBF during the music was compared with silent rest conditions in the same subjects, activations were seen, as expected, in areas presumed to represent perceptual and cognitive responses to music (primary auditory cortex, auditory association cortex, superior temporal sulcus bilaterally, temporal gyrus of the right hemisphere, in the right superior temporal pole, and adjacent insula). In addition, responses were found in limbic and paralimbic areas, which included the left subcallosal cingulate, the anterior cingulate, left retrosplenial cortex and right hippocampus,

and the left nucleus accumbens and cerebellum. The researchers compared these results with those from the earlier studies by members of the same team^{147,148} and suggest that areas such as the subcallosal cingulate are related to the direct experience of occurrent emotions rather than discriminate processing for emotion and that different areas are specifically activated during the pleasant physical responses known as “chills.” They go on to propose that the superior temporal pole and adjacent insula may serve as a point of bifurcation in neural circuitry for processing music. They also suggest that neurons from that region project to limbic and paralimbic areas involved in emotional processing and to premotor areas possibly involved in discrimination and structural processing of music. Although research has increased our appreciation of the complexity of brain activation by music, much more study is needed to validate a model of limbic network activity in human emotional responses to musical stimuli. Clinically, music can be used to improve mood and increase patient motivation to participate in rehabilitation treatment. Case studies^{174,175} suggest that music can be used to decrease crying by infants and toddlers during physical therapy treatment. West has participated in both developmental and rehabilitation settings as a music therapist in co-treatment with physical and occupational therapists. The music therapist first does a thorough assessment of the individual’s preferences and responses to music, then provides music selected or composed specifically to provide motivating energy, pleasant associations, and positive affective states to accompany the motor activity. This individualized, live-music approach allows the music therapist to modify the musical elements as needed in the moment, working in a real-time limbic partnership with both the client and the physical or occupational therapist. Music or pleasure sounds can be used to help neutralize or balance the limbic influence on motor expression. Obtaining a limbic-neutral impact is critical before evaluating functional movement in order to accurately determine true motor system involvement.

Many types of emotions create motivation, such as pleasure, reward processes, emotions associated with addiction, appreciation of financial benefits, amusement, sadness, humor, happiness, and depression.^{163,173b,176-179} Some emotions tend to drive learning, whereas others may discourage learning, whether that learning be cognitive or motor.

Integration of the Limbic Network as Part of a Whole Functioning Brain

Motivation, alertness, and concentration are critical in motor learning because they determine how well we pay attention to the learning and execution of any motor task. These processes of learning and doing are inevitably intertwined: “We learn as we do, and we do only as well as we have learned.”¹⁸⁰

Both motivation (“feeling the need to act”) and concentration (“ability to focus on the task”) are interlinked with the limbic network. The amygdaloid complex with its multitude of afferent and efferent interlinkages is specially adapted for recognizing the significance of a stimulus, and it assigns the emotional aspect of feeling the need to act. These neuroanatomical loops have tremendous connections with the reticular system. Hence, some authors call it the reticulolimbic network.^{56,157} The interaction of the limbic

network and the motor generators of the brain stem and ultimate direct and indirect modulation over the spinal system lead to need-directed and therefore goal-directed motor activity. It also filters out significant from insignificant information by selective processing and storing the significant for memory, learning, and recall. These interconnected neuroloop circuitries reinforce the concept that areas have both specialization and generalization and thus work closely together with other areas of the brain.^{169,181}

Goal-directed or need-directed motor actions are the result of the nervous system structures acting as an interactive system. Within this system (Figure 5-4), all components share responsibilities. The limbic network and its cortical and subcortical components represent the most important level. In response to stimuli from the internal or external environment, the limbic network initiates motor activity out of the emotional aspect of feeling the need to act. This message is relayed to the sensory areas of the cerebral cortex, which could entail any one or all association areas for visual, auditory, olfactory, gustatory, tactile, or proprioceptive input. These areas are located in the prefrontal, occipital, parietal, and temporal lobes, where they analyze and integrate sensory input into an overall strategy of action or a general plan that meets the requirements of the task. Therefore these cortices recognize, select, and prepare to act as a response to relevant sensory cues when a state of arousal is provided by reticular input. The limbic cortex (uncus,

parahippocampal gyrus /isthmus, cingulate gyrus, and septal nucleus) has even greater influence over the sensorimotor cortices through the cingulate gyrus, both directly and indirectly through association areas.¹⁸²⁻¹⁸⁴ The thalamus, cerebellum, and basal ganglia contribute to the production of the specific motor plans. These messages of the general plan are relayed to the projection system. The limbic structures through the cingulate gyrus also have direct connections with the primary motor cortex. These circuits certainly have the potential to assist in driving fine motor activities through corticobulbar and corticospinal tract interactions. The thalamus, cerebellum, basal ganglia, and motor cortices (premotor, supplementary motor, and primary motor) contribute to the production of the specific motor plans.⁵⁶ Messages regarding the sensory component of the general plan are relayed to the projection system, where they are transformed into refined motor programs. These plans are then projected throughout the motor system to modulate motor generators throughout the brain stem and spinal system.⁵⁶ Limbic connections with (1) the cerebellum, basal ganglia, and frontal lobe^{56,185-189} and (2) the motor generator within the brain stem enable further control of limbic instructions over motor control or expression. If the limbic and the cognitive systems decide not to act, goal-driven motor behavior will cease. An individual's belief (emotional and spiritual) can inhibit even the most basic survival skills, as has been clearly shown in history when individuals with particular

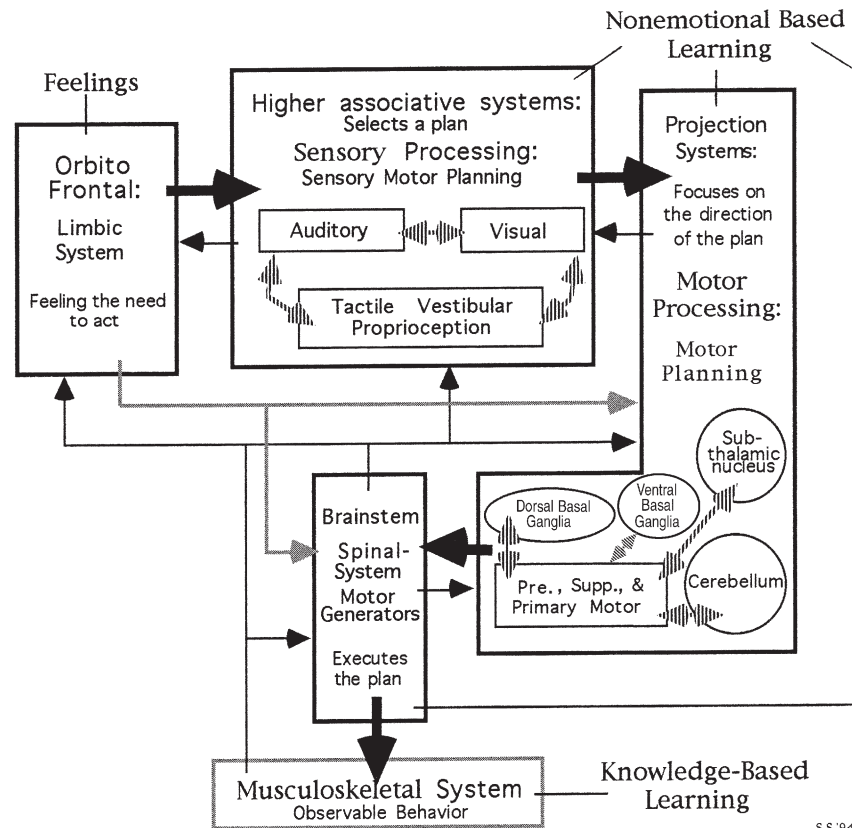

Figure 5-4 ■ Functional and dynamic hierarchy of systems based on both limbic and motor control interactions. (Adapted from Brooks VB: *The neural basis of motor control*, New York, 1986, Oxford University Press.)

religious beliefs were pitted against vicious predators and those people chose not to defend themselves.

Within the projection system and motor planning complexes, the specifics are programmed and the tactics are given a strategy. In general, “what” is turned into “how” and “when.” The necessary parameters for coordinated movement are programmed within the motor complex as to intensity, sequencing, and timing to carry out the motor task. These programs, which incorporate upper motor neurons and interneurons, are then sent to the brain stem and spinal motor generators, which in turn, through lower motor neurons, send orders regarding the specific motor tasks to the musculoskeletal system. (See Chapters 3, 4, and 8 for more specific in-depth discussion.) The actions performed by each subsystem within the entire limbic–motor control complex constantly loop back and communicate to all subsystems to allow for adjustments of intensity and duration and to determine whether the plan remains the best choice of responses to an ever-changing three-dimensional world.^{138,186,187}

The limbic network has one more opportunity to modify and control the central pattern generators and control the body and limbs through direct connections to the spinal neuronetwork.^{110,190-193} That is, the limbic network can alter existing motor plans by modulating those generators up and down or altering specific nuclear clusters and varying the patterns themselves. Therapists as well as the general public see this in sports activities when emotions are high, no matter the emotion itself. Individuals who have excellent motor control over a specific sport may find high-level performance difficult as the stress of competition increases. Having control over emotional variance as well as motor variance with a functional activity is an accurate example of empowerment. Thus, for a therapist to get a true picture of a patient’s motor system’s function, the limbic network should be flowing in a neutral or balanced state without strong emotions of any kind. Generally, that balance seems to reflect itself in a state of safety, trust, and compliance. Once the motor control has been achieved then the therapist must reintroduce various emotional environments during the motor activity to be able to state that the patient is independent.

In summary, the limbic complex generates need-directed motor activity and communicates that intent throughout the motor system.^{110,191,194,195} This step is vital to normal motor function and thus client care. Clients need the opportunity to analyze correctly both their internal environment (their present and feed-forward motor plans and their emotional state) and the external world around them requiring action on a task. The integration of all this information should produce the most appropriate strategy available to the patient for the current activity. These instructions must be correct, and the system capable of carrying out the motor activity, for effortless, coordinated movement expression to be observed. If the motor system is deficient, lack of adaptability will be observed in the client. If the limbic complex is faulty, the same motor deficits might present themselves. The therapist must differentiate what is truly a motor system problem versus a limbic influence over the motor system problem.

Schmidt¹⁹⁶ stresses the significance of “knowledge of results feedback” as being the information from the environment that provides the individual with insights into task

requirements. This insight helps the motor system correctly select strategies that will successfully initiate and support the appropriate movement for accomplishing the task. This knowledge of results feedback is required for effective motor learning and for forming the correct motor programs for storage.^{197,198}

The reader may better understand the role of the limbic network in motor programming through a nonmedical example. Imagine that you are sitting in your new car. The dealer has filled the tank with necessary fuel. The engine, with all its wires and interlocking components, is totally functional. However, the engine will not perform without a mechanism to initiate its strategies or turn on the system. The basal ganglia or frontal lobe motor mechanism plays this role in the brain. The car has a starter motor. Yet the starter motor will not activate the motor system without the driver’s intent and motivation to turn the key and turn on the engine. The limbic complex serves this function in the brain. Once the key has been turned, the car is running and ready for guidance. Whether the driver chooses reverse or drive usually depends on prior learning unless this is a totally new experience. Once the gear has been selected, the motor system will program the car to run according to the driver’s desires. It can run fast or slow, but for the plan to change, both a purpose and a recognition that change is necessary are required. The car has the ability to adapt and self-regulate to many environmental variables, such as ruts or slick pavement, to continue running the feed-forward program, just as many motor systems within the CNS, especially the cerebellum, perform that function. The limbic network may emotionally choose to drive fast, whereas one’s cognitive judgment may choose otherwise. The interactive result will drive the pedal and brake pressure and ultimately regulate the car. The components discussed play a critical role in the total function of the car, just as all the systems within the CNS play a vital role in regulating behavioral responses to the environment.

Brooks⁶⁹ distinguishes insightful learning, which is programmed and leads to skills when the performer has gained insight into the requirements, from discontinuous movements, which need to be replaced by continuous ones. This process is hastened when clients understand and can demonstrate their understanding of what “they were expected to do.” Improvement of motor skills is possible by using programmed movement in goal-directed behavior. The reader must be cautioned to make sure that the client’s attention is on the goal of the task and not on the components of the movement itself. The motor plan needs programming and practice without constant cognitive overriding. The limbic/frontal system helps drive the motor toward the identified task or abstract representation of a match between the motor planning sequence and the desired outcome. The importance of the goal being self-driven by the patient cannot be over-emphasized.*

Without knowledge of results, feedback, and insight into the requirements for goal-directed activity, the learning is performing by “rote,” which merely uses repetition without analysis, and meaningful learning or building of effective motor memory in the form of motor holograms

*References 24, 28, 31, 111, 199, 200.

will be minimal. Children with cognitive and limbic deficits can learn basic motor skills through repetition of practice, but the insights and ability to transfer that motor learning into other contexts will not be high (see Chapters 12, 13, and 14).

Schmidt¹⁹⁶ suggests that to elicit the highest level of function within the motor system and to enable insightful learning, therapy programs should be developed around goal-directed activities, which means a strong emotional context. These activities direct the client to analyze the environmental requirements (both internal and external) by placing the client in a situation that forces development of “appropriate strategies.” Goal-directed activities should be functional and thus involve motivation, meaningfulness, and selective attention. Functional and somatosensory retraining uses these concepts as part of the intervention (see Chapters 4 and 9). Specific techniques such as proprioceptive neuromuscular facilitation, neurodevelopmental therapy, the Rood method, and the Feldenkrais method can be incorporated into goal-directed activities in the therapy programs, as can any treatment approach, as long as it identifies those aspects of motor control and learning that lead to retention and future performance and allows the patient to self-correct.¹⁹⁶ With insights into the learned skills, clients will be better able to adjust these to meet the specific requirements of different environments and needs, using knowledge of response feedback to guide them. The message then is to design exercise activities or programs that are meaningful and need directed, to motivate clients into insightful goal-directed learning. Thus, understanding the specific goals of the client, patient-centered learning, is critical and will be obtained only by interaction with that client as a person with needs, desires, and anticipated outcomes.^{201,202} A therapist cannot assume that “someone wants to do something.” The goal of running a bank may seem very different from that of birdwatching in the mountains, yet both may require ambulatory skills. If a client does not wish to return to work, then a friendly smile and the statement, “Hi, I’m your therapist and I’m going to get you up and walking so you can get back to work,” may lead to resistance and decreased motivation. In contrast, a therapist who knows the goal of the client may help him or her become highly motivated to ambulate; that client may be present in the clinic every day to meet the goal of birdwatching in the mountains although never wishing to walk back into the office again.

Clinical Perspectives

The Client’s Internal System Influences Observable Behavior. At least once a year almost any local newspaper will carry a story that generally reads as follows: “Seventy-nine-year-old, 109-pound arthritic grandmother picks up car by bumper to free trapped 3-year-old grandson.”

We read these articles and at first doubt their validity, questioning the sensationalism used by the reporter. But we know that these events are real. That elderly lady picked up the car out of fear of severe injury to her grandchild. Emotions can create tremendously high tonal responses, either in a postural pattern such as in a temper tantrum or during a movement strategy such as picking up a car. Conversely, fear can immobilize a person and make it impossible to create enough tone to run a motor program or actually move. Evaluating muscle power or tone production in relation to

emotional state (versus a pure reflection of motor control) is an aspect of evaluation often overlooked.

Limbic Influence on Emotional Output: The F²ARV and GAS Continua

Some of the earliest understanding of the limbic network was of its role in “fight or flight.” It is important that clinicians not only understand but also recognize two powerful limbic motor response programs: the fear and frustration, anger, rage, and violence continuum (F²ARV) and the general adaptation syndrome (GAS).

F²ARV (Fear and Frustration, Anger, Rage, and Violence or Withdrawal) Continuum. One sequence of behaviors used to describe the emotional circuitry of the limbic network through the amygdala is the F²ARV continuum^{157,203,204} (Figure 5-5). This continuum begins with fear or frustration. This fear can lead to avoidance behavior.²⁰⁵ If the event inducing the fear or frustration continues to heighten, avoidance behaviors can continue to develop.²⁰⁵ In a simple example, we recall or have seen these behaviors in our teens and as young adults, when the challenges faced in high school can lead to *avoidance* of activities. Alternately, extreme fear and frustration can also lead to *anger*. Anger is a neurochemical response that is perceived and defined cognitively (at the cortical level) as anger. If the neurochemical response continues to build or is prolonged, the anger displayed by the person may advance to *rage* (internal chaos) and finally into *violence* (strong motor response). A common societal example is in the case of domestic discord and violence. Women who attain the level of rage may become withdrawn and thus become victimized by a partner who is also in rage or inflicting physical or emotional violence.²⁰⁶ Another current example is posttraumatic stress disorder (PTSD), in which the prolonged stress of deployment and unique challenges of warfare lead to limited adaptive reserves in warriors and returning veterans. Suicide and domestic violence have become a more common occurrence between deployments, necessitating a dramatic shift in mental health policy in the last 5 years.²⁰⁷⁻²¹⁰

How quickly and completely any individual will progress from fear to violence is dependent on several factors. First, the genetic neurochemical predisposition (initial wiring) will influence behavioral responses.²⁰⁴ Second, “soft-wired” or conditioned responses resulting from experiences and reinforced patterns will influence output. For example, it is commonly known that abusive parents were usually abused children^{203,211}; they learned that anger quickly leads

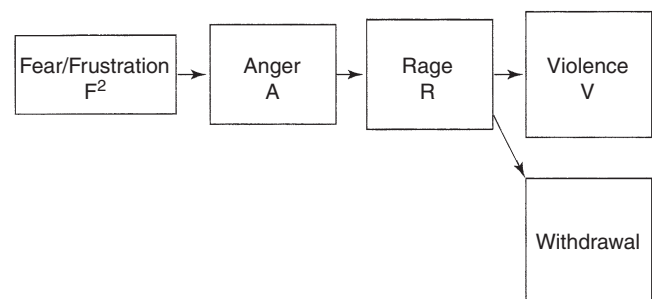

Figure 5-5 ■ Fear and frustration, anger, rage, and violence or withdrawal: F²ARV continuum.

to violence and that the behavior of violence was somehow acceptable. Last, the quality and intensity of the stimulus initiating the continuum will influence the level of response.

The neurochemistry within an individual's CNS, whether inherently active or altered through drugs or injury, will have great influence on the plasticity of the existing wiring.^{40,212} Repetitive or prolonged exposure to negative environmental stimuli may also lead to a chronically imbalanced neurochemical state that results in a lowered threshold or tolerance to a given stimulus. Chemistry or wiring can become imbalanced from damage, environmental stress, learning, or other potentially altering situations, changing an individual's control over this continuum.^{56,106-108,213,214} When neurochemical imbalance exists, these behaviors will persist, and balance may be restored only through natural neurochemical activity (e.g., sleep, exercise, diet, spirituality) or medication support (chemical replacement).

Therapists need to be acutely aware of this continuum in clients who have diffuse axonal shearing within the limbic complex. Diffuse axonal shearing is most commonly seen and reported in research on individuals with head trauma^{215,216} (see Chapter 24). Resulting lesions within the limbic structures may cause an individual to progress down this continuum at a rapid speed. This point cannot be overemphasized. Patients with an accelerated F²ARV continuum may physically strike out at a clinician or caregiver out of simple frustration during care. Knowing the social history of the client and the causation of the injury often can help the therapist gain insight into how an individual patient might progress down this continuum. Not all head-injured patients had prior difficulty with the F²ARV continuum; however, it is important to note that many individuals received their head injuries in violent confrontational situations or in wartime conflict. Some individuals, primarily females, when confronted with stress, anger, and potential violence from another, will withdraw and become depressed. This behavior, similar to violence, will change the structure of the limbic network.⁵⁵

GAS (General Adaptation Syndrome). The autonomic responses to stress also follow a specific sequence of behavioral changes and are referred to as the *general adaptation syndrome*.²¹⁷⁻²²³ The sequential stages of GAS are a direct result of limbic imbalance and can play a dramatic role in determining client progress.

Stress can be caused by many internal or external factors, often unique to the individual. Examples include pain, acute or chronic illness or the ramification of illness, confusion, sensory overload, and a large variety of other potential sources. The initial reaction to a stressor is a neurochemical change or "alarm" that triggers a strong sympathetic nervous system reaction. Heart rate, blood pressure, respiration, metabolism, and muscle tonus will increase. It is at this stage that the grandmother lifts the car off the child as in our previous example. If the overstimulation or stress does not diminish, the body will protect itself from self-destruction and trigger a subsequent parasympathetic response. At this time, all the symptoms reverse and the client exhibits a decrease in heart rate, blood pressure, and muscle tonus. The bronchi become constricted, and the patient may hyperventilate and become dizzy, confused, and less alert. As the blood flow returns to the periphery, the face may flush and

the skin may become hot. The patient will have no energy to move, will withdraw, and again will exhibit decreased postural tone and increased flexion.

This stress or overstimulation syndrome is characterized by common symptoms as described earlier.^{140,224-231} If the acute symptoms are not eliminated, they will become chronic and the behavior patterns much more resistant to change.

GAS is often seen in the elderly, with various precipitating health crises,²²¹ and also in neonatal high-risk infants (see Chapter 11), victims of head trauma, and other clients with neurological conditions. The initial alarm can be precipitated by moderate to maximal internal instability with less intensive external stress, or by minimal internal instability with severe external sensory bombardment. For instance, in the elderly, stresses such as change of environment, loss of loved ones, failing health, and fears of financial problems can each cause the client's system to react as if overloaded.²²³ As another example, individuals with head trauma (Chapter 24), vestibular dysfunction (Chapter 22B), inflammatory CNS problems (Chapter 26), and brain tumors (Chapter 25) often possess hypersensitivity to external input such as visual environments, noise, touch, or light. In these individuals, typical clinical environments and therapeutic activities may create a sensory overload and trigger a GAS response.

Stress, no matter what the specific precipitating incident (confusion, fear, anxiety, grief, or pain), has the potential to trigger the first steps in the sequence of this syndrome.^{224-229,232} The clinician's sensitivity to the client's emotional system will be the therapeutic technique that best controls and reverses the acute condition.

Similarly, patients with dizziness and instability, particularly within visually stimulating environments, can develop feelings of panic, which can evolve into full attacks and agoraphobic responses.²³³ These individuals avoid participating in activities that put them within visually overstimulating environments in an effort to control the dizziness and prevent the associated autonomic reactions. Similar types of reactions have been documented, such as space-motion discomfort (SMD),²³⁴ postural phobic vertigo,²³³ visual vertigo,²³⁵ and dizziness of "psychogenic" origin. Often these individuals are referred first to psychology or psychiatry. However, there is an underlying physiologic explanation for these symptoms. In a majority of individuals with SMD, there is a documented increase in vestibular sensitivity (increased vestibulo-ocular reflex [VOR] gain) and an impairment in velocity storage (shorter VOR time constant).²³⁶ In addition, the dorsal raphe nucleus (DRN of the midbrain and rostral pons) is the largest serotonin-containing nucleus in the brain and directly modulates the firing activity of the superior and medial vestibular nuclei. It is this interaction between serotonin and vestibular function that helps to explain the link between vestibular and anxiety disorders. It can also help explain how patients with sleep disorders or other serotonin-depleting disorders develop vestibular-like symptoms and anxiety.^{237,238}

Although there are physiological reasons underlying the vestibular system disorder in a majority of these cases, the symptoms triggered are part of a spectrum of limbic responses to aberrant vestibular, cerebellar, and brain stem interactions. Normal clinic activity or typically appropriate

therapeutic activity may trigger an autonomic cascade versus the desired somatomotor response. The rehabilitation of the resultant visual and postural movement dysfunction is typically more complicated in the absence of limbic network management. The clinician's strategic prescription (or "dosing") of therapeutic activities with careful monitoring of the client's emotional system and physiological response will be one of the therapeutic techniques that best controls the aberrant responses and allows vestibular adaptation and compensation to occur. This must be done to manage limbic network activity for successful motor learning to occur.

The F²ARV and GAS continua are often interrelated in individuals who have direct or indirect limbic network involvement. The therapist needs to be aware that a patient may overrespond to stress, frustration, or fear of failure in both cognitive and motor activities. The initial response may be an escalation of the F²ARV continuum with what then seems like a rapid withdrawal or a heightened state of anger (GAS). There are many ways to help the patient balance these autonomic reactions and continue to learn within the therapeutic setting. The Bonny Method of Guided Imagery and Music is a music-centered psychotherapy method that has been used extensively with individuals recovering from various types of trauma.²³⁹⁻²⁴² In reviewing specific Bonny Method treatment approaches used with trauma patients, Körlin²⁴² describes a cyclical process whereby an important initial treatment period emphasizes the mobilization of inner resources, alleviating vulnerability and increasing the patient's self-confidence. This phase uses carefully selected music that elicits positive limbic states and "bodily manifestations with qualities of warmth, energy, strength, movement, nourishing, and healing, all belonging to the implicit realm of positive vitality affects and mental models" (p. 398). The individual is then better equipped to face a period of confrontation with painful or traumatic material or the challenges faced within a therapeutic rehabilitation environment. Successful confrontation of difficult realities is then followed by a new phase of resource mobilization and consolidation of healthier behaviors that begin to replace dysfunctional defenses such as avoidance, behavioral extremes, or substance abuse.

This process continues in repeated cycles of rest-resourcing and working-confronting. The clinical success of this approach suggests that for some patients it may be advantageous to purposefully facilitate positive or pleasant physical and affective experiences before engaging in more challenging work. Although it may be impractical to provide appropriate music selections on the basis of individual assessment in the therapeutic environment (e.g., physical, occupational, music), other modalities such as heat, massage, or ultrasound treatment may also elicit relaxed, receptive physical states. The treating professional can also become aware during assessments or treatments of environmental auditory input that may trigger stress responses in patients who have limbic network involvement or who may have experienced traumatic physical or emotional injuries. These triggers can be something as simple as the therapist's tone of the voice in a sentence to the patient or as complex as the multiple-noise environment of a busy rehabilitation setting. Some patients may need to be scheduled for early morning, during lunchtime, or in the late afternoon to provide a decrease in the auditory environment.

Decreasing stimulation versus increasing facilitation may lead to attention, calmness, and receptiveness to therapy. When the client feels that control over her or his life has been returned, or at least the individual is consulted regarding decisions (informed consent, forced choices), resistance to therapy or movement is often released and stress is reduced. Even clients in a semicomatose state can participate to some extent. As a clinician begins to move a minimally responsive client, resistance may be encountered. If slight changes are made in rotation or trajectory of the movement pattern, the resistance is often lessened. If the clinician initially feels the resistance and overpowers it, total control has been taken from the client. Instead, if the clinician moves the patient in ways her or his body is willing to be moved, respect has been shown and overstimulation potentially avoided.

No single input causes these limbic responses, nor does one treatment counteract their progression. Being aware of clinical signs is critical. In a time when therapists are often rushed by the realities of a full schedule or stressed by third-party or short discharge demands, a clinician may inadvertently miss key signs and opportunities to treat. In addition, he or she may actually create a less optimal environment by physically moving faster than the pace best tolerated by the patient, who may need more time to process stimuli or to practice a target skill. The challenge for both the therapist and the patient is to find harmony within the given environment to allow for optimal outcomes.

Developing limbic network assessment tools (or repurposing existing tools) for their ability to screen or identify the presence of direct or indirect limbic involvement is of critical value. In addition, the ability to discriminate the type of limbic involvement (decreased responsiveness and withdrawal from increased responsiveness or overresponsiveness) is important to treatment planning. Treatment techniques will be discussed later in the chapter. However, the specific techniques appropriate for treating these syndromes are tools all therapists possess. These tools range from simple variations in approach (e.g., lighting, sound, smell) to more formal therapeutic techniques, such as the Feldenkrais approach, or The Bonny Method of Guided Imagery and Music.²³⁹ How each clinician uses those tools is a critical link to success or failure in clinical interaction.

Specific Limbic Influences on Motor System Output.

Throughout the existence of humankind, emotions have been identified in all cultures. A child knows when a parent is angry without a word being spoken. A stranger can recognize a person who is sad or depressed. People walk to the other side of the road to avoid being close to someone who seems enraged. Emotions are easily recognizable as they are expressed through motor output of the face and body. Emotions similarly have an impact on functional motor control. The effect and intensity of emotions and limbic influence on motor control are an important part of the therapy evaluation. [Table 5-1](#) helps differentiate the level of limbic activity with observed behavioral states cross-referenced with various medical conditions.

Fear. Fear is often associated with pain, be it somatic or emotional. To the individual in pain, pain is just pain. [Figure 5-6](#), A illustrates two people who are on a rollercoaster which could create automatic responses of fear. The boy looks scared and obviously exhibits fear. The woman

TABLE 5-1 ■ INTERACTIONS AMONG LIMBIC STATE, MEDICAL CONDITIONS, AND BEHAVIORS*

LIMBIC STATE	OFTEN ASSOCIATED WITH	OBSERVED BEHAVIORS
Neutral	Health and wellness	Relaxed state
Low	Depression, stroke	Decreased eye contact, crying Lack of motivation
High	Anxiety and panic disorders Vestibular disorders Mild or traumatic head injury Blast injury, PTSD	Anxiety, anger, fear, increased respiratory rate, higher blood pressure, high muscle tension or tone, hyperactivity
Overload (F ² ARV, GAS)	Traumatic head injury Blast injury, PTSD, frail individual (either young or old), physiologically unstable individual	Violence, extreme withdrawal, loss of inhibition, reversal of expected behavior

GAS, General adaptation syndrome; F²ARV, fear and frustration, anger, rage, violence; PTSD, posttraumatic stress disorder.

*Many individuals with neurological dysfunction fall into these categories.

Figure 5-6 ■ A, Two individuals riding a rollercoaster. Individual on right looks scared; this facial expression represents fear. The facial expression of the individual on the left could represent enjoyment, with eyes open and a smile, or extreme fear, with hyperextension of her head causing her mouth to open. **B**, Individual's facial expression after the rollercoaster stopped. She was unable to relax her facial muscles for over 2 minutes because she had been so scared or demonstrated extreme fear.

could be expressing joy or fear given her motor responses. Her eyes seem fixed, which might lead to the assumption that she is truly in fear. She may not have control over her facial responses and could be exhibiting an extreme reaction to fear. If that were the case, this would be a limbic motor reaction, which could be semiautomatic. This extension pattern, if limbic, could trigger hyperextension of the neck, causing opening of the mouth. In [Figure 5-6, B](#), the rollercoaster has stopped, and she still has the same expression. In fact, it took over a minute before she was able to relax her face and regain the feeling that she had some control over her emotional reaction. Her next reaction to occur was crying and observable frustration in her inability to control her initial response. The amygdala nuclei plays a critical role in regulation of facial responses to fear, pain, and other incoming stimuli.²⁴³ This is often observed in healthy normal individuals such as seen in [Figure 5-6](#) and similarly can be seen in patients who are extremely fearful, no matter the cause.

Fear of falling is a common problem with the elderly, especially the elderly who have various neurological diagnoses.^{244,245} Therapists working with individuals who have a

fear of falling need to first acknowledge that the fear is normal and then make sure that when the individual moves, he or she does not fall. Trust will be discussed later in the chapter, but fear often precedes the development of trust. Fear is an emotional response and thus is initiated and controlled by the limbic network.

Fear of pain is another emotional response housed within the limbic network that drives many individuals' motor responses. Whether individuals have fear of movement after a musculoskeletal injury,²⁴³ fear of going to the dentist after a dental procedure,²⁴⁶ fear of pain intensity after a chronic pain problem,²⁴⁷ or fear of falling,²⁴⁸ fear will drive motor responses, and that fear will often lead to a lower quality of life.²⁴⁴ For that reason alone, therapists need to differentiate the limbic system's and the motor system's summated responses when observing the movement patterns of the individual in therapy.

Anger. Anger itself creates muscle tone through the amygdala's influence over the basal ganglia and the sensory and motor cortices and their influence over the motor control system. This is clearly exhibited in a child throwing a

temper tantrum (Figure 5-7) or an adult putting his fist through a wall. How far a client or a friend will progress through the F²ARV continuum (discussed in the previous section) depends on a large number of variables. When a client loses control, the therapist must first determine whether the intervention forced the client beyond her or his ability to control. If so, changes within the therapeutic environment need to be made to allow the client opportunities to develop control and modulation over that continuum.

Creating opportunities to confront frustration and fear or even anger in real situations while the client practices modulation will lead to independence or self-empowerment. The client simultaneously needs to practice self-directed motor programming without these emotional overlays. Thus, true motor learning can result. In time, practicing the same motor control over functional programs when confronted with a large variety of emotional situations should lead to independence in life activities and thus meet a therapeutic goal.

Similarly, being unaware of a client's anger may lead the therapist to the false assumption that that individual has adequate inherent postural tone to perform activities such as independent transfers. If the client is angry with the therapist and performs the transfer only to get the therapist "off my case," when the client is sent home she or he may be unable to create enough postural extension to perform the transfer. Thus this transfer skill was never functionally independent because the test measurements were based on limbic or frontal influence over the extensor component of the motor system. The client needs to learn how to do the activity without the emotional overlay. When a therapist is

Figure 5-7 ■ Extensor behavior responses caused by anger. ("Angry Boy," Vigeland Sculpture Grounds in the Frogner Park, Oslo, Norway. Adapted from photo by Normann.)

unwilling, unaware, or unable to attend to these variables, the reliability or accuracy of functional test results becomes questionable.

For example, West was asked to consult with a rehabilitation team to devise a treatment program to address violent rage episodes in a 40-year-old man with moderate physical and severe cognitive functioning deficits resulting from a brain aneurysm. He would escalate very rapidly along the F²ARV continuum when presented with environmental challenges such as passing another patient with his wheelchair in the hallway. Although his physical rehabilitation had progressed well and he had regained much independence in mobility, because his assaultive outbursts posed risks to other patients as well as to caregivers, this patient appeared to be heading for placement in a locked facility, a more restrictive environment than he would need considering his level of physical limitation. Although this unfortunate man had no short-term memory function and no insight about his behaviors, West found during her assessment that he was highly responsive to calming music and was able to access some intact long-term memories that could be used to elicit a relaxation response. A highly positive limbic state of deep relaxation was thus elicited, and simple verbal cues were then presented to develop a conditioned response that any staff member could then call forth with the verbal cue alone. The entire rehabilitation team was briefed on the use of this intervention and reported success using this approach in the milieu as well as during physical therapy and occupational therapy treatments when the patient would become resistant and angry in response to therapist instructions. The patient was trained to self-regulate by giving himself the same verbal cue when confronted with challenging situations. This treatment supported the patient's ability to regain emotional controls and allowed him the opportunity to be placed in a less-restrictive community environment. West observed this individual maintaining his progress in positive behavioral adaptation in a group home environment more than a year after the intensive inpatient rehabilitation treatment protocol had been completed. The patient never recalled a previous music therapy treatment session and asked each time to have the purpose of the treatment explained to him. But his body remembered the set of behavioral experiences, and he quickly complied with the relaxation procedure. The success of this approach demonstrates that even in the absence of short-term memory and other cognitive functions usually considered essential for new learning, the skillful engagement of positive limbic states and intact areas of patient functioning (strengths) can support development of new adaptive skills, which can be generalized to new environments.

Grief, Depression, or Pain. Emotions such as grief or depression can be expressed by the motor system.^{56,249} The behavioral responses are usually withdrawal, decreased postural extension, and often a feeling of tiredness and exhaustion (Figure 5-8). Sensory overload, especially in the elderly, can create low muscle tone and excessive flexion. Again, because of the strong emotional factor, these motor responses are considered to be the result of the limbic network's influence over motor control.¹¹⁰ Learned helplessness is another problem that therapists need to avoid.²⁵⁰ When patients are encouraged to become dependent, their chances of benefiting from services and regaining motor function are drastically reduced.^{251,252}

Figure 5-8 ■ **A**, Behavior responses elicited by concern, pain, and grief. **B**, Pain or grief elicits flexion and can modify postural extension. (A from Vigeland Sculpture Grounds in the Frogner Park, Oslo, Norway. Adapted from photo by Normann.)

Pain is a complex phenomenon, and the more it is understood, the more complex it becomes²⁵³⁻²⁵⁷ (see Chapter 32). The concept of pain and pain management is discussed in detail in both Chapters 18 and 32. Hippocampal volume has been identified as a variable in pain ratings in the elderly.²⁵⁸ Whether the pain is peripherally induced or centrally induced because of trauma or emotional overload, often the same motor responses will exist. A withdrawn flexor pattern from pain makes postural activities exhausting because of the work it takes to override the existing central pattern generators. Thus, daily living activities, which constantly require postural extension against gravity, may be perceived as overwhelming and just not worth the effort. The therapist needs to learn to differentiate between peripheral physical pain and central or emotional pain and between mixed peripheral and central induced pain. To the patient, “pain is pain!”²⁵⁹⁻²⁶⁶

Client-Therapist Bonding. Bonding projects relaxation, whereas lack of bonding reflects isolation. Because of the potency of the limbic network’s connections into the motor system, a therapist’s sensitivity to the client’s emotional state would obviously be a key factor in understanding the motor responses observed during therapy. This requires that a therapist first understand her or his own feelings, emotional responses, and communication styles that are being used within any given clinical or social environment.²⁶⁷⁻²⁷⁴

In **Figure 5-9** an entire spectrum of motor responses can be observed in four statues. A client who feels safe can relax and participate in learning without strong emotional reactions. The woman being held in **Figure 5-9, A** is safe and relaxed. The man and woman are interacting through touch with the warmth and compassion that are often observed in the client-therapist interaction of an experienced or master clinician. In **Figure 5-9, B**, the client and clinician seem to flow together during the treatment as if they shared one motor system. When looking at the therapist and client or looking at the man and woman in the statue, it becomes obvious that the two figures seem to flow together. In the statue, those two figures make one piece of art.

With clinical emphasis on clients generating and self-correcting motor programming, it would perhaps seem reasonable for a therapist to conclude that he or she need not, or should not, touch the patient. This conclusion may be accurate when considering the motor system in isolation and assuming that patients can self-correct errors in motor programs. When correction by the therapist is through words rather than touch, external feedback through the auditory system has replaced internal feedback from the somatosensory system. The voice, as well as touch, can be soothing and instill confidence.²⁷⁵ Yet language in and of itself will not replace the trust and safety felt both physically and emotionally through the deep pressure of touch as illustrated in

Figure 5-9 ■ **A**, Grief, depression, and compassion responses are seen in the center figures, and rigid, stoic, distancing behaviors are observed in the two left statues. **B**, Compassion is easily recognized in the clinic between a therapist and the client. (**A** from Vigeland Sculpture Grounds in the Frogner Park, Oslo, Norway. Adapted from photo by Normann.)

Figure 5-9. Bonding and trust occur much more often through touch than through conversation.²⁷⁶ Recall, also, that verbal instructions require intact auditory processing and translation from declarative to procedural information, a cognitive ability that the client may not possess.

Referring again to **Figure 5-9, A**, the two men in the statue on the left demonstrate a lack of bonding. In fact, if the artist could have brought them closer together, they might just have rejected or repelled each other with greater intensity. If one of the men were the therapist and one the patient, little interaction would be occurring, and thus an assumption that learning is occurring is probably false. The therapist could do nothing to the other person (and vice versa) without that person perceiving the act as invasive, negative, or even disrespectful, with little consideration of the person's individual values. The therapist's responsibility is to open the patient's receptiveness to learning, not to close it.^{277,278}

These pictures clearly illustrate two types of therapist-client interactions. If an artist can clearly depict the tonal characteristics of emotion, certainly the therapist should be able to recognize those behaviors in the client.²⁷⁹ If a client is frustrated or angry and simultaneously has rigidity, spasticity, or general high tone, then a therapist might spend the entire session trying to decrease the motor response. If the client could be helped to deal with the anger or frustration during the therapy session and neutralize the emotion and achieve a *limbic neutral* state, then the specific problems could be treated effectively. Differentiating the limbic network component from the motor control system when establishing treatment protocols has not typically been within the spectrum of a therapist's skills. It is a skill that must be developed and practiced, as it is clear that the influence of an overactive or overloaded (*limbic high*) or underactive (*limbic low*) limbic network state may drastically alter the consistent responses of the motor systems and thus dampen the procedural learning and limit the success of the therapeutic setting. Carryover of procedural learning (Chapter 4) into adaptive motor responses needs to be practiced with consistency.⁵⁶

Many factors in an interactive setting, such as therapy, cannot be identified, but certain limbic or emotional factors

may play a role in that gifted clinician's skill. Although therapists are trained to be skilled observers of patient behavior, the development of "master clinician" capabilities also requires self-awareness on the part of the helping professional. "Behavioral activity can often tell us about the inner state of another or ourselves" (p. 19).²⁸⁰ The willingness to be aware of one's own internal state increases the therapist's ability to perceive subtleties in the patient's responses.

Achieving a limbic neutral state in the client by carefully modifying the therapeutic environment will facilitate effective motor learning. There are many core tenets and techniques necessary to effectively achieve this neutral state, internal and external therapeutic environment, and optimal learning in the client.

Trust. Trust is a critical component of a successful therapy session.²⁸¹ The therapist gains the client's trust by his or her actions. The therapist may also build trust through sincere acknowledgment that the patient has life-limiting functional problems and that those problems are limiting normal participation. Trust is further developed when the therapist's words can be supported by data. When the therapist can illustrate the presence of functional limitations and generate a treatment plan with the patient using objective data, a bond and trust between the patient and the therapist are created.²⁸² In today's environment the use of reliable, valid, objective tests and measures allows for this form of communication, which has not existed to the same extent in the past. Honesty and truth lead to trust.^{119,283-287}

A trusting relationship is strengthened when an agreement or "contract" can be established that sets the boundaries for discomfort (fatigue, dizziness, nausea, imbalance) or pain that the patient will experience within a therapeutic session. As one example, telling a person that you will not hurt them is a therapist-patient contract. If the therapist continually ranges a joint beyond a pain-free range, that behavior is dishonest and untruthful and will not lead to trust. Trust can be earned by stopping as soon as the client verbalizes symptoms or shows pain with a body response such as a grimace. Being sensitive to a patient's pain, no matter the cause, and working with the patient to eliminate that pain

often lead to very strong bonding and trust that will lead to compliance and learning. Ignoring the pain may be perceived as insensitivity and lack of caring, which can lead to distrust and often resistance to learning or performance.

As another example, a patient with vestibular dysfunction associated with significant dizziness and nausea will experience symptoms within the course of recovery (adaptation and compensation), but those symptoms must be carefully controlled in intensity and duration. Symptoms poorly controlled can trigger an ANS or GAS cascade and elevate the limbic state, preventing learning and recovery and destroying trust.

Because these symptoms can be overt or covert, the therapist needs to be aware of both the physical and emotional responses of the patient. The use of analog or perceived exertion scales can be a valuable way to make the covert more overt to the therapist. Symptoms are valuable to the therapist as well as the patient to create environments for change, but the intensity of those stimuli need close monitoring because they can dramatically affect motor responses and ultimately overwhelm the CNS and prevent learning. Compliance to participate is limbic, and the limbic system has tremendous control over intentional movement, no matter the context of the environment.¹¹⁹

Once a client gives his or her trust, a clinician can freely move with the client and little resistance caused by fear, reservations, or need to protect the self will be felt or observed. When the patient is *limbic neutral* (the limbic network is emotionally neutralized), the tightness or limitations in movement that are present on examination can be considered true impairments within those systems or sub-systems. Examination and interventions at this time will more consistently reflect true motor performance. Once limbic neutral has been achieved and examination is complete, it is recommended, for example, that if the pain is a result of peripheral tightness or joint immobility, the therapist does not elicit pain during that session. Deal with those issues in the next session after gaining the trust of the client. Trust by the therapist or the client does not mean lack of awareness

of potential danger. Trust means acceptance that although the danger is present, the potential for harm, pain, or disaster is very slight and the expected gain is worth the risk (in this case, delay in intervention). In **Figure 5-10**, the student's trust that the instructor will not hurt her can be seen by her lack of protective responses and by her calm, relaxed body posture. The student is aware of the potential of the kick but trusts her life to the skills, control, and personal integrity of the teacher. Those same qualities are easily observed in patient-therapist interactions when watching a gifted clinician treat clients. The motor activities in a therapeutic setting may be less complex than in **Figure 5-10**, but in no way are they less stressful, less potentially harmful, or less frightening from the client's point of view.

In addition, therapists must first trust themselves enough to know that they can effect changes in their clients.^{7,288} Understanding one's own motor system, how it responds, and how to use one's hands, arms, or entire body to move someone else is based partly on procedural skills, partly on declarative learning, and partly on self-confidence or self-trust. Trusting that one, as a therapist, has the skill to influence the motor response within the patient has a limbic component. If a therapist has self-doubts about therapeutic skills, that doubt will change performance, which will alter input to the client. This altered input can potentially alter the client's output and vary the desired responses if the client's motor system cannot run independently.

Responsibility. Very close to the concept of trust is the idea of responsibility. Accepting responsibility for our own behavior seems obvious and is accepted as part of a professional role.²⁸⁹ Accepting and allowing the client the right to accept responsibility for her or his own motor environment are also key elements in creating a successful clinical environment and an independent person.*

Figure 5-11 illustrates the concept through the following example: The instructor asked the student to perform a

*References 24, 28, 31, 150, 290, 291.

Figure 5-10 ■ Trust relaxes the limbic network's need to protect. **A**, The skill of the teacher is obvious. **B**, The student trusts that she is in no danger.

motor act, in this case, to perform a kick to the teacher's head. The kick was to be very strong or forceful and completed. The student was instructed not to hold back or stop the kick in any way, even though the kick was to come within a few inches of the teacher's head. This placed tremendous responsibility on the student. One inch too far might dangerously hurt the instructor, yet one inch too short was not acceptable. The teacher knew the student had the skill, power, and control to perform the task and then passed the responsibility to the student. The student was hesitant to assume the responsibility, for the consequence of failure could have been very traumatic. However, the student trusted that the teacher would not ask for the behavior unless success was fairly guaranteed. That trust reduced anxiety and thus neutralized the neurochemical limbic effect on the motor system of the student, giving her optimal motor control over the act.²⁹² Once the task was completed successfully, the student gained confidence and could repeat the task with less fear or emotional influence while gaining refinement over the motor skill.

Although the motor activities described in this example are complex and different from functional activities practiced within the clinic by therapists and clients, the dynamics of the environment relate consistently with client-therapist roles and expectations. A gifted clinician knows that the client has the potential to succeed. When asked to perform, the client trusts the therapist and assumes responsibility for the act. The therapist can facilitate the movement or postural pattern, thereby ensuring that the client succeeds. This feeling of success stimulates motivation for task repetition, which ultimately leads to learning. The incentive to repeat and learn becomes self-motivating and then becomes the responsibility of the client. As the therapist relinquishes control and empowers the client to more and more of the function, novelty to the learning is occurring.

Current literature has shown that people are more motivated by novelty and change than by success at mastery or

accomplishment of a goal.^{90,292,293} The limbic complex and its interwoven network throughout the nervous system play a key role in this behavioral drive.²⁹⁴ The task itself can be simple, such as a weight shift, or as complex as getting dressed or climbing onto and off of a bus. No matter what the activity, the client needs to accept responsibility for her or his own behavior before independence in motor functioning can be achieved. Although the motor function itself is not limbic, many variables that lead to success, self-motivation, and feelings of independence are directly related to limbic and prefrontal lobe circuitry. The variance and self-correction within the movement expression also create novelty and motivation to continue to practice.^{90,292-295}

As another clinical example of responsibility, in a patient with vestibular dysfunction and dizziness compounded by anxiety, symptoms of dizziness are necessary during treatment to drive CNS change. The therapist has a responsibility to prescribe the appropriate activities, dosage (intensity, timing, and so on), and environment to retrain sensory organization and balance (motor output). The patient can be given the responsibility of monitoring and managing her or his own symptoms within these activities, for instance, by agreeing on the maximal level of dizziness the patient and therapist are willing to accept within the therapeutic activity. A tool as simple as a verbal or visual analog scale can empower the patient to manage symptoms, dampen the limbic network response, and improve motor output for balance control.

Flexibility and Openness. Another component of a successful clinical environment deals with learning and flexibility on the part of the therapist. A master clinician sees and feels what is happening within the motor control output system of the client. Letting go of preestablished belief of what will happen is difficult.^{296,297} It is important for a clinician to be open to what is present as the motor expression. This openness is critical to actually identifying what is being expressed by the nervous system of the patient. Master clinicians do not get stuck on what they have been taught but use that as a foundation or springboard for additional learning. Learning is constantly correlated to memories and new experiences.

To the therapist, each client is like a new map, sparsely drawn or sketchy at the beginning, but one that is constantly revised as the terrain (client) changes. The initial medical diagnosis may link to many paths provided within the map, but the comorbidities can result in great variance among patients.²⁹⁸ That initial map might be a critical care pathway for the client, given her or his neurological insult. That pathway is a map, but only a sketchy one, and may not even be a map that a particular patient falls within in spite of his or her medical diagnosis. It is the therapist's responsibility to evaluate the patient and determine whether that pathway or map will work or is working and when changes in that map need to be altered. That is, the therapist must let go of an outdated map or treatment technique and create a new one as the environment and motor control system of the client change. This transference or letting go of old maps or ideas is true for both the client and therapist. If a position, pattern, or technique is not working, then the clinician needs to change the map or directions of treatment and let the client teach the therapist what will work. The ability to change and select new or alternative treatment techniques is based on

Figure 5-11 ■ The teacher relinquishes the task to the student, and the student trusts the teacher is right even if self-doubt exists.

the attitude of the therapist toward selecting alternative approaches. Willingness to be flexible and open to learning is based on confidence in oneself, a truly emotional strategy or limbic behavior. Master clinicians have learned that the answers to the patient's puzzle are within the patient, not the textbooks.

Figure 5-12 depicts two maps with a beginning point and a terminal outcome or goal in each. The parameters of the first map illustrate the boundaries of that therapist's experience and education. The clinician, through training, can identify what would seem to be the most direct and efficient way or path toward the mutually identified goal of the therapist and client. When the client becomes a participant within the environment or map, what would seem like a direct path toward a goal might not be the easiest or most direct path for the client. If empowerment of the client leads to independence, then allowing and encouraging the client to direct therapy may provide greater variability, force the client to problem solve, and lead to greater learning. The therapist needs to recognize when the client is not going in the direction of the goal. For example, the client is trying to perform a stand-pivot transfer and instead is falling. If it is important to practice transfers, then practicing falling is inappropriate and the environment (either internal or external) needs modification. Falling can be learned and practiced at another time. Once both strategies are learned, the therapist must empower the patient to take ownership of the map. In the examples of transferring, if the therapist asks the client to practice transfers and if the client starts to fall, a change in required motor behavior must be made and the opportunity given to the client to self-correct. In that way the client is gaining independent control over a variety of environmental contexts and outcomes. Within the same

figure (Figure 5-12) is a second map. That second map might represent another professional's interaction and goal with the same client. It is during these overlapping interactions that both professionals can empower the patient to practice, and that practice will help lead to those functional goals established by both practitioners. In some situations a clinician from one profession may guide a client toward obtaining the functional skill necessary for a member of the second profession to begin guiding the client toward the expected outcomes of the second profession. These interlocking dependencies of the client and the professions are illustrated in Figure 5-12. If the client begins therapy striving for the first goal and ends at the functional outcome of the second goal, then additional functional outcomes have been achieved and both professions interacted for the ultimate prognosis for the patient. That interaction requires respect and openness of both professionals toward each other as well as toward the client. Those attitudes and ultimate behaviors are limbic driven.

Matching maps should be a collaborative effort instead of coincidence. These collaborative efforts include interactions with all professions within the rehabilitation setting. Occupational and physical therapists are very familiar with collaboration, and both often approach interventions as a team effort. There are many additional therapists and individuals within that same setting who could also collaborate. Recreational therapists, psychologists, nurses, family members, and music therapists are but a few. Within a profession such as music therapy, the existence of two maps may overlap within a multidimensional environment. When a physical or occupational therapist needs to challenge a patient, the music therapist may be able to calm the system at the same time (overlapping maps). Research on affective responses to consonance and dissonance in music supports the creation of a map within a rehabilitation environment that could overlap with either physical, occupational, or speech therapy. Words such as *relaxed* or *calm* correlated positively with higher levels of consonance in the music, whereas adjectives associated with negative emotions (*unpleasant, tense, irritable, annoying, dissonant, angry*) were found to correlate positively with higher levels of dissonance.¹³³ Creating a whole environment where potential frustrations within motor learning could be balanced with higher levels of consonance in the music would potentially balance the limbic network emotional response within the overlapping maps and bring balance or stability to the limbic network's influence on motor learning and control. A later study by Peretz and colleagues¹⁴⁸ related the same variables to a happy-sad rating task. Given the research evidence for activity within the limbic network as it relates to music,^{144,299} motor learning,³⁰⁰ and cognitive enhancement,³⁰¹ a natural multiple map system would be easy to incorporate within a therapeutic setting. The clinician needs to appreciate the uniqueness of each map while holding onto the concept of the interaction of the two maps.

Vulnerability. To receive input from a client that is multivariable and simultaneous, a therapist has to be open to that information. If a clinician believes that he or she knows before meeting the client, then the client falls into a category of a recipe for treating the problem. Using the recipe does not mean the client cannot learn or gain better perceptual

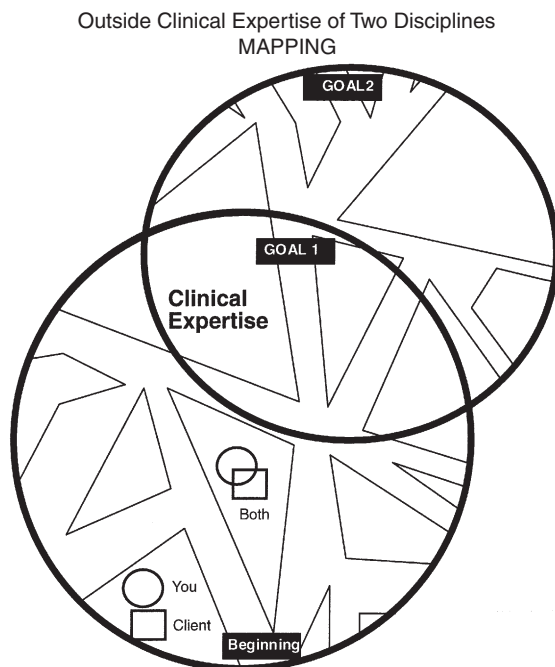

Figure 5-12 ■ Concept of clinical mapping including client and therapist and the interactions and importance of overlapping professional goals and staying within the professional expertise.

and cognitive, affective, or motor control, but it does mean that the individuality of the person may be lost. A more individualized approach would allow the clinician to identify through behavioral responses the best way for the client to learn how to sequence the learning, when to make demands of the client, when to nurture, when to stop, when to continue, when to assist, when to have fun, when to laugh, or when to cry. An analogy might be going to a fast food restaurant versus a restaurant where each aspect of the meal is tailored to one's taste. It does not mean that both restaurants are not selling digestible foods. It does mean that at one eating place the food is mass produced with some choices, but individuality, with respect to the consumer, is not an aspect of the service. Unfortunately, managed care, limited visits, reduced time for treatment, and therapists' level of frustration all are pushing therapeutic interventions toward a "one size fits all" philosophy that may increase the time needed for learning, not reduce it.

To be open totally to processing the individual differences of the client, the clinician must be relaxed and non-threatened, and feel no need to protect himself or herself from the external environment. This environment needs to project beyond the therapist-client relations and envelope all disciplines interacting with the client.³⁰² In order for these interactions to occur, the clinician's emotional state requires some vulnerability, allowing him or her to be open to new and as-yet-unanalyzed or unprocessed input. This vulnerability implies the role not of an expert who knows the answers beforehand but of an expert investigator. Being open must incorporate being sensitive not only to the variability of motor responses but also to the variability of emotional responses on the part of the client.^{303,304} This vulnerability leads to compassion, understanding, and acceptance of the client as a unique human being. It can also be exhausting. Therapists need to learn ways to allow openness without taking on the emotional responsibility of each patient.

Limbic Lesions and Their Influence on the Therapeutic Environment

Many lesions or neurochemical imbalances within the limbic network drastically affect the success or failure of physical, occupational, and other therapy programs. This chapter does not discuss in detail specific problems and their treatment, but instead it is hoped that identification of limbic involvement may help the reader develop a better understanding of specific neurological conditions and carry that knowledge into Section II, where the specific clinical problems are discussed.

Substance Abuse (See Chapter 24). The anterior temporal lobe (especially the hippocampus and amygdala) has a lower threshold for epileptic seizures than do other cortical structures.⁵⁶ This type of epilepsy is produced by use of systemic drugs such as cocaine and alcohol. The seizure is often accompanied by sensory auras and alterations in behavior, with specific focus on mood shifts and cognitive dysfunction.³⁰⁵ Obviously, the precise association between behavior and emotions or temporolimbic and frontolimbic activity is not understood, yet the associations and thus their impact on a therapeutic setting cannot be ignored.^{217,306}

Whether street bought, medically administered, or ingested for private or social reasons (such as in alcohol consumption),

drugs and alcohol can have dramatic effects on the CNS and often are associated with limbic behavior.³⁰⁷ Korsakoff syndrome, caused by chronic alcoholism and its related nutritional deficiency, is identified by the structural involvement of the diencephalon with specific focus on the mammillary bodies, and the dorsal medial and anterior nucleus of the thalamus⁵⁶ usually shows involvement (see the anatomy section and Figure 5-13). This syndrome is not a dementia but rather a discrete, localized pathological state with specific clinical signs. The most dramatic sign observed in a client with Korsakoff syndrome is severe memory deficits.^{252,308-310} These deficits involve declarative memory and learning losses, but the most predominant problem is short-term memory loss.³¹¹ As the disease progresses, clients generally become totally unaware of their memory loss and are unconcerned. Initially, confabulation may be observed,³¹² but in time most clients with a chronic condition become apathetic and somewhat withdrawn and are in a profound amnesic state. They are trapped in time, unable to learn from new experiences because they cannot retain memories for more than a few minutes and are unable to maintain their independence^{252,308-310,313}; many may become social isolates and homeless.

The use of alcohol affects not only adults but also children and adolescents. Still another population of children affected by alcohol abuse has surfaced as a specific clinical problem. These children are infants who have the effects of fetal alcohol syndrome. A variety of researchers have investigated the effects of alcohol and other toxic drugs on neuromotor and cognitive development.³¹⁴⁻³¹⁹

Alzheimer Disease (See Chapter 27). In Alzheimer disease, the hippocampus and nucleus basalis are the most severely involved structures, followed by neurofibrillar degeneration of the anterotemporal, parietal, and frontal lobes.^{252,320-323}

Initially the symptoms fall into several categories: emotional, social, and cognitive. Usually the symptoms have a gradual onset. Depression and anxiety often are seen during the early phases because of the neuronal degeneration within the prefrontal lobes and limbic network.^{322,324-326} During the second stage, the emotional, social, and intellectual changes become more marked. Clients have difficulty with demands, business affairs, and personal management. Their memory and cognitive processing continue to deteriorate, whereas their awareness of the problem is often

Figure 5-13 ■ Anatomy of the limbic network: schematic illustration.

still insightful, causing additional anxiety and depression. During this phase clients may be unable to recognize familiar objects and become scared because they are losing control of the environment both internally and externally. Thus the client may become combative out of a defensive (fight-or-flight) autonomic response. For that reason, therapists need to make sure the client feels safe during therapy to optimize the learning and compliance. The third phase manifests itself with moderate to severe aphasic, apraxic, and agnosic problems. Object agnosia, the failure to recognize objects, is a typical sign of advancing Alzheimer disease. Distractibility and inattentiveness are also common signs of this third stage. The final stage of Alzheimer disease is marked by an individual who is uncommunicative, with little meaningful social interaction, who often takes on the features of the Klüver-Bucy syndrome (see Chapter 13). Thus they exhibit emotional outbursts, inappropriate sexual behaviors, severe memory loss, constant mouth movements, and often a flexor-type postural pattern. In this latter phase, the client is virtually decorticate and clinically indistinguishable from persons with other dementias. The prognosis of Alzheimer disease was only a few years ago totally bleak, but today there are hopes that in the future, pharmacological interventions may slow and even reverse the damage inflicted by this disease.³²⁷⁻³³⁰

In spite of future treatments, the continual degeneration of the limbic network is a key distinguishing factor in Alzheimer disease.^{109,331-333} Many clients in the past have been misdiagnosed as having other problems such as intracranial tumors, normal pressure hydrocephalus, multiinfarct dementia, or alcoholic or chronic drug intoxication.³³⁴⁻³³⁷ Similarly, many clients with tumors, multifaceted dementias, alcoholism, or heart attacks resulting in hippocampal damage may be diagnosed with Alzheimer disease. When the disease is correctly evaluated and diagnosed, however, it becomes obvious that the limbic-cortical area involved from phase 1 through the last phase is interacting with other areas of the brain and constantly affecting the behavioral patterns of the patient.³³⁸⁻³⁴¹ Owing to the neurochemical sensitivity and production within the limbic network, drugs are often used to prevent or slow the progression of Alzheimer disease (see Chapter 36).³⁴²⁻³⁴⁶ Similarly, a genetic predisposition has been found in some patients with Alzheimer disease^{56,347-349}; thus, gene therapy may prove to have great therapeutic value.³⁵⁰ Because music is able to activate many different brain areas, it is particularly valuable in the treatment of persons at all stages of Alzheimer disease³⁵¹ and can effectively be used during physical or occupational therapy. Long after declarative memory is lost, individuals can sing entire songs (procedural memory), dance with a loved one they no longer recognize (procedural memory), or be soothed and calmed by hearing someone who cares about them singing familiar favorite songs or lullabies (limbic response). This is why the power of music is so great, especially as observed in individuals with Alzheimer disease who have lost declarative memory. In earlier phases of the disease, individuals who have lost words can recall words such as song lyrics through the linking with melody. When melody is lost, individuals still retain rhythmic responses. At the palliative stage of Alzheimer disease care, agitated patients are observed to calm to simple music such as familiar lullabies. Thus Alzheimer disease patients are

able to continue to respond to music through the progression of the disease, and the response to rhythm may represent overlearned motor responses that are tied to positive limbic states. For example, nonambulatory individuals, when presented with familiar and preferred music, may stand and move with the rhythm of the sound. Their bodies may remember how to dance with the spouse whose name they no longer know.³⁵² A physical or occupational therapist can instruct a caregiver to use music as part of everyday activities. The therapeutic effects of music to engage and maintain attention, activate long-term memory, and modulate emotion states are well suited to the needs of both the person with Alzheimer disease and his or her caregivers.³⁵²

Head Injury (See Chapter 24).

Traumatic Injury. One potentially severe limbic problem that can be present after traumatic closed head injury is diffuse axonal injury.^{215,216,353-356} The long associative bundles or fibers that transverse the cortex on a curved route can be sheared by an impact or a blow to the head. One of these long associative bundles is the cingulate fasciculus, which coordinates the amygdala and hippocampal projections to and from the prefrontal cortex. Many basic perceptual strategies, such as body schema, hearing, vision, and smell, are linked into the emotional and learning centers of the limbic network through the cingulate fasciculus.³⁵⁷ Thus, declarative learning through sensory and cognitive processing can become impossible. If the pathways to and from the hippocampus and amygdala are sheared bilaterally, total and permanent global anterograde amnesia will be present.^{109,358,359} If destruction of both tracts on one side occurs, but the contralateral side is left intact, the individual can compensate, but learning will be slower or the rate of processing delayed.¹⁵⁷ If only one tract on one side is damaged, such as the tract to and from the hippocampus, the amygdaloid system on the same side will compensate but be slower than without the lesion.¹⁵⁷ Thus the specific degree of involvement will vary and depend on the extent of shearing. Those with total shearing on both sides will usually be in a deep coma and will not survive the injury.³⁶⁰ Those with less severe insult will show signs ranging from total amnesia to minor delays in declarative learning.³⁶¹ The emotional problems of traumatic head injury can often be associated with other limbic problems such as posttraumatic stress syndrome. This problem is especially apparent when treating soldiers injured on the battlefield who have returned home.³⁶²

Integrating various professions becomes a critical aspect of an injured soldier's rehabilitation. When the interaction of the limbic network and higher control is considered, additional variables can be taken into consideration within the therapeutic environment. In treating more than 200 patients who had trauma, Körlin²⁴² found that certain kinds of musical elements often triggered intrusive and traumatic reexperiences of the event. (For a theoretical discussion of this phenomenon, see Goldberg.³⁶³) The phenomenon of auditory triggering has implications for the rehabilitation setting, where patients may be recovering from traumas related to accident, injury, or difficult medical procedures. Both environmental noise and "background" music may present auditory triggers that elicit limbic network and ANS activity. Thus the potential for eliciting the F²ARV continuum during a physical or occupational therapy treatment session is

always present, and the therapists need to be acutely aware of background noise.

Cerebral contusions (bruises) have long been a primary sign of traumatic head injury.³⁶⁴ Regardless of area of impact, the contusions are generally found in the frontal and temporal regions. There are long-term neuropsychological ramifications after mild traumatic brain injury even when there is no loss of consciousness.³⁶⁵ The regions most frequently involved are orbitofrontal, frontopolar, anterotemporal, and lateral temporal surfaces.

The limbic network's connection to these areas would suggest the potential for direct and indirect limbic involvement. The greater the contusion, the greater the likelihood that the limbic structures might simultaneously be involved. Impulsiveness, lack of inhibition, and hyperactivity are a few of the clinical signs associated with orbitofrontal or limbic involvement.³⁶⁶ The dorsomedial frontal region, involved in the hippocampal-fornix circuit (once referred to as the *Papez circuit*),³⁶⁷ when damaged seems to induce a pseudodepressed state, including slowness, lack of initiation, and perseveration.

Nontraumatic Head Injuries: Anoxic or Hypoxic Brain Injury. Lack of oxygen to the brain, regardless of the cause, seems not only to have a dramatic effect throughout the cortex but also selectively damages the hippocampal regions.³⁶⁸ The loss of hippocampal declarative memory systems bilaterally would certainly provide one reason for the slowness in processing so commonly observed in head injury.³⁶⁹ A hypothesis could also be made regarding the limbic network's interrelation with other cortical and brain stem structures. In cases of hypoxia, many structures interconnecting in the limbic network are potentially affected, so information sent to the limbic network may be distorted. These distortions could cause tremendous imbalances within the limbic processing system, with not only attention and learning problems but also the hypothalamic irregularity often seen in head trauma. Individuals who demonstrate obstructive sleep apnea, another cause of hypoxia, have been shown to have an imbalance in the hippocampal area.³⁷⁰ This imbalance may lead to severe cognitive dysfunction.³⁷¹ This preexisting hypoxic environment certainly can have a long-term effect on any patient who has CNS damage at any age.

A therapist always needs to understand the environment within which the injury occurred as well as being aware of preexisting complications. If the injury was sustained in a violent confrontation, such as a fight or a frightful experience such as a near-drowning, the emotional system had to be at a high level of metabolic activity at the time of the insult. If the event was anoxic, then those areas with the highest oxygen need or at the highest metabolic state might be the most affected or damaged after the event. Knowing that information, a therapist's analytical problem-solving strategies should guide her or him toward limbic assessment.

Summary of Limbic Problems with Head-Injured Clients.

The behavioral sequelae after any head injury reflect many signs of limbic involvement. In studies of both the pediatric and adult populations,^{353-355,357,365,372,373} behaviors of impulsiveness, restlessness, overactivity, destructiveness, aggression, increased tantrums, and socially uninhibited behaviors (lack of social skills) are frequently reported. These behaviors

all reflect a strong emotional or limbic component. Given Moore's concept of a limbic network that MOVES us and the F²ARV continuum regarding emotional control over noxious or negative input, it is no wonder so many clients have difficulty with personal and emotional control over their reactions to the therapeutic world. If the imbalance were within the client, then the external environment would be one possible way to help center the client emotionally.^{374,375} This centering requires that the therapist be sensitive to the emotional level of the client. As the client begins to regain control, an increase in external environmental demands would challenge the limbic network. If the demand is excessive, the client's emotional reaction as expressed by motor behavior should alert the therapist to downgrade the activity level.

Head injuries affect many areas of the CNS. A client with spasticity, rigidity, or ataxia may exhibit an increase in those motor responses when the limbic network becomes stressed. Learning to differentiate a motor control problem from a limbic problem that influences the motor control systems requires that the therapist be willing to address the cause of the problems and their respective treatments.³⁷⁶ Each client is different, no matter the commonalities of the site or extent of the lesions, because of prior learning, conditioning of the limbic network, and their respective perception of quality of life.³⁷⁷ The response of two clients to the same clinical learning environment may have great variance and should not surprise the clinician. Thus the therapist needs to give undivided attention to the client at all times and be willing to make moment-to-moment adjustments within the external environment to help the client maintain focus on the desired learning.

Vestibular Disorders. The vestibular system has extensive neuronal connections and commissural influences on the limbic network and structures; conversely, the limbic network has significant influence on the vestibular nuclei. Details of the neuroanatomical connections are described later in this chapter.

It is generally accepted that vestibular dysfunction results in erroneous input to the CNS. This erroneous sensory information creates a mismatch between the external (afferent) cues and the internal conceptual model for movement contained by the cerebellum. This mismatch creates an imbalance in vestibular and cerebellar signals to the CNS, flooding the central limbic structures and resulting in symptoms such as vertigo, motion sickness, nausea, or decreased postural control. Detection of this mismatch results in an attempt by the cerebellum to compensate for the imbalance, which becomes a core tenet of recovery.³⁷⁸ Alternately, this neural stimulation may create an internal stressor, and trigger an adverse limbic response, such as a GAS response.

Newer evidence from animal research has demonstrated that vestibular lesions result in dramatic changes in the morphology and function of the hippocampus. Of note is that bilateral vestibular lesions have been associated with hippocampal atrophy. The hippocampus makes unique contributions to memory, both spatial and nonspatial. Thus vestibular lesions impair learning and memory, particularly those tasks that require spatial processing. In addition to the more well known deficits in spatial and gravitational orientation for balance control, vestibular lesions can also result

in impaired cognition, learning, and memory through damage to this connection. Decreased concentration, thought processes, and memory are among the most common complaints in patients with vestibular disorders. In the past these complaints were often attributed to competitive resources, suggesting that cognitive resources were being devoted to the basic tasks of staying balanced during function. It is now clear that there is a true physiologic explanation for these secondary symptoms, which are quite limiting to activity and participation in normal daily activities, particularly working. It has also been suggested that treatment activities that stimulate the function of the vestibular system also stimulate activity within the hippocampus and can improve memory, which has important implications for treatment.³⁷⁹⁻³⁸⁷

Thus vestibular dysfunction can influence the therapeutic environment both in the assessment and the treatment of this system. However, the vestibular system is not a primary consideration of most physicians and therapists during evaluation. On the basis of benchmarking data from within specialized balance centers, the average patient with a vestibular disorder (dizziness or imbalance) travels within the medical system an average of 52 months before finding a solution. During this time, he or she has seen on average four physicians. There is also at least one visit to the emergency department in crisis and one visit to a psychiatrist. Typically there has been no rehabilitation referral or intervention during this time.³⁸⁸

The patient with a chronic vestibular disorder can have myriad symptoms, including vegetative, autonomic, motoric, cognitive, psychological, and behavioral symptoms that are often misdiagnosed during this search for an outcome as other, more serious medical diagnoses. As an example, of those patients diagnosed with dizziness or imbalance of a psychologic origin, evidence has determined that more than 70% of these patients have underlying vestibular dysfunction on key vestibular function tests (electronystagmography and calorics, rotary chair, computerized dynamic posturography, auditory brain stem response, and acoustic reflexes).^{233,235,389-391} Conversely, of those patients with chronic dizziness and imbalance, only 16% were found to have dizziness of a true psychogenic origin.³⁹² Acknowledgment of a patient's symptoms, use of data, and explanation (in understandable detail) that there is a physiologic explanation for his or her complaints builds the client-therapist relationship and begins to neutralize the client's abnormal limbic state (anxiety versus depression). It can lower the GAS or autonomic cascade, maximizing the treatment time before the onset of limiting symptoms (i.e., raise the symptom threshold).

Even patients with motion sickness have documentable physiologic and functional changes. Some of the best current evidence is in our military personnel with symptoms of motion sickness. On examination, these soldiers have physiological changes identifiable by results of rotary chair (60% with abnormally long time constants) and computerized dynamic posturography (70% with abnormal sensory organization test [SOT] condition 5 and 6).³⁹³

Patients who have sustained a mild head injury, postconcussive syndrome, blast exposure or injury (positive or negative pressure event), or whiplash often have concomitant involvement of the vestibular apparatus or nuclei. This

often goes undetected within the initial medical workup and management plan excepting in specialty vestibular practices.³⁹³⁻³⁹⁷ When the disorder is undetected and left unchecked, the patients do not respond to standard treatment interventions. They also complain of atypical symptoms or responses to these typical treatments. When the patient does not respond in predictable ways to standard treatment, the label "aphysiological" is applied, particularly in situations where disability or secondary gain is a factor. Fortunately there are well established performance criteria that can effectively differentiate true balance or vestibular impairment from embellishment for secondary gain.³⁹⁸ (Refer to Chapters 22A and 22B.)

In treatment, recovery is based on long-term compensation mediated by the cerebellum, and symptoms must be reproduced for recovery to occur. However, stimulation of the vestibular system must be controlled, with every effort made to maintain a limbic (emotional) neutral state. Some patients have true vestibular dysfunction that affects only motor responses, whereas other patients have true limbic psychiatric problems that do not manifest themselves with vestibular symptoms. These two behaviors are located at the polar ends of the curve between limbic motor and vestibular motor dysfunction. Before prescribing appropriate intervention strategies, the clinician must be clear regarding the degree of limbic overlay on the vestibular dysfunction, and the question "What are the best vestibular and limbic interactive environments that will challenge and drive neuroplastic change?" must be answered. Although researchers^{233,390} have identified tools that differentiate the two extremes, today researchers are trying to clarify the midrange of patients who clearly have symptoms on the basis of the interaction of both systems.^{398,399} Development of tools that can further discriminate whether the behaviors are first driven by vestibular and followed by limbic responses, or vice versa, is a key to treatment planning.

Parkinson Disease. The motor impairments seen in individuals with Parkinson disease are widely accepted, understood, and treated by physical and occupational therapists (see Chapter 20). What is not commonly synthesized by physical and occupational therapists, no matter the working environment (hospital, outpatient, rehabilitation, home health), is that individuals diagnosed with Parkinson disease often have limbic involvement.

Masked expression is accepted as a motor sign of this disease and is linked directly to the rigidity expressed within the motor system. Yet, a masked expression is also associated with fear as an emotion (see Figure 5-6). Similarly, the ability to extinguish this fear response or masked expression is also based on the infralimbic prefrontal lobe and the number of dopamine receptors.⁴⁰⁰ These areas may not be directly damaged by Parkinson disease, but the amount of available dopamine is dramatically reduced. Given this interaction, patients with Parkinson disease may have difficulty facially expressing what they are feeling. Thus, when a therapist sees a patient with a fixed facial expression, that therapist cannot draw a conclusion from that facial expression.

Similarly, depression is commonly associated with any individual with a degenerative disease.^{401,402} Obviously, depression from a neuroanatomical perspective is housed with the limbic system. Depression from a motor response

perspective causes lower postural tone with increased flexion in the neck (see Figure 5-8, B). This pattern within the trunk is also often described as the postural patterns of an individual with Parkinson disease. The question arises, “Is the tone generated from the motor system alone, from the limbic influence on the motor system alone, or from a combination of the two?”

Individuals working in a psychological setting (inpatient and outpatient) may focus on the psychoemotional problems without addressing the functional motor involvement. It is not infrequent that an individual with this disease may simultaneously exhibit signs of psychosis and other potential psychiatric problems.⁴⁰³⁻⁴⁰⁷ It is critical for therapists, despite the physical setting, to develop and understand the entire spectrum of the problems associated with this disease.

Cerebrovascular Accidents (See Chapter 23). The most common insult in CVA results in occlusions within tributaries of the middle cerebral artery.⁵⁶ When this occlusion is in the right hemisphere, studies have shown that clients are often confused and exhibit metabolic imbalance.⁴⁰⁸ The primary problem of this confused state is inattention. After brain scans, it has been shown that focal lesions existed within both the reticulocortical and limbic cortical tracts, suggesting direct limbic involvement in many middle cerebral artery problems.⁶⁶

With the use of magnetic resonance imaging (MRI), specific lesion deficits after CVA can help physicians and therapists identify specific motor and limbic behavioral problems that would limit quality of life of the patients.⁴⁰⁹⁻⁴¹¹ Many clients who have had a CVA do not have direct limbic involvement, yet the stresses placed on the client,^{412,413} whether external or internal, are often reflected in the limbic network’s influence over cognition and the motor control systems.⁴¹⁴ Everyday existence as well as performance of motor tasks required during therapy are usually valued highly in the client’s life. This value or stress placed on the limbic network overflows into the motor system and never allows it to relax, as observed by noting the increase of tonus in the unaffected leg. The client is usually unaware of this buildup of tonus but can release it once attention is drawn to it. If attention is never directed toward these tension buildups, a therapist trying to decrease tonus in the affected arm or leg will always be interacting with the associated patterns from the less-involved extremities.

Tumor (See Chapter 25). Any brain tumor, regardless of whether it directly affects the limbic structures, will certainly arouse the limbic network because of the stress, anxiety, and emotional overlays of the diagnosis. The degree of emotional involvement will obviously affect the declarative learning of the client as well as the limbic network’s influence over motor response.

Tumors specifically arising within limbic structures^{415,416} can cause dramatic changes in the client’s emotional behavior and level of alertness, especially with hypothalamic tumors.⁴¹⁷ The behaviors reported include aggressiveness, hyperphagia, paranoia, sloppiness, manic symptoms, and eventual confusion.⁵⁶ Tumors within the hypothalamus cause not only behavioral abnormalities but also autonomic endocrine imbalances, including body temperature changes, menstrual abnormalities, and diabetes insipidus.¹⁰⁹

When the tumor is located within the frontal and temporal lobes, associated with limbic structures, psychiatric problems may manifest, ranging from depression to anorexia to psychosis.^{109,418} Obsessive-compulsive disorder resulting from limbic tumor has been used as a tumor marker for relapse.⁴¹⁹ Amnesia has been reported in patients with dorsomedial thalamus, fornix, midbrain, and reticulolimbic pathway lesions. This again reinforces the importance of the limbic network’s role in storage.^{109,420,421}

The neurochemistry within the limbic network is very complex and will be discussed within the next large section, but even without a keen understanding of the specific chemistry, therapists need to recognize behavior and mood changes within the client. These changes often signal neurochemical problems affecting the individual’s motor system. If medical intervention includes medicine, pharmacists should be able to explain how those behaviors are being regulated by pharmacological intervention. Literature is now reporting that what were once thought idiopathic seizures are now believed to be neurochemical imbalances with the limbic structure and may someday be controlled with medications that directly affect the immune system.⁴²²

Ventricular Swelling after Spinal Defects in Utero, Central Nervous System Trauma, and Inflammation (See Chapters 15, 24, and 26). Although the effects of ventricular swelling after trauma, inflammation, and in utero cerebrospinal malformations are not discussed in great detail in the literature with respect to limbic involvement, the proximity of the lateral and third ventricle to limbic structures cannot be ignored. It is common knowledge that most people exposed to hot, humid weather begin to swell; become more irritable, less tolerant, and moody; and may complain of headaches. Some people become aggressive, others lethargic. All these behaviors are linked to some extent with limbic function. Thus, ventricular swelling causing hydrocephalus, whether caused by trauma, inflammation, or obstruction, would potentially affect the limbic structures. Reported behavioral changes such as seizures, memory and learning problems, personality alterations, alertness, dementia, and amnesia can be tied to direct or indirect limbic activity.⁵⁶

Summary of Clinical Problems Affected by Limbic Involvement. It is easy to identify limbic problems when the behaviors deviate drastically from normal responses. It is much more difficult to determine subtle behavior shifts in clients. The therapist should be sensitive to these minor mood shifts because they may represent early signs of future problems. Similarly, noting that a particular client is always irritable and has difficulty learning on hot days should help direct the therapist toward establishing a treatment session that regulates humidity and temperature to optimize the learning environment. The limbic network is not just a neurochemical bundle of nuclei and axons found within the brain. It is a pulsating center that links perception of the world and the way an individual responds to that perception. Quality of life is a value, and that value has a strong limbic component. If functional outcomes leading to maintaining or improving the quality of life of our clients is the goal of both physical and occupational therapy,^{291,423,424} then the limbic network is no less important during examination, evaluation, prognosis, and intervention than the motor system itself.

THE NEUROSCIENCE OF THE LIMBIC NETWORK

Basic Anatomy and Physiology

A brief overview of the anatomy and physiology of the limbic network is presented in the following sections. The reader is referred to a variety of textbooks and websites for a more in-depth understanding of this system^{56,119} and how higher thought might be much more complex than previously identified.^{44,68,425-427}

Basic Structure and Function

The limbic network can best be visualized as consisting of cortical and subcortical structures with the hypothalamus located at the central position (Figures 5-13 and 5-14). The hypothalamus is surrounded by the circular alignment of the subcortical limbic structures vitally linked with one another and the hypothalamus. These structures are the amygdaloid complex, the hippocampal formation, the nucleus accumbens, the anterior nuclei of the thalamus, and the septal nuclei (see Figure 5-13). These structures are again surrounded by a ring of cortical structures collectively called the “limbic lobe,” which includes the orbitofrontal cortex, the cingulate gyrus, the parahippocampal gyrus, and the uncus. Other neuroanatomists also include the olfactory system and the basal forebrain area (see Figure 5-14). Vitally linked and often included in the limbic network as the “mesolimbic” part is the excitatory component of the reticular activating system and other brain stem nuclei of the midbrain. Some consider components of the midbrain a very important region for emotional expression.⁸⁶ Derryberry and Tucker⁸⁶ found that attack behavior aroused by hypothalamic stimulation is blocked when the midbrain is damaged and that midbrain stimulation can be made to elicit “attack behavior” even when the hypothalamus has been surgically

disconnected from other brain regions. Recent research has clearly identified the neurochemical precursors to this aggressive behavior.^{53,56,428-430} This “septo-hypothalamic-mesencephalic” continuum, connected by the medial forebrain bundle, seems to be vital to the integration and expression of emotional behavior.⁴³¹ The linking of other brain structures to emotions came initially from the work of Papez,³⁶⁷ who first identified the hippocampal-fornix circuit. He saw this as a way of combining the “subjective” cortical experiences with the emotional hypothalamic contribution. Earlier, Broca⁷¹ labeled the cingulate gyrus and hippocampus “circle” as “the great limbic lobe.” Today, the concept of the limbic network and its interaction with sensory inputs and motor expression has become extremely complex.⁴³² Mood can change motor output, and motor activity can change mood.^{421,433}

Klüver and Bucy⁴³⁴ linked the anterior half of the temporal lobes and the amygdaloid complex to the limbic network. They showed changes in behavior, with specific loss of the amygdaloid complex and anterior hippocampus input, resulting in (1) restless overresponsiveness, (2) hyperorality of examining objects by placing them in the mouth, (3) psychic blindness of seeing and not recognizing objects and the possible harm they may entail, (4) sexual hyperactivity, and (5) emotional changes characterized by loss of aggressiveness. These changes have been named the *Klüver-Bucy syndrome* (see Chapter 13).⁴³⁵ Myriad connections link the amygdala to the olfactory pathways, the frontal lobe and cingulate gyrus, the thalamus, the hypothalamus, the septum, and the midbrain structures of the substantia nigra, locus coeruleus, periaqueductal gray matter and the reticular formation. The amygdala receives feedback from many of these structures it projects to by reciprocal pathways.

At the heart of the limbic network is the hypothalamus. The hypothalamus, in close reciprocal interaction with most

Figure 5-14 ■ Limbic network circuitry with parallel and reverberating connections and with medial forebrain bundle.

centers of the cerebral cortex and the amygdala, hippocampus, pituitary gland, brain stem, and spinal cord, is a primary regulator of autonomic and endocrine functions and controls and balances homeostatic mechanisms. Autonomic and somatomotor responses controlled by the hypothalamus are closely aligned with the expression of emotions.^{429,436-438}

In the temporal lobe, anteromedially is the amygdaloid complex of nuclei, with the hippocampal formation situated posterior to it. Located medial to the amygdala is the basal forebrain nuclei, which receive afferent neurons from the reticular formation, the hypothalamus, and the limbic cortex. From this basal forebrain, efferents project to all areas of the cerebral cortex, the hippocampus, and the amygdaloid body, providing an important connection between the neocortex and the limbic network. These nuclei represent the center of the cholinergic system, which supplies acetylcholine to limbic and cortical structures involved in memory formation. Depletion of acetylcholine in clients with Alzheimer disease relates to their memory loss.^{192,320,321,439}

Interlinking the Components of the System

The limbic network has many reciprocating interlinking circuits among its component structures, which provide for much functional interaction and also allow for continuing adjustments with continuous feedback (Figure 5-15).^{56,429} The largest pathway is the fornix.⁴⁴⁰

Another limbic pathway is the stria terminalis, which originates in the amygdaloid complex and follows a course close to the fornix to end in the hypothalamus and septal regions. The amygdala and the septal region are also connected by a short direct pathway called the *diagonal band of Broca*. A third pathway, the uncinata fasciculus, runs between the amygdala and the orbitofrontal cortex.^{56,441,442}

The medial forebrain bundle and other parallel circuits (see Figure 5-14) are vital connections of the limbic network.⁴⁴³

These pathways course through the lateral hypothalamus to terminate in the cingulate gyrus in its ascending limb and in the reticular formation of the midbrain in its descending part; these pathways have strong interconnections and control over the periaqueductal gray area.¹⁹² These links enable the limbic network itself and the non-limbic-associated structures to act as one neural task system. No portion of the brain, whether limbic or nonlimbic, has only one function.⁵⁶ Each area acts as an input-output station. At no time is it totally the center of a particular effect, and each site depends on the cooperation and interaction with other regions. For therapists the concept of neuroplasticity within the motor system is incorporated into our theories of motor learning, but we still have difficulty integrating sensory, emotional, and motor components as interactive elements in motor performance. Yet research is identifying that these neurocircuitries are present and interactive.⁴⁴⁴

The parvocellular reticular formation (PCRF, or lateral medullary reticular formation), together with the nucleus tractus solitarius, receives both vestibular and nonvestibular input from the cortex, cerebellum, and limbic network and is considered functionally as the vomiting center. It also receives input from the area postrema (floor of the fourth ventricle), which contains the chemoreceptor region for the production of vomiting in response to noxious chemicals. Commissural fibers from the vestibular nuclei complexes run through the PCRF and connect the vestibular nucleus to the reticular formation through axon collaterals. The PCRF also projects fibers to the parabrachial nuclei that contain the respiratory centers and to the hypoglossal nucleus.³⁷⁸ Visceral autonomic input from multiple sources, including the vestibular nuclei, converges in the parabrachial nucleus. The locus ceruleus and autonomic brain stem nuclei also receive vestibular nuclear input.^{234,445-448} Thus, cardiovascular activity and respiration (brain stem-mediated autonomic

Figure 5-15 ■ Interlinking neuron network within the limbic network. (Adapted from Kandel ER, Schwartz JH, Jessell TM: *Principles of neural science*, ed 4, New York, 2000, McGraw-Hill.)

activity), as well as vomiting, are highly influenced by the status of the vestibular system. If we could understand how cold to the neck or forehead, pressure to the wrist, or taste or olfactory input of ginger interacts with known autonomic reactions and nausea in response to chronic vestibular or interneuronal connections problems, the synthesis of many aspects of health care delivery would no longer be a mystery. Obviously, these older treatment techniques are effective and have been for thousands of years, but to today's researchers the "why" drives the desire to better understand the neuromechanisms underlying the observable responses. There are three different types of drugs that neuroanatomically suppress or modulate vestibular input and thus have a dramatic effect on dizziness and nausea.⁴⁴⁹

Research involving functional MRI (fMRI) supports the concept that there is increased activity within the inferior frontal cortex when nausea is induced by either vestibular stimulation or ingestion of an emetic.⁴⁵⁰ This research verifies that there is a strong interconnection among vestibular input, limbic nuclei, and autonomic responses.⁴⁵¹

There are also connections between the parabrachial nucleus and higher brain centers, including the amygdala, which is known to be critical in the development of conditioned avoidance, such as found in agoraphobia, as an example. Thus, vestibular input results in a sensory stimulus that may induce a state of general autonomic discomfort as a trigger of avoidance that precedes the onset of a panic attack.^{378,445,451,452}

Vestibular firing rates are modulated and regulated from the DRN of the midbrain and rostral pons. The DRN is the largest producer of serotonin in the brain and explains the significant linkage between vestibular dysfunction and anxiety, and sleep deprivation and anxiety.²³⁷

Vestibular lesions in animals result in dramatic changes in the morphology and function of the hippocampus. Of note is that bilateral vestibular lesions have been associated with hippocampal atrophy. The hippocampus is responsible for spatial and gravitational orientation, cognition, learning, and memory (spatial and nonspatial).³⁷⁹⁻³⁸⁷

During the past decade anatomical pathways have been identified that are descending motor tracts that terminate in the caudal brain stem and spinal cord.⁴⁵³⁻⁴⁵⁵ These pathways help modulate the activity level of somatic and autonomic motor neurons. Some of these tracts receive direct and indirect afferent information from the periphery and are part of the interneuronal projection system to motor neurons. They are found in the caudal brain stem, in the spinal cord, and between the two and play a role in the generation of fixed action patterns such as biting and swallowing, which have a strong emotion context linked to the motor program.^{456,457}

Some of the pathways are linked with the ventromedial and lateral systems, identified for many years as part of the proximal and axial and distal motor control system, modulated by a variety of structures.^{192,457} They connect the limbic network to the brain stem and spinal neuronal pools. These tracts do not seem to synapse on what would be considered true motor nuclei of the brain stem (e.g., red nucleus, vestibular nuclei, lateral reticular nuclei, interstitial nuclei of Cajal, or inferior olive). However, these pathways do connect with raphe nuclei, periaqueductal gray matter, and locus coeruleus. The medial components of these tracts originate within the medial portion of the hypothalamus, and

the lateral portion originates in the limbic network (lateral hypothalamus, amygdala, and bed nucleus of the stria terminalis). The prefrontal area may be the master controller over this regulatory system.⁴⁵⁸⁻⁴⁶¹ The functional motor implication of these tracts is determined by whether the fibers project as part of a medial or lateral descending system. The medial system, through the locus coeruleus, periaqueductal gray matter, and raphe spinal pathways, plays a role in the general level of activity of both somatosensory and motor neurons. Thus the emotional brain or limbic network has an effect on both somatosensory input and motor output. These fibers can alter the level of excitation to the first synapse of somatosensory information, thus altering the processing or importance of that information as it enters the nervous system. Similarly, it can alter the level of motor generators involved in motor expression, which may account for the extension with anger and flexion with depression. The lateral system seems to be involved in more specific motor output related to emotional behavior and may explain some of the loss of fine motor skill when one is placed in an emotional situation such as competition. To differentiate whether the tonal conditions of a client are a result of limbic imbalance or problems within the traditionally accepted motor system, the clinician would need to observe the emotional state and how it changes within the client. If the abnormal state consistently alters with mood shifts, then limbic involvement causing motor control disturbances would be identified. Human social behavior requires motor expression, yet that behavior is driven through the limbic circuitry.^{444,462-464} Neuroimaging has helped to reduce uncertainty concerning the anatomical pathways, and neurochemistry has widened the possibilities of variations across synaptic connections.⁴⁶⁵⁻⁴⁶⁷

Neurobiology of Learning and Memory

Functional Applications for an Intact System

"Ultimately, to be sure, memory is a series of molecular events. What we chart is the territory within which those events take place."¹²³ Although expressed more than four decades ago, these words are still accurate. They were expressed by a master clinician and researcher, a clinician who watched behavior, emphasized neuroscience, stressed accurate documentation, and always was respectful and aware of patient interaction and how that affected motor behavior.

The brain stores sensory and motor experiences as memory. In processing incoming information, most sensory pathways from receptors to cortical areas send vital information to the components of the limbic network. For example, extensions can be found from the visual pathways into the inferior temporal lobe (limbic network).^{56,468,469} Visual information is "processed sequentially" at each synapse along its entire pathway, in response to size, shape, color, and texture of objects. In the inferior temporal cortex, the total image of the item viewed is projected. In this way the sensory inputs are converted to become "perceptual experiences." This also applies to other sensory stimuli, such as tactile, proprioceptive, and vestibular. The process of translating the integrated perceptions into memory occurs bilaterally in the limbic network structures of the amygdala and the hippocampus.^{56,470-481}

Before the limbic network's impact on learning and memory can be delved into, a clear understanding of what is

meant by these functions is needed. Current theories support a “dual memory system” that uses different pathways in the nervous system. Terms such as *verbal* and *nonverbal*, *habit* versus *recognition*, *intrinsic* and *extrinsic*, and *procedural* and *declarative* have been given to these two memory systems. These systems do not operate autonomously, and many therapeutic activities seem to combine these memory systems to achieve functional behavior.⁵⁶ In reality, the complexity of memory is not a two-category system. Verbal and nonverbal memory both interact with declarative function.⁴⁸² Even within spatial memory, additional areas of integration and parallel circuitry have been identified.^{483,484}

For this discussion, two specific categories of learning—procedural and declarative—will be used, although in today’s neuroscience environment, the terms *implicit* and *explicit memory* are used as frequently. Both categories of learning have been correlated to limbic function.⁴⁸⁵⁻⁴⁸⁷ Declarative (explicit) memory entails the capability to recall and verbally report experiences. This recall requires deliberate conscious effect, whereas the procedural counterpart is the recall of “rules, skills, and procedures (implicit),”⁵⁶ which can be recalled unconsciously.

Procedural learning is vital to the development of motor control. A child first receives sensory input from the various modalities through the thalamus, terminating at the appropriate sensory cortex. That information is processed, a functional somatosensory map is formulated,^{124,488} and the information is programmed and relayed to the motor cortex. From there, it is sent to both the basal ganglia and the cerebellum to establish plans for postural adaptations, refinement of motor programs, and coordination of direction, extent, timing, force, and tone necessary throughout the entire sequence of the motor act. Storage and thus retrieval of memory of these semiautomatic motor plans are thought to occur throughout the motor control system.⁵⁶ The complexity of this process has had an impact on the study of motor control and variables that might affect that control.⁴⁸⁹

The frontal lobe, basal ganglia, and cerebellum are critical nuclei for changing and modulating existing programs.⁵⁶ Many interlocking neuronetworks establish pathways allowing for the conceptualization of research on motor theory concepts of reciprocity, distributed function, consensus, and so on (see Chapter 4). Procedural learning and memory do not *necessitate* limbic network involvement as long as an emotional value is not placed on the task. This memory deals with skills, habits, and stereotyped behaviors. This motor system is involved in developing procedural plans used in moving us from place to place or holding us in a position when we need to stop.⁵⁶

Unlike procedural learning and memory, declarative (explicit) learning and memory require the wiring of the limbic network. Recent literature has clearly identified that the basal ganglia and cerebellum both play roles in cognitive function, especially as it relates to category learning tasks.⁴⁹⁰ This type of learning is closely associated with limbic function, further identifying the complexity of what was considered two entirely separate systems. Declarative thought deals with factual, material, semantic, and categorical aspects of higher cognitive and affective processing. A strong emotional and judgmental component is linked with declarative thought. Thus as soon as a motor behavior has value placed on the act, it becomes declarative as well as procedural, and

the limbic network may become a key element in the success or failure of that movement.^{491,492} Most functional tasks or activities practiced in a clinical setting have value attached to them. That value can be clearly seen by observing the emotional intent placed on the activity by the client.⁴⁹³

The two reverberating or reciprocal pathways, or circuits, within the limbic network most intimately involved in declarative learning are (1) the amygdaloid, dorsomedial thalamic nucleus, and cortical pathways and (2) the hippocampal, fornix, anterior thalamic nucleus, and cortical pathways.

The hippocampus may be more concerned with sensory and motor signals relating to the external environment, whereas the amygdala is concerned more with those of the internal environment. They both contribute in relation to the significance of external or internal environmental influences.^{475,494-499} The hippocampus is rich in stem cells and may be a primary nuclear mass that directs the bodily systems to heal after injury. This is especially true when the external environment is enriched and nurtures the emotional environment for that healing.^{500,595}

The amygdaloid circuits seem to deal with strongly emotional and judgmental thoughts, whereas the hippocampal circuits are less emotional and more factual. The amygdala may be more involved in emotional arousal and attention, as well as motor regulation, whereas the hippocampus may deal with less emotionally charged learning. These limbic circuits seem crucial in the initial processing of material that leads to learning and memory. Once the thought has been laid down within the cortical structures, retrieval of that specific intermediate and long-term memory does not seem to require the limbic network, although new associations will need to be run through the system.^{56,471,473,475}

A third component in the memory pathway involves the medial diencephalon, a structure that contains the thalamic nucleus. When this region is destroyed by neurotrauma such as strokes, neoplasms, infections, or chronic alcoholism, global amnesias result, owing to the destruction of the amygdala and hippocampus. The amygdala and hippocampus send fibers to specific target nuclei in the thalamus, and the destruction of these tracts also causes the same amnesic effect. It appears that the limbic network and the diencephalon cooperate in the memory circuits. The medial diencephalon seems to be another relay station along the pathway that leads from the specific sensory cortical region to the limbic structures in the temporal lobe to the medial diencephalic structures and ends in the ventromedial part of the prefrontal cortex (Figure 5-16).^{56,501,502}

As shown in Figure 5-16, memories may be stored in the sensory cortex area, where the original sensory input was interpreted into “sensory impressions.” Today, concepts regarding memory storage suggest that declarative memory is stored in categories similar to a filing system. Those categories or files seem to be stored in several cortical areas bilaterally depending on the context.^{503,504} This system allows for easy retrieval from multiple areas. Memory has stages and is continually changing. It was once thought that the hippocampus only dealt with long-term memory, but it is now accepted that it also supports multi-item working memory.⁵⁰⁵ To go from short-term to long-term memory, the brain must physically change its chemical structure (a plastic phenomenon). Memory first begins with a representation

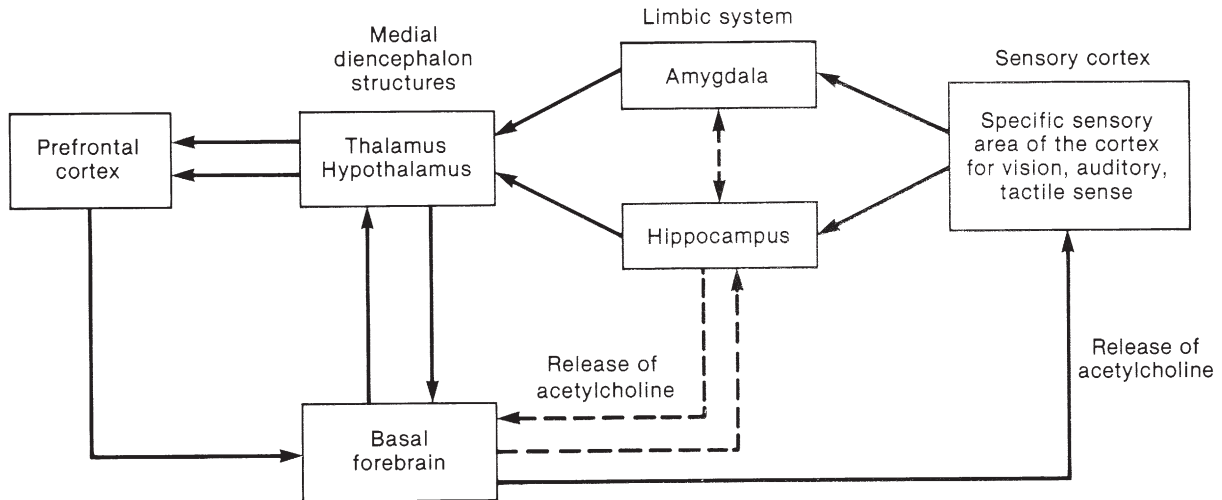

Figure 5-16 ■ The basal forebrain closes the circuit and causes changes in sensory area neurons, which could lead to correct perception and stored memory. This is neurochemical dependent.

of information that has been transformed through processing of perceptual systems. The transferring of this new memory into a long-lasting chemical bond requires the neuronetwork of the limbic complex. Owing to the multiple tracts or parallel circuits in and out of the limbic network and throughout neocortical systems, clients, even with extensive lesions, can often learn and store new information.^{56,506} This may also explain why damage to the limbic network structures does not destroy existing memory nor make it unavailable because it is actually stored in many places throughout the neocortex. The circular memory circuit illustrated in Figure 5-16 shows only one system. The reader must remember that many parallel circuits function simultaneously. The circular memory circuit shown reverts to the original sensory area after activation of the limbic structures to cause the necessary neuronal changes that would inscribe the event into retrievable stored memory.⁵⁰⁷ This information can be recognized and retrieved by activation of storage sites anywhere along the pathway.^{56,508}

The last station or system to be added to the circuit is the “basal forebrain cholinergic system,” which delivers the neurochemical acetylcholine to the cortical centers and to the limbic network, with which it is richly linked. The loss of this neurotransmitter is linked to memory malfunctioning in Alzheimer disease. Currently, many chemicals are being studied for their influence on brain structures and specially limbic structures.^{509,510} Similarly, loss of this cholinergic system plays a key role in dementia problems in Parkinsonism.⁵¹¹ Performance of visual recognition memory can be augmented or impaired by administration of drugs that enhance or block the action of acetylcholine.⁵¹²⁻⁵¹⁴

It has also been shown that the amygdala and hippocampus are interchangeably involved in recognition memory.⁵¹⁵ The hippocampus is vital for memory of location of objects in space, whereas the amygdala is necessary for the association of memories derived through the various senses with a specific recognition recall. For example, a whiff of ether might bring to mind a painful surgical experience or the sight of some food may cause a recall of its pleasant smell. Removal of the amygdala brings out the behavior shown in

Klüver-Bucy syndrome. For clients with this neurological problem, familiar objects do not bring forth the correct associations of memories experienced by sight, smell, taste, and touch and relate them to objects presented.⁵¹⁶ Association of previously presented stimuli and their responses appear to be lost. Animals without amygdaloid input had different response patterns that ignored previous fears and aversions. Thus the amygdala adds the “emotional weight” to sensory experience. Loss of the amygdala takes away many positive associations and potential rewards, thereby altering the shaping of perceptions that lead to memory storage.

When stimuli are endowed with emotional value or significance, attention is drawn to those possessing emotional significance, selecting these for attention and learning. This would give the amygdala a “gatekeeping” function of selective filtering. The amygdala may enable emotions to influence what is perceived and learned by reciprocal connection with the cortex. Emotionally charged events will leave a more significant impression and subsequent recall. The amygdala alters perception of afferent sensory input and thereby affects subsequent actions.^{126,517,518}

In the human, memory functioning has been associated with the phenomenon of long-term potentiation observed in hippocampal pathways.⁵⁶ This potentiation of synaptic transmission, lasting for hours, days, and weeks, occurs after brief trains of high-frequency stimulation of hippocampal excitatory pathways. Whether this phenomenon is caused by alteration at the presynaptic or postsynaptic terminals has not been established, and the complexity continues to evolve.²⁵⁰ The question remains whether there is an increased amount of neurotransmitter released presynaptically (glutamate) or whether the expected amount is producing a heightened postsynaptic response. Or, are both sites involved⁵⁶? Even a third hypothesis regarding nonsynaptic neurotransmission or exocytoses with receptor sites on the surface of neurons beyond postsynaptic sites may help guide our understanding of memory and memory storage in the future.^{56,192} Recent literature has linked a neurotropic factor usually considered for long-term potentiation within the

hippocampus as a factor in amygdala-dependent learning, thus reiterating the interaction between these two nuclei and their role in memory and learning.¹²⁶

Learning and memory evoke alterations in behavior that reflect neuroanatomical and neurophysiological changes.^{56,115} These alterations include the phenomenon of long-term potentiation as an example of such changes. The hippocampus demonstrates the importance of input of long-term potentiation in associative learning. In this type of learning, two or more stimuli are combined. Tetanizing of more than one pathway needs to occur simultaneously. When only one pathway is tetanized, the effect is decreased synaptic transmission. Long-term potentiation, requiring the cooperative action of numbers of coactive fibers, is engendered and formed by the “associative” interaction of afferent inputs. Thus, long-term potentiation serves as one model for understanding the neural mechanism for associative learning. Interacting with this neural mechanism are hormones, which, combined with stress, can change the specific circuitry active during the experience.⁵¹⁹ As our understanding of the complexity of the limbic network evolves, limbic responses to input stimuli need to be differentiated from limbic memory and initiation of a response without the stimuli. Recent research has shown that the amygdala is not only involved in learning related to emotional experiences but is also responsible for changing motor expression or conditioned response generated as part of an autonomic fear expression.^{444,520}

Learning and Memory Problems after Limbic Involvement

For initial declarative learning and memory, the combination of hippocampus and amygdala of the limbic network is required.⁵⁶ For memory formation to occur, there must be a storing of the “neural representation” of the stimuli in the association and the processing areas of the cortex. This storage occurs when sensory stimuli activate a “cortico-limbo-thalamo-cortical” circuit.⁵⁶ Although there is not one single all-purpose memory storage system, this circuit serves as the “imprinting mechanism,” reinforcing the pathway that activated it. On subsequent stimulation, a stimulus recognition or recall would be elicited. In associative recall, stored representations of any interconnected imprints could be evoked simultaneously.⁵⁶

A vital processing area for all sensory modalities is located in the region of the anterior temporal lobe. This area is directly linked with the amygdala and indirectly with the hippocampus. The hippocampus and amygdala are also linked both structurally and functionally to each other and to specific thalamic nuclei. Clients with temporal epileptic seizures and whose temporal lobes have been surgically removed develop global anterograde amnesia—that is, amnesia develops for all senses, and no new memories can be formed. Experimental removal of only the hippocampus does not bring about these changes, although processing is slowed down. When both the hippocampus and the amygdala are removed bilaterally, the amnesia is both retrograde and global. It is postulated that the amygdala is the area of the brain that adds a “positive association,” the reward part to stimuli received and passed through processing. In this way, stimulus and reward are associated by the amygdala, and an emotional value is placed on them.^{521,522}

It appears that limbic involvement in the declarative memory creates a chemical bond that allows cortical storage of “stimulus representation” necessary for subsequent recognition and recall of the information.^{56,471,473,474,494}

When declarative and procedural learning from a clinical reference is analyzed, a separation of functional mediation can be observed. Clients with brain lesions localized in the limbic network components of the amygdala and hippocampus have the ability to acquire and function with “rule-based” games and skills but have lost the capacity to recall how, when, or where they gained this knowledge or to give a description of the games and skills learned. Relating this to clinical performance, clients may develop the skill in a functional activity but not the problem-solving strategies necessary to associate danger or other potentially harmful aspects of a situation that may develop once out of the purely clinical setting.^{212,428,523-525} Similarly, if a client needs to learn a procedural task such as walking, transfers, eating, and so on, it may be extremely important to direct the attention off the task while the task is being practiced procedurally. As knowledge about the complexity of memory evolves, the clear dichotomy between explicit and implicit learning or declarative and procedural learning is being questioned by current research.⁵²⁶ This study clearly demonstrates that anterograde amnesia affects learning that is dependent on combining a novel association with the development of memory compared with its accessibility to consciousness. As the specificity and generalizability of memory come under scrutiny, a question arises regarding the differentiation of semantic memory from music perception, music production, and music memory.⁵²⁷ If emotional and associational aspects of music memory are different from declarative memory and if both are different from procedural memory, then perhaps music may be used to activate existing robust and rich neural networks linking different kinds of memory and learning, and/or elicit neuroplasticity potentials, to address therapeutic goals.⁵²⁸

Neurochemistry

Discussion of the limbic network’s intricate regulation of many neurochemical substances is not within the scope of this chapter. Yet therapists need to appreciate how potent this system can be with respect to neurochemical reactions. The amount of research reflecting new understanding of the role of neurochemistry in brain function is inundating the pharmacological research literature on a monthly basis.^{479,529-536}

The hypothalamus, the physiological center of the limbic network (see [Figures 5-2](#) and [5-14](#)), is involved in neurochemical production and is geared for passage of information along specific neurochemical pathways.

Squire and colleagues⁵³⁷ consider it the major motor output pathway of the limbic network, which also communicates with every part of this system. Certain nuclei of the hypothalamus produce and release neuroactive peptides that have a long-acting effectiveness as neuromodulators. As such, they control the levels of neuronal excitation and effective functioning at the synapses. By their long-lasting effects, they regulate motivational levels, mood states, and learning. These peptide-producing neurons extend from the hypothalamic nuclei to the ANS components and to the nuclei of the limbic network, where they modulate

neuroendocrine and autonomic activities. The importance of these neuropeptides is being recognized as research begins to unravel the mysteries of the limbic network's role in the regulation of affective and motivated behaviors.^{56,140,192,538-540} Lesions in the medial hypothalamus affect hormone production and thus alter regulation of many hormonal control systems.⁵⁶ For example, clients with medial hypothalamic lesions may have huge weight gain because of the increase of insulin in the blood, which increases feeding and converts nutrients into fat. Similarly, this weight gain may be caused by hyperphagic responses resulting from the loss of satiety. General hyperactivity and signs of hostility after minimal provocation can also be observed. These problems are often encountered in patients with head trauma.

Lesions in the lateral hypothalamus lead to damage of dopamine-carrying fibers that begin in the substantia nigra and filter through the hypothalamus to the striatum. Lesions, either along this tract or within the lateral hypothalamus, lead to aphagia and hypoarousal. Decreased sensory awareness contributing to sensory neglect is also present in lateral hypothalamic lesions. The decreased awareness may be caused by a decrease of orientation to the stimuli versus awareness of the stimuli once they are brought to conscious attention. These lesions cause the client to exhibit marked passivity with decreased functioning. Bilateral infarcts within the mammillothalamic tract create an acute Korsakoff syndrome.⁵⁴¹

As noted earlier, depression is clearly identified as a limbic function. A functional deficiency in monoamines, especially serotonin, is hypothesized to be a primary cause of depression.^{542,543} The serotonin systems originate in the rostral and caudal raphe nuclei in the midbrain. Ascending serotonergic tracts start in the midbrain and ascend to the limbic forebrain and hypothalamus; they are concerned with mood and behavior regulation. Damage with direct or indirect limbic involvement results in the client exhibiting depression. Descending pathways to the substantia gelatinosa are involved in pain mechanisms and have also been linked through a complex sequence of biochemical steps to the increased sensitization of the presynaptic terminals of the cutaneous sensory neurons, leading to a hyperactive withdrawal reflex or hypersensitivity to cutaneous input.⁵⁶ This would account for the behavior patterns seen in clients with head trauma, when the therapist sees a flexed posture with a withdrawn or depressed affect yet with an extremely sensitive tactile system.

It is hypothesized that the underlying pathophysiological mechanism of one form of schizophrenia involves an excessive transmission of dopamine within the mesolimbic tract system.⁵⁶ The dopaminergic cell bodies are located in the ventral tegmental area and the substantia nigra. Some of these neurons project to the limbic network. These projections go to the nucleus accumbens, the stria terminalis nuclei, parts of the amygdala, and the frontal entorhinal and anterior cingulate cortex. It is the projection to the nucleus accumbens that seems critical because of its influence over the hippocampus, frontal lobe, and hypothalamus. This nucleus may act as a filtering system with respect to affect and certain types of memory, and the dopaminergic projections may modulate the flow of neural activity.⁵⁶ The masked facies caused by the impaired motor activity seen in clients with Parkinson disease and the paranoid-schizophrenic

behaviors observed in some clients with CNS damage may directly reflect these mesolimbic dopaminergic systems.

The specific roles of the noradrenergic pathway are numerous and affect almost all parts of the CNS. The center for the noradrenergic pathways is located within the caudal midbrain and upper pons. Its nucleus is referred to as the *locus coeruleus*. This nucleus sends at least five tracts rostrally to the diencephalon and telencephalon.⁵⁶ Of specific interest for this discussion are the projections to the hippocampus and amygdala. The axons of these neurons modulate an excitatory effect on the regions where they terminate.⁵⁶ Thus the activation of this system will heighten the excitation of the two nuclei within the limbic network intricately involved in declarative learning and memory. Hyperactivation may cause overload or the lack of focus of attention.⁵⁴⁴ Decreased activity may prevent the desired responses. Attention to task may depend on continuing noradrenergic stimulation. These tracts from the midbrain rostrally play a key role in alertness. The correlation of alertness and attention to performance of motor tasks as well as to learning can be demonstrated.⁵⁶ Again, these research findings reiterate previous statements regarding a therapist's role in balancing the neurochemistry within the client's limbic network. From a clinical perspective, a therapist will observe a relaxed, motivated, alert participant in the learning environment and will observe better carryover because the chemical interactions will only enhance the learning.

More than 200 neurotransmitters have been identified within the nervous system.⁵⁶ How each transmitter and the interaction of multiple transmitters on one synapse affect any portion of the CNS is still unclear. Certainly, some relationships have been identified. Novelty-seeking behavior of the limbic network seems to be dopamine dependent,⁵⁴⁵ whereas melatonin receptors seem to coordinate circadian body rhythm.⁵⁴⁶ Adrenal corticosteroids modulate hippocampal long-term potentiation.⁵⁴⁷ The complexity of this system still challenges many researchers.

In conclusion, the neurochemistry of the limbic network is intricately linked to the neurochemistry of the brain and the body organs regulated by the hypothalamus. All systems within the limbic circuitry seem to be interdependent, with the summation of all the neurochemistry being the determinants of the specific processing of information. Similarly, the interdependence of the limbic network with almost all other areas of the brain and the activities of those areas at any time reflect the complexity of this system.

THE LIMBIC CONNECTIONS TO THE "MIND, BODY, SPIRIT" PARADIGM

As neuroscientists, safe and deep within a Western allopathic model of linear research, establishing efficacy and evidence-based practice for what is taught to new learners is critically important.^{290,291,548} Yet there are too many unexplainable behavioral unknowns occurring daily in the clinical environment that cannot be researched using standard Western research tools common to physical or occupational therapists. Identifying with treatment approaches that base their philosophy on energy fields, flow patterns of those fields through the body, rhythms that do not seem to be proven as existing, or planes of consciousness and belief seems to contradict that comfortable groundedness of basic science. Thus for many health care practitioners, denial of

all those potential parameters that might affect evaluation and intervention outcomes is an easy way to feel safe and linked to what is believed to be efficacy- or evidence-based practice within respective professions. Most allopathic medical physicians within the clinical environment are the first to reject what seem like irrational claims or ideas regarding philosophical approaches. Therapists are not far behind those physicians with their attitudes and verbal expressions toward both patients and colleagues who bring in ideas regarding potential approaches that seem to be outside of our reductionistic, linear research models used to establish efficacy. In the clinical arena, clinicians are realizing that effectiveness of practice with objective outcome measures is another way to establish evidence. Similarly, effectiveness can be subdivided into variables that pose questions. Researchers might be able to select variables that can be researched to establish efficacy of treatment approaches used within a clinical environment. Western medicine has taught both medical practitioners and therapists to strongly question anything that reflects concepts of energy, healing, or spiritual beliefs with regard to outcomes of therapy. Yet electromagnetic tools have been embraced by physicians and neuroscience researchers in the form of computed tomography, MRI, PET, and fMRI to diagnose and study neurological damage and neuroplasticity. These evaluation and research tools create their own electromagnetic field while the human body is placed within that field.^{549,550} Practitioners can still deny that there is a natural energy field and that this field has anything to do with health, but it is getting harder and harder to deny the presence of such a force. All of us have received an electric shock between our body and a metal surface. That shock is called an *electromagnetic charge*, and the voltage depends on the inherent voltage of that individual. Where did this voltage come from? What is meant by *inherent voltage of an individual*? We all have learned that there is a static electromagnetic field around us, but it is very hard to identify how that charge might affect our body systems. As long as practitioners do not inquire about the physics of these energy fields and the bioelectric or biochemical reactions of our human cells to these fields, the idea that the electromagnetic and electrochemical fields have nothing to do with neuroplasticity and changes with patients after neurological insults unfortunately can remain a myth. Over a decade ago, some allopathic physicians stepped out of their established model and developed a subspecialty in psychoneuroimmunology. Checking PubMed for articles from 2012, a reader can find over 1120 published articles under the term *psychoneuroimmunology*. This subspecialty incorporates the relationships among emotion, the endocrine and immune systems, and the CNS and peripheral nervous system.^{22,113,114,551} As the limbic neuronetwork intricately links various nuclei that deal with emotion, endocrine production, and autoimmunity, there is little doubt that this system is involved with belief in healing, emotions, and spirituality. “Despite such conceptual progress, the biological, psychological, social and spiritual components of illness are seldom managed as an integrated whole in conventional medical practice.”²³

Fortunately or unfortunately, there are scientists and therapists who are “myth busters” and challenging the rigid paradigm of linear research, stating that there are many more variables and multiple systems involved in neurorecovery or

neuroplasticity than have yet been identified. Physicians and neuroscientists studying the effects of disease and neuroplasticity after trauma⁵⁴⁹ or application of drugs⁵⁵²⁻⁵⁵⁴ are trying to unravel a complex maze of chemical and electrical reactions at a level of the cell membrane.⁴⁴ Quantum physicists are studying the universe and the electromagnetic pull of suns on planets and solar systems on one another.⁵⁵⁵⁻⁵⁵⁷

Science is a long way from unraveling the mysteries explored by cellular biologists and quantum physicists and how they might relate to each other. But many scientists trust that there is a relationship. As humans, we are made up of billions of these cells; each cell has a membrane potential and the ability to adapt and change; and they play an important role in the existence of our species. Similarly, the universe is made up of billions of masses; each has some relationship to energy pull, whether that be one solar system in relation to another, one planet in relationship to a sun, one moon in relationship to a planet’s oceans, one person in relationship to the gravity on a planet, or one person in relationship to another person. If those cells are what makes a person human, and if what holds the person together is electromagnetic energy, then it is hard to ignore the possibility that one person might affect another person just by being present.⁵⁵³

Therapists want to study the interaction of brain responses between a practitioner and the client during a therapeutic treatment session.⁵⁵⁸ It is obvious that this interaction cannot be explained by one variable within linear space, nor that it is one variable alone that is causing all change over a linear set in time. Establishing efficacy on what seems to be a multidimensional construct using a basic science research model is not realistic. Thus efficacy research on the totality of the mind, the physical body, and the human spirit eludes basic scientist researchers in a manner similar to the way that researching the effectiveness of intuition eludes psychiatric researchers.

As research practitioners we use various tools to manipulate both the internal and external environments within which our clients function to measure effectiveness of specific or generalized outcomes. Each person is so complex and unique that finding the best combination of tools and environments has a very person-specific answer.^{554,559} Thus what we as researchers are trying to do is find evidence that shows that one treatment paradigm has a better chance of creating change than another, without placing rigid restrictions that say all persons will optimally benefit from any one particular approach.⁵⁶⁰⁻⁵⁶⁷ MRI, PET, and fMRI tools are certainly capable of identifying changes in the CNS after interventions. Even when researchers or clinicians try to control as many variables as possible, many additional external and internal input possibilities exist.

This brings us full circle to the question regarding additional variables that might affect health, well-being, and recovery outcomes from therapeutic interventions.⁵⁶⁸⁻⁵⁷⁵

After 30 years of clinical practice and hearing Western physicians say, “Physical therapy and occupational therapy just make the patients *feel* better,” it is obvious, first, that many physicians do not understand the depth and breadth of our professions or what is provided to the clients. Second, those physicians do not understand the limbic interconnections to “feel better” and how that might drive the neuroplasticity of the CNS and the autoimmune system’s response to

disease or pathology.⁵⁷⁵⁻⁵⁸² Similarly, after many patients have been observed over the last 40 years regaining consciousness, whether the vegetative state lasted 6 months, 9 months, a year, or 4 years, the fact remains that each individual shifted from what might be considered a level 2, 3, or 4 on the Rancho Levels of Cognitive Functioning to a 6, 7, or 8 on the same scale after 5 to 20 minutes. This reality made me ask the question from the beginning of my professional career, “What are the variables that cause changes in these clients?” The answers are not yet fully understood, although the behavioral outcomes keep presenting themselves. Every time a patient comes out of this vegetative state, I [DAU] feel wondrous, emotional, and humbled. Something happens that is far beyond our scientific understanding, something simple but extremely complex, cellular and universal, all at the same time. Similarly, the bond between that therapist and that client is very strong and deeply spiritual. The memory of those patients stays forever embedded in the mind of the therapist even if the clinical environment existed for only 30 minutes. All the words used to explain such clinical experiences link closely to the limbic network and its role in creating change, both within the therapist and the patient; certainly at this time, these experiences fall outside the paradigm of Western medical science. According to a report on the BBC, the use of appropriate fMRIs shows that many individuals in a vegetative state are awake but still have little to no awareness because of the severe brain injury.⁵⁸³ This explains the fact that a therapist “feels” that a patient is aware but does not explain how the therapist-patient interaction brings that client to a conscious state of attention.

Medical schools and health science programs are becoming increasingly aware of the need to train the practitioners of the future to enter into a healing relationship with the whole patient,⁵⁸⁴ a relationship that empowers the patient to engage endogenous healing capacities, even while we work to better understand these mechanisms through both basic and applied research. Master clinicians have long appreciated this dynamic healing relationship, which affects both the therapist and patient. Thus even when our patients can verbally communicate with the therapist, it is still important to listen directly to the body, and on a deeper level, to more subtle input that we do not yet have the ability to describe and quantify with scientific method. It has been demonstrated that even for persons in very low awareness and response states, appropriately selected music can provide time-organized and emotionally meaningful stimuli to gently activate intact neural networks, and to communicate with the person still alive inside the disabled body.⁵⁸⁵ The sounds we make and the way we touch communicate to the deeper levels of being and do not require words to convey caring, instill hope, and motivate the will to keep trying to get better.

The success or failure of many forms of alternative medical practice, and for that matter Western allopathic medicine and therapeutic practices, may depend on the limbic network.^{557,573,586} At times research can prove unequivocally that certain variables do not show a healing effect, after double blind studies.⁵⁸⁷ If a patient “believes” an intervention will work, even if it is a placebo, the chances of success far exceed those when the patient does not think it will work.⁵⁸⁸⁻⁵⁹¹ If it is a placebo and the body heals, then logic dictates that

the body and the mind did the healing. Similarly, when the drug itself aided in neuroplasticity and change, is it the drug itself or the individual’s belief that the drug will work that creates the change or both? How these changes occur is yet to be totally understood, but research substantiates that both neurochemical and neuroelectrical changes occur within an individual’s physical body when the individual believes that change is possible.^{119,120,570,576,587,590}

When I was a novice therapist, a nurse once said, “I am very glad you are not a nurse because you are so idealistic. You believe these patients in comas are going to wake up and walk out of here. And what is even worse is that most of them do!” That moment should have told me that I would be clashing with allopathic doctrine throughout my professional career, but instead I was confused about the nurse’s use of the term *idealistic*. If the patients awoke and walked back into life with function and quality, then should that not be considered a *realistic* expectation? In that same job situation, my boss asked me to treat all the patients who were considered vegetative; once they were awake, my colleagues would treat them from there. My response was, “Emotionally for both the patient and myself, I could not do that. Once I bonded with a person, gained his or her trust, and found the patient was willing and capable of regaining consciousness, I could not just abandon the patient and go on to another person.” The significance of that statement took many years to understand, and it was not until I began my study of the limbic network that I truly comprehended the accuracy of that perception, once considered naïve.^{570,578,586,592,593} It was not until the writing of this edition that I could shrug off comments such as “This has nothing to do with physical therapy.”^{3,22,23,60,594}

After 45 years of practice and often treating individuals in front of colleagues in workshop situations, I cannot deny that something more than just “feeling good” occurs during physical or occupational therapy interventions although that feeling good is certainly a limbic response. When working with clients, I find myself feeling very open and bonding in some way that is neither “physical” nor “mental”—and thus the only option left is a definition of “spiritual.” If, when treating a patient in a vegetative state, that bond tells me that the patient is lost within another plane of consciousness and wants to regain consciousness as defined by healthy people, and the physical body of the patient seems capable, then the treatment is goal directed, the direction of the intervention is identified, and thus the outcome is selected by the patient. The map has been established, and together the patient and the therapist proceed. As with all therapists, the intervention will be guided by the motor responses and control of the patient and the window within which the patient can run those programs independently. At times, when treating clients in a vegetative state, I feel unable to locate the “spirit”; at other times it feels as if that person has not decided whether to venture to an awake state, but more often I sense a frightened, confused individual who just wants to find her or his way back to what we call “life or reality.” Those patients often gain consciousness during therapy. It is not a miracle, nor can I ever say, “I healed something.”⁵⁹⁵ The term *healing* refers to a concept of “whole.” The only person who can regain the structure of the whole is the patient.⁵⁹⁶

As a therapist, I am a teacher or a guide, helping others relearn and regain control over their respective lives. If after

a 30-minute treatment session a person regains feeling and control of an extremity 18 years after a CVA or regains functional use of a hand 6 years after incomplete spinal cord injury, there is more to the intervention than merely following a clinical pathway or a treatment regimen geared to all individuals at a specific stage of a disease process or a specific motor impairment.

One variable that always seems to be present when clients achieve dramatic recovery is strong motivation by the patient to retain the control and an appreciation for the instruction on how to do that. A strong bond or compassionate appreciation for each other always seems to be present as another interlocking variable. Thus the clinical question “What is spirituality?” presented itself to me more than 30 years ago. It is a variable that is very difficult to define. That variable, when researched, has been shown to affect health and healing in individuals with health problems. *Spirituality* and *healing* are both words that each individual defines according to her or his own beliefs, cultural experiences, and use of verbal language.^{425,426,597-601} The literature is available for those who wish to pursue this topic.^{360,516,602-609}

Over the last 5 years since the fifth edition was published, thousands of articles dealing with health, healing, spirituality, energy fields, quality of life, energy medicine, and emotional balance have been published in a large variety of types of journals.^{610,611} Within this chapter a system that affects all areas of the CNS and peripheral function has been discussed. How this system is affected by or affects one’s spirituality is open for many lifetimes of future study.^{612,613} Yet if spirituality affects healing and an individual believes that this potential is available, then this variable may play a critical role in patient compliance, neuroplasticity, and the limbic interface with other treatment procedures.^{614,615} Ignoring this variable is no different from ignoring cognitive perceptual deficits when dealing with abnormal motor behavior. Owing to the strong emotional foundation for an individual’s spirituality, one could easily assume that the limbic network plays a strong role in establishing and storing memories that reflect these beliefs.

Until we can measure simultaneous synaptic activity of all interactions within the therapist’s and the client’s CNS, we will not, from a grounded neuroscience efficacy base, be able to demonstrate exactly what occupational, speech, music, cognitive, or physical therapists do, even though we know they play a role.⁶¹⁶ Until then, outcomes need to be measured objectively. Even if interactions seem unmeasurable and subjective, clinicians still need to record the event change in the patient record and not bury that outcome deep somewhere in the subconscious level of the therapist’s mind. The mind, the body, and the spirit are connected as a whole. If therapists treat only one part, it may help the whole, but if the whole is treated simultaneously, the outcome is more likely to change the whole.^{617,618} The concept is no different from focusing on strengthening an isolated muscle and hoping it will lead to functional use versus strengthening that muscle in functional patterns and in relation to other muscles that also work together within that movement sequence.

After years of clinical experience and thousands of patients responding positively to various interventions, the question arises regarding clinical decision making and choice of interventions. There is not a “variable” that has been identified that guides that decision. It has been shown

that humans bring to consciousness about 10% of all incoming information. Yet the human brain is making decisions using 100% of the input information. Given that relationship, quite a bit of human decision making may be based on nonconscious information regarding the external and internal world.¹¹⁹ Thus the word all neuroscientists shudder over—*intuition*—may to a large extent be the unraveling of that nonconsciously received data.⁶¹⁹ I have effectively taught colleagues how to feel blood pressure and heartbeats of clinical partners by just barely touching the top of the hand, which might be explained by the high level of sensitivity of Meissner corpuscles within our skin.⁶¹⁸ If a clinician can sense an autonomic response such as heart rate when touching a patient’s skin, then knowing how the limbic network is interacting within a motor response can also be deduced. This would allow the clinician to modulate the rate used to move the patient during an activity such as bed mobility, while maintaining a consistent state of the motor generators. That steady state should decrease any need for limbic fear by the patient. Fear has been shown to be very detrimental to motor performance.⁶²⁰⁻⁶²² Therapists may interpret these tactile responses as intuitive, but they are not. When one clinician seems to know how fast to move the patient and another clinician has no idea how to determine that decision or control that variable, we say it is the *art* of therapy and not the *science*. Yet it is the science of therapy. Similarly, helping someone shift consciousness levels seems similar to hypnosis. The exact identification of these variables is very hard, let alone finding reliable and valid research tools. This may just be a case of one clinician being open to receiving information and processing it. The other therapist, for some reason, is either not receiving or not processing the available information. This is not an example of “intuition.”

Intuition has been a source of fascination over centuries. Recently, with consumer dissatisfaction with health care and the assurgency of alternative medical practices, intuition has again sparked the interest of scholars and the public. To many it reflects mystery, magic, and even voodoo. Individuals with a strong ethnic, cultural, and even religious bias may find it hard to scientifically analyze this human strategy. For more than 35 years my husband has answered questions I have posed in my mind. It took at least the first decade for my left brain to actually accept that I was not subvocalizing the thought or that he could not have extrapolated the thought from an environmental stimulus. Yet he consistently has told me he hears me ask the question or state a fact. Obviously, my thoughts have traveled to the primary and associative receiving areas of his left temporal lobe and he “hears” the thought in my voice. The dilemma that confronted me as a scientist is, if the information was not input through his eighth cranial nerve, how did it enter into his system? The answer would seem to be intuition. A definition might be knowing something without entering the data through traditional input systems. The next question is “What is intuition?”

Unfortunately, after 35 years of study, I cannot answer that question. I do acknowledge that it is something, it can be learned, and master clinicians use it as a part of their clinical decision making, even if they choose not to verbalize it to their colleagues or even acknowledge it within their conscious mind. Much research and literature are available regarding intuition.^{119,623-646} Yet the answer to that simple

question “What is intuition?” is unavailable and does not seem so simple. No answer exists that has shown to be definitively efficacious and reliable, although research over the last 10 years has begun to identify components of intuition.⁶²³⁻⁶⁴² It may be that intuition is more than one variable and can be accessed in more than one way. In fact, after studying various alternative medical practices, all using very different interventions based on different philosophies and belief systems, it seems as if all approaches may be tapping into the same human system, just opening to that system through different paradigms.

In the late 1960s, I [DAU] was beginning to present an integrated approach to neurological disabilities and integrating various treatment philosophies using the behavioral responses of patients and known science to guide intervention. I was told at that time that integrating approaches could not be done and that I would potentially injure patients by using approaches from different philosophical techniques. Today, of course, with our understanding of motor control, motor learning, and neuroplasticity, an integrated approach from the 1960s based on a systems model is what we do. I now present the same model when looking at complementary approaches to intervention and the concept of intuition. There are a number of variables that seem to open one’s intuition: bonding, being dedicated to the patient, having openness in listening to the patient, letting preconceived knowledge be a springboard from which to expand that knowledge, having not only a willingness to learn but an insatiable appetite to continue learning, and possessing the ability to let go of one’s importance and just be another person within the environment. These variables may be the best place for a learner to begin learning how to develop this skill. It would seem as if intuition is like an aptitude. Some individuals come into this life already with a high level of potential, others are nurtured to develop that potential, and still others never have an opportunity or an environment in which to develop those strategies. Some individuals have had strong intuitive senses from childhood but share those experiences with few, if any, other people. Experiencing intuition is an all-knowing experience. One knows something first, then one becomes emotional regarding that knowledge. It is a knowledge that has a “wholeness” component and then has a strong emotional base. For example, I *knew* I was going to lose a parent. Which parent, I did not know, but I moved home for a year to make sure there wasn’t anything I should have said to either parent before I went on with my life. A year later I was married and home for a holiday. When I left I cried all the way back to my and my husband’s dwelling across the country because I knew I would never see my father again. I was right; he passed 2 weeks before I was to return home. My father had been a very healthy man with no health issue that would indicate any life-threatening health problems. I had known what was going to happen as a whole (intuition) and then had had a very strong emotional response to that intuition. Also, when my brother called to say that our father was critically ill, I had already adjusted to the probability of his loss and was the one individual within the family who could make cognitive decisions or answer press questions by phone. If I were to hazard a guess, the intuitive center is probably in the right anterior temporal lobe owing to the “whole” understanding and its strong emotional connection. If that proves true, it will solidify the limbic network’s connection to intuition. Experiences often

create the first questions that lead to hypotheses and later to research that establishes efficacy.

Until 40 years ago, I [DAU] hid from most people that aspect of my person because I was becoming a neuroscientist and wanted to be grounded in scientific efficacy like all my colleagues. Unfortunately, my clinical experiences did not allow me to hide that intuitive aspect of my clinical decision making from my family or close colleagues or those colleagues who recognized that something had happened during a treatment that made no sense whatsoever. Those individuals recognized changes within the patient that, although very positive, should not have happened or were very far from our basic scientific understanding. I treated a woman who had a severe head injury and who after 6 months was at a Rancho level III. After 30 minutes of intervention the woman volitionally moved all of her limbs and trunk without cognitive confusion. That motor function and cognition might be partially explained by recent research using fMRI.⁵⁸³ But something that goes far beyond today’s fMRI followed the intervention. I innocently stepped out of the safety of scientific understanding. I shared with my colleagues this woman’s medical and social history. That information was critical to their understanding the course of progression of this woman through the rehabilitation process. I discussed the patient’s social background, her education, her family, her children, and her husband, who had shot her in the head. This all made perfect sense, until the head of the department asked me how I knew that information. I said, “I read it in the chart.” The director informed me that I had not seen the chart. I said, “You told me?” The director responded with, “We did not discuss the case!” I asked if I had been wrong, and the director said “no.” In fact, she was amazed at how accurate I had been and just wondered how I had known that about the patient.

At that moment, my life was changed. I could no longer hide whatever this “intuition” was, nor could I truthfully tell colleagues what I had done during interventions without bringing up this topic. Also, I could only tell them ways to develop intuition but had no understanding of the basic neuroscience behind its function. I could not tell anyone exactly what it was because I did not know. That unknown is still present, although some of the variables may have been identified. The future will unravel those answers. What I have found since that day is that “masters,” whether they are physicians, therapists, or teachers, often use this additional source of information gathering to help them in their clinical reasoning. I do not make this statement lightly nor without tremendous professional risk. I will leave you with an interaction that solidified my belief that this direction of scientific study needs to be pursued. Two decades ago, I was a keynote speaker at an international neurosurgical conference on brain tumors. I was the token “other,” and the only speaker who was not a neurosurgeon. I presented the topic “The Limbic System’s Influence on Motor Output.” With this audience of 500 neurosurgeons and 50 token others, I, of course, used charts and pictures and based every sentence on efficacy-based scientific research. At dinner that night when all the speakers were together, the master neurosurgeon whom everyone acknowledged asked if he could sit next to me. I was aghast—a little nervous but honored nonetheless. He opened by saying, “I think many physical and occupational therapists are intuitive.” With that, I knew him, his life, his experiences, and so on. I let my left brain validate

my intuition and said, “Yes, it is like walking into a room, looking at a patient, knowing where and what type of tumor he has, and using instruments such as PET studies to validate what you already know!” He responded with a smile and said, “Yes, it is exactly like that!” I do not need to continue to discuss the fascinating interactions of that night but leave the reader with the thought that even the master of the masters in neurosurgery uses intuition as a variable in clinical decision making, and it gave this man one additional bit of information that his colleagues could not use in clinical reasoning. No physician or therapist uses intuition as the only variable; intuition just gives additional information that helps in the process of clinical reasoning. It would seem as though intuition is highly integrated into the limbic network.

As said previously, intuition is knowing something and as a result experiencing great emotion, such as “I know, thus I fear.” If the sequence of events begins with an emotion or fear and leads to what is perceived as knowledge or truth, one might question whether intuition was the driving force behind the belief. When emotions become elevated an individual may progress with “I fear, thus I think I know.” Research that looks at intuition assumes that when the limbic network is involved, the experience is highly emotional, and one might argue that an individual can be highly emotionally charged and still be neutral as far as a balance in emotions. Fear is not what drives intuition; instead it is emotional balance. Emotional balance or centering is not a state of being without emotion but rather a heightened state of emotional awareness without emotion, all at the same time. To become truly intuitive, one needs to become emotionally centered. In our everyday world where each of us is overstimulated as a day-to-day experience, this emotional balance is extremely difficult to achieve. It is even harder to find that balance in a clinical arena where patients are arriving with more acute diseases along with chronic secondary problems, often patients’ schedules overlap with other patients’ time, and therapists not only are limited with time for intervention but also find that the number of allowed visits falls well short for optimal opportunity for learning by the patient. That reality does not mean that the therapists’ responsibility has changed. It is always up to the therapist to find those avenues by which better care may be provided within the existing environment. This reality just says that the challenges and questions are enormous. Finding emotional balance within that environment is very hard. Yet intuition seems to be a variable that gives some colleagues additional information that is then used as part of the clinical reasoning process.

Intuition as a variable needs to be identified, studied, researched, and taught once it is clearly understood. It is up to all of us to find the answers to these questions and the solutions to today’s clinical problems and develop evidence-based practice to progress into the twenty-first century.^{647,648}

The concept of integration of mind, body, and spirit as a critical element in maintaining or regaining quality of life between birth and death is not new.⁶⁴⁹⁻⁶⁵² Western society has tried to separate this concept into three distinct categories. The mind is made up of perception, cognition, and emotion. The body is made up of all systems external to the nervous system such as peripheral organs, muscles, bones, and skin. Both the peripheral and central motor systems, which control the body, are also included in the concept of body. The last component, the spirit, is a transcendental concept and is thought to depend on individuals’ beliefs.

Some individuals believe that spirit means belonging to a religious order. Others define spirit or spirituality as beyond religion—the essence that links the person to a greater energy force. For decades this last category has been considered outside the domain of responsibilities of Western allopathic health care delivery and was comfortably relegated to religious leaders or spiritual guides.

Today, everything is changing. Some scientists refer to energy fields around cells; others talk about energy fields around solar systems. Complementary practitioners talk about energy fields around the living organisms. Physicians are being taught cultural sensitivity training while in medical school to be more empathetic to the populations of people they will service. Physical therapy curricula are responsible for creating culturally sensitive professionals.⁶⁵³ Occupational therapy programs are responsible for including spirituality as one of the competencies a graduate is to have met.⁶⁵⁴ None of these professions has identified how these competencies relate to evaluation and intervention outcomes after treatment, but even the accrediting bodies believe they are important. Thus even at the entry level, for student therapists, emphasis is placed on making sure not only that the therapists’ limbic systems have become sensitive to spirituality, but also that they be able to identify its significance in their clients’ lives. Where does the interaction of the mind, body, and spirit play a critical role in quality-of-life issues and empowerment of the patient? The answers to that question cannot be found within this text or any other text in print today. Individuals with strong beliefs in a specific paradigm that includes spirituality can project the answer to this question, but establishing efficacy is an entirely different issue. Our professions are tethered to research, science, behavioral observations, and current knowledge. We as clinicians can stretch that tether. Much of our early treatments developed from behavioral observations that included individuals’ beliefs that clearly required the limbic network for processing, storage, and direct effect on bodily system reactions. If a patient lacks motivation, a therapist knows part of the job is to motivate the person. If the person believes his “God” will heal him, the therapist should never undermine that belief because everyone knows it cannot hurt and often creates a positive change.⁶⁵⁵ How that interaction occurs is unknown today, but clinical observation would reinforce that it does help. Because spirituality uses belief and hope, memory of those feelings must be processed and later stored with the help of the limbic network.

These dilemmas exist with every professional dealing with health and wellness and quality-of-life issues. I [DAU] will leave you with one additional example. I spent over 2 months in the ICU a few years ago after a severe fall that caused two fractures of the pelvis, followed by severe internal hemorrhages. To summate the medical problems, I had 18 initial arterial ruptures treated with radiological interventional surgery, followed by four more ruptures 1 week later leading to more surgery. I also had bilateral kidney failure, a large pulmonary embolism on the right side, pulmonary collapse in the left inferior lobe, massive internal infections, infusion of 12 units of blood, thrombophlebitis, fevers of over 105° F, very low blood pressure, and low oxygen absorption, along with external bleeds through most external orifices. In addition, the two bleeds destroyed my adrenal glands bilaterally, throwing me into another life-threatening imbalance of chemistry within my body. The doctor kept

telling my husband with confidence that I would die. As my husband had been told this many times before, he kept telling the doctor he would wait for 3 days after I had been declared dead before he would accept that conclusion. Two weeks after the initial hospitalization, the doctor came into the room. He shut the door, sat down in a chair, addressed both of us and asked, “I know what medical problems you have had, I know that we did everything medically that we could, but it was not enough, so *how come you are still alive?*” I responded with, “There is a lot more to healing than what we understand, and that is what is fun about being a health professional.” Life has taught me the lesson, whether as an intuitive, as a neuroscientist, or as a therapist, that there will be unknowns or mysteries along one’s life journey. Sometimes one can solve the problems or answer the questions, but more often than not one just has to file them in memory with the hope that one will sometime find an answer. The unknowns are always present even as answers are discovered. Having those unknowns creates an exciting challenge and adventure for every clinician who has or will have the opportunity to interact with individuals who have been brought into the health care delivery system because of a CNS problem. Those individuals want to be considered as a whole human being even if part of their physical body is dysfunctional. A circle has been drawn, and this chapter needs to end with a question. What is that whole? Refer to [Case Study 5-1](#) as a clinical example.

SUMMARY

The complexity and interwoven neurological arrangement of the limbic network may seem overwhelming. A reader who tries to grasp all parts on first study will feel lost and

defeated, which is a true limbic emotion. Thus this chapter has been presented in three parts. The first part introduces the system and its potential clinical application. This section, in and of itself, has many interwoven components, for nothing in the limbic network functions in isolation. Yet the mysteries of this complex neurological network, when identified, may hold the answers to many clinical questions regarding the art and gift of a master clinician. The second part introduces in more detail the basic anatomy and physiology of the limbic network. It is hoped that once the student or clinician has been drawn to the conclusion that this system may be a key to clinical success, she or he might be willing to delve into the science of the system. This path of exploration is challenging, difficult, and frustrating at times but certainly worth the effort once understanding has been achieved. The last section opens up the minds of the readers when and if they so choose to address these unknown variables. The limbic network is very complex, is very interactive with all parts of the human body, and may hold many answers about patients’ responses and recovery. The reader’s journey has just begun, and the future will open up many more avenues of research and clinical study as well as many more questions.

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 659 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

CASE STUDY 5-1

A 25-year-old first-grade teacher with a history of whiplash has been referred by the neurology department 5 months after a motor vehicle accident with complaints of severe dizziness and imbalance. She is unable to recall the accident; however, there was evidence to suggest that she struck her head on the steering wheel and briefly lost consciousness. Results of diagnostic testing (MRI, electroencephalography) are inconclusive. Medical management to date has been limited to central depressant medications (alprazolam [Xanax], diazepam [Valium]; see Chapter 36). She has received physical therapy since the accident for neck and back pain, which exacerbated her symptoms. She denies specific assessment or treatment of her dizziness or imbalance until this time. Her medical history includes a hospitalization 3 months after the motor vehicle accident with “intractable migraine, postconcussive syndrome.” Of note is a previous head injury 2 years before with moderate to severe postconcussive syndrome, including vertigo and migraines. She has been referred for psychological assessment and management and was recently diagnosed with obsessive-compulsive disorder. She is now referred to physical therapy for a full postural control and vestibular assessment. The differential medical diagnosis is postconcussive syndrome, rule out aphysiological performance (psychogenic, secondary gain). The physician believes that a large part of her problem is based within the medical psychiatric domain, but he is willing to widen his paradigm to include other possibilities and obtain additional data to assist in his patient’s management. The

patient’s goal is to eliminate the dizziness and imbalance and return to normal activity and work.

PHASE I: EVALUATION

Unaware of being observed, the patient walks into physical therapy extremely slowly, holding the wall, watching the ground, and stopping periodically to close her eyes. Her color is pale, her build small and thin, and her clothing loose. She is, however, well groomed. Her steps are shortened in length, widened in width, and limited in swing time. She demonstrates no segmental movement of the head or trunk, walking en bloc (rigidly) without arm swing. As she sits down to begin the evaluation session, she smiles. She periodically closes her eyes as people move around her. There is visible extraneous eye movement, although no immediate visualization of nystagmus (eyes opened or closed). She is pleasant and cooperative with no overt signs of anxiety in quiet sitting.

System Impairment

- Dizziness with severe nausea and vomiting (at least once weekly)
- Dizziness Visual Analog Scale 7.5/10 and Dysequilibrium Visual Analog Scale 7.0/10 (with 10 representing the most severe symptoms imaginable)
- Decreased concentration and memory; forgetfulness
- Visual diplopia and blurriness with visual headaches
- Depression of central vestibular function (treated with medication)

Continued

CASE STUDY 5-1—cont'd

- Decreasing body mass as observed by loose clothing and supported by reports of severe nausea
- Emotional stability: fight or flight; in both active F²ARV and active GAS (autonomic) states:
 - She reported that she was capable of rapid change from a state of calm to fits of rage with her family and other support systems.
 - Anger and rage alternated with reports of depression and avoidance.
 - She reported photophobia with hypersensitivity to light and sound.

Activity: Client Report

- Impaired balance for function, with near falls in dark and eyes-closed environments. Patient reports one true fall in the shower with her eyes closed.
 - Impaired balance within visually challenging environments.
 - Sleep deprivation and extreme fatigue.
 - Long-term stress and sensory intolerance and overstimulation
- It is important for a clinician to remember that the long-term stress associated with a chronic disability of this nature can result in a decrease in serotonin, which influences the hypothalamus and modulation of the vestibular nuclei through the DRN. Loss of sleep can alter levels of serotonin and other neurotransmitters. A decrease in serotonin results in further depression and *loss of sleep*, resulting in a physiological *fatigue*. It also can result in an increase in sensitization of presynaptic terminals of the cutaneous sensory nerves, contributing to the *sensory bombardment* and overstimulation.⁶⁵⁶

Participation in Life (Client Report)

- She attempted to return to work as a first-grade teacher but had a severe exacerbation of all symptoms in the classroom.
- She is unable to drive and requires assistance for shopping.
- She lives alone in an apartment and is independent in function, modified by her symptoms.
- Disability Rating is $\frac{4}{5}$ (recent severe disability, medical leave).⁶⁵⁷
- Dizziness Handicap Inventory (DHI) score is significant for physical and emotional impact of her dizziness, including depression. (Total disability score is $\frac{78}{100}$, functional subscore $\frac{28}{32}$, emotional subscore $\frac{30}{40}$, and physical subscore $\frac{20}{28}$.³⁹⁰)

Based on the signs and symptoms obtained in the intake phase and subjective reporting, the preliminary physical therapy hypothesis would be the presence of a probable vestibular dysfunction of a mixed central and peripheral cause, a sensory integration dysfunction, and anxiety overlay. The patient clearly has limbic network overload. It will be the therapist's responsibility to differentiate that from physical motor system problems with the assessment and treatment. The examination phase is designed to confirm or refute and redirect this hypothesis. (See Chapter 22b for clarification of these specific vestibular tests and measures.)

Oculomotor

Oculomotor examination was performed, with results supportive of the hypothesis of vestibular involvement, although inconclusive for peripheral versus central versus combination.

Gaze instability—Clinical dynamic visual acuity test revealed a significant five- to six-line deterioration in dynamic visual acuity when head was moving, with loss of postural control in posterior-left direction and symptom exacerbation during testing.

Balance Stability

- SOT of sensory balance function⁶⁵⁸ showed an across-the-board dysfunction pattern,¹⁴ although results were incomplete because the patient was not able to complete all 18 trials of the test protocol as a result of extreme symptoms (nausea, respiratory, and anxiety symptoms, particularly on conditions 2, 3, 5, and 6).
- Total dependence (overreliance) on visual information for balance stability.
- Center of gravity position shift significantly leftward and anterior of midline.
- Excessive use of a hip strategy for basic equilibrium (versus ankle), even with stable surfaces or the smallest perturbation.
- Inability to effectively:
 - Use somatosensory or vestibular sensory cues on functional demand (reweight)
 - Organize the sensory inputs to the CNS to facilitate appropriate motor output
 - Dampen ANS/vegetative response, particularly in visual-vestibular mismatch conditions (SOT 3 and 6)
- Aphysiological criteria—Aphysiological responses on SOT raw data traces (exaggerated sway frequency and lateral sway responses). Motor Control Test (of automatic motor responses) results would have strengthened conclusions made regarding an aphysiological component but were unavailable to this clinician at the time of the examination.⁶⁵⁸

Function and Gait

Self-selected velocity of 1.82 ft/sec (normal preferred gait speeds in a 20- to 30-year-old woman should be closer to 3.47 ft/sec).¹⁴ The patient watched the floor for the entire distance with no head or trunk or arm movement. Thus vision was clearly directing each step and was adjusted to decrease extraneous visual flow or input. When she was encouraged to focus on a distant object, velocity declined to 1.34 ft/sec and the patient veered consistently leftward 100% of the distance. She could be encouraged to walk at 2.86 ft/sec (normal encouraged gait speeds should approach 6.43 ft/sec), with an increase in instability and a leftward loss of balance, not requiring assistance to regain necessitating assistance.

The interactions of the patient and therapist (limbic bonding, as referred to previously within this chapter) became a critical element in the examination. The patient had to trust the therapist that if she followed the therapist's direction in examination, she would not fall or incur additional symptoms outside her control. The therapist, during the evaluation, empowered the patient to take responsibility for her functional movement while making sure the patient was successful if willing to take the risk. This aspect of the therapeutic interaction is a limbic-neutral technique, and its success or failure will be reflected in the motor responses of the patient.

Confirmatory Tests and Measures

- Intact sensation but extreme hypersensitivity to vibratory input (with strong ANS response)
- Normal strength and range of motion

Multiple rests were required throughout the examination to decrease symptomatology (nausea, increased respiration, sweating) to patient tolerance. Testing reproduced all subjective dizziness, and there was a resultant gross instability with loss of balance in the posterior direction, necessitating assistance. Imbalance, nausea, and anxiety were residual for 10 minutes after testing.

CASE STUDY 5-1—cont'd

In the evaluative phase, the working hypothesis after the examination phase was as follows:

- **Diagnoses** as identified by therapist:
 - *Medical*—mixed central and peripheral vestibular presentation without confirmatory medical diagnostics or diagnosis. Further medical workup required.
 - *PT Rehabilitation*²⁹¹—Primary Problem: Practice Pattern 5D: Acquired impairment of the central nervous system; Secondary Problem: Practice Pattern 5A: Primary prevention of falls
 - **Characterized** by (1) SMD with VOR impairment, probable high gain, with gaze instability, (2) central processing impairment, (3) postural control impairment with somatosensory dependence, and (4) limbic high state with autonomic response to testing procedures and frequent rests required.
 - **Prognosis:** Fair for modified community level independence, physiologically complicated by history and chronicity. Improvement intratrial is a positive physiological sign. However, anxiety overlay and history may have psychogenic versus physiological impact on recovery.
 - **Red Flags:** Watch for (1) additional central signs, (2) signs of secondary gain, (3) F²ARV and GAS limbic cascade, or (3) social service issues.

PHASE II: INTERVENTION

1. There are three objectives of the treatment phase driven by findings in the clinical assessment:
 - a. Monitor and manage limbic symptoms through environment change of input systems (vision, auditory, kinaesthetic) with the goal of the limbic network going neutral if possible.
 - b. Maximize sensory integration, central processing, compensatory impairments of the vestibulospinal reflex (balance control) and VOR (gaze control).
 - c. Integrate gains in balance and gaze control into functional activity with and without emotional overlays.
2. Treatment approach:
 - a. Patient-oriented (limbic) approach.

Goal: Maximize internal locus of control and trust; quiet the limbic influence (facilitate limbic neutral) to set an environment appropriate for motor learning and functional change.

Techniques:

 - Awareness and validation of the problem. Provide the patient with objective findings of organic and functional involvement (sensory organization, dynamic visual acuity, and other testing). Many of these patients have been told for years that it is “in their head.” The statement is accurate but the intent is condescending and implies some psychological dysfunction.
 - Awareness of and participation in the plan and approach. The treatment plan should have strong emotional meaning to the patient to turn the “limbic key” to maximize involvement and motivation. It should be goal directed intrasession and intersession. Achieving proper motivation and reward maximizes neuroplastic change.⁶⁵⁹
 - b. The correct patient-therapist pairing for effective execution of the plan. Safe clinician contact may actually be part of the rehabilitation plan, with gradual reduction based on limbic and functional improvements.
 - The correct environment to effect change. Use appropriate voice (timbre, pitch, volume), appropriate pacing (onset of sound or other stimuli), sound, light, consistency, and predictability.
- b. Balance retraining using sensory reorganization (reweighting).

Gaze stability (VOR) retraining

Goal: Appropriate timing and predictability of sensory treatment: “dose” to achieve desired limbic and functional outcomes.

 - Expose the patient to the problem sensory conditions identified during the examination, presenting first the easier conditions and progressing the difficulty and complexity on the basis of patient response. Force the development of sensory integration, compensation, or substitution, as well as the development of new and appropriate movement strategies.
 - Provide for selective attention through predictable, short segments of sensory integrative challenge.
 - Avoid sensory overload through proper exercise prescription (intensity, duration, repetitions, frequency) during sensory integrative treatment.
 - Provide for maximal motor learning environment by keeping the limbic network quiet while achieving the correct balance between error detection and correction versus demotivation through making mistakes.
 - Provide knowledge of performance and knowledge of results frequently. As one example, computerized visual biofeedback provides direct one-on-one feedback of body position in space and motor performance.
- c. Functional activity requires complex integration of balance and gaze control.
 - Gait training at controlled pacing in stable environments, progressing to changing pace within predictable visual environments, to unstable visual environments and variable surface environment.
 - Hippotherapy (an activity meaningful to the patient), at a controlled cadence provided by the animal, provides predictable sensory input (somatosensory, vestibular, auditory, and olfactory), controlled rhythmic visual flow, and neutral warmth in a meaningful, goal-directed activity (as identified by the patient). This can be a very limbic-neutralizing activity when fear is controlled as a factor.
- d. If the patient does not progress in a physiologically normal manner or limbic signs remain unchanged (or increase) then psychological management may take precedent over (or be required before) recovery in

Continued

CASE STUDY 5-1—cont'd

rehabilitation (motor learning and neuroplasticity within the CNS) can be achieved.

- Successful life outcome is affected by early management. The extent to which a mild dizziness problem becomes chronic is dependent mainly on the psychological reaction to the symptoms.²³³
- There are specific management strategies associated with anxiety-type disorders within psychology, including use of medications. One theory of recovery from psychology problems is referred to as exposure. Although exposure is meant to cause habituation of the patient to the triggering events, in our case exposure actually will lead to forced use of the appropriate sensory system(s) as required in activities of daily living.

CONCLUSION

What makes this a clinical problem within the domain of the limbic network is that this woman's limbic network was overriding all other systems. At first glance this person was referred to therapy with typical vestibular and balance dysfunction. She was anything but typical and could not be approached with a "standard protocol," or failure for both the therapist and the patient was inevitable. The role of the patient within this setting was to gain an appreciation and integration of how her vestibular, motor, and limbic networks were interacting and when she went into system overload and why. The therapist's role was to (1) help the patient gain this body awareness, (2) empower the patient with regard to her potential for recovery, (3) design interventions that would nurture patient success, (4) collaborate with the patient on needed interventions regarding practice and novelty within the environment along with consistency of

practice, and (5) allow the patient to improve at a pace her CNS could manage.

After 4 months of intervention the therapist moved and thus did not follow up on the long-term outcome of this case. Although the therapist does not know whether the patient reached her ultimate goals, it was obvious after 4 months that the client was changing in the direction of functional control and participation in life.

The long-term permanent changes that may or may not have occurred with this patient's vestibular, motor, or limbic networks are not known. The essential role of complete history taking and dedication to reality by the therapist is obvious. The therapist's success within this case was dependent on her ability to listen and watch (visually, auditorily, and emotionally [limbic]) as the patient unfolded the mystery of her CNS problems. The patient was the key to successfully unlocking her complex subsystem problems. In the health care world of stress, limited visits, and expected outcomes after intervention, it is far too easy to blame the patient for our failure as clinicians. It is also easy to quickly identify that the patient has problems in other system areas outside our scope of practice and thus infer that it is those areas that are limiting improvement. The difficulty is that all professions are doing the same thing, and the patient is drowning in the repercussions of the waves. Partnering interventions both with other professionals and with the client should optimize an environment that nurtures long-term learning and plastic changes within the CNS. The limbic network drives our attention, our motivation, and our willingness to take risks into unknown environments. How you as a clinician accompany those patients throughout the learning experience will depend on your limbic network as much as theirs.

CHAPTER 6

Psychosocial Aspects of Adaptation and Adjustment during Various Phases of Neurological Disability

ROCHELLE McLAUGHLIN, MS, OTR/L, MBSR, and GORDON U. BURTON, PhD, OTR/L

KEY TERMS

adaptation
adjustment
bonding
coping
family network
loss and grief
mindfulness
problem solving
sexuality
support systems

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe adaptation and adjustment as parts of a flexible and flowing process, not as static stages.
2. Describe elements of the grief process that deal with age, cognition, and developmental level.
3. Integrate the elements of mindfulness, problem solving, loss, cognitive functioning, and coping, as well as significant others' coping and learning styles, into the treatment process to encourage adaptation.
4. Integrate the family of the client and the client's styles of coping into therapeutic treatment strategies to be used in the clinic.
5. Respect aspects of sexuality in treatment and consider them when treating the client.
6. Accept the role of patient advocate and the responsibility to report any abuse. Each clinician is responsible for knowing state law as part of her or his state licensure requirements.

It is a part of the human condition to have intense life experiences. There are a variety of ways in which we can respond and adjust to these kinds of life experiences. Adjusting to a disability is an ongoing process, just as adjusting to all other aspects of life is for everyone. This process of moving forward is a lifelong one. In moving forward with a disability it is important to turn toward and confront the situation, thereby opening up to the potential hidden within the situation. If we turn away and deny the situation, we are at risk of never fully coming to terms with and adjusting to the life experience. Adjusting to a disability is not unilateral. The family and support system must be involved in this process. Therapists may be tempted to treat the impairment in isolation and not be involved in the adjustment process for the individual or their support system. This would be a major mistake. Technicians address the mechanical (technical) aspects of treatment, but clinical professionals must treat the whole person and must be involved in the process of adjustment at all times. It is a fatal flaw to reduce the individual to just the impairment and not see or try to understand the bigger picture with regard to what is really needed during treatment intervention. A technician may obtain good physical results, but if the individual has not adapted to the life-altering event, the physical results may never be maximized. If the individual's support system has not adjusted to the impairment, those individuals may hold the client back from optimal functioning or put unnecessary pressure on the individual simply out of a lack of knowledge. Proper training and practice can allow for the

empowerment of the client and the support system. In this chapter we will pursue topics that cover important aspects of the adjustment process for the individual with a disability and his or her support system.

PSYCHOLOGICAL ADJUSTMENT

In clinical practice, theoretical foundations for adjustment to disability appear to be elusive because they represent a fluid process: all people are constantly changing. This is especially true for people who have recently become physically disabled. They do not reach a certain state of adjustment and stay there but progress through a series of adaptations. Therapists see clients in a crisis state¹⁻⁶ and therefore identify their adjustment patterns from this frame of reference. How well the individual adjusts to the crisis, however, does not necessarily indicate how well he or she will adjust to all aspects of the disability, or the rate of progress from one point of adaptation to another.⁶⁻¹⁵ Disabilities are an unimaginable insult to an individual's self-perception.¹⁶⁻¹⁹ A month or even a year after the injury may not be long enough to put the disability into perspective.^{10,16,17,19-22}

For most people, progressing from the shock of injury to the acceptance of and later adaptation to disability is a process filled with psychological ups and downs. Several authors have discussed the possible stages of adjustment and grieving.^{10,14} The research of Kübler-Ross²³ into death and dying has application to this topic of adjustment to disability. She discussed the concept of loss and grief in relation to life; loss of function may result in just as profound

a reaction. The practice of mindfulness may be important in disengaging individuals from automatic thoughts, habits, and unhealthy behavior patterns and thus could play a key role in fostering informed and self-endorsed behavioral regulation, and adjustment to catastrophic life events.²⁴ Peretz²⁵ and others²⁶⁻²⁸ discuss the grieving process in relation to the loss of role function as well as loss of body function. These losses must be grieved for before the client can fully benefit from therapy or adjust to a changed body and lifestyle. Therapists must be aware that the client can and must deal with the death of certain functional abilities.

Some authors have questioned the concept of stages of adjustment,^{1,29} and call for more empirical research into adaptation and adjustment; this has been started.³⁰ One alternative concept that has been developed is cognitive adaptation theory.³¹ This concept examines self-esteem, optimism, and control. In this theory, if the individual feels good about himself or herself and has an optimistic view of life and a sense of control over life, the individual will adapt to the functional limitations and will participate in life. Cognitive adaptation theory does not consider the organic changes that may take place when brain damage has occurred, but the basic goals are very much worth taking into consideration. These should be examined in relation to the limbic system (see Chapter 5) because limbic involvement is crucial to reaching all goals and plays a key role in establishment of motivation.

The components of successful psychological adjustment to a physical disability (activity limitations) are varied. To bring a client to a level of function that is of the highest quality possible for that individual, therapists must look holistically at the psychosocial aspects and at the adjustment processes involved, evaluate each component, and integrate the processes into the therapeutic milieu to promote growth in all areas. There is much more to evaluation and treatment than just the physical component; the mind and body have incredibly interrelated influences, and both must be understood, evaluated, and treated individually and as a whole.

WE UNDERSTAND MORE ABOUT SUFFERING THAN WE THINK

Clinical professionals have a wellspring of knowledge to draw from beyond their extensive traditional education. We are all human beings, and being human comes with a great deal of innate suffering. If we bring awareness to the fact that we have all suffered in our lives, we may not feel so separate from our clients. We may realize that we have more to offer our clients than just the knowledge we have gained about their disability and how we might help them gain function. The more we allow ourselves to slow down and be present with suffering—our own or that of another—the more we will be able to be open to the mystery and joy of our lives just as they are without requiring them to be any different.³² It may be our lifetime's journey to be servants of the healing arts; this is our job, and it also takes enormous skill and bravery to bear witness to the full catastrophe of the human condition.³² One of the benefits of our profession is the stimulus to examine our lives through the experiences of others. This can improve our function and help us grow as professionals and individuals, but if we are not open to the clients' experiences we may not find a reason to examine and grow from our own experiences.

If we haven't endured great suffering personally, we have borne witness to it—"9/11" is a perfect example of this. If we acknowledge this fact, then maybe we can acknowledge that we are more connected to our clients than we once thought and that we have more to offer our clients in terms of their ability to adjust to their disability than we once imagined.

AWARENESS OF PSYCHOLOGICAL ADJUSTMENT IN THE CLINIC, SOCIETY, AND CULTURE

Working with individuals with functional limitations requires that we cultivate a holistic and all-encompassing perspective: to visualize how they might best participate within their own homes and communities, and in the context of their society and a given time. This is a dynamic and constantly changing process. The clinician must develop an intervention that will appropriately stimulate the individual and all their potential caregivers to maximize the potential for the highest-quality life possible. The skilled clinician initially evaluates the individual's physical and cognitive capabilities depending on the type of functional limitations. The more subtle psychological aspects of the client's ability to function need to be assessed at some level. These include the individual's support system and/or family network and its ability to adjust to the imminent changes in lifestyle. It would be a tragic situation for a clinician to ignore the individual's psychological adjustment or consider it to be less important in any way.^{19,33-36}

Livneh and Antonak³⁷ have introduced a consolidated way to look at adaptation as a primer for counselors, which should be examined by therapists. They use some of the same basic concepts, such as stress, crisis, loss and grief, body image, self-concept, stigma, uncertainty or unpredictability, and quality of life, to frame their approach. They also consider the concepts of shock, anxiety, denial, depression, anger and hostility, and adjustment in a format that is usable by the therapist.

Livneh and Antonak³⁷ mention that one of the aspects that the therapist must watch out for is a form of coping called *disengagement*. This style of coping may be demonstrated through denial or avoidance behavior that can take many forms. It can result in substance abuse, blame, or just refusal to interact. Research regarding people with head injuries has demonstrated that if a premorbid coping style for a person was to use alcohol or other drugs, the client may revert to these same styles of coping, which can result in poor physical and emotional rehabilitation.³⁸ It is important to help the individual out of this quagmire. The skills of a therapist are likely not enough to do this in the short time that the client is in treatment, so a referral to social work, psychology, or psychiatry is required to help support the long-term process. It is still the therapist's job to understand the process of adjustment, the indications regarding how an individual is adjusting, key concepts for how to engage with an individual who is adjusting, and how to set personal boundaries so that the clinician is less likely to be overwhelmed by the process of adjustment and disability. In light of all this, it is still the primary job of the therapist to help promote and maximize the engagement in functional activities. These activities are behaviors that must be goal oriented (patient,

family, and therapist driven), demonstrating problem solving and information seeking and involving completion of steps to positively move forward into life with the disability and to maximize independence (promoting function).

The rest of this section introduces the reader to some of the psychological change components that may be assessed and acknowledged. The last section will attempt to demonstrate possible ways that these components can be taken into account as an aspect of therapy.

Growth and Adaptation

The clinician must keep in mind the context from which the client is coming. Just days or even hours ago the individual may have been going about daily life without difficulty. The trauma may be multifaceted: (1) physical trauma, (2) emotional trauma occurring to the individual's support system, and (3) trauma of each of these systems interacting (the support system trying to protect the individual, and the client trying to protect the support system). The interaction of these multifaceted components of the trauma may lead to posttraumatic distress syndrome. This syndrome usually happens within the first 6 months after the injury. This syndrome may be observed more often in women³⁹ but because of cultural barriers it can be hidden in men. It happens more often when there has been a near-death situation.^{40,41} The client may blame others, try to protect others, or be so self-absorbed that little else in the world may be seen or heard. It may be helpful to get psychological help for the individual early in therapy if this is preventing optimal outcomes or creating obstacles in therapy.^{4,15,42-45}

It is the therapist's job to develop a trusting relationship with the client. Through this relationship the individual can be guided to focus on the goals of therapy and work on a positive perspective about the future. One of the errors of the medical system is that of focusing on the disease outcomes and pathology and not on the person and the positive capabilities still within the individual's grasp.¹⁹ This focus on the negative or loss may cause the individual to see only the injury, disease, or pathological condition and nothing else. In a Veterans Administration hospital, spouses of people with spinal cord injuries formed a group in which the group's focus was on why the partners got married in the first place; the group never looked at the physical limitations as disabling. After a little while people came to the conclusion that they did not marry their spouses for their legs and the fact that the legs no longer worked was not a major issue after all. This started the decentering from the medical disability model and the focus started to be placed on the people and the families' future. If we can help clients focus on their functions and not their dysfunctions, the effect of therapy after treatment will be much better. More work needs to be done to help clients see the potential they will have in the future to live their lives with the highest quality possible.^{34,46-50} The World Health Organization developed a model that differentiates the disease pathology model of medicine and focuses on individuals' activities in life and the ability to participate in those interactions. This model, the International Classification of Functioning, Disability and Health (ICF), has been enthusiastically accepted by the therapy world, and the professions of both occupational and physical therapy use it as a reference model for practice.

Focusing on how to participate, move, and function in the world is one of the keys to helping the client and the family work toward its future.^{33,49,51-54}

The therapist needs to help the client focus on the direction of treatment objectives and to demonstrate how therapy translates into meeting the client's goals.^{19,55} To discover the client's true goals, the therapist must gain the trust of the client and establish sound lines of communication. Distrust from health professionals may obstruct the adjustment process and lead to negative consequences.⁵⁶ Whenever possible, the client's support system should be enlisted to help establish realistic support for the client and the goals of both the client and the family. It has been found that if the client trusts the health professional, the client will be more adherent and will seek assistance when it is needed (see Chapter 5 for additional information).^{57,58}

A New Normal

When we experience a decline in our ability to carry out our everyday routine tasks, regardless of the cause of our "disability," we may experience incredible degrees of despair. Many societies emphasize a very specific idea of what it means to be normal. There doesn't appear to be a great deal of flexibility in what this standard of normal is, regardless of one's cultural background. When an individual fails to live up to or no longer fits this norm, there can exist a tremendous amount of mental and emotional suffering. Because our bodies and minds are so intricately connected, our physical being is adversely affected by the mental and emotional anguish. On top of what the individual may already be experiencing physically, suddenly there is another layer of mental-physical anguish that is far too easily ignored and unattended to by clinical professionals. However, once we are aware of the multifaceted potential for human suffering with regard to adjusting to a disability, we may be empowered to assist the individual with a nonlinear, multifaceted approach. Researchers and theorists from various psychotherapy traditions have begun to explore the potential value of the therapeutic relationship by making direct references to different levels of validation as a means of demonstrating warmth, genuineness, empathy, and acceptance and reiterate how important it is for therapists to reflect back to the patient that their feelings, thoughts, and actions make sense in the context of their current experience. The therapist articulates an expectation that the treatment collaboration will be effective in an attempt to convey hope and confidence in their ability to work together.⁵⁹

We can guide our clients in identifying a new normal for themselves, all the while allowing them and their support system to grieve the loss of the old normal. As the Harvard psychologist Ellen Langer described in her book *Mindfulness*, "if we are offered a new use for a door or a new view of old age [or disability], we can erase the old mindsets without difficulty."⁶⁰ We can offer our clients a new view of themselves by showing them what they are capable of as they rebuild their lives. We can also help them acknowledge what is present in this moment and what the reality of the situation is. This does not have to be a problem to be suffered over but is a situation to be dealt with carefully and fully in the present moment. A woman who has lived with multiple sclerosis for over 30 years described how the relief of suffering does not require restoring physical function to

some perceived level of normality. “Suffering is relieved to the extent that patients can learn to integrate bodily disorder and physical incapacity into their lives, to accommodate to a different way of being” (p. 591).⁶¹ According to research by De Souza and Frank,⁶¹ their subjects with chronic back pain expressed regret at the loss of capabilities and distress at the functional consequences of those losses. They found that facilitating “adjustment” to “loss” was more helpful than implying the potential for a life free of pain as a result of therapeutic interventions.

Guiding the individual through practice and repetition of basic functional activities will allow the client to identify for himself or herself how to live successfully in this world again and cultivate this “different way of being.” At the same time we can encourage these clients to mindfully plan for and visualize their future (see practice later) during specific times of their day so that their minds are not in constant worry mode or rehearsing, which can cause a great deal of anxiety about the future. We can assist our clients in planning for that future, especially in a medical environment where shorter rehabilitation stays are the norm.

Without any need to apologize for their loss, just simply being with them in the moment in a nonjudgmental way and allowing them to grieve can be a powerful tool for healing. Acknowledging the loss and the suffering may help clients move forward with their lives in a new way. “Acceptance [of what is] doesn’t, by any stretch of the imagination, mean passive resignation. Quite the opposite. It takes a huge amount of fortitude and motivation to accept what is—especially when we don’t like it—and then work wisely and effectively as best we possibly can with the circumstances we find ourselves in and with the resources at our disposal, both inner and outer, to mitigate, heal, redirect, and change what can be changed.”⁶²

Practice: Mindful Planning and Visualization of Future

- Find a time when you are alone; you need only a few minutes every day for this practice.
- Allow this time to be specifically for future planning and visualization, not worrying.
- If you find yourself worrying about the future at other times during the day, acknowledge that there will be a specific time devoted to planning and visualizing. Worrying throughout the day will bring a great deal of mental anguish during times when you need to focus attention on an important task or rehabilitation intervention.
- Use a journal to record thoughts and ideas on paper so that the thoughts do not have to stay in the mind and be rehearsed. Write down concerns as well as plans.
- Try to let go of planning during daily activities and tasks until the next scheduled Mindful Planning Session, or, if necessary, allow this moment to be the next planning session but be sure to stop whatever else you are doing and be fully present in the planning process.

Societal and Cultural Influences

Culture, subcultures, and the culture and beliefs of the given family are all aspects of the client that the therapist must be aware of.^{22,52,63-69} This concept gets into the beliefs about the world and maybe a belief about the cause of the disability or at least how the client is viewing the disability. Asking “why

do you think this happened to you?” can lead to an enlightening experience. “Causes” may range from “God is punishing me” to “I deserved it” to “life is against me.”

From an early age, people in our society are exposed to misconceptions regarding the disabled person.⁷⁰⁻⁷³ If in the therapeutic environment, however, the client and family have their misconceptions challenged constantly, they may start reformulating their concept of the role of the disabled person. As this process progresses, therapists and other staff can help make the expectations of the disabled person more realistic. Therapists can schedule their clients at times when they will be exposed to people making realistic adjustments to disabilities. Use of individuals who have been successfully rehabilitated as staff members (role models) can help to dispel the misconception that people with disabilities are not employable.⁷⁴⁻⁷⁶

This process of adaptation to a new disability can be considered as a cultural change from a majority status (able bodied) to a minority status (disabled). Part of the adaptation process can be considered as an acculturation process, and the therapist can help facilitate this process.^{16,72,77,78}

The cultural background of the individual also contributes to the perception of disability and to the acceptance of the disabled person. Trombly⁷⁹ states that perception and expression of pain, physical attractiveness, valuing of body parts, and acceptability of types of disabilities can be culturally influenced. One’s ethnic background can also affect intensity of feelings toward specific handicaps, trust of staff,⁷⁹ and acceptance of therapeutic modalities.⁸⁰⁻⁸⁴

The successful therapist will be sensitive to the cultural values of the client and will attempt to present therapy to the client in the most acceptable way. For example, in the Mexican culture it is not polite to just start to work with a client; rapport must first be established. Sharing of food may provide the vehicle to accomplish rapport. Thus, the therapist might schedule the first visit with a Mexican client during a coffee break. The therapist must remember that the dysfunctional client may be the one who can least be expected to adjust to the therapist and that the therapist may need to adjust to the client, especially in the early stages of therapy.

Gaining trust is one of the crucial links in any meaningful therapeutic situation.^{58,85,86} Trust will create an environment that facilitates communication, productive learning, and exchange of information.^{75,86} Trust is important in all cultures and will be fostered by the therapist who is sensitive to the needs of the client. This sensitivity is necessary with every client but will be manifested in many different ways, depending on the background and needs of the individual in therapy. A client of one culture may feel that looking another person in the eyes is offensive, whereas in another culture refusal to look into someone’s eyes is a sign of weakness or lack of honesty (shifty eyed).⁸⁷ Thus although it is impossible to know every culture or subculture with which the therapist may come into contact, the therapist must attempt to be sensitive to the background of the client. Even if the therapist knows the cultural norms, not every person follows the cultural patterns, and thus every client needs to be treated as an individual in the therapeutic relationship. It should be the therapist’s job to be sensitive to the subtle nonverbal and verbal cues that indicate the level of trust in the relationship. The therapist will obtain this information

by being open to the client, not open to a textbook. The client is the owner of this information and will share it with everyone he or she trusts.

Trust is often established in the therapeutic relationship through physical activities. The act of asking a client to transfer from the chair to the bed can either build trust or destroy the potential relationship. If the client trusts the therapist just enough to follow instructions to transfer but then falls in the process, it may take quite some time to reestablish the same level of trust, assuming that it can ever be reestablished. This trusting relationship is so complex and involves such a variety of levels that the therapist should be as aware of attending to the client's security in the relationship as to the physical safety of the client in the clinic.^{58,85} If the client believes that the therapist is not trustworthy in the relationship, then it may follow that the therapist is not to be trusted when it comes to physical manipulation of a disabled body. If the client does not know how to use the damaged physical body and thus cannot trust the body, then lacking trust in the therapist will only compound the stress of the situation.^{58,85,88} Chapter 8 provides more information on the neurological components of this interaction during the intervention process.

The client's culture may be alien to the therapist, even though both the clinician and client may be from the same geographical region. A client's problems of poverty, unemployment, and a lack of educational opportunities^{76,86,89,90} can all result in the therapist and client feeling that therapy will be unsuccessful, even before the first session has begun. Such preconceived concepts held by both parties may not be warranted and must be examined. These preconceived concepts can be more reflective of failure of rehabilitation than any physical limitation of the client.

Cultural and religious values may also result in the client feeling that he or she must pay for past sins by being disabled and that the disability will be overcome after atonement for these sins. Such a client may not be inclined to participate in or enjoy therapy. The successful therapist does not assault the client's basic cultural or religious values but may recognize them in the therapy sessions. If the therapist feels that the culturally defined problems are impeding the therapeutic process, the therapist may offer the client opportunities to reexamine these cultural "truths" in a non-judgmental way and may help the client redefine the way the physical limitations and therapy are seen.⁹¹ Religious counseling could be recommended by the therapist, and follow-up support in the clinic may be given to the client to view therapy not as undoing what "God has done" but as a way of proving religious strength. Reworking a person's cultural and religious (cognitive) structure is a sensitive area, and it should be handled with care and respect and with the use of other professionals (social workers and religious and psychological counselors) as appropriate.

The hospital staff can be encouraged to establish groups in which commonly held values of clients can be examined and possibly challenged.^{16,91-97} Such groups can lead the client to a better understanding of priorities and may help the person see the relevance of therapy and the need to continue the adjustment process. This can also prepare the client to better accept the need for support groups after discharge. The therapist may be able to use information from such group sessions to adjust the way therapy sessions

are presented and structured to make therapy more relevant to the client's values and needs. Value groups or exercises⁹⁸ can be another means used by the therapist for evaluation and understanding of the client.

Beliefs and values of cultures and families can play a profound role in the course of treatment. Such things as physical difficulties, which can be seen, are usually better accepted than problems that cannot be seen, such as brain damage that changed an individual's cognitive abilities or personality.⁹⁹ A person with a back injury may be seen as lazy, whereas a person with a double amputation will be perceived as needing help. At the same time, in some cultures a person who has lost a body part may be seen as "not all there" and should be avoided socially. Therefore being attuned to the culture and beliefs of the client is imperative in therapy. The reader is encouraged to refer to texts on cultural issues in health care such as *Culture in Clinical Care* by Bonder, Martin, and Miracle¹⁰⁰; *Cultural Competence in Health Care: A Practical Guide* by Rundle, Carvalho, and Robinson¹⁰¹; and *Caring for Patients from Different Cultures* by Galanti¹⁰² for more detailed discussions on how culture and beliefs affect health care.

Establishment of Self-Worth and Accurate Body Image

"The true value of a human being is determined primarily by the measure and the sense in which he has attained liberation from the self."

—Albert Einstein

Self-worth is composed of many aspects, such as body image, sexuality, and the ability to help others and to affect the environment. The body image of a client is a composite of past and present experiences and of the individual's perception of those experiences. Because body image is based on experience, it is a constantly changing concept. An adult's body image is substantially different from the body image of a child and will no doubt change again as the aging process continues. A newly disabled person is suddenly exposed to a radically new body, and it is that individual's job to assess the body's capabilities and develop a new body image. Because the therapist is at least partially responsible for creating the environmental experiences from which the client learns about this new body, the therapist must be aware of the concept. In the case of an acute injury, the client has a new body from which to learn. The therapist can promote positive feelings as the therapist instructs the client how to use this new body and to accept its changes.^{1,16,20,27,103,104}

Because in "normal" life we slowly observe changes in our bodies, such as finding one gray hair today and watching it take years for our hair to turn totally white, we have the luxury of slowly adapting to the "new me." Change usually does not happen quite so slowly and "naturally" when trauma or a disease affects the nervous system. This sudden loss of function creates a void that only new experiences and new role models can fill.

The loss of use of body parts can cause a person to perceive the body as an "enemy" that needs to be forced to work or to compensate for its disability. In all cases the body is the reason for the disability and the cause of all problems. The need for appliances and adaptive equipment can create a sense of alienation and lack of perceived "lovability" resulting from

the “hardness of the hardware.” People tend to avoid hugging someone who is in a wheelchair or who has braces around the body because of the physical barrier and because of the person’s perceived fragility; a person with physical limitations is certainly not perceived as soft and cuddly.^{20,27,52,102,103} Both the perception that these individuals are not lovable and their labored movements can sap the energy of the disabled and discourage social interaction or life participation. To accept the appliances and the dysfunctional body in a way that also allows the disabled person to feel loved is surely a major challenge.

In the case of a person who will be disabled for the long term, such as the person with cerebral palsy or Parkinson disease, the therapist is attempting to teach the client how to change the previously accepted body image to one that would allow and encourage more normal function. In short, the therapist has two roles. One role is to help lessen the disabled body image. The second is to teach a functional disabled body image to a newly disabled person. The techniques may be the same, but in both cases the client will have to undergo a great amount of change. The person with a neurological disorder or neurologically based disability may assume that he or she will not be capable of accomplishing many things with his or her life. The therapist is in a unique position to encourage development of and maximize the client’s level of functional ability. The individual may then expect more of himself or herself. The newly disabled person must change the expectations; however, he or she has little concept of what is realistic to expect of this new body. At this point, role models can be used to help shape the client’s expectations. If the client is unable to adjust to the new body and change the body image and self-expectations, life may be impoverished for that individual. Pedretti¹⁰⁵ states that the client with low self-esteem often devalues his or her whole life in all respects, not just in the area of physical dysfunction.^{1,16,20,27,103,104}

One way the client can start exploring this new body is by exploring its sensations and performance. Dr. Jon Kabat-Zinn developed a guided “body scan” meditation that can help individuals learn how to become more connected and in tune with the sensations of the body.⁶² This kind of practice is about learning to pay attention to the body in a new way and can be very helpful in developing an accurate body image and improve self-awareness. The client with a spinal cord injury may also use the sensation of touch to “map out” the body to see how it reacts.¹⁰⁶ They may ask themselves the following questions: Is there a way to get the legs to move using reflexes? Can positioning the legs in a certain way aid in rolling the wheelchair or make spasms decrease? What, if anything, stimulates an erection or lubrication? Such exploration will start the client on the road to an informed evaluation of his or her abilities.

The therapist’s role is to maximize the client’s perceptions of realistic body functioning. Exercises can be developed that encourage exploration of the body by the individual and, if appropriate, the significant partner. Functioning and building an appropriate body image will be more difficult if intimate knowledge of the new body is not as complete as before injury.⁹ The successes the client experiences in the clinical setting coupled with the client’s familiarity with his or her new body will result in a more accurate body image and will contribute to the client’s feelings of self-worth.

The last aspect of self-worth is often overlooked in the health fields. This aspect is the need that people have to help others.¹⁰⁷ People often discover that they are valuable through the act of giving. Seeing others enjoy and benefit from the individual’s presence or offering increases self-worth. Situations in which others can appreciate the client’s worth may be needed. Unless the client can contribute to others, the client is in a relatively dependent role, with everyone else giving to him or her without the opportunity of giving back. Achieving independence and then reaching out to others, with therapeutic assistance if necessary, facilitates the individual’s more rapid reintegration into society. The therapist should take every opportunity to allow the client to express self-worth to others through helping.

The ability to expand one’s definition of oneself is a key factor in adjusting to a disability. Expanding the definition of oneself in terms of all the roles and responsibilities one has can help the individual comprehend the enormity of who he or she is. The individual may begin to understand how he or she is so much greater than just the job he or she once performed and so much greater than the role he or she once played. This practice can cultivate understanding of how complex our species is and how much we have to offer the world, differently abled or not (see journal activity, Box 6-1).

Sense of Control

“Oh, I’ve had my moments, and if I had to do it over again, I’d have more of them. In fact, I’d try to have nothing else. Just moments, one after another, instead of living so many years ahead of each day.”

—*Nadine Stair, 85 years old, Louisville, Kentucky*

As Drs. Roizen, and Oz stated in their book *You: The Owner’s Manual*, we can control our health destiny.¹⁰⁸ Although we can’t always control what happens to us (no matter how fit we are), there are some things we can control: our attitude, our determination, and our willingness to take our own health into our own hands.¹⁰⁸

Adjusting to a disability can make clients feel as though they have very little control over their lives; they may feel

BOX 6-1 ■ JOURNAL ACTIVITY

Write down three words that someone who loves you would choose to describe you. Choose qualities that you think others appreciate about you, such as *intelligent, funny, kind, organized*.

Write down the ways that you express those qualities in your life. Maybe it is when you garden, write, draw, or listen.

Write down your ideal vision of the world. Maybe it is, “I envision a world that is free of violence” or “where everyone has access to knowledge about how to keep our oceans clean” or “where children are well cared for.”

Put it all together in one statement: “I will use my intelligence, humor, organization, and kindness, through writing, drawing, gardening, and listening to help create a world that is peaceful, where children are well cared for, and where the oceans are clean.” Then do it!

helpless, as though their health is in everyone else's hands but their own. This feeling can cause incredible suffering and emotional anguish on top of their physical or cognitive disability. If we focus solely on treating the disability and ignore what may be going on for our clients mentally and emotionally, we may be creating even more suffering for them. Clinical professionals have the opportunity to guide their clients toward a new way of relating to their disability by focusing on what they do have control over as well as identifying ways in which they may relate differently to those situations over which they do not have control.

Dr. Jill Bolte-Taylor says this eloquently in a passage from her book:

"I've often wondered, if it's a choice, then why would anyone choose anything other than happiness? I can only speculate, but my guess is that many of us don't exercise our ability to choose. Before my stroke, I thought I was a product of my brain and had no idea that I had some say about how I responded to the emotions surging through me. On an intellectual level, I realized that I could monitor and shift my cognitive thoughts, but it never dawned on me that I had some say in how I perceived my emotions. . . . What an enormous difference this awareness has made in how I live my life."¹⁰⁹

As Dr. Bolte-Taylor describes, all of us have the choice to be in relation to the present moment fully, or we can allow our thoughts and emotions to "take us for a ride" as though we were on automatic pilot.¹⁰⁹ If we allow our minds and emotions to take over our experience of the present moment, we can easily be dragged along into rehashing our past events that led up to the disability, which can create more suffering and emotional anguish. We also may be rehearsing what our lives will be like without allowing the dust to settle, without waiting until we have a clearer picture of what implications the disability may have for us. An unacknowledged rehashing and rehearsing can create an incredible sense of lack of control over one's life, thereby increasing anxiety and depression. Approximately 70% of our thoughts in any particular waking state can be considered to be daydreams, and they can often be unconstructive.¹¹⁰ In an experience sampling method, Klinger and his colleagues found that "active, focused problem-solving thought"¹¹¹ made up only 6% of the waking state. According to Baruss, "it would make more sense to say that our subjective life consists of irrational thinking with occasional patches of reason"¹¹⁰ while we are participating in our daily activities. Especially when one is participating in menial, basic self-care activities, our mind is often in another place. If an individual is frequently disconnected from the present moment, tending to ruminate over the past or future events, he or she may experience significant negative effects from this distraction. Rumination, absorption in the past, rehashing, or fantasies and anxieties about the future can pull one away from what is taking place in the present moment. Awareness or attention can be divided, such as when people occupy themselves with multiple tasks at one time or preoccupy themselves with concerns that detract from the quality of engagement with what is focally present, and this can increase anxiety and depression.¹¹²

According to Drs. Oz and Roizen,¹⁰⁸ these emotions can cause high blood pressure, as well as disrupting the body's normal repair mechanism, and also constrict our blood vessels, making it even harder for enough blood to work its way through the body. They go on to say that learning relaxation techniques such as yoga and meditation can help us handle these damaging feelings in a healthier way. We know now that these mind states affect our bodies profoundly—for example, a feeling of helplessness appears to weaken the immune system.¹⁰⁸ If we can teach our clients to be mindful of and pay attention to their "mind states"—also known as "thoughts"—at any given moment during therapeutic intervention, we may be able to encourage a greater sense of control and facilitate greater mental and emotional adjustment to the individual's disability. According to a 2008 article by Ludwig and Kabat-Zinn in *JAMA*, "the goal of mindfulness is to maintain awareness moment by moment, disengaging oneself from strong attachment to beliefs, thoughts, or emotions, thereby developing a greater sense of emotional balance and well-being."¹¹³ Anat Baniel, in her book *Move into Life*, describes how research shows that the moment we bring attention and awareness to our movements moment by moment, the brain resumes growing new connections and creating new pathways and possibilities for us.¹¹⁴

According to a research study by Dr. Jon Kabat-Zinn¹¹⁵ of the Stress Reduction Program at the Center for Mindfulness in Medicine, Health Care, and Society, the practice of mindfulness meditation used by chronic pain patients over a 10-week period showed a 65% reduction on a pain rating index. Large and significant reductions in mood disturbance and psychiatric symptoms accompanied these changes and were stable on follow-up. Another study looked at brain imaging and immune function after an 8-week training program in mindfulness meditation.¹¹⁶ The study demonstrated that this short program in mindfulness meditation produced demonstrable effects on brain and immune function. The results of a clinical intervention study by Brown and Ryan¹¹² showed that higher levels of mindfulness were related to lower levels of both mood disturbance and stress before and after the Mindfulness-Based Stress Reduction (MBSR) intervention. Increases in mindfulness over the course of the intervention predicted decreases in these two indicators of psychological disturbance. Evidence has indicated that those faced with a life-threatening illness often reconsider the ways in which they have been living their lives, and many choose to refocus their priorities on existential issues such as personal growth and mindful living.¹¹⁷

These findings suggest that meditation may change brain function and immune function in positive ways. "Meditation" as it is taught in this 8-week program is simply an awareness and attention training: a way of learning how to pay attention in the present moment to our thoughts and emotions and coming to understand how our thoughts and emotions affect our bodies. It may sound simple but actually can be incredibly challenging. However, an instant stress reliever can be bringing awareness to the breath. Deep breathing can act as a mini-meditation and from a longevity standpoint is an important stress reliever.¹⁰⁸ Shifting to slower breathing in times of tension can help calm us and allow us to perform, whether mentally or physically, at higher levels.¹⁰⁸

Another study, focused on Coping Effectiveness Training (CET), consisted of weekly 60-minute psychoeducational group intervention sessions focused into six topic areas and was adapted from the protocol Coping Effectively with Spinal Cord Injury.¹¹⁸ The treatment protocol was structured to provide education and skill building in areas of awareness of reactions to stress; situation appraisal; coping strategy choice; interaction among thoughts, emotions, and behaviors; relaxation; problem solving; communication; and social support.¹¹⁹ There was a significantly positive correlation between the learned coping strategies and the disabled individual's ability to adjust in a healthy way.

Hope and Spiritual Aspects to Adjustment

Through great suffering there is incredible potential for us to transcend the mental and emotional limits of the physical body. As clinical professionals we need to be aware of this capability. As described by Dr. E. Cassel in the *New England Journal of Medicine*, “Transcendence is probably the most powerful way in which one is restored to wholeness after an injury of personhood. When experienced, transcendence locates a person in a far larger landscape. The sufferer is not isolated by pain but is brought closer to a transpersonal source of meaning and to the human community that shares those meanings. Such an experience need not involve religion in any formal sense; however, in its transpersonal dimension, it is deeply spiritual.”¹²⁰ Parker Palmer, a writer and teacher, describes it this way: “Traacherous terrain, bad weather, taking a fall, getting lost—challenges of that sort, largely beyond our control, can strip the ego of the illusion that it is in charge and make space for true self to emerge.”¹²¹ Eckhart Tolle describes the ego as complete identification with form—physical form, thought form, emotional form.¹²² The more we are identified with the physical realm, the more we will suffer when our attachment to stuff or “form” becomes torn.

“For all of us, our willingness to explore our fears, to live inside helplessness, confusion, and uncertainty, is a powerful ally. Acknowledging our repeated exposure to human suffering—our own and others’—and the seductive draw of numbness and melancholy that provides temporary escape is necessary if we are to be renewed.”³² Dr. Santorelli goes on to say that “there is no way out of one’s inner life, so one had better get into it.”³² “On the inward and downward spiritual journey, the only way out is in and through.”¹²¹

Practice: The Willingness to Embrace What Is

1. Become aware of the moments when “resistance to what is” is noticed. This may manifest itself as anxiety, sadness, fear, depression, anger.
2. As soon as anger arises (for example), notice how it manifests itself physically in the body. It may be tension in the muscles, a quickened or palpating heartbeat, or sweating.
3. Note what the sensation feels like in the body without trying to make the moment different than it is. Acknowledge whatever is present in the moment.
4. Note that we are not the anger, we are the awareness of it.
5. Note what the awareness does. Journal any thoughts or feelings about the practice.

Dr. Jon Kabat-Zinn, in his book *Coming to Our Senses*, states, “It seems as if awareness itself, holding the sensations

without judging them or reacting to them, is healing our view of the body and allowing it to come to terms, at least to some degree, with conditions as they are in the present moment in ways that no longer overwhelmingly erode our quality of life, even in the face of pain or disease.”⁶²

“Mystery surrounds every deep experience of the human heart: the deeper we go into the heart’s darkness or its light, the closer we get to the ultimate mystery of God [the Universe].”¹²¹

Religious and spiritual beliefs can be assistive in the process of adjusting to a disability. Johnstone, Glass, and Oliver highlight that religion and spirituality are important coping strategies for persons with disabilities.⁶⁷ According to Dr. Jill Bolte-Taylor in her book *My Stroke of Insight: A Brain Scientist’s Personal Journey*, “Enlightenment is not a process of learning but a process of unlearning.”¹⁰⁹ Western society rewards the skills of the “doing” left brain much more than the “being” right brain, which can significantly hinder our process of spiritual growth. The focus of our lives becomes more about obtaining positions, roles, and “stuff.” We begin to identify ourselves with all of this when in reality the positions, roles, and stuff can be taken from us at any moment. “When we are obsessed with . . . productivity, with efficiency of time and motion, with projecting reasonable goals and making a beeline toward them, it seems unlikely that our work will ever bear fruit, unlikely that we will ever know the fullness of spring in our lives.”¹²¹

There is a much deeper definition of ourselves that goes beyond all of the material possessions and the roles that we may ever play. According to Eckhart Tolle,¹²² when forms that we identify with, that give us a sense of self—such as our physical bodies—collapse or are taken away, it can lead to a collapse of the ego, because ego is identification with “form.” When there is nothing to identify with anymore, who are we? When forms around us die, or death approaches, Spirit is released from its imprisonment in matter. We can finally understand that our essential identity is formless, spiritual.¹²² Cultivating greater understanding of these concepts and delving more into the spirit can provide a great deal of relief for all of us who are suffering.

There is a wonderful quote by former Secretary-General of the United Nations U Thant, as he describes how he envisions the spiritual:

“Spirituality is a state of connectedness to life.

It is an experience of being, belonging and caring.

It is sensitivity and compassion, joy and hope.

It is harmony between the innermost life and the outer life or the life of the world and the life of the universe.

It is the supreme comprehension of life in time and space, tuning of the inner person with the great mysteries and secrets that are around us.

It is the belief in the goodness of life and the possibility for each human person to contribute goodness to it.

It is the belief in life as part of the eternal stream of time, that each of us came from somewhere and is destined to somewhere, that without such belief there could be no prayer, no meditation, no peace, and no happiness.”¹²³

Spirituality is something that provides hope, connection with others, and reason or meaning of existence for many (if not most) people. It is amazing that the medical community has been slow to accept the power of spirituality because this is an area that gives meaning to so many peoples' lives. Spirituality has been linked to health perception, a sense of connection with others, and well-being.^{66,67,124-130}

Anything that helps the client put the disability into perspective and helps the client move on with life in a healthy way is good. The Western medical system was based on diagnosis of pathology and how best to cure disease, but there has been a slow but fruitful shift toward a more holistic view of the healing process and prevention. The National Institutes of Health now has a National Center for Complementary and Alternative Medicine (<http://nccam.nih.gov>). Almost every major hospital and university in the country now has an integrative health center (e.g., <http://stanfordhospital.org/clinicsmedServices/clinics/complementaryMedicine> and www.osher.hms.harvard.edu). Although this small but steady shift in the focus of medicine has gained momentum, one of the dangers of the medical system is still the entrapment in pathology to the point where the client may not see anything but his or her pathology. Spirituality can help the client and the family to see that there is more to life than pathology, stimulate interaction with others, put the functional limitations in perspective, give meaning to life (and the disability), and give the person hope and a sense of well-being.* This is what we all want for the client and the family. Refer to Chapters 1, 5, and 39 for additional content.

Adjustment Using the Stage Concept

Each person has his or her own coping style, and each should be allowed to be unique. Kerr¹³³ describes five possible stages of adjustment:

Shock: "This really isn't happening to me."

Expectancy for recovery: "I will be well soon."

Mourning: "There is no hope."

Defense: "I will live with this obstacle and beat it."
(healthy attitude) "I am adjusted, but you fail to see it."
(neurotic attitude)

Adjustment: "It is part of me now, but it is not necessarily a bad thing."

In light of current research, it is important for the therapist to realize that these are not lockstep stages and are to be thought of as concepts to help with the understanding of common reactions of all individuals.^{134,135} Some individuals may settle in one stage for quite some time or may even skip stages altogether, whereas others may move through the stages quickly. This is an incredible individual process.

Shock

The individual in shock does not recognize that anything is actually wrong. The client may totally refuse to accept the diagnosis. The client may even laugh at the concern expressed by others. This stage is altered when the person has an opportunity to test reality and finds that the physical or cognitive condition is actually limiting the ability to participate in functional activities. If this stage continues, it may

signify either a lack of mental health or an inability to cognitively realize the situation.

Expectancy for Recovery

The client in the stage of expectancy for recovery is aware that he or she is disabled but also believes that recovery will be quick and complete. The person may look for a "miracle cure" and may make future plans that require total return of function. Total recovery is the only goal, even if it takes a great deal of time and effort to achieve. Key signs of this stage are resentment of loss of function and the feeling that the whole body or mind is necessary to do anything worthwhile. The staff can stimulate a change from this stage by giving clear statements to the client that the damage is permanent (if in fact that is true), by transferring the person home or to the rehabilitation unit, or by discontinuing therapy. Any one of these occurrences can help make the client realize the permanence of the disability. It is also important to not take away an individual's hope. In the case of an individual who has experienced a stroke or a brain injury, we know now that the brain is capable of repairing itself throughout a lifetime—though we need to be clear that we do not know how much recovery will occur, if any. This all depends on the severity of the damage and the lifestyle of the client—for example, smoking, stress, and/or lack of participation in meaningful activity, all of which impede progress.

Mourning

During the stage of mourning the individual feels that all is lost, that he or she will never achieve anything in life. Suicide is often considered. The individual may feel that characteristics of the personality (such as courage or will) have also been lost and must be mourned as well. Thus, motivation to continue therapy or the will to improve may be impeded. The prospect of total recovery may no longer be held, but at the same time there appears to be no other acceptable alternative. This feeling of despair may be expressed as hostility, and as a result therapists may view the individual as a "problem patient." It is possible for a client to remain at this stage with feelings of inadequacy, dependence, and hostility. However, it is also possible for therapeutic intervention to facilitate movement to the next stage by creating situations in which the client may feel that "normal" aspirations and goals can be achieved. In this circumstance, normal would not include such "low-level" activities as dressing or walking; these are all activities that were taken for granted before the injury. Normal, though, would include performing the job the client was trained to do. Such activities would also include playing with or caring for a child or family. This would be seen as self-actualization by Maslow.¹³⁶

Defense

The defense stage has two components. The first represents a healthy attitude in which the client actually starts coping with the disability. The individual takes pride in his or her accomplishments and works to improve independence and become as "normal" as possible. The person is still very much aware that barriers to normal functioning exist and is bothered by this fact but also realizes that some of the barriers can be circumvented. This healthy stage can be undermined and possibly destroyed by well-meaning family,

*References 66, 67, 124, 126, 127, 131, 132.

friends, and therapists who encourage the individual to see only the positive aspects and who do not allow the client to examine feelings about the restrictions and barriers of the condition. Conditions that lead to the final stage of adjustment are the realization that the whole body or mind is not needed to actualize his or her life goals and that needs can be actualized in other ways. A therapist should watch for opportunities to facilitate this transition. There is a fine line between hopelessness and hope of regaining function. Taking away any hope of regaining quality of life leads to helplessness and may take away the motivation for neuroplasticity within the patient's central nervous system. Thus, helping the patient be realistic and reality oriented while not taking away hope is a skill all therapists need to cultivate.

The negative alternative during the defensive stage is the neurotic defensive reaction. The client refusing to recognize that even a partial barrier exists to meeting normal goals typifies this. The client may try to convince everyone that he or she has adjusted.

Adjustment

In the final stage, adjustment, the person sees the disability as neither an asset nor a liability but as an aspect of the person, much like a large nose or big feet. He or she is accepting what is, not resisting what is. Functional limitation or inability to participate in any life activity is not something to be overcome, apologized for, or defended. Kerr¹³³ refers to two aspects or goals of this stage. The first goal is for the person to feel at peace with his or her god or greater power: the client does not feel that he or she is being punished or tested. The second goal is for the client to feel that he or she is an adequate person, not a second-class citizen. Kerr¹³⁷ believes that "It is essential that the paths to those more 'abstract goals' be structured if the person is to make a genuine adjustment." She also believes that it is the health care professional's job to offer that structure.

Acceptance or adjustment is at least as hard to achieve and maintain in life for the disabled person as happiness and harmony are for all people.¹³⁸ Adjustment connotes putting the disability into perspective, seeing it as one of the many characteristics of that person. It does not mean negating the existence of or focusing on the condition. Successful adjustment may be defined as a continuing process in which the person adapts to the environment in a satisfying and efficient manner. This is true for all human beings, able-bodied or disabled. There are always obstacles to overcome in attempting the goal of a happy and successful life.^{16,92,138,139}

People and circumstances change. Maintaining a balanced state of adjustment is not easy, especially for the person with limitations. I recall a woman who had achieved a stable state of acceptance of her quadriplegic condition. One day she called in a panic because, as she saw it, she "wasn't adjusted anymore." She had moved into a college dormitory and wanted to go out for a friendly game of football with her new friends but suddenly saw how physically limited she was. She had grown up in a hospital and had never had to face this situation. After discussing this, she was able to put things into perspective and was able to talk over her feelings of isolation with her friends, who, without hesitation, altered the game to include her. Keeping a balanced perspective is hard in a world that changes constantly.

White¹⁴⁰ stated that without some participation, there can be no affecting the environment and thus no sense of self-satisfaction. Fine¹⁴¹ and King¹⁴² point out that without satisfaction from affecting the environment, reinforcement is insufficient to carry on the behavior, and the behavior will be extinguished. Thus satisfaction and performance must be linked. If the patient has not adjusted to his or her new body, however, little satisfaction can be gained from such everyday activities as walking, eating, or rolling over in bed.¹⁴³ To define adjustment on a purely performance basis is to run the risk of creating a "mechanical person" who might be physically rehabilitated but, once discharged, may find that he or she lacks satisfaction, incentive, and purpose. The psychological state of adjustment is what makes self-satisfaction possible.

Body Image

"Self-care is never a selfish act—it is simply good stewardship of the only gift I have, the gift I was put on this earth to offer to others. Anytime we can listen to true self and give it the care it requires, we do so not only for ourselves but for the many others whose lives we touch."¹²¹

Body image is an all-encompassing concept that looks at how the person and to some extent the support systems view the person and roles that are expected to be assumed. Taleporos and McCabe²⁰ found that clients had negative feelings about their bodies and general negative psychological experiences after injury. Even when clients do not have disfigurements that are readily observable, they often still report changes in body image and negative feelings of self-worth.

One of the issues that may arise relating to body image is sexuality. This concept may take many behavioral forms: flirting, harassment, questions about fertility, or questions regarding whether the client is capable of performing the sex act at all. Flirting may be a sign that clients have had assaults on their femininity or masculinity. By flirting, clients are often trying to determine whether they still are seen as a sensual being. In this case the therapist may need to set boundaries by saying that he or she is not allowed to date or flirt with clients. This is to make sure that the client does not think that it is something about the disability that is the "turnoff." Sensitivity must be used because the client could think that "if a medical person finds me repulsive then no one will ever see me as attractive." It is important for the therapist to try to ascertain the intent behind the behavior. Usually this can be accomplished by evaluating how he or she feels about the interaction. If the therapist feels unthreatened and does not feel demeaned when the client is flirting, he or she still needs to report this to the therapist of record. If the therapist feels defensive, demeaned, or very uncomfortable, then he or she may be experiencing harassment. It is never warranted or "part of the job" to be harassed, and the client's behavior must be stopped immediately by alerting the client that the behavior is making the therapist feel uncomfortable and that it must stop now. Again, the therapist needs to go to the supervisor or team to mention this behavior. It can often be the case that other team members are experiencing the same behavior and it can be dealt with as a team. If the behavior is considered a chronic problem by the team, a treatment plan needs to be designed to stop the behavior. It is important to remember that sexual health

should not be a neglected area of client treatment. It may take time for the appropriate questions to be asked by the client.^{28,144-148}

Questions about any physical performance are within the domain of therapy. If the client is asking for information regarding sex (e.g., positioning options) it is a subject that needs to be addressed in a respectful manner. If the questions are regarding fertility, capability, and the like, then these should be referred to an appropriate medical person. None of these questions should be discouraged or neglected, because this area is important for your clients' motivation and sexual health.^{149,150} It is important for the therapist to know that in spinal cord injury, fertility will generally not be impaired for a woman, but issues of lubrication before sex should be addressed by the appropriate person. Men may have erection problems and ejaculation issues, but these too can be addressed by the appropriate person. It is now known that fertility in spinal cord–injured men may be possible and should not be ruled out.^{146,151-154}

Awareness of Sexual Issues

Sexuality is usually one of the last areas to be assessed by clinical staff, but it is one area mentioned as having great importance to family members and the client.^{83,104,155,156} Sexuality involves more than just the sex act; it incorporates characteristics such as sexual attraction, sexual identification, sexual confidence, and sexual validation.^{104,155,156} It is a predictor of adjustment to disability, of success in vocational training, and of marital satisfaction when the woman is disabled.^{28,73,147,148,156-162}

Sexuality (sensuality) is representative of how the person is dealing with his or her world. If the person feels inadequate as a sexual, sensual, and lovable human being, there is little chance that the person will also feel motivated to pursue other avenues of life.^{83,156,163} This area of function must be assessed with great sensitivity to the individual's feelings.^{143,148,163-165}

The framework for assessing sexuality differs with the therapist. Some therapists see sexuality as an activity of daily living and incorporate it into the evaluation. Others feel the client needs information about body mechanics to perform the sex act; thus positioning and reflex inhibiting patterns are assessed. Still others have found it a motivating force when range of motion and muscle control are worked on. A further discussion of these concerns follows in the section on adult sexuality.

Development of Sensuality (Sexuality)

Even before birth, the sense of touch¹⁶⁶ and the ability to distinguish pleasurable and unpleasurable tactile sensations begin to develop. Pleasurable feelings are comforting, and attempts are made to prolong them; for example, a baby cries when nursing is stopped. If satisfaction is not derived from this interaction on a regular basis, a feeling of anxiety may develop, the child may withdraw from interaction with others, and distrust may develop.¹⁶⁶ If pleasure in interaction with others is obtained in the first 3 years, the ability to maintain the warmth of being close and being nourished is translated into trust (that all needs will be satisfied by the caretaker) and lovability (bonding). It is here that a sense of intimacy is initiated.^{106,167} By the age of 5 years, the ability to explore the world by using the hands and mouth, as well

as other parts of the body, allows the individual to develop communication, self-gratification, and a feeling of competence.^{106,140,167}

This feeling of competence is derived from the effective use of the body to meet its needs and to accomplish tasks. By the age of 8 years, body parts and body processes are usually named and the child perceives the body as good. At this time intimacy between the self and another person is further refined, as are roles. During puberty, body changes and sexual tension are heightened. Self-acceptance is based on the person's perception of how effectively he or she has accomplished the previous tasks.^{106,167-169}

The preceding is an oversimplification of the first 20 years of life, but the role of sensuality and sensation cannot be overemphasized. This is especially true for those professionals who constantly interact with clients in a physical manner such as handling. The intervention the therapist provides when the client is, or feels he or she is, in a dependent state can have a direct impact on how the client may perceive himself or herself in the future.

Pediatric Sensuality

The child needs to learn to enjoy the body. The therapist should help the client to distinguish between therapeutic touch and "fun" sensual touch, such as tickling or cuddling. It is important for clients to distinguish between the two so that they do not "turn their bodies off" to touch. For example, a woman with cerebral palsy stated during an interview that therapy was either painful or so clinical that she disassociated herself from sensations in her body during therapy. Later in life this became a problem when she was married. She stated that it took 7 years of marriage before she could enjoy the sensations of being touched by her husband.

The therapy session should also help the client develop a sense of personal ownership of the body.^{81,155,170} This aspect is often neglected when working with children.^{81,167} The therapist often does not ask permission to touch a client, thus suggesting that the client lacks the right to control being touched by others. The last thing the therapist would desire to communicate, especially to a child, is that any person has the right to handle and touch the client's body. Child molestation with a disabled population is just beginning to be recognized as a problem in this country, with possibly one third of the female and male population being victimized.⁸¹ It is hard to think of a more likely victim than a person who has (unintentionally) been taught that he or she does not have the right to say "No" to being touched and who cannot physically resist unwanted advances and in some cases cannot even communicate that abuse has taken place. The effects of this can be seen in adults. When one client was asked why tone increased in her lower extremities when she was touched, her response was, "I was sexually abused by my father in the name of therapy, and therapy and sexual abuse are synonymous at this point." No wonder she had not wanted to reenter therapy!

One way of helping clients "own" their respective bodies (besides asking permission to touch) is by naming body parts and body processes using correct terminology (as opposed to baby talk), thus making it possible for the client to communicate and relate appropriately.^{81,167,170,171} This can be accomplished as the need arises, or it can be encouraged

through the use of anatomically correct puzzles or dolls during therapy sessions.

One goal of therapy may be to develop the concept that the body (in the case of persons with the congenital disabilities) or the “new body” (in the case of those with acquired disabilities) is acceptable and good,¹⁶⁷⁻¹⁷¹ thus giving the client a more positive attitude toward his or her body and toward therapy. Pointing out a particularly positive aspect of the client’s body and mentioning this regularly can encourage this attitude. This feature could be the hair, the eyes, or a smile, but it should be an aspect of the client that can be seen and commented on by others as well. Commenting on how well the body feels when it is relaxed or how good the sun feels on the body helps the client recognize that the body can be a positive source of pleasure.

Another message that can negatively affect the client in later life is the concept that individuals with movement dysfunction are asexual and will never have sexual needs or partners.^{73,148,169-173} Although it may not be appropriate to deal directly with the concept in therapy with a child, the therapist might mention that he or she knows of a person with a functional problem such as the client’s movement limitations who is married or who has children. In this way the therapist communicates that there is a possibility that the “normal” sex roles of the child may be fulfilled in the future. Without this possibility being presented, the child may think that there is no chance that all the movies, books, and television programs that deal with normal adult interactions apply to individuals with functional limitations, a belief that leads to poor socialization and further alienation from participating in life.*

Adult Sexuality

Discussing positioning to reduce pain and spasticity or to enable the client to more comfortably engage in sexual relations will help the client deal with problems before they reveal themselves. Because sexual hygiene may be considered as an activity of daily living, it may fall within the domain of therapy.

The client may feel that his or her sexual identity is threatened by a newly acquired disability and may try to assert sexuality through jokes, flirting, or even passes toward the therapist. In these cases it is important for the therapist to realize that what is often being looked for is the confirmation that the client is still a sexual and sensual human being; thus the therapist’s response is very important.^{106,170,171,173,174} If the therapist rejects or even ridicules the client, it may be a very long time before the client can even think of attempting such a confirmation of personal attractiveness. The client may feel that because the therapist rejects the client and the therapist is familiar with the disabled, there is little chance anyone who is not familiar with the disabled could accept the client as lovable.¹⁷⁵ The therapist should not be surprised by such advances and should deal with the situation in a professional manner. The therapist should also realize that approximately 10% of the population is homosexual and be prepared for advances from clients of the same sex. The therapist needs to be as professional as possible in acknowledging this client as with any other. All of the therapist’s

interactions should be directed toward creating an environment that will promote a stronger and more well-adjusted client.^{106,170,171,173}

The therapist’s response to sexual advances must be tempered with an understanding of the possible cause for the behavior. The client may be cognitively impaired and may not even be aware of the inappropriateness of some forms of sexual behavior, or the client may be trying to control others through acting-out behaviors. The client may have been sexually aggressive even before the injury. At no time should the therapist allow himself or herself to be sexually harassed. If the therapist feels harassed, the therapist must take control of the situation and find a way to stop the client’s behavior. This is usually achieved by confronting the issue. Not dealing with inappropriate behavior will allow it to continue and may be detrimental to the medical team and to the client’s normal participation in life.^{145,156,170,171}

The therapist can assist the client in moving through the stages of self-awareness to appreciate that the client is still sensual, sexual, and huggable. This process can be done through everyday interaction; it may entail encouraging the family to embrace the client and may even call for the therapist to role model these behaviors at times.¹⁷⁴ The therapist may provide reading materials to the client and family directly by reviewing and answering questions or indirectly by having such books as *Reproductive Issues for Persons with Physical Disabilities*,¹⁷⁵ *Sexuality and the Person with Traumatic Brain Injury: A Guide for Families*,¹⁷⁶ and *Sexual Function in People with Disability and Chronic Illness*¹⁷⁷ available for their reading. In this way, the individual and significant others are made aware of possible options for the expression of intimacy and of the fact that this part of life is not over.

Because the therapist is in a situation of one-to-one treatment involving touching, moving, and handling the client’s body, he or she may frequently be the natural person from whom the individual may seek information. If this natural curiosity does not appear to be forthcoming, however, the therapist can give the client an opening. For example, during an evaluation of motor skills, the person may be asked if there are any problems in such areas as sexual positioning. The topic need not be pursued any further by the therapist, but when the client is ready to deal with the subject area, he or she will probably remember that the therapist brought it up and may be a person to approach when dealing with these issues.^{163,170,178}

Other ways of presenting sexual information are to have literature available on the client’s ward so that those who are interested may pursue the topic in private, to have a group discussion (interested clients, clients and significant others, or whatever group the client and therapist might choose to assemble), or to have literature in the department waiting room.

It is important for the therapist to be aware of some of the aspects of sexuality that may or may not affect the client as a result of trauma or disease. Fertility is seldom affected in women.¹⁷⁹⁻¹⁸³ Men, on the other hand, may experience dysfunction of the penis and testicles and/or fertility.^{55,69,184-186}

Devices may be used and adapted to allow for sexual gratification of the client (masturbation) or significant others. Stimulant drugs such as sildenafil citrate (Viagra) or other aids may be used to enhance a person’s sex life. Sensation

*References 73, 106, 148, 171, 173, 174.

should be checked and sexual activities modified (or the client should be alerted to the problem) to avoid breakdowns or medical complications. Positioning modifications may be needed to allow for better energy conservation, joint protection, motor control, maintenance of muscle and skin integrity, and pleasure. Clients may have questions regarding modifications that may be needed for the use of birth control devices or contraindications regarding the use of such devices. Clients may also need equipment (e.g., vibrators) modified if hand function is involved. Complications that may affect function and mobility of the client may arise as a result of pregnancy. Delivery may present some unique situations that may also need to be addressed. After delivery the disabled parent may require modifications to the wheelchair, or consultations may be needed to achieve an optimal level of function in the parenting role. All of these possibilities point to the fact that sexual issues must be dealt with throughout the treatment of all individuals with disabilities, whether the functional limitations are progressive, stable, or correctable.^{175,179,187} The therapist may approach these needs or aspects of function while taking a client's sexual history. Clients have repeatedly called for more attention to be paid to sexual concerns. This is not sex counseling or therapy, and the therapist should not try to deal with deep psychosexual issues. The therapist must be informed and needs to provide information that relates to the therapist's areas of expertise, especially because other medical personnel may not have the knowledge to correctly analyze the components of some of these activities.^{45,55,69,175,182,183,188-190}

Any of these issues may present themselves during the medical screening phase of evaluation, whereas others become issues as the patient is adjusting to and questioning functional limitations caused by the disease or condition. Once the patient has identified the need for this information, the therapist, whether through referral, group work, or individual discussions, needs to address the questions and must not deny the patient answers because the therapist is uncomfortable.

All the clinical problem areas that need assessment and evaluation and that have been mentioned previously are examined in relation to treatment planning in the clinical setting in the following sections.

Support System

Earlier literature hinted that partner relationships may be negatively affected by a member being disabled. Within the last few years this concept has been questioned in regard to some disabilities such as adult-onset spinal cord injuries,¹⁸⁹ whereas pediatric spinal cord injury and other disabilities may result in relationship problems.^{191,192} It has been shown that adjustment and quality of life can be adversely affected by the physical environment being inadequate, thus making the person more dependent. The result of the dependence appears to be poor relationships.¹⁹³⁻¹⁹⁵ This can also be seen with the families in which a member has had a brain injury.^{196,197} In studies on muscular dystrophy it was found that physical dependence is not the only variable needing to be considered. Psychological issues need to be identified and considered as part of intervention.^{198,199} Recent literature has identified a number of elements that the client and the family may need help to work on, such as "to assist them to develop new views of vulnerability and strength, make

changes in relationships, and facilitate philosophical, physical and spiritual growth."¹⁹⁸ Turner and Cox¹⁹⁸ also felt that the medical staff could facilitate "recognizing the worth of each individual, helping them to envision a future that is full of promise and potential, actively involving each person in their own care trajectory, and celebrating changes to each person's sense of self."¹⁹⁸ Man¹⁹⁹ observed that each family copes differently in relation to a brain-injured family member and that the family's structure should be explored to develop intervention guidelines. It has also been noted that health care professionals should view the situation from the family's perspective to approach and support the family's adaptation.²⁰⁰ This should be done to help the client and the family accept the disability but at the same time to help them keep the negative views of society in perspective.⁷⁰ In general, it has also been found that family support is a significant factor in the client's subjective functioning^{201,202} and that social engagement is productive.^{89,203} According to Franzén-Dahlin, Larson, and colleagues,²⁰⁴ enhancing psychological health and preventing medical problems in the caregiver are essential considerations to enable individuals with disabilities to continue to live at home. Their research found that evaluating the situation for spouses of stroke patients was an important component when planning for the future care of the patient.

When working with children it is important to realize that they often feel responsible for almost anything that happens in life, such as divorce, siblings getting hurt, or general arguments between parents. It is important that the therapist help the client and the siblings realize that they are not responsible for the client's condition. Part of this magical thinking that often appears is the concept that "bad things happen to bad people." Thus, the child is bad because a bad thing has happened or the adult is bad just because the disease or trauma has occurred. It is important to be sensitive to this ideation and help dispel this maladaptive thought pattern because it is not true or productive for the client, the siblings, parents, or spouses within a family and may cause further adjustment problems later in treatment. Siblings of the client should be helped to see their roles as good siblings and should not be placed in the role of caretakers of a sibling with special needs. In this way all children can grow naturally without any one of the children being overly focused on. At the same time, it is a fact of life that the disabled child will probably need physical assistance, therapy, increased medical care, and thus more time devoted to him or her, and this is just a fact of life.

It should always be noted by the medical establishment that having a disability is expensive in ways that we are often not aware of. There are the obvious medical costs of therapy, surgery, drugs, wheelchairs, or orthoses, but there are other costs such as the possibility of extra cost of transportation, catheters for urination, wheelchair maintenance, adaptive clothing, and the like that are continuing costs not covered by most insurance plans. These costs add up and contribute to the emotional costs and demands on the family. The significant others may feel the need to work more to have the money to cover such expenses, but then that person is not around to help out. This is but one of the many dilemmas that must be acknowledged for the support system of the disabled person. The family may be encouraged to contact such groups as the Family Caregiver Support Network

(www.caregiversupportnetwork.org) to get information and assistance with such diverse topics as being a caregiver, legal and financial aid, and communications (this group tends to focus on the adult but still may be a wonderful aid). Such groups will give information to all who need it and help to empower the family. This takes the focus off of the medical condition and may help the family to gain a better, more balanced perspective on the condition.

Loss and the Family

In this chapter the client's support system is referred to as the *family*. The family may be composed of spouses, parents, children, lovers (especially in gay and lesbian relationships), friends, employers, or interested others such as church groups, civic organizations, or individuals. The people in the support system may go through the same stages of reaction and adjustment to loss that the client does.^{1,9,141,205-207}

Family Needs

The family will, at least temporarily, experience the loss of a loved family member from the normal routine. During the acute stage the family may not have concrete answers to basic questions regarding the extent of injury, the length of time before the injured person will be back in the family unit, or possibly whether the person will live.

During this phase, the family network will be in a state of crisis.⁹ New roles will have to be assumed by the family members, and the "experts" will not even tell them for how long these roles must be endured. If children are involved, they will probably demand more attention to reassure themselves that they will remain loved. Depending on the child's age, the child will have differing capabilities in understanding the loss (see the section on examination of loss). Each member of the family may react differently to bereavement, and each may be at a different stage of adjustment to the disability (see the section on adjustment). One member may be in shock and deny the disability, whereas another member may be in mourning and may verbalize a lack of hope. The family crisis that is caused by a severe injury cannot be overstated.^{98,206-209}

Role changes in the family may be dramatic.^{64,74,92,210-212} Members who have never driven may need to learn that motor skill; one who has never balanced a checkbook may now be responsible for managing the family budget; and those who have never been assertive may have to deal forcefully with insurance companies and the medical establishment.^{9,57,173,213,214}

The family may feel resentment toward the injured member. This attitude may seem justified to them because they see the person lying in bed all day while the family members must take over new responsibilities in addition to their old ones. In a study by Lobato, Kao, and Plante,²¹⁵ Latino siblings of children with chronic disabilities were at risk for internalizing psychological problems. The medical staff may not always understand the stress that family members are under and may react to the resentment expressed either verbally or nonverbally with a protective stance toward the client. Siding with the "hurt" client may alienate the family from the medical staff and may also drive a permanent wedge between family members. This long-term situation may undermine the compliance of family members' involvement in home programs and ultimately the successful outcome of long-term intervention.

Parental Bonding and the Disabled Child

The parental bonding process is complicated and is still being studied.⁴⁸ The process may start well before the child is even conceived. The parents often think about having a child and plan and fantasize about future interactions with the child; after conception the planning and fantasizing increase. During the pregnancy the mother and father accept the fetus as an individual, and after the birth of the child the attachment process is greatly intensified. The "sensitive period" is the first few minutes to hours after the birth. During this time the parents should have close physical contact with the child to strongly establish the attachment that will later grow deeper.^{216,217} There is an almost symbiotic relationship between mother and child at this time: infant and mother behaviors complement each other (e.g., nursing stimulates uterine contraction). It is important at this point for the child to respond to the parents in some way so that there is an interaction. In the early stages of bonding, seeing, touching, caring for, and interacting with the child allow for the bonding process. When this process is disturbed for any reason, such as congenital malformations or hospital procedures for high-risk infants, problems may occur later.

When the parents are told that their child is going to be malformed or disabled, it is a massive shock. The parents must start a process of grieving. The dream of a "normal" child must be given up, and the parents must go through the loss or "death" of the child they expected before they can accept the new child. Parents often feel guilty. Shellabarger and Thompson²¹⁸ state that parents feel the deformed child was their failure.¹ The disabled child will always have a strong impact on the family, sometimes a catastrophic one.^{1,8,9,218,219} A study by Ha, Hong, Seltzer, and Greenberg²²⁰ found that compared with parents of nondisabled children, parents of disabled children experienced significantly higher levels of negative affect, poorer psychological well-being, and significantly more somatic symptoms. Older parents were significantly less likely to experience the negative effect of having a disabled child than younger parents.

In a study by Arnaud, White-Koning, and colleagues²²¹ greater severity of impairment was found to not always be associated with poorer quality of life; in the moods and emotions, self-perception, social acceptance, and school environment domains, less severely impaired children appeared to be more likely to have poor quality of life. Pain was associated with poor quality of life in the physical and psychological well-being and self-perception domains. Parents with higher levels of stress were more likely to report poor quality of life in all domains, which suggests that factors other than the severity of the child's impairment may influence the way in which parents report quality of life.

Parents must be encouraged to express their emotions, and they must be taught how to deal with the issues at hand. Techniques for accomplishing these goals are discussed in later sections.^{48,217,219}

The Child Dealing with Loss

If a parent is injured, the young child may experience an overwhelming sense of loss. Child care may be a problem, especially if the primary caregiver is injured. The child will

probably feel deserted by the injured parent and may demand the attention of the remaining parent. This will increase the strain on all family members.⁶⁴

If the child is the client, his or her life will have undergone a radical change: every aspect of the child's world will have altered. Loved objects and people will help to restore the child's feeling of security. It is of major importance to explain to the child in very simple terms what is going on and to allow the child the opportunity to express feelings both verbally and nonverbally. It is important to use play and art as the medium of communication for children.

The hospital setting is threatening to all people, but children are especially susceptible to loss of autonomy, feelings of isolation, and loss of independence. Senesac (see Chapter 12) has stated that the severity of the disability is not as important a variable in the emotional development of the child as are the attitudes of parents and family.^{2,8} Parents must attempt to be aware of the child's inability to understand the permanence (or transience) of the loss of function.⁸ They will also need to help the child feel secure by bringing in familiar and cherished objects. A schedule should be established and kept to promote consistency. Play and art should be encouraged, especially types that allow the child to vent feelings and deal with the new environment. Any procedures or therapies should be presented in a relaxed and playful way so that the child has time to think and to feel as comfortable as possible about the change. The parents may often need to be reminded to pay attention to the children in the family without disabilities during this acute stage.

The Adolescent Dealing with Loss

The adolescent is subject to all of the feelings and fears that other clients express. Adolescents are in a struggle to achieve autonomy and independence, and they often are ambivalent about these feelings. When an adolescent is suddenly injured and has to cope with being disabled, it can be a massive assault on the individual's development.^{139,222} According to research conducted by Kinavey,⁵⁰ findings imply that youth born with spina bifida face biological, psychological, and social challenges that interfere with developmental tasks of adolescence, including identity formation. Therapists are urged to direct intervention toward humanizing and emancipating the physical and social environment for youth with physical disabilities to maximize developmental opportunities and potential while fostering positive identity.

Kingsnorth, Healy, and Macarthur⁴⁹ stated that with advances in health care, an increasing number of youth with physical disabilities are surviving into adulthood. For youth to reach their full potential, a number of critical life skills must be learned. Specific learning opportunities are important, as youth with physical disabilities may be limited in the life experiences necessary to acquire these skills. Therapists are in the unique position of fostering these kinds of environments to encourage adolescents to engage in critical life skills such as problem solving, decision making, goal setting, critical thinking, communication skills, assertiveness, self-awareness, and skills for coping with stress. Life skills differ from instrumental daily living skills. Daily living skills are the activities required to function independently in the community and include skills such as financial management, meal preparation, or navigation in the community. An

approach emphasizing life skill development can, however, be used to acquire daily living skills.

The adolescent appears to react differently from other age groups to the knowledge of his or her own terminal illness. The adolescent often feels that he or she has gone through a very painful process (initiation) that will soon lead to the "joys and rights" of adulthood. Unlike persons in older age groups, who might feel that they can look back and gain solace from the past, the adolescent feels that he or she will have what Britto and colleagues²²² term "death before fulfillment" and thus may react by feeling cheated by life. This same pattern may occur with the disabled adolescent.²²³ The therapist must be acutely aware of these feelings so that therapy may be presented in the most effective manner for the client to find challenge and fulfillment in life.²²⁴

Family Maturation

The family also has a maturational aspect. If the injured person is a child and if the family is young with dependent children at home, the adjustment may not be the problem that it would be for a family whose children are older. In the latter case, parents have begun to experience freedom and independence, and they may find adjusting to a return to a restricted lifestyle difficult or even intolerable. They may have the feeling that they have already "put in their time" and should now be free. If the disability interrupts the child's developmental process, future conflict may arise because the parents will eventually want retirement, relaxation, and freedom. Parents may feel guilty and try to repress this normal response.

The reverse may also be true. The parents may be feeling that the children have left them ("empty nest syndrome"), and they may be too willing to welcome a "dependent" family member back into the home. This may lead to excessive dependence or anger toward the parents on the part of the client. All these factors must be taken into consideration by the therapist when therapy is presented to the client and family.

The therapist can develop a greater understanding of the client and family by being aware of the normal human developmental patterns. These patterns identify some of the major hurdles that must be overcome in the client's life.

Coping with Transition

In the acute stage of a family member's injury, the family must be helped to deal with the crisis at hand. During this phase, the family must first be allowed to cope with the emotional impact of what is happening with a loved one. Second, the family should be helped to see the situation as a challenge that if overcome will facilitate growth. Third, adaptation within the family unit must occur for the situation to be overcome.

Brammer and Abrego²²⁴ have developed a list of basic coping skills that they have broken into five levels. In the first level the person becomes aware of and mobilizes skills in perceiving and responding to transition and attempts to handle the situation. In the second level the person mobilizes the skills for assessing, developing, and using external support systems. In level three the person can possess, develop, and use internal support systems (develop positive self-regard and use the situation to grow). The person in level four must find ways to reduce emotional and physiological distress (relaxation, control stimulation, and verbal

expression of feelings). In level five the person must plan and implement change (analyze discrepancies, plan new options, and successfully implement the plan). Using this model, the therapist and family can evaluate the coping skill level of the family. The therapist and staff can then help promote movement toward the next level of coping with the transition. These levels are also broken into specific skills and subskills so that the therapist can grade them further.

One of the more damaging aspects of hospitalization to all involved is that the hospital staff focuses on the disability rather than on the individual's strengths.^{76,206,225} Centering on the disability can lead to a situation in which client, family, and staff see only the functional limitations and not the potential ability of the client.

Decentering from the loss of function will be examined further in this chapter. If the family relationship was positive before the insult and if the client is cognitively intact, then the focus must be directed toward the relationship's strengths as well as toward the client's and family's individual cognitive and emotional strengths.⁹¹ In the initial acute stage of adjustment, crisis intervention may help the family use its strengths and at the same time deal with the situation at hand.

To adequately deal with the crisis, the family should do the following:

1. Be helped to focus on the crisis caused by the disability; identify the situation to stimulate problem solving; identify and deal with doubts of adequacy, guilt, and self-blame; identify and address grief; identify and deal with anticipatory worry; be offered basic information and education regarding the crisis situation; and be helped to create a bridge to resources in the hospital and in the community for support and to see their own family resources.^{48,226-229}
2. Be helped to remember how they have dealt successfully with crises in the past and to implement some of the same strategies in the present situation.
3. Work with the family as a unit during crisis to help strengthen the family and facilitate more positive attitudes toward the client. These attitudes by the family will improve the client's attitudes or feelings toward the injury and hospitalization.^{92,212,230-233} Encouraging family-unit functioning in this situation will decrease the amount of regression displayed by the client. If the family is encouraged to function without the client, however, more damage than good may be done.^{1,139}

TREATMENT VARIABLES IN RELATION TO THERAPY

Skilled therapy intervention focuses on maximizing participation in functional activities, participation in life, and behavioral change. Livneh and Antonak¹³⁴ promote the following activities for the health professional:

1. Assisting clients to explore the personal meaning of the disability. "Training clients to attain a sense of mastery over their emotional experiences." A way of doing this would be to help the client not to demonstrate emotional outbursts or to help the client look at his or her emotions and to put them into perspective.
2. Providing clients with relevant medical information. "These strategies emphasize imparting accurate

information to clients on their medical condition, including its present status, prognosis, anticipated future functional limitations, and when applicable, vocational implications." This may be done by helping the client and family access resources such as PubMed (www.ncbi.nlm.nih.gov/pubmed) online or find medical references in the library.

3. Providing clients with supportive family and group experiences. "These strategies permit clients (usually with similar disabilities or common life experiences) and, if applicable, their family members or significant others, to share common fears, concerns, needs, and wishes." This can be done in rather unobtrusive ways such as scheduling clients with the same disability at the same time so that they meet in the waiting room or while doing group mat activities. Another option is hiring individuals with limitations who are health care professionals and can discuss and role model positive behaviors and answer relevant questions from the client's perspective. Remember that clients are all potential teachers for you as well as other clients.
4. Teaching clients adaptive coping skills for successful community functioning. "These skills include assertiveness, interpersonal relations, decision making, problem solving, stigma management, and time management skills." This would entail role-playing situations that may occur in the community, such as an able-bodied person asking why the client is in a wheelchair; preaching to the wheelchair user because he or she must have offended God in some way—otherwise the person would not be in a wheelchair; or telling a woman that it is such a shame that she is disabled because she is so good looking and could have found a man if it were not for the disability. Role playing can also be used to help a person deal with the possibly awkward experience of going to bed with a new partner and having to explain how to be undressed, or what those tubes coming out of the body are for, or what positions are best for someone with this condition.

ROLE OF THE THERAPEUTIC ENVIRONMENT

Whenever possible in therapy the functional activity should be presented and structured to promote empowerment, problem solving, and adjustment. Adjustment and adaptation to life form a dynamic process that allows for the person to interact with life in a meaningful and productive way that encourages the person to enjoy life (Figure 6-1).^{17,80,234-237} We see the client at a very stressful time, and we need to make this time as productive for the client and the family as possible.

This section examines issues the therapist and staff should know to create a therapeutic environment that will facilitate psychological adjustment and independence of the client with activity limitations. The physical and the attitudinal environment of the treatment facility plays a major role in the way the client views the services that are rendered.

Recall a time before you became a member of the medical community. Think about how awe inspiring the people in white coats were, how strange the smells of the hospitals were, how busy it all seemed, and how puzzling the secret

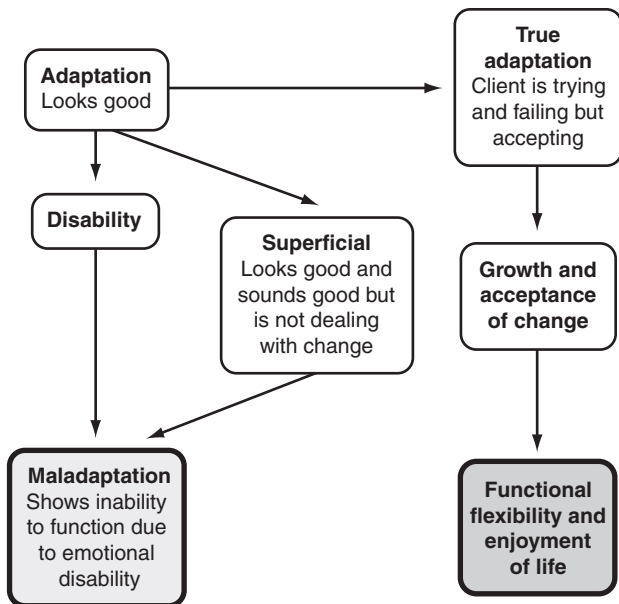

Figure 6-1 ■ Possible directions of the adaptive process.

medical language was. It all seemed overwhelming then, and it still is to newcomers, especially newly admitted patients and their families. The hospital usually appears impersonal,²³⁸ sterile, monotonous, and confusing, and all status accumulated outside the hospital means little inside.

The therapist needs to take the setting into account when dealing with the client. The environment can be altered in a variety of ways. Therapy staff could wear street clothes, decorate the department or hospital with posters and lively colors, and allow clients to bring some personal items into the hospital.

The nature of the therapy process can often lead the therapist to see only the disability and not the person—as occurs, for example, when a client is referred to by his or her disability rather than by name. This stereotyping of those with disabilities can lead the therapist to concentrate on the lack of abilities rather than on the strengths of the clients. The real danger is that the client and family will also start to focus on the functional limitations of the client and feel that their family relationship is now permanently altered. The accuracy of this perception may have to be evaluated as part of the adjustment process. The wife of a man with paraplegia said with a sudden burst of insight, “I didn’t marry him for his legs—this doesn’t change the relationship.” Often so much attention is directed toward the disability that tunnel vision develops. One way to try to get a better perspective is to look at the bigger picture. A variety of questions can be asked that may help the therapist gain a greater insight into the client as a person (Box 6-2).

After the therapist is aware of the strengths of the client, these strengths may be capitalized on in therapy to help the client realize them and build confidence. Clients often reported that they were not complimented in therapy and especially that they never received feedback that their bodies were desirable²³⁹ or that they were doing things correctly.^{11,76,175,176,240} A logical thought by the client is, “If the therapist cannot see anything desirable about me,

BOX 6-2 ■ QUESTIONS TO HELP GAIN INSIGHT INTO THE CLIENT AS A PERSON

The following questions can be asked:

What would this person be doing if he or she did not have this condition?

What is stopping the person from reaching these goals now?

Who will marry this person and why?

What are his or her positive traits?

What will this person do for a living?

What will this person do for enjoyment?

How will this person bring others enjoyment?

What would this person be doing if there was no disability?

How is the disability stopping the person from actualizing their goals? (These are the goals that need to be worked on.)

Similar questions can be asked of the client to explore ways of helping the client have a meaningful life:

What do you look like and function like now?

What will you look like after therapy?

What important things would you be doing now if you were not in need of treatment?

What activities or forms of productivity were you involved in before, and which were important to you?

Which of these things do you still do?

What if anything is preventing you from doing these things now?

How does this condition affect your being a lover of life, family, significant other, and so on?

How will this condition affect your important life goals, your activities, and your ability to do meaningful activities?

How much different would your life look if it were not for this condition?

Will any of the above be stopped by your condition, and if so how?

and the therapist deals with the individuals with similar problems all the time, then there must not be anything good about me.” Positive, sincere comments to client and family can add a motivational factor to treatment that may have been missing.^{76,232}

Providing opportunities to be outdoors can help clients cultivate a sense of connection with something that is larger than themselves. At the most basic level there is more oxygen outside, and in general the air is fresher than indoors. “And looking at a faraway horizon or sky can help us gain needed perspective on our small world, bounded by our bodies and our lives.”²⁴¹

The last and possibly the most important aspect in creating an environment that will foster growth and adjustment in the client is a staff whose members are well adjusted and aware of their own personal needs. Just as coping skills are necessary for the client, the staff, too, must be capable of coping with the stresses of the emotional and physical pain of the client and the client’s family. The therapist must also deal with his or her own personal reactions to the sometimes devastating situations others are in.^{76,232,242} Exposure to such

situations often elicits introspection on the part of the staff that can result in emotional turmoil for staff members and affect their own personal relationships. This emotional energy needs to be directed in a productive way so that the energy does not turn into chaos within the staff interaction or become a destructive force for the client.

To decrease the possibly distractive nature of this emotional energy, the staff should be made aware of their own coping styles, and they should be allowed to vent their reactions to particularly distressing client case loads in a positive, supportive group. Group meetings can be used to handle some of the inevitable tension, especially if there is a respected member who is skilled in group work. This is not a psychotherapy session (although psychotherapy may be warranted in some situations) but rather an opportunity to test reality and remove tension before it is incorrectly directed toward fellow staff members. These sessions can make use of the four elements of crisis intervention mentioned in the previous section, as well as information from others.^{177,232} Other times that this stress reduction can be achieved are in supervision or during coffee breaks, as long as the sessions are productive.

The staff can use these sessions to better understand their various reactions to stress and to explore their coping styles.^{211,232,243,244} Ideally, this knowledge of coping styles and stress reduction will decrease staff burnout and aid the staff to help clients and their families deal with stress more successfully.^{139,240-244} There are also MBSR courses held in most hospitals, universities, and communities and can be found online at www.umassmed.edu/cfm/mbsr.

The need to have a staff that is supportive is of paramount importance because the attitude of rehabilitation personnel has emerged as one of the chief motivating factors in rehabilitation.^{1,92,137} In fact, the use of humor has been found to be assistive in the process of adjustment. In a study by Solomon,²⁴⁵ aging well was related to aspects of humor. It seemed to affect aging well through its relationship with perceived control. Physical health, satisfaction with housing, and relationships with family and friends were also positively influenced by humor. One suggestion by McCreddie and Wiggins²⁴⁶ is that stress can be coped with through distraction, which lessens the negative physical effects of stress. Humor is also known to have a number of potential benefits in relation to interpersonal skills or social support.²⁴⁷ Specific aspects such as empathy, intimacy, and interpersonal trust have all been positively correlated with a sense of humor and subsequently with interpersonal relationships. According to McCreddie and Wiggins,²⁴⁶ a degree of rapport with the patient is necessary before humor can be used, and humor should be used only after a level of empathy, caring, and competence has been clearly demonstrated. This interaction of therapy and societal interactions explains why the World Health Organization model went from a disability or handicap model to a model of functional ability and participation in life. Although the International Classification of Diseases (ICD-9 or ICD-10) deals with physicians and disease categories, therapy clearly separates itself into a clear model that stresses the strength of an individual and his or her potential to participate in and have quality of life (www.who.int/classifications/icf).

Rogers and Figone¹⁴³ developed the following suggestions that could benefit the therapist when trying to create a supportive environment:

1. It is helpful to use the same staff member to develop the relationship and to provide continuity of care.
2. Concerned silence is most appreciated, although pushing is sometimes necessary.
3. Staff members should anticipate the need to repeat information graciously.
4. Cumbersome, hard-to-repair adaptive equipment should not be used after discharge.
5. Give clients responsibility so that they feel they have some control over therapy.
 - a. The client should be allowed to pick his or her own advocate from the team.
 - b. The client should be given a choice of activities (e.g., which exercise comes first).
 - c. Professionals should avoid placing the client in an inferior status. In time the client starts thinking this way (feeling like a “second-class citizen”).
6. Psychological support is attributed to noncounseling personnel. Personal matters are better discussed with staff members with whom the client has developed a relationship.^{2,173,227}
7. Willingness to allow the client to try and fail is more helpful than controlling the client.

Bolte-Taylor¹⁰⁹ developed “forty things I needed the most” during her rehabilitation for her stroke. Here are a few:

1. I am not stupid, I am wounded. Please respect me.
2. Come close, speak clearly, repeat yourself if necessary, and enunciate.
3. Approach me with an open heart, slow your energy down, take your time.
4. Be aware of what your body language and facial expressions are communicating to me.
5. Make eye contact with me, encourage me.
6. Honor the healing power of sleep.
7. Protect my energy. No talk radio, TV, or nervous visitors! Keep my visitations brief.
8. Speak to me directly, not about me to others.
9. Clarify for me what the next step or level is so I know what I am working toward.
10. Celebrate all of my little successes. They inspire me.

CONCEPTUALIZATION OF ASSESSMENT AND TREATMENT

Assessment

The one component that weaves through all of Rogers and Figone’s¹⁴³ seven points is the need for the therapist to be involved with the client in a therapeutic relationship—that is, to know where the client is “coming from.” To know where the client is coming from is to be aware of and sensitive to the person’s total psychosocial frame of reference.^{2,227}

The therapist who knows his or her own beliefs, reference points, and prejudices can evaluate whether an assessment result or treatment sequence reflects the client’s needs and values or those of the therapist. In the first half of this chapter, several assessments were discussed

that could be summarized into the following three major components:

1. Preinjury
 - a. Values and prejudices (value systems, culture, and prejudgments) of the client and family members before the injury
 - b. Developmental stage of the client and family members
 - c. Cognitive level of the client and family members
 - d. Ability of the client and family members to handle crisis
2. Components to be evaluated leading to adjustment
 - a. Loss and grief process for the client and family members
 - b. Adjustment process for the client and family members
 - c. Transitional stages for the client and family members
 - d. Role changes for the client and family members
 - e. Age or cognitive level of client and family members^{9,139,227,248}
 - f. Sexual adjustment for the client and spouse
3. Techniques used to elicit adjustment and independence
 - a. Crisis intervention strategies
 - b. Letting the client and family take control
 - c. Expression of emotion, both verbally and nonverbally
 - d. Problem solving
 - e. Role playing
 - f. Praise
 - g. Education
 - h. Support groups

Once an assessment has been made of the client and family members' stages of psychological adjustment, the client's occupational history and roles, and their preinjury attitudes and beliefs, a treatment protocol can be established. This protocol will need to incorporate steps toward stage change and possibly attitudinal change. Because these changes require learning on the part of the client and family, an environment that optimally facilitates these changes must be established.*

Therapy can be seen as a form of education in which the client and the client's family are taught how the client should use his or her body. The education process is not limited to the physical aspects of therapy, however. The client is also taught how to look at and think about the body and the disability. If the staff is nonverbally telling the client and the family that the client is not capable of making decisions and of being independent, it follows that the client may indeed feel dependent and incapable of making decisions. Giles²¹¹ and others^{207,211,249,252,253} stated that there was an inverse relationship between independence and distress. Distress causes further anxiety and decreases the learning potential of the client. There are ways, however, for the therapist to encourage independence on the part of the client and his family.

Specific Therapeutic Interventions

"Engagement in leisure-like activities may not only help people 'feel better' in the immediate context of coping with rehabilitation treatments, but may help sustain coping efforts as individuals learn to live with ongoing functional limitations."²⁵⁴

Problem-Solving Process

The family unit, including the client, should be encouraged to take active control over as much of the client's care and decision making as possible.* This can be done in every phase of the rehabilitation process. A family conference with the rehabilitation staff should actively involve the client and family in all stages of planning and treatment, up to and including discharge. The family (including the client) should be briefed ahead of time to prepare questions that they want answered or problems that need to be addressed. Rogers and Figone¹⁴³ report that conferences with family members that excluded the client engendered suspicion^{2,211}; therefore if the client is capable, the client may educate the family in regard to what is happening in the hospital and in rehabilitation. Conversely, family involvement facilitates and shortens the rehabilitation process and encourages reintegration into the community.^{8,207,249,253} The family can also be educated regarding the side effects and interactions of medication with publications such as the *Physicians' Desk Reference*.²⁵⁸ Later in the rehabilitation process the client and family can be encouraged to arrange transportation services, find and evaluate housing, and supervise attendant care. All these activities allow the client and the family to be more in control of the environment and thus to feel independent.

In the context of one-on-one therapy, giving choices can foster client responsibility and independence. Making a decision about the order of treatment activities (such as on which side of the bed to transfer out of or which direction to roll one's wheelchair first) can give the individual a sense of self-worth that can continue to grow. This will cultivate a belief by the client and family that they are strong, with rights that need to be met. Moving out of the role of the victim, the client begins to exercise responsibility and to take action, such as applying for extended health benefits or getting a second consultation when an important medical decision needs to be made. If the client and family start to realize that they do not have to be a casualty of the medical establishment and if they find ways to control the medical establishment,^{92,234,259} they are better able to discard the role of victim.

In some centers, such as the occupational therapy clinic at San Jose State University, clients have been taught the art of self-defense to make sure that they never have to fall into the victim (dependent) role. It should be noted, however, that this knowledge on the part of the client and family can be used in ways that the therapist may not always agree with. At such times it may help to adopt a philosophical attitude toward the situation and to view it as a positive direction for the client in terms of moving from victim to advocate in the rehabilitation process.

The steps of crisis intervention, which were mentioned in the previous section, can be used to help the family understand and analyze their needs in the crisis situation. Once the family has discovered that they are in crisis, they will then be able to create strategies that they can use to overcome present and future problems.

Problem solving is another element the therapist may use to help the client and family gain independence and control.†

†References 19, 52, 207, 211, 249, 250, 252, 253, 255, 256.

Persson and Rydén²² acknowledged the importance of this when they found that there were a few significant categories to adjustment: self-trust, problem-reducing actions (problem solving), change of values, and social trust. Acknowledgment of reality and trust in oneself was found to be significant, and they identified the importance of understanding coping processes from the disabled person's point of view. In a phenomenological study by Bontje, Kinébanian, Josephsson, and Tamura,²⁶⁰ participants stated they used already familiar problem-solving strategies and personal resources as well as resources in their social and physical environments to identify prospects of potential solutions and to create solutions to overcome constraints on occupational functioning.

Rather than having the client routinely learn how to accomplish a specific task, the client or family must be encouraged to think through the process from the problem to the solution and to accomplishment of the task. To achieve this activity analysis, the client would have to know the basic principles behind the activity¹⁴³ and may then be responsible for educating the family. An example of this would be a transfer from the wheelchair to the toilet. If the therapist simply has the client memorize the steps in the task, the client or family members will not necessarily be able to generalize this procedure to a transfer to the car. If the client learns the principles of proper body mechanics, work simplification, and movement, the client or family member may be more able to generalize this information to almost any situation and to solve problems later when the therapist is unavailable.²⁵² Rogers and Figone¹⁴³ have noted that although the client and family may fail at times during these trials, the therapist should let them be as independent and responsible as possible: let them try it their way, even if they are not successful the first time.

Pictures or slides of a restaurant, movie theater, or public building can be used to facilitate discussion and problem solving by the family unit when analyzing potential architectural barriers in the environment. Thus in the future when the family is presented with a problem or a barrier, they will have the resources to overcome it rather than be devastated by it.

Role playing in combination with support groups can also be used to defuse potentially painful situations and operate independently. While the client is still in the safe environment of the rehabilitation setting, simulations of incidents can be created for them to practice problem solving with supervision to help anticipate potential situations. They can be asked what they would do when a stranger (possibly a child) approaches the client and asks why he or she is in a wheelchair or is disabled or what they would do when a waiter asks the family member to order for the disabled client. All of these situations are potentially devastating for all involved; however, if role playing and support groups are used in advance to help all members of the family (client included) to satisfactorily handle and feel in control of the situation, the family will not be as likely to be traumatized by a similar occurrence. The result is that the family will not be as inclined to be overwhelmed by social situations and will be able to socialize in a much freer, more gratifying way.^{77,79,261}

Cognitive-behavioral therapy has been used for clients and spouses with success.⁹³⁻⁹⁵ Psychosocial support groups

have been called for throughout the literature.* Throughout the therapeutic process, the client and the family need to be praised frequently, and credit needs to be given for the gains made by the client and family members. Granted, the therapist may have engineered the gains, but the family and client are the ones who need the reinforcement. As Bolte-Taylor¹⁰⁹ suggested, celebrate all of the little successes—they can help inspire the client and their family. Through gratifying experiences the family will unite to overcome the disability. They need to know that they can survive in the world without having the medical staff constantly there to solve the family's problems. In short, they need the strategies and resources that will allow them to be independent outside the medical model.

Yet another way to encourage independence can be applied to working with parents of disabled children.¹³ The parents should be educated about normal and abnormal growth and development, including physical, cognitive, and emotional growth, so that the family can maintain some perspective and objectivity about their child's various levels.^{8,92,167,236} The parents can then better understand the needs of those children with disabilities and those without in the family. Armed with this knowledge, the parents and children will not be frustrated with unreal expectations or unreal demands. Education of the parents could take place at local colleges, at the hospital, or even in a parent's group.

Support Systems

Groups are often used to increase motivation, provide support, increase social skills, instill hope, and help the client and family realize that they are not the only ones who have a disabled family member. This will help the client and family establish a more accurate set of perceptions about the disabled individual and allow for greater independence of the client and family.^{1,9,92,135,261,265} Problem solving can be encouraged and value systems can be clarified. Client or family support groups can be used to relieve pressure that might otherwise be vented in therapy. Lawrie Williams, a mother of two daughters who experienced serious medical challenges, is the author of a series of articles about parental roles in family-centered care. One article in particular highlights the role parents can play in helping other families through parent-to-parent support programs. Williams first experienced the support of another parent when one of her daughters was young, and later realized she could use her own experiences professionally. For the past 6 years, Williams has been the coordinator of the Parent Support Program at the Center for Children with Special Needs, Children's Hospital and Regional Medical Center in Seattle, Washington.²⁶⁶

Liveh and Antonak¹³⁴ found that in a chronic-care ward family involvement helped the client and the family improve their status. Schwartzberg²⁴⁹ and Schulz¹²⁸ and others^{1,98,107,248,267-269} have reported great success in the use of support groups with individuals who had brain damage. Support groups can also be used to educate the client about the client's disability to increase independence.[†]

†References 1, 207, 248, 253, 270, 271.

Kreuter and colleagues²⁷¹ and Taanila and colleagues^{13,270} found that independent physical functioning and knowledge about one's condition were exceedingly important in moving through the phases of the rehabilitation process.^{75,234,265,272} A guide to facilitating support groups has been published by Boreing and Adler,²⁷⁴ and it has been found to be useful, especially by laypeople establishing such groups.*

The Adult Client with Brain Damage

The adult client with brain damage and the needs of the family will be specifically, yet briefly, examined here. Brain damage can affect the cognitive, perceptual, emotional, social, and neurological systems of the individual and can be incredibly disruptive and catastrophic to the client's and family's lives. When a person sustains a brain injury and is hospitalized, emotional support for the family (client included) is the primary need to be met initially. The therapist should attempt to convey warmth and a caring attitude, especially during the family's initial contacts.²⁷⁵ Typical complaints about the acute period involve impersonal hospital routines and lack of definite information about the patient's status.^{13,92,175,229,276} Unfortunately, definite information is usually not available at the earliest stages.

Later the family must deal with the physical changes in the client's body; what may be even more injurious to the family are the psychological, cognitive, and social changes in the client.[†] People with cerebrovascular accidents have been found to be more clinically depressed than orthopedic patients are. The libido²⁶³ and the emotional systems are also affected.^{75,176-178,226} It has further been shown that persons who survive a cerebrovascular accident or other impairment and who have a full return of function do not return to normal life because of a lack of social and emotional skills.[‡] Families of cerebrovascular accident victims have also reported that social reintegration is the most difficult phase of rehabilitation.²⁷⁷ Lack of socially appropriate behaviors has been one of the most troublesome complaints of people who deal with the person with a traumatic brain injury.¹⁷⁶ Therapists may be able to help alter this syndrome by encouraging appropriate behavior and by structuring

therapy situations to reteach the client appropriate behavioral and social interaction skills. A technique called *dialectical behavioral therapy* has been used with people with mental health disorders, and it appears to be a promising approach. One study by Miller and colleagues²⁷⁸ found significant reductions in suicidal symptoms; the most highly rated skills included distress tolerance and mindfulness skills. The goals of a dialectical behavioral therapy program designed for individuals with mild traumatic brain injury include decreasing the individual's self-defeating behaviors and cognitions, cultivating understanding of the individual's abilities and impairments, and increasing behavioral and cognitive skills that will lead to a greater sense of self and feelings of self-esteem. The program is designed to improve each patient's ability to accept his or her life as it is and to function independently.²⁷⁹

Better follow-up care needs to be implemented when dealing with the adult with brain damage.^{1,98,107,248,267-269} In some areas there are outpatient, privately funded programs that can help support the brain-injured individual and his or her family on discharge from hospital settings. These resources must be recommended for follow-up care as needed.

It may not be possible for the client and family to constantly come to the clinic for support and follow-up, but telephone conversations can be scheduled on a periodic basis, or the exchange of letters or audiotapes can also be used. With the increased availability of video recorders, the day may come when a follow-up may be performed on videotapes and sent via the Internet by clients living in rural areas. Support groups are being used increasingly to facilitate client and family adjustment and accommodation to disability, as well as reentry into the community.*

CASE STUDY 6-1 ■ PUTTING EVALUATIONS AND TECHNIQUES INTO PRACTICE

Joan, a married 30-year-old woman, has had a T2 spinal cord injury. She has worked as a computer programmer for the past 8 years, except for a short maternity leave when she gave birth to her daughter, who is now 6 years old. Joan was always very active physically and often stated that she felt sorry for her physically disabled neighbor because the neighbor could not hike, be active, or enjoy the outdoors. Joan's husband, age 33 years, is attempting to visit Joan regularly and care for their daughter, a role that is new for him.

The therapist has assessed several things regarding Joan's developmental stage, adjustment stage, social and cultural influences, and family adjustment reactions. The two adult

family members are probably in Sheehy's²⁸¹ "catch-30" stage, in which the person reevaluates his or her life and relationships. Joan already "knows" that the physically disabled cannot enjoy a physically active life and is also feeling that everything she has worked for in her career is lost. She appears to be in the mourning stage of adjustment. Her daughter and husband have to adjust to radical role changes. Cognitively, Joan's young daughter is not going to understand the permanence of the disability and may be inclined to act out as the result of the turmoil. The husband will have to be assessed to determine his stage of adjustment to her disability.

Continued

CASE STUDY 6-1 ■ PUTTING EVALUATIONS AND TECHNIQUES INTO PRACTICE—cont'd

The therapist has determined that Joan's transfers need further work but would like to use the adaptive process to stimulate adjustment. The therapist has devised a treatment session to meet the goals of promoting the defense stage of adjustment, decreasing Joan's prejudice against the disabled, encouraging problem solving, increasing her feelings of self-worth, proving to her that she can take care of her daughter through interacting with children, and having her decenter her focus from her disability to her ability. The therapist has contacted the recreational therapist (who has paraplegia) to plan a collaborative session at the park across the street from the hospital. Because the recreational therapist works in the pediatrics ward, it is determined that the children with spina bifida should come and play tag, transferring from log to log in the playground.

The stage is now set. Joan will be asked to help supervise the children. The adaptive process will be used to teach Joan how to transfer using the environment. The transfer will be organized subcortically because she will be attending cortically to the children's needs and to the game itself. Joan will be actively affecting her personal environment, and if everything goes well, the act of helping the children will increase her self-worth and will also be

self-reinforcing. Within this treatment session, the therapist has used the recreational therapist as a role model to change Joan's prejudice against the disabled being active in the outdoors and to show Joan that she can still be a parent although she is disabled. The therapist may also increase Joan's knowledge of how to interact with children from a wheelchair by giving a few hints and then having Joan transfer up a set of stairs to reach one of the children.

If we want to carry this scenario further, the therapist could introduce Joan to a child who is interested in computers and who needs help with a programming problem (Joan's computer background will be used, which will increase Joan's feelings of self-worth and help her focus on her abilities rather than her disabilities). On the way back to the ward, the therapist and Joan may discuss how the family is dealing with the crisis they are in and help her realize how the family has made it through other crises in the past and how those previously successful strategies could be used in this situation. Support groups and psychological counseling are mentioned as resources. The session may end with Joan planning the next therapy session and thus starting to take control of her life.

CHAPTER 7

Differential Diagnosis Phase 1: Medical Screening by the Therapist

WILLIAM G. BOISSONNAULT, PT, DHSc, FAAOMPT, FAPTA,
and DARCY A. UMPHRED, PT, PhD, FAPTA

KEY TERMS

Differential Diagnosis Phase 1
Differential Diagnosis Phase 2
Medical screening
Patient referral
Review of systems screening
Causational systems interaction

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify the difference between Differential Diagnosis Phase 1, medical screening, and Phase 2, diagnosis of impairments and functional limitations.
2. Analyze the concept of body system and subsystem screening.
3. Develop a mechanism for body system screening to be used with clients with preexisting neurological dysfunction.
4. Analyze the significance and importance of performing a medical screening for all clients who interact in a therapeutic environment with occupational or physical therapists.
5. Differentiate between direct causation of a clinical symptom as opposed to system causation of a clinical problem.

Traditionally, the term *differential diagnosis* has referred to a process used by physicians to diagnose disease. This process typically involves three distinct steps. Step 1 is taking a thorough history, including an investigation of the patient's medical history, presenting complaints, and a review of systems. Step 2 is the performance of the physical examination. This history and the findings of the physical examination will lead to a diagnosis or to step 3, the identification of necessary tests, including laboratory tests, diagnostic imaging modalities, and so on. The goal of the three steps is the formulation of a specific diagnosis that will lead to the implementation of the appropriate medical treatment and an accurate prognosis.

For the professions of physical and occupational therapy the concepts associated with and use of the term *differential diagnosis* are still evolving and under debate. A recent editorial describes diagnosis in physical therapy as complex and controversial, with diverse views existing.¹ For physical therapists (PTs), the guiding premise is that the differential diagnostic process fits within the Patient/Client Management Model described in the *Guide to Physical Therapist Practice*² (Figure 7-1) and within *The Guide to Occupational Therapy Practice*.³ The therapist attempts to organize the history and physical examination (including tests and measures) findings into clusters, syndromes, or categories. There are certain clusters of findings that suggest the presence of disease or an adverse drug event and warrant communication with a physician. There are other symptoms and signs that are consistent with conditions that still fit into the older disablement framework. In the world today, the model of choice of all therapists is the World Health Organization (WHO) International Classification of Functioning, Disability and Health (ICF), which moves away from the consequences of disease classification to a health focus classification. Thus a shift in how one looks at disease and its impact on health and

wellness not only has changed the words used by therapists but also incorporates external societal limitations that our clients face.⁴ These changes do not affect the way a therapist should medically screen before formulating a clinical diagnoses based on movement dysfunction. These conditions are inherent in the interrelationships among impairments, functional or activity limitations, and participation in life and are appropriate for physical or occupational therapy interventions.^{2,3,5,6}

The process of differentiating the cluster of findings that warrant communication with a physician regarding concerns about a patient's health status compared with those that do not will be called *Differential Diagnosis Phase 1*.⁷ In this scenario a physician will ultimately diagnose the patient's illness, but the PT's and occupational therapist's (OT's) examination findings and subsequent patient referral contribute to the diagnosis being generated. For many of these illnesses, the use of advanced imaging, laboratory testing, and/or tissue biopsy is necessary for the diagnosis to be made.⁸ Numerous examples exist in *Physical Therapy Journal* and *Journal of Orthopaedic and Sports Physical Therapy* of published case reports and case series describing such action taken by PTs.

If the decision is reached that the symptoms and signs do fall within the scope of practice of PTs and OTs, a second level of differential diagnosis occurs. Now the therapist attempts to categorize the examination findings into the specific diagnostic categories that will specifically guide the choice of treatment interventions and the development of a prognosis. This second level of diagnosis is called *Differential Diagnosis Phase 2*⁷ and is the focus of Chapters 8 and 9. Figure 7-2 illustrates where Differential Diagnosis Phase 1 and Phase 2 fit into the Patient/Client Management Model.

The purpose of this chapter is to discuss the medical screening components associated with Differential Diagnosis

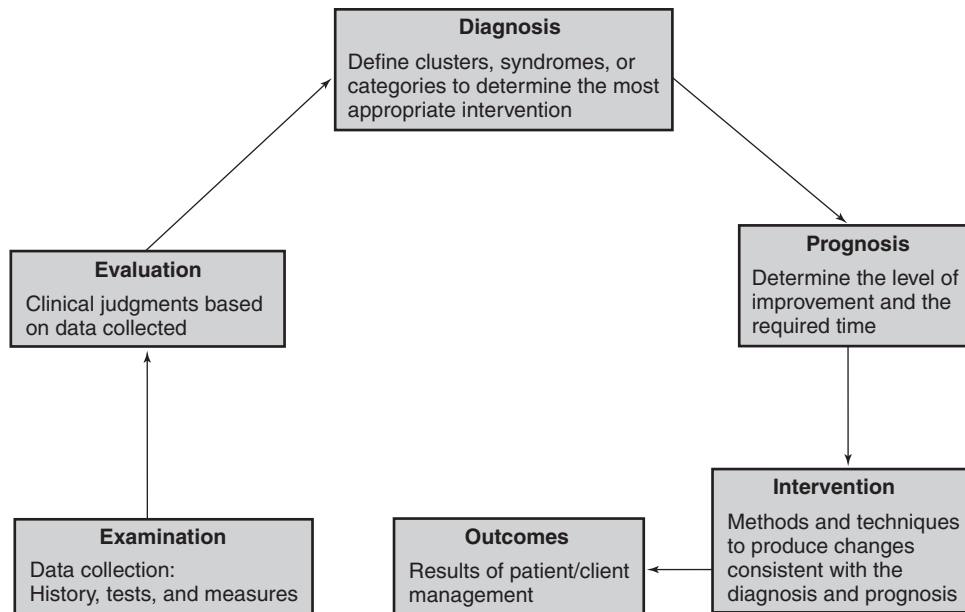

Figure 7-1 ■ Patient/client management model. (Adapted from [American Physical Therapy Association](#): Guide to physical therapist practice. *Phys Ther* 81:43, 2001, with permission of the American Physical Therapy Association.)

Phase 1, including identification of patient health risk factors, recognition of atypical symptoms and signs, review of systems, and within-systems review. Methods to collect this information during a patient examination are also presented. The critical importance of therapists developing these visual and analytical skills is that they can lead to identification of

the differences between direct causation of movement dysfunction pain syndromes arising from disease versus a system causation that may or may not be directly connected to a specific disease. The therapist referral often plays a critical role in providing the doctor the patient behaviors observed as system causation with or without a disease

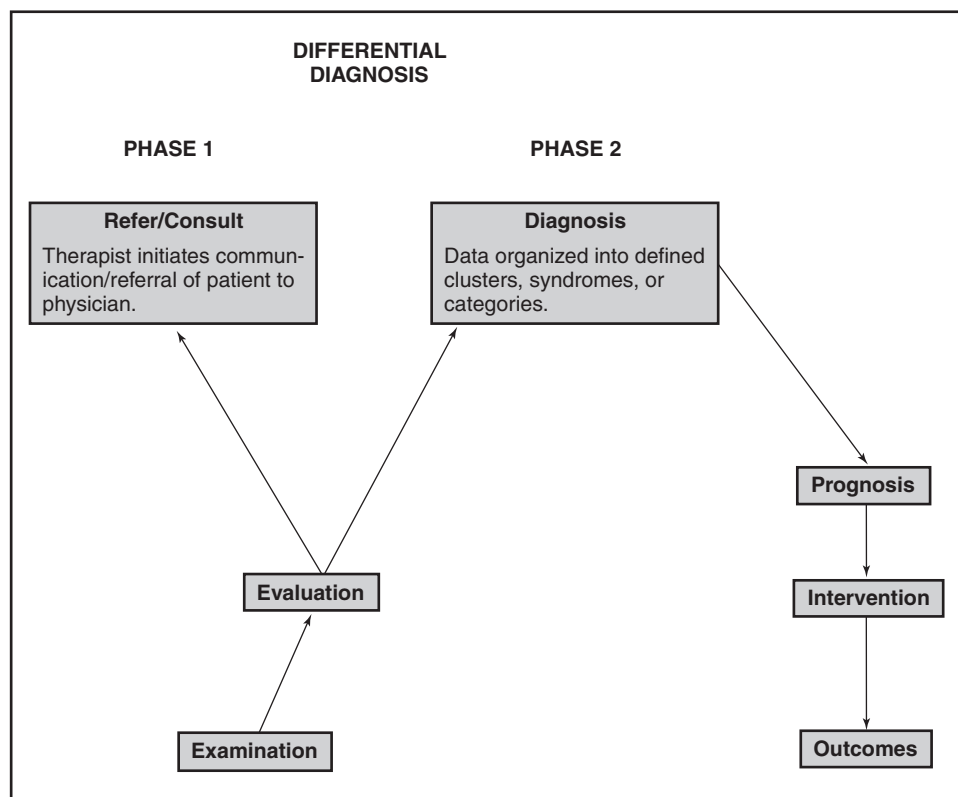

Figure 7-2 ■ Patient/client management model showing Differential Diagnosis Phase 1 and Phase 2. (Modified from [Umphred DA \[Chair\]: Diagnostic Task Force, State of California, 1996–2000, California Chapter of American Physical Therapy Association.](#))

classification. Patient case scenarios are used to illustrate the important medical screening principles.

DIFFERENTIAL DIAGNOSIS PHASE 1: MEDICAL SCREENING

The *Guide to Physical Therapy Practice*^{2,9} and *The Guide to Occupational Therapy Practice*³ clearly describe the therapists' responsibility to refer patients/clients with health concerns to other practitioners. The emphasis of the following discussion is detecting clinical manifestations that suggest the specific need for physician intervention. Typically the initial warning signs associated with these scenarios include a recent onset or exacerbation of symptoms such as pain, weakness, numbness, dizziness, falls, confusion, and so on—common complaints of patients with neurological disorders. Therapists may also detect symptoms or signs unrelated to the primary medical neurological condition but that could be related to an existing comorbidity or a medication side effect. In addition, a general health and wellness screen may reveal a need for a psychological, dermatological, or other nonneurological medical consultation.

As opposed to Phase 2, the goal of Differential Diagnosis Phase 1 is *not* to formulate a specific diagnosis on the basis of these clinical manifestations. A therapist's Phase 2 diagnosis is primarily a group of motor behaviors representing movement dysfunction and how it limits independence in life activities and an individual's ability to participate in life. The Phase 1 process identifies signs and symptoms that are health or disease and pathology driven and, when they have been identified, directs a referral to a medical specialist. In fact, providing a specific diagnosis or labeling a cluster of examination findings when referring a patient to a physician because of health status concerns (e.g., peptic ulcer disease, endometriosis, new or progressive neurological problems) could place the therapist outside the scope of his or her practice. Having the ability to formulate such a specific systemic, neurological, or visceral disease or pathology diagnosis is not necessary to meet the responsibilities described in the Guides to Practice. Once the therapist's concerns have been communicated, it is then up to the physician to diagnose the presence of such disease entities.

The purpose of the therapist's medical screening is to (1) identify existing medical conditions, (2) identify symptoms and signs suggesting that an existing medical condition may be worsening, (3) identify neurological manifestations that suggest an acute or life-threatening crisis, and (4) identify symptoms and signs suggestive of the presence of an occult disorder or medication side effect. This medical screening has always taken place within the clinical framework of PTs' and OTs' practices, but as practitioners become more autonomous, this screening must become more comprehensive, requiring tools and documented evaluation results. **Figure 7-3** is an example of an examination scheme leading to the decision to treat the patient, to treat *and* refer the patient, or to refer the patient. Phase 2 may also include the decision to refer the patient to another practitioner (e.g., dietician, social worker, clinical psychologist) for services augmenting the therapy or to social programs such as wellness clinics that will encourage the patient to participate in movement activities even though he may need individualized therapeutic intervention. The following material focuses on the components of this scheme most directly related to the medical screening process leading to a patient referral.

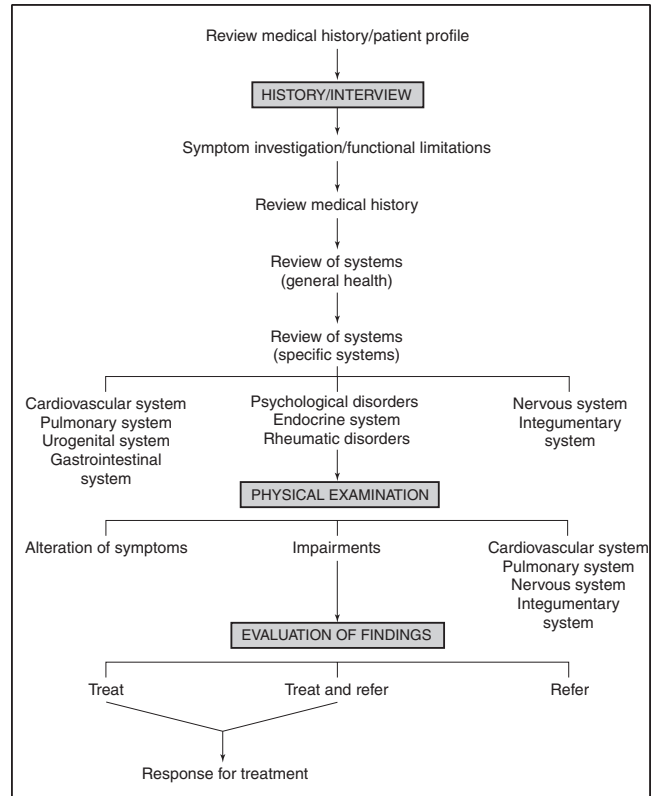

Figure 7-3 ■ Patient examination scheme. (Taken from notes from course by W. G. Boissonnault, 1998.)

Identifying Patients' Health Risk Factors and Previous Conditions

Owing to the considerable overlap in symptomatic presentation of impairment-related conditions and those requiring physician examination, identifying existing health risk factors for occult diseases is important. Numerous factors have an effect on the patient's risk for compromised health status, including age, sex, race, occupation, leisure activities, pre-existing medical conditions, medication usage (over-the-counter and prescription drugs), tobacco use, and substance abuse or the interaction of some of these conditions, and family medical history.

Of these, a personal history of a current or recent medical condition, current medication use, and a positive family history (e.g., mother and aunt with a history of breast cancer, father diagnosed with prostate cancer at the age of 58 years) are the most relevant risk factors for the potential presence of an occult condition. For example, the history of a previous episode of depression significantly increases the risk of a second episode compared with the risk that someone who has never had an episode of depression will have his or her first such episode.¹⁰ The greater the number of existing risk factors, the more vigilant the therapist should be for the presence of warning signs suggestive of disease and the more extensive the other medical screening components will need to be. Those increased risk factors, whether within one system or multiple systems, can lead to clinical behaviors that are the summation of the systems problems and their interactions that affect movement. Physicians should be able to depend on the therapist to recognize these interactive symptoms and refer the patient back to either the referring physician or to another specialist.

There are different methods to collect this medical history and patient profile information, including a review of the medical record and use of a self-administered questionnaire, depending on the practice setting and patient population. Figure 7-4 is an example of a self-administered questionnaire that could be completed by the adult patient, a family member, or a caregiver. As noted in Figure 7-3, a quick scanning review of this information should occur, if possible, before the patient interview is begun. The therapist will have a head start in organizing the history and physical examination, knowing what to prioritize and at least initially what parts of the examination can be deemphasized. The utility and accuracy of a self-administered questionnaire in patient populations germane to therapists' practice, similar to the one illustrated in Figure 7-4, have been described, with the conclusion that such a tool can be a valuable adjunct to the oral patient interview.¹¹

Affirmative answers to previous or current illness questions should direct the therapist to consider what the potential impact may be on the patient's symptoms, choice of examination and treatment techniques, rehabilitation potential, and risk for additional illness. For example, the presence of existing chronic kidney disease (e.g., renal failure) should alert the therapist to numerous potential complications including patient fatigue, weakness, and impaired concentration, all of which could interfere with rehabilitation efforts. Chronic renal failure is also marked by paresthesia and muscle weakness, which could mistakenly be associated with other neurological conditions. Renal osteodystrophy is yet another complication associated with chronic renal failure. The concern of compromised bone density should direct the therapist to use techniques that carry a reduced risk of skeletal injury. A series of follow-up questions for the affirmative answers will assist the therapist in determining the relevance (if any) of each item (see Figure 7-5 for examples of follow-up questions for selected information categories).

Having the self-administered questionnaire completed before the scheduled time of the initial visit will improve the therapist's efficiency. Mailing the questionnaire to the patient before the visit or having the patient arrive 10 to 15 minutes before the appointment would allow for the form's completion without taking time away from the actual examination itself. Once the questionnaire has been completed, taking 1 to 2 minutes to scan it before the interview should be all that is necessary for the therapist to begin formulating questions and organizing the physical examination. The inability of the patient to recall information or complete the questionnaire may be another sign that medical clearance is necessary before progression to Phase 2.

Symptomatic Investigation of Functional Restriction

The chief presenting symptoms or functional restriction typically provides the reason for therapy services being sought and can provide the initial warning sign(s) of potential medical issues needing to be addressed. Despite pain not typically being the chief complaint of many patients with primary neurological conditions, a relatively mild pain is often the initial complaint associated with a serious pathological condition; a dull diffuse ache is often the initial presenting complaint associated with tumors of the musculoskeletal (MSK) system.¹² This relatively minor complaint can easily

be overlooked by therapists working with patients who have neurological involvement and signs and symptoms (e.g., weakness, numbness) that are much more debilitating and cause more functional limitations than the pain complaints do. Although investigating pain complaints may not be the initial priority for these therapists, at a later visit such questioning is very important, especially if it continues, increases in intensity, shifts, or enlarges its region with no causation. Effective medical screening involves the interpretation of a patient's description of symptoms, functional limitations, and the corresponding physical examination findings. Descriptions of symptoms associated with neuromusculoskeletal impairments (loss or abnormality of physiological, psychological, or anatomical structure or function) generally reveal a fairly consistent and predictable pattern of onset and change over a defined period of time. In addition, the neurological and MSK impairments noted during the physical examination should match with the functional limitations described by the patient or the caregiver. If these expectations are not met, it does not necessarily mean the patient has cancer or an infection, but doubt should be raised on the therapist's part whether therapy is indicated.

Patients many times are not aware that presenting symptoms or signs suggest a condition better addressed by a physician as opposed to a PT or an OT. For example, Mr. S. had a cerebrovascular accident 6 months ago with resultant mild residual left hemiplegia. At the time of discharge from rehabilitation services he was independent in all activities of daily living, but residual left upper extremity weakness remained. When visiting his internist for a routine checkup, he complained that over the prior 3 weeks he had lost some functional skills and was having difficulty with self-care. The physician then referred Mr. S. to the therapy clinic for evaluation and treatment. Mr. S. states he has been less active and just needs some help regaining his motor function. During the history taking he states that he is experiencing a deep, dull, aching sensation in the lower lumbar spine and right buttock. He assumes it has developed as a result of his inactivity and thus saw no reason to bother the physician with this problem. As Mr. S. continues to describe his difficulties, he also notes a constant deep ache in the right shoulder that he relates to increased use of his right arm to compensate for the left arm weakness. The physical examination of the low back, pelvis, and right shoulder reveals that the existing symptoms do not vary with active or passive range of motion, resisted testing, or postural holding. In addition, quantity of motion is normal for these regions and motor programming appears intact. At this point the therapist cannot explain the symptoms from an impairment standpoint; therefore, depending on other examination findings, including the patient profile and medical history, communication with the internist may be warranted. The following information describes some of the subcategories associated with symptom investigation.

Location of Symptoms

A body diagram can be a valuable tool to document the location of symptoms expressed verbally or nonverbally by patients with identified neurological deficits. Besides pain and altered sensation, patterns of abnormal tone, asymmetrical posturing, and areas of weakness can also be noted on the body diagram (Figure 7-6). Numerous body structures are potential pain generators, including visceral structures.

Figure 7-4 ■ Self-administered questionnaire to collect medical history information. (Modified from Boissonnault WG, Koopmeiners MB: Medical history profile: orthopaedic physical therapy outpatients. *J Orthop Sports Phys Ther* 20:2–10, 1994, with permission of the Orthopaedic and Sports Sections of the American Physical Therapy Association.)

Medical History Follow-up Form

1. Have you EVER been diagnosed as having the following condition(s)?

Heart condition Yes No

Follow-up questions:

- Describe your heart condition?/What is your heart condition?
- Current problem or previous problem and now fully resolved?
- If a current problem
 - Which doctor is following you for this condition?
 - When is your next follow-up visit?
 - What symptoms do you experience when your heart problem acts up?
 - How do you treat your problem if it's acting up?
 - How does your heart problem interfere with your daily activities/lifestyle?
 - Has the MD placed you on any restrictions owing to your heart problem?

2. Has anyone in your immediate family (parents, sister[s], brother[s]) ever been treated for any of the following:

Cancer Yes No

Follow-up questions:

- Who in your family has the history of cancer?
- What type of cancer?
- At what age were they diagnosed?
- What is their current health status?
- Does anyone else in your family have cancer?

Figure 7-5 ■ Potential follow-up questions for affirmative answers on the self-administered questionnaire. (From W. G. Boissonnault, course notes, 1998.)

Figure 7-7 and Table 7-1 illustrate local and referred pain patterns from various visceral organs. Although the presented pain patterns illustrate those most commonly noted, clinicians should be aware of other potential patterns. For example, ischemic heart disease—the complaint of left chest wall and left upper extremity pain, pressure, or tightness—is not the classic presentation for women and many of the elderly. Besides what is noted in Figure 7-7 and Table 7-1, pain from the heart can also be experienced in the right shoulder or biceps, jaw and tooth, epigastric, and interscapular regions.^{13,13a}

Because there is so much overlap between pain locations associated with visceral disease and neuromusculoskeletal conditions, the results obtained in and of themselves have minimal use in differentiating MSK from non-MSK conditions. Being familiar with the visceral pain patterns will be extremely important, however, when deciding which body systems to screen during the review of systems. Besides noting where symptoms are located, it is equally important to document areas of no complaints (see Figure 7-6). Once the patient has reported symptoms (e.g., low back and right buttock aching, see Figure 7-6), therapists should clarify. Screening to eliminate the possibility of symptoms being present down the back and up the front of the legs; in the pelvis, stomach, chest, neck and face areas; or between the shoulder blades and in the arms is critical. If there is one

Figure 7-6 ■ Body diagram illustrating symptom location. Body areas with no known symptoms or abnormalities are marked with a checkmark. (From Boissonnault WG, editor: *Examination in physical therapy practice—screening for medical disease*, ed 2, New York, 1995, Churchill Livingstone.)

Figure 7-7 ■ Possible local and referred pain patterns of visceral structures. (From Boissonnault WG, editor: *Examination in physical therapy practice—screening for medical disease*, ed 2, New York, 1995, Churchill Livingstone.)

body area so involved that all the patient's and practitioner's attention is focused on it, a relatively mild but potentially serious symptom may be overlooked elsewhere. Placing a checkmark over each body region devoid of symptoms or other abnormal findings is one way to document such information and record change over time.

Symptom Pattern

Aspects of the patient's chief complaint other than symptom location are very relevant to the process of differential diagnosis, in particular a description of how and when the symptoms changed over a defined period of time. Complaints of pain, paresthesia, and numbness associated with primary MSK conditions typically change in a consistent manner over a 24-hour period. The patient will report that the symptom intensity increases with the assumption of specific postures such as left side lying or sitting or with specific activities such as walking, driving, or 2 hours of computer work. Conversely, patients typically can relate paresthesia or pain relief with avoiding certain postures or activities, the assumption of certain postures, wearing an arm sling, and so on. Night pain investigation also falls under this subcategory of patient data. Pain that wakes an individual from sleep and for which changing positions in bed does not provide relief is more concerning than if the pain is positionally related. If the pattern of symptom aggravation and alleviation is that there is no consistent pattern, such as pain that comes and goes independently of the patient's posture, activities, or time of day; night pain is the patient's most intense pain; or paresthesia or pain moves from one body region to another inconsistently with common pain referral patterns or identified medical conditions, then the therapist should start

thinking whether physical or occupational therapy is what the patient truly needs.¹⁴

In general, when symptoms such as weakness or numbness associated with primary neurological conditions are investigated, the 24-hour reference point to assess symptom change is not realistic. Except for an acute onset or exacerbation, these symptoms tend not to fluctuate that quickly with change in posture or position. Understanding the pathogenesis of primary neurological disorders will allow for detection of symptom change unusual for the patient. This will lead to follow-up questions to determine whether this change may represent a medically serious situation. Similarly, a change in the biomechanical alignment of a joint (e.g., the shoulder), may immediately alter the patient's pain response, indicating a direct relationship between MSK imbalance in joint stabilization and gravitational pull, for which therapy would be appropriate.

History of Symptoms

The therapist must also scrutinize the patient's report of the onset of the symptoms. Pain and paresthesia or numbness associated with neuromusculoskeletal impairments typically can be related to trauma, either on a macro or a micro level, or to a medical event such as a cerebrovascular accident. More often than not it is repetitive overuse or cumulative trauma that leads to tissue breakdown and inflammation (see Chapter 18). Patients with neurological impairments resulting in postural abnormalities and abnormal movement patterns are at risk for such conditions. If a patient's symptoms are truly insidious, meaning not related to macro or micro trauma, or there has not been a significant change in activity level that reasonably accounts for

TABLE 7-1 ■ VISCERAL PAIN PATTERNS

STRUCTURE	SEGMENTAL INNERVATION	POSSIBLE AREAS OF PAIN REFERRAL
PELVIC ORGANS		
Uterus including uterine ligaments	T10-L1, S2-4	Lumbosacral junction Sacral Thoracolumbar
Ovaries	T10-11	Lower abdominal Sacral
Testes	T10-11	Lower abdominal Sacral
RETROPERITONEAL REGION		
Kidney	T10-L1	Lumbar spine (ipsilateral) Lower abdominal
Ureter	T11-L2, S2-4	Upper abdominal Groin Upper abdominal Suprapubic Medial, proximal thigh Thoracolumbar
Urinary bladder	T11-L2, S2-4	Sacral apex Suprapubic Thoracolumbar
Prostate gland	T11-L1, S2-4	Sacral Testes Thoracolumbar
DIGESTIVE SYSTEM ORGANS		
Esophagus	T6-10	Substernal and upper abdominal
Stomach	T6-10	Upper abdominal Middle and lower thoracic spine
Small intestine	T7-10	Middle thoracic spine
Pancreas	T6-10	Upper abdominal Lower thoracic spine Upper lumbar spine
Gallbladder	T7-9	Right upper abdominal Right middle and lower thoracic spine, including caudal aspect scapula
Liver	T7-9	Right middle and lower thoracic spine
Common bile duct	T6-10	Upper abdominal Middle thoracic spine
Large intestine	T11-12	Lower abdominal Middle lumbar spine
Sigmoid colon	T11-12	Upper sacral Suprapubic Left lower quadrant of abdomen
CARDIOPULMONARY SYSTEM		
Heart	T1-5	Cervical anterior Upper thorax Left upper extremity
Lungs and bronchi	T5-6	Ipsilateral thoracic spine Cervical (diaphragm involved)
Diaphragm (central portion)	C3-5	Cervical spine

Modified from Boissonault WG, Bass C: Pathological origins of trunk and neck pain, I. Pelvic and abdominal visceral disorders. *J Orthop Sports Phys Ther* 12:192–207, 1990, with permission of the Orthopaedic and Sports Sections of the American Physical Therapy Association.

the complaints, the therapist should again be concerned about the source of the symptoms. A worsening of symptoms (e.g., numbness, weakness, spasticity, swelling) associated with an existing medical condition should be investigated by the therapist with the same scrutiny. The therapist always needs to ask, “Is there a reasonable explanation for the worsening?” An increase in the intensity of the complaints or the involvement of additional body regions could signal a progression of the disease.

Review of Body Systems

By design, *review of systems* screening allows the therapist to detect symptoms secondary (and maybe unrelated) to the reason therapy has been initiated.¹⁵ The review of systems allows for a general screening of body systems for symptoms suggesting the presence of an adverse drug reaction, occult disease, or worsening of an existing medical condition. Suspicions of any of these scenarios would warrant communication with a physician. Checklists of symptoms and signs for each body system can be used by the PT or OT during the patient interview (Box 7-1). To keep the checklists manageable in length, the therapist should investigate presenting complaints and symptoms and the patient’s medical history before the review of systems, as noted in Figure 7-3. For example, on review of the cardiovascular and peripheral vascular system checklist items associated with heart conditions in Box 7-1, important items appear to be omitted, such as chest pain, claudication, a history of heart problems, hypertension, high cholesterol levels, and circulatory problems. If symptoms have already been investigated by use of a body diagram, the therapist would already know whether the patient has chest pain. If symptom change (aggravation or alleviation) over a 24-hour period has already been investigated, the therapist would know whether claudication is an issue. Finally, if the patient’s medical history has already been discussed, the therapist would know whether heart problems, hypertension, or circulatory problems existed.^{13a}

All of the checklists in Box 7-1 need not be used for every patient. The location of symptoms will direct the therapist in deciding which checklists should be included in the initial examination. Figure 7-7 and Table 7-1 can be used to link pain location with visceral systems that could be the source of the complaints. Table 7-2 provides a summary of potential pain locations and diseases of the pulmonary, cardiovascular, gastrointestinal, and urogenital systems. Other symptom characteristics can also alert the therapist to the possible involvement of the endocrine, nervous, and psychological systems. Symptoms, including pain and paresthesias that come and go irrespective of posture, activity, or time of day and that appear to move among the various body regions, can be associated with these systems as well as the visceral systems. In addition to the identification of the location and characteristics of symptoms, a patient’s medical history will also help the therapist decide which systems to screen. A positive medical history, such as a heart problem, would direct the therapist to investigate the patient’s condition, including possible use of the cardiovascular and peripheral vascular checklist as well as the questions listed in Figure 7-5. The therapist also needs to be aware of the medications taken by the patient to medically manage these pathological conditions. Similarly, therapists need to be able to analyze how the drugs potentially affect functional

movements and functional loss. Often, that means a therapist must have a working professional relationship with a clinical pharmacist (see Chapter 36). Use of a general health checklist (Box 7-2) can assist the therapist in prioritizing the inclusion of the checklists in the systems review checklists box during the initial visit. The symptoms noted in this checklist can be associated with disease of most of the body’s systems, as well as with systemic disease and adverse drug events.

If the patient or caregiver (on the patient’s behalf) replies yes to any *review of systems* question, the therapist must determine whether there is a reasonable explanation for the complaint, whether the physician is aware of the complaint, and, if so, whether the complaint has worsened since the patient last saw the physician. When the given explanation is not satisfactory, the physician is unaware of the complaint, or the symptom is worsening, communication with the physician is warranted. Similarly, most physicians look at direct causation: complaint to disease. Therapists need to look at system causation because we see the end result of the combinations of the problems: disease, maturation, environmental factors, and other nondisease causations. All the checklists do not need to be covered during the initial visit. If the patient says “no” for each of the general health items, the patient’s health history is uneventful, and the therapist is comfortable with the description of the chief complaints (including pattern and onset), then the therapist can proceed with the evaluation of specific impairments and functional limitations with some confidence that Differential Diagnosis Phase 2 and therapy intervention are very likely appropriate. The review of systems then takes a lower priority. The result is that the therapist could decide to delay the use of the appropriate systems review checklists until the patient’s second or third visit. If the patient answers “yes” to general health items and has an inconsistent pain pattern, the appropriate review of systems then takes a higher priority and should be covered during the initial visit.

Musculoskeletal System

Box 7-3 provides the checklist for the MSK system. In addition, as with all other body systems, the general health checklist also provides a level of screening for conditions of the MSK system such as infections, metastatic cancers, and rheumatic disorders (e.g., rheumatoid arthritis). Identifying patient risk factors for these conditions is a key for recognizing when to be suspicious. For example, those at highest risk for MSK cancers are those (1) over the age of 50 years and under 20 years, (2) having a previous history of cancer (e.g., breast, lung, prostate, thyroid, and kidney—the most common cancers to metastasize to the axial skeleton), (3) having a positive family history of cancer, and (4) having had exposure to environmental toxins. Those individuals at highest risk for MSK infections report or demonstrate (1) current or recent infection (e.g., urinary tract, tooth abscess, skin infection), (2) history of diabetes with use of large doses of steroids or immunosuppressive drugs, (3) elderly age, and (4) spinal cord injury with complete motor and sensory loss.¹⁶ Last, the primary risk factors for rheumatoid arthritis include (1) female sex, (2) age (peak) 30 to 40 years, and (3) positive family history.¹⁷

The other category of MSK conditions for which therapists need to be vigilant is fractures. The pain and deformity

associated with most sudden-impact, traumatic fractures make for an obvious presentation. However, trauma sufficient to cause a fracture may not be so obvious in a patient with decreased bone density. Lifting a gallon of milk, experiencing a mild slip or bump, or trying to open a window that is stuck may be sufficient to cause a fracture in a patient with a history of chronic renal failure, multiple sclerosis, rheumatoid arthritis, hyperparathyroidism, gastrointestinal

malabsorption syndrome, and long-term corticosteroid, heparin, anticonvulsant, and cytotoxic medication use. The most common locations for such fractures include vertebral bodies, the neck of the femur, and the radius. Observation of posture and body position may provide a clue that something may have changed structurally. For example, with vertebral compression fractures the thoracic kyphotic curve may be accentuated, accompanied by a very pronounced

TABLE 7-2 ■ LINKING PAIN PATTERNS AND VISCERAL SYSTEMS

PAIN LOCATION	VISCERAL SYSTEMS
Right shoulder (including shoulder girdle)	Pulmonary Cardiovascular Gastrointestinal
Left shoulder (including shoulder girdle)	Cardiovascular Pulmonary
Upper thoracic or midthoracic spine	Cardiovascular Pulmonary Gastrointestinal
Lower thoracic and upper lumbar or midlumbar spine	Peripheral vascular Pulmonary Gastrointestinal
Lumbopelvic region	Urogenital Gastrointestinal Urogenital Peripheral vascular

BOX 7-2 ■ GENERAL HEALTH CHECKLIST

Fatigue
Malaise
Fever, chills, sweats
Nausea
Unexplained weight change
Dizziness, lightheadedness
Unexplained paresthesia, numbness
Unexplained weakness
Unexplained cognitive and emotional changes

BOX 7-3 ■ MUSCULOSKELETAL SYSTEM SCREENING

Insidious onset of symptoms
Atypical pain pattern (aggravating or alleviating factors)
Night pain (progressive and/or nonpositional)
Early morning stiffness lasting longer than 30 to 60 minutes
Inadequate relief of symptoms with rest or rehabilitation
Inability to alter symptoms during the physical examination
Lack of impairments that match patient's functional limitations
Atypical physical examination findings (e.g., masses, unexplained atrophy, or weakness)

apex of the curve that was not present before. With femoral neck fracture the lower extremity is often positioned in external rotation and appears shortened compared with its counterpart.¹⁸

Causing potential confusion for the clinician are diseases (especially in the early stages) of the MSK system, which may mimic mechanical MSK conditions. The

patient may report a specific event or time of onset of symptoms, and a pain pattern of increasing pain with weight bearing on the involved extremity over time and lessening relief of pain with assumption of non-weight-bearing positions—all typical findings with impairment-driven symptoms. The therapist may also be able to provoke symptoms during the physical examination as the involved bony area is mechanically loaded. When the history and physical examination findings are evaluated, an unusual finding or pattern will emerge, or the patient will not respond to treatment as expected, making the therapist step back and consider alternative hypotheses regarding the origin of patient symptoms, especially if the risk factors listed earlier are present.

Integumentary System

Screening of the integumentary system is not typically based on the presence or absence of pain, paresthesia, or numbness. As with the nervous system, some degree of screening of the integumentary system occurs with every patient regardless of the presenting diagnosis. Skin cancer has the highest incidence of all the cancers,¹⁹ and therapists generally see a number of exposed body areas during the postural assessment and regional examination that make up the physical examination. In fact, as noted in [Figure 7-3](#), screening the skin begins during the patient interview. During the interview the therapist can be looking at areas of exposed skin such as the face, neck, arms, and feet. As with screening of the other body systems, the therapist's goal is not to identify a melanoma or differentiate squamous cell and basal cell carcinoma but simply to identify skin lesions with atypical presentations. Once the patient has been referred to the physician, disease will be ruled out or diagnosed. [Box 7-4](#) can be used to assess any mole or other skin marking. The items noted are atypical for a benign lesion, more suggestive of a pathological condition.²⁰ Selected items from [Box 7-4](#) have been highlighted, resulting in an acronym—*A* (asymmetry), *B* (borders), *C* (color), *D* (diameter), and *E* (evolving)—that has been used to educate the public for self-screening.²¹ If the therapist notes any of these findings and the patient reports a recent change in the size, color, or shape of the lesion and that a physician has not looked at the lesion, a referral would be warranted.

Besides skin lesions, abnormal general skin color can be a manifestation of a number of conditions. [Table 7-3](#) summarizes abnormal skin color changes. Occasionally, some of

BOX 7-4 ■ SKIN LESION SCREENING—PATHOLOGICAL CHARACTERISTICS

Multivariant color
Black or blue-black color
Irregular borders
Nondistinct (“fuzzy”) borders
Size: 6 mm or larger in diameter
Asymmetrical shape
Friable tissue
Ulcerations
Evolving (changing size, shape, color)

TABLE 7-3 ■ ABNORMAL COLOR CHANGES OF THE SKIN

COLOR CHANGE	PHYSIOLOGICAL CHANGE	COMMON CAUSES
White, pale (pallor)	Absence of pigment or pigment changes Blood abnormality Temporary interruption or diversion of blood flow Internal disease	Albinism, lack of sunlight Anemia, lead poisoning Vasospasm, syncope, stress, internal bleeding Chronic gastrointestinal disease, cancer, parasitic disease, tuberculosis
Blue (cyanosis)	Decreased oxygen in blood (deoxyhemoglobin)	Methemoglobinemia (oxidation of hemoglobin), high blood iron level, cold exposure, vasomotor instability, cerebrospinal disease
Yellow	Jaundice, excess bilirubin in blood, excess bile	Liver disease, gallstone blockage of bile duct, hepatitis pigment (conjunctivae are also yellow)
Gray	High levels of carotene in blood (carotenemia)	Ingestion of food high in carotene and vitamin A
Brown (hyperpigmentation)	High level of metals in body Disturbances of adrenocortical hormones	Increased iron, bronze-gray; increased silver, blue-gray Adrenal pituitary Addison disease

From Shapiro C, Skopit S: Screening for skin disorders. In Boissonnault WG, editor: *Examination in physical therapy practice—screening for medical disease*, ed 2, New York, 1995, Churchill Livingstone.

the most obvious abnormalities are the most difficult to note when one is so focused on items more directly related to therapeutic intervention.

Nervous System

As with the integumentary system, the nervous system is screened to a degree for all patients. The systems review checklists in [Box 7-1](#) include items that provide a very gross, general screening of the nervous system. The therapist should be vigilant for the presence of any of these items in all patients during the initial and subsequent visits. For patients with preexisting findings from this checklist, the therapist must be vigilant for a worsening of

the observed abnormalities. Covering the items in the nervous system checklist should add little time to the therapist's initial examination. Assessing for facial asymmetries and tremors can take place during the interview. Observing balance, movement patterns, and muscle atrophy can occur while watching the patient ambulate into the examination area, during the interview, and as the patient changes positions during the physical examination. Last, impaired mentation may become apparent during the interview or the physical examination as the patient struggles to appropriately answer questions or follow directions. [Case Studies 7-1](#) and [7-2](#) illustrate the importance of this general screening.

CASE STUDY 7-1

A 55-year-old elementary school teacher was referred with a diagnosis of cervical degenerative disk disease at C5-6 and C6-7. Her chief complaint was posterior cervical aching and a sense of neck weakness. Functionally, the patient's primary concern was her increasingly difficult time making it through her workday. She taught first-grade students, so much of her workday was spent with her neck and trunk in a forward flexed position. The patient stated that this persistent flexion posturing was a significant factor for the worsening of her symptoms as her workday progressed. As the interview continued, a tremor of the patient's right hand and forearm was observed as the arm rested on her thigh. When questioned about the observed tremor she stated it started 4 or 5 months ago. She admitted the tremor appeared to be getting worse and that she did not mention it to her physician. No other positive neurological findings were noted. After the initial examination was completed, the concern about the tremor was discussed

and the patient consented to allow her primary care physician (the referring physician) to be called to discuss the finding. The physician facilitated a referral of the patient to a neurologist. Approximately 1 month later, after the neurology consultation and tests, the patient was diagnosed with Parkinson disease. During that month the patient continued to receive physical therapy care for her cervical complaints. In this example, performance of Differential Diagnosis Phase 1 showed the presence of a new symptom (tremor of the right hand) that was not consistent with the medical diagnosis of degenerative disk disease. This symptom triggered the decision by the therapist to refer the patient back to the physician for that specific clinical sign, which led to the additional diagnosis of Parkinson disease. With the patient having been referred to the physician, therapy was also initiated. Differential Diagnosis Phase 2 was performed, which resulted in the decision to treat the cervical complaints of the patient.

CASE STUDY 7-2

A 75-year-old woman was sent to physical therapy with the diagnosis of moderate to severe osteomalacia of the spine. The physician referred her to a PT. The therapist evaluated her spine and noted weakness, pain, and tightness. The plan of care included strengthening and stretching, with the assumption that the pain would subside once the muscles could better support the spine. The therapist did not do a medical screen, and for much of the therapy program the patient exercised without supervision. Both the patient and the husband felt physical therapy was not helping at all. The patient and her husband discussed this problem with a neighbor who was also a PT. The neighbor referred them to another PT who had extensive manual therapy background and used the *Guide to Physical Therapy Practice* as a cornerstone to practice. The new therapist performed a medical screen as part of the examination and noticed that the woman had some general weakness in her left side that did not coincide with the original diagnosis. The symptoms were very subtle and the therapist asked her if she was having any difficulty with daily living activities. She said “no,” so the therapist treated her for her back impairments but monitored her neurological signs. The treatment went far

beyond strengthening and stretching muscles, and the patient was very excited about therapy and how much improvement she was making. At the next treatment session her neurological signs were still subtle but enhanced, so the patient was told that she needed to see her primary care physician for examination and consideration of diagnostic imaging. She continued with PT for three more sessions with her pain almost resolved. Per the therapist’s recommendation she saw her physician after the second treatment. The physician ordered magnetic resonance imaging, and it revealed a grapefruit-sized nonmalignant tumor in her right lower frontal-temporal area. The tumor was removed and the patient recovered after 2 weeks of rehabilitation. The woman and her family believe that it was the PT that saved not only her quality of life, but also her life itself. The first PT, by not doing a medical screening examination, did not identify the occult neurological problem. If the second therapist’s medical screening and referral to the doctor had not been performed, the first therapist could have been deemed negligent and cited in a liability suit; importantly, the patient’s tumor may have caused more permanent damage as it grew undiagnosed within her cranium.

Depression. Depression is a commonly encountered psychological disorder that is associated with significant morbidity and mortality.^{10,22-24} The systems review checklists in [Box 7-1](#) contain items the therapist can use to help make the decision to refer a patient for consultation. If the patient has suicide ideation, the physician should be contacted before the patient leaves the clinic. For the first eight items on the depression checklist, concern should be raised when the therapist detects four or five of the items present daily for a minimum of 2 weeks and resulting in the patient having difficulty functioning at home, work, or school, socially, or in rehabilitation. Of the four or five items, one of them should be depressed or irritable affect or apathy. An exception to the 2-week time frame is during periods of bereavement. When people are faced with a significant loss, it is not uncommon for them to experience a number of the checklist items as they work through the grieving process (refer to Chapter 6).¹⁰ It is reasonable for these people to experience these symptoms for up to 2 months. A neurological event such as a cerebrovascular accident could easily trigger a major clinical depressive disorder, and the depression could significantly impede rehabilitation progress. The therapist may be in a position to facilitate a psychological consultation.

Considering that approximately 15% of people with true major clinical depression commit suicide,¹⁰ therapists need to be vigilant for warning signs that the patient may be considering this action. See the suicide screening shown in [Box 7-5](#) for a list of warning signs. Once the patient acknowledges suicidal ideation, follow-up questions would be appropriate to investigate the patient’s plan and how readily available the resources are regarding the reported method of attempt. This is all-important information to be reported when the therapist contacts the physician. Therapists should be very familiar with their facility’s “suicide protocol or procedure” in terms of what information should be collected from the patient and who should be contacted.

BOX 7-5 ■ SUICIDE WARNING SIGNS

- History of major clinical depression, chemical dependency, schizophrenia, or previous suicide attempt
- Expressions of hopelessness
- The sense that the patient is “giving up”
- An abrupt improvement in patient mood

PHYSICAL EXAMINATION

In addition to this discussion of observation screening for the integumentary and nervous systems, other screening principles are associated with the physical examination. The therapist should have expectations of physical examination findings based on the existing medical diagnosis and data from the history. There should be a correlation between the described functional limitations and the noted impairments. Using the clinical example previously described, the right shoulder pain Mr. S. was experiencing would be expected to increase or decrease in intensity with palpation, movement assessment, or special tests. Not only was the therapist unable to alter the ache, but the shoulder motion and motor control also appeared intact. Essentially there is nothing for the therapist to treat. The inability to alter a patient’s complaints and the lack of neuromusculoskeletal impairments one would expect with the medical diagnosis and the reported functional limitations should again raise concern about the source of the symptoms. The physical examination also includes elements of the systems review.

The *Guide to Physical Therapy Practice* describes the systems review, in part, as a brief or limited examination

of the anatomical and physiological status of the cardiovascular and pulmonary, integumentary, MSK, and neuromuscular systems.¹ For the purposes of this chapter the discussion will focus on assessment of height and weight and assessing heart rate and blood pressure. Being overweight or obese can significantly increase the risk of development of a number of serious conditions (Table 7-4). Using patient height and weight to calculate body mass index (BMI) can be a valuable measure to identify patients who may need a dietary consultation to prevent disease states or minimize morbidity associated with current illnesses. BMI is calculated by dividing body weight (in kilograms) by height (in meters). Table 7-4 provides a summary of disease risk associated with BMI and waist circumference.

Resting blood pressure and pulse rate and rhythm are also important values to be routinely measured. See Table 7-5 for a summary of blood pressure values for adults. Table 7-6 presents normal resting pulse rate parameters for therapists

to consider when examining a patient. A 30-second monitoring period after a 2- to 5-minute rest period is recommended to obtain baseline rate values.²⁵ Resting blood pressure values can also provide important screening information. As with assessing pulse rate, resting blood pressure should be assessed after a 5-minute rest period. Variations from the normative values may lead therapists to additional assessment of the vascular system and the central autonomic nervous system and then to a patient referral.

Examination Summary

For many patients a single red flag finding does not warrant a referral, but a cluster of history and physical examination findings does increase disease probability to the point where a referral is indicated. Two examples that are germane to a number of individuals with neurological conditions are deep venous thrombosis (DVT) and pulmonary embolus (PE). DVT affects approximately 2 million individuals in the United States annually, making it the third most common

TABLE 7-4 ■ DISEASE RISK RELATIVE TO NORMAL WEIGHT AND WAIST CIRCUMFERENCE

	BMI (KG/M ²)	OBESITY CLASS	MEN ≤102 CM (≤40 INCHES) WOMEN ≤88 CM (≤35 INCHES)	>102 CM(>40 INCHES) >88 CM (>35 INCHES)
Underweight	<18.5		—	—
Normal	18.5-24.9		—	—
Overweight	25.0-29.9		Increased	High
Obesity	30.0-34.9	I	High	Very high
	35.0-39.9	II	Very high	Very high
Extreme obesity	≥40	III	Extremely high	Extremely high

*Not taking antihypertensive drugs and not acutely ill. When systolic and diastolic blood pressures fall into different categories, the high category should be selected to classify the individual’s blood pressure status. In addition to classifying stages of hypertension on the basis of average blood pressure levels, clinicians should specify presence or absence of target organ disease and additional risk factors. This specificity is important for risk classification and treatment.

†Based on the average of two or more readings taken at each of two or more visits after an initial screening.

‡Optimal blood pressure regarding cardiovascular risk is less than 120/80 mm Hg. However, unusually low readings should be evaluated for clinical significance.

TABLE 7-6 ■ RESTING PULSE RATE IN BEATS PER MINUTE

	AVERAGE	LIMITS
Norms	120-160	—
Fetal	120	70-190

Modified from Jarvis C: *Physical examination and health assessment*, ed 4, Philadelphia, 1992, WB Saunders.

cardiovascular disease.²⁶ A sobering estimation is that approximately 50% of those with a DVT are asymptomatic in early stages.²⁷ Clinicians are challenged to identify patients at greater risk for this condition who do not have the obvious signs and symptoms of calf pain, swelling, and redness. The following clinical decision rule has been validated

in ambulatory patient populations (Table 7-7). Of note for the neurological population, a history of spinal cord injury does not appear in this rule even though it is considered a strong risk factor for DVT. The authors assume there were very few patients with spinal cord injury in the validation research.

Similarly for PE, a clinical decision rule exists for screening (Table 7-8). PE is associated with high morbidity and mortality, highlighting the critical nature of timely detection. Hull describes PE as one of the “great masqueraders” of medicine because of the often nonspecific presenting symptoms and signs.²⁸ Wells and colleagues estimate that 50% of PEs go undiagnosed.²⁹

Clinician concern regarding the possibility of a DVT and/or a PE being present would warrant urgent communication with the patient’s physician.

RESPONSE TO TREATMENT

Frequently during Differential Diagnosis Phase 1 the therapist will decide referral of the patient to a physician is not warranted and will proceed to Differential Diagnosis Phase 2 and determine whether physical therapy is warranted or no intervention recommended. As treatment is initiated and progresses, the therapist must remain vigilant for the appearance of symptoms and signs discussed throughout this chapter. In addition, correlating subjective and objective changes as treatment progresses will help the therapist decide whether further intervention is warranted or whether referral back to the physician or other health care practitioner is appropriate. For example, if a patient reports a significant improvement or worsening, one would expect the therapist to note a corresponding change in posture, movement ability, palpatory findings, or neurological status. If the expected correlation between patient report and physical examination findings is not found, the therapist should begin considering that therapy may not be warranted. A careful review of systems and symptom investigation would again be necessary as part of the return to Differential Diagnosis Phase 1.

TABLE 7-7 ■ CLINICAL DECISION RULE FOR DEEP VENOUS THROMBOSIS (DVT)

CLINICAL CHARACTERISTIC	SCORE
Active cancer (treatment ongoing, or within previous 6 months or palliative)	1
Paralysis, paresis, or recent plaster immobilization of lower extremities	1
Recently bedridden >3 days, or major surgery in past 12 weeks requiring general or regional anesthesia	1
Localized tenderness along distribution of deep venous system	1
Swelling of entire leg	1
Calf swelling >3 cm greater than asymptomatic side (measured at 10 cm below tibial tuberosity)	1
Pitting edema confined to symptomatic leg	1
Collateral superficial veins (nonvaricose)	1
Alternative diagnosis is as likely as or more likely than DVT	-2
KEY	
SCORE	SIGNIFICANCE
-2 to zero	Low probability of DVT: 5% (95% confidence interval [CI], 4.0%-8.0%)
1-2	Moderate probability of DVT: 17% (95% CI, 13%-23%)
3 or greater	High probability: 53% (95% CI, 44%-61%)

From Wells PS, Anderson DR, Bormanis J, et al: Value of assessment of pretest probability of deep-vein thrombosis in clinical management, *Lancet* 350(9094): Dec 20-27;1795-1798, 1997.

TABLE 7-8 ■ “WELLS” CRITERIA FOR DETERMINING PROBABILITY OF PULMONARY EMBOLISM (PE)

CRITERION	POINT VALUE FOR CRITERION
Clinical signs of deep venous thrombosis (DVT)	3.0
Heart rate >100 beats per minute	1.5
Immobilization for 3 days or longer, or surgery in previous 4 weeks	1.5
Previous diagnosis of PE or DVT	1.5
Hemoptysis	1.0
Patients with cancer receiving treatment, treatment stopped in past 6 months, or receiving palliative care	1.0
Alternative diagnosis less likely than PE	3.0
Pretest probability of PE is low with a score <2 points; moderate with a score 2 to 6 points; and high with a score >6 points.	

Data from Wells PS, Anderson DR, Rodger M, et al: Excluding pulmonary embolism at the bedside without diagnostic imaging: management of patients with suspected pulmonary embolism presenting to the emergency department by using a simple clinical model and a d-dimer. *Ann Intern Med* 135:98–107, 2001.

CONCLUSION

If all diseases manifested with a high fever, coughing up blood, and blood in the urine, the medical screening process would be a simple one. Unfortunately, many diseases initially manifest with subtle complaints, intermittent symptoms or mild pain, stiffness, subtle weakness or paresthesias, or acute dementia. If these complaints are brought to a physician's attention by the patient, they often are not severe enough to warrant extensive diagnostic testing. Many patients or family members simply ignore symptoms or physiological changes, rationalizing that everything is okay, the family member is just old, or he or she simply does not like to see physicians or is too busy. All of the scenarios can account for patients with occult disease seeing therapists. The fact that PTs and OTs tend to spend a moderate amount of time with patients over a period of weeks or months can facilitate the detection of subtle manifestations. In addition, as therapists develop rapport with patients and family members, information may be shared that they were uncomfortable disclosing initially. Always remember that acute dementia is never normal and is reflective of an acute problem rather than simply of aging.

The responsibilities of the PT and OT related to screening for symptoms and signs that indicate the involvement of another health care practitioner are clearly stated in the *Guide to Physical Therapy Practice*² and *The Guide to Occupational Therapy Practice*.³ The process associated with Differential Diagnosis Phase 1 allows for the appropriate medical screening yet keeps therapists within their scope of practice. The therapist simply communicates to the physician the list of clinical findings. The physician will determine whether new or additional medical tests are needed to rule out or diagnose specific diseases. Facilitating the timely referral of patients to physicians is an important role for therapists working within a collaborative medical model. It is this model that best serves the needs of our patients. For additional information related to the medical screening process, the readers are directed to four other textbooks.^{25,30-32}

With changes in health care delivery and physicians also being asked to see more patients in less time, it is critical that all health care practitioners include an adequate medical screening component to their examinations. If quality-of-life issues are truly an important component of health care delivery, then Differential Diagnosis Phase 1, medical screening, has and will continue to be a professional expectation and responsibility placed on each PT and OT. Because consumers are accessing therapeutic services through more direct means, that responsibility will remain and grow in importance as part of both professions' education and practice. Over the next few years PTs' and OTs' roles will continue to evolve in the arena of primary care. Medical screening performed by the therapist will guide patients to a physician and could become a key component of maintaining the health and quality of life of that consumer.

In the future another choice will have to be considered as part of the role of a movement specialist. The results of Phase 1 and 2 assessments may determine that neither a medical referral nor therapeutic intervention itself is appropriate. In this situation, the patient might benefit from community activities but would not need a movement specialist, especially if the physician also has determined that medical intervention is not necessary.

CHAPTER 8

Differential Diagnosis Phase 2: Examination and Evaluation of Functional Movement Activities, Body Functions and Structures, and Participation

KEY TERMS

activity limitations
body system problems and impairments
evaluation
examination
participation restrictions

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Differentiate the medical diagnosis made by the physician from the diagnosis made by a movement specialist.
2. Identify the differences among activity limitations, participation restrictions, and impairments in specific body structure and function.
3. Choose appropriate examination tool(s) from each category of the ICF model—body system problems and impairments, activity limitations, and participation restrictions.
4. Identify resources used to analyze the usefulness and psychometric properties of outcome measures that address body system impairments, activity limitations, and participation restrictions.
5. Discuss the role of support personnel and assistants in the examination process.
6. Evaluate the results of the clinical examination to establish a therapy diagnosis that drives intervention planning.

Since the beginning of the evolution of practice for movement specialists within the health care arena, clinicians have been expected to examine a client's functional performance and draw conclusions from the examination. The synthesis of information gathered has led to the establishment of short- and long-term goals, a prognosis concerning the likelihood of the goals being achieved, and the time it will take to achieve those goals. Similarly, the selection of the most effective and appropriate intervention strategies will guide the therapist and patient toward the desired outcomes. Today, clients are referred for physical and occupational therapy with "evaluate and treat" orders as the common referral pattern used by physicians or other health care providers. With direct access to physical and occupational therapy becoming a reality in many states across the United States and other countries, many patients are walking into clinics because they have decided that therapy is the best alternative to assist with their functional problems. Whether through self-referral or referral from another medical or health care practitioner, once a client enters into a therapeutic environment, clinicians must first determine whether the individual is medically stable at a body system level (see Chapter 7) and an appropriate candidate for therapeutic intervention. Once medical screening has been completed and the therapist determines that there are no red flags to suggest that the client needs to be referred for additional disease or pathology examination or does not need therapeutic intervention, then the client enters into Phase 2 of the evaluation process

(Figure 8-1). In this phase it is important to examine and identify the client's strengths that will facilitate recovery of functional movement, as well as what the client is unable to do functionally.

Numerous tools are used to examine clients with physical complaints and problems with functional movement. Many of these tools directly measure specific strengths and weaknesses of *body system structures and functions*, helping the clinician to identify specific impairments of a client that are causes of functional loss. Each body system or impairment tool is intended for a specific purpose and is designed to supply the user with a given outcome measure in a predetermined set of values.

Other tools measure a client's ability or limitation for performing functional *activities*. These tools are designed to examine the performance of a client during various functional skills and activities of daily living. Functional tools also provide the user with a predetermined set of values. These tools, however, do not directly supply information about the cause of the client's functional movement problems. The user must extrapolate information from the results of each functional test and then choose the appropriate body system or impairment measurement tools to determine the combination of impairments that may be contributing to the limitations in the client's ability to perform daily living activities or participate in normal life interactions.

A third category of assessment is the administration of *participation* outcome measures. These are designed to

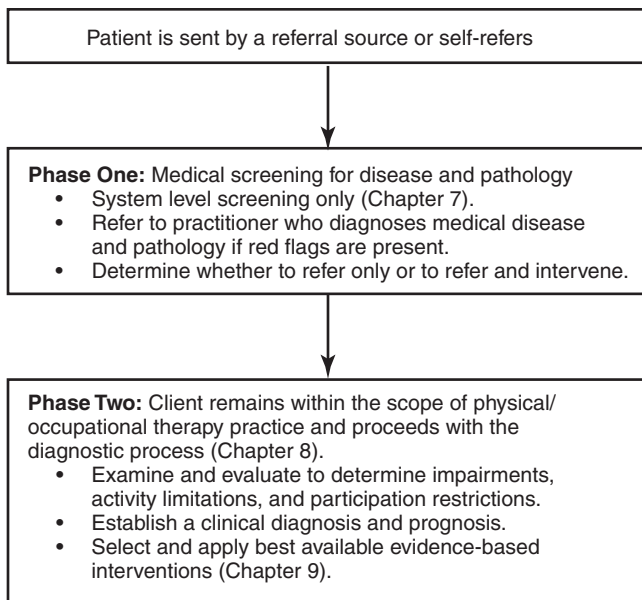

Figure 8-1 ■ The diagnostic process used for best practice by physical and occupational therapists.

assess a client's involvement or restriction in domestic, community, social, and civic life situations. These tools examine the client's perspective on the effects of his or her health condition on the ability to function in major life areas, interpersonal interactions and relationships, and quality of life.

The process of examination and evaluation occurs throughout the entire episode of care. The therapist must be constantly assessing the patient's health status during each encounter. Initially the therapist may miss something important that does not become identified until more complex activities are introduced. Once the subtle body system problems become obvious, the therapist may need to go back to identify more in-depth causes and fine-tune intervention strategies. The intervention strategy may proceed in various directions depending on whether the patient and therapist mutually agree that the goal should stress adaptation and compensation versus regaining function through motor learning.

To be able to provide information that is meaningful in determining the best possible intervention for a particular patient, the examination tools selected by the clinician must be objective, reliable, valid, and appropriately matched with patient expectations. These tools should also communicate necessary information in a language that is understandable to all health care professionals and the payer responsible for funding the services (see Chapter 10). With the limitations on visits within the clinical setting and the critically important variable of motivation and adherence of the patient, the setting of goals and the selection of intervention strategies need to be established through patient-centered participation.¹⁻¹⁰

This chapter has been developed to help the reader work through the problem-solving and decision-making process for selecting appropriate tests. It is not within the scope of this chapter or text to explain each examination tool in detail. However, the reader is presented with an extensive

list of tests for body function and structure, activity, and participation in [Appendix 8-A](#).

SELECTION OF APPROPRIATE TESTS AND MEASURES

After the patient history and interview and the review of systems, the next step in the patient/client management process is the selection of appropriate tests and measures that will identify the most important patient problems that require therapeutic intervention. In the clinical environment, the therapist often approaches this process by first identifying the functional activities that the patient is able and not able to do (activity limitation or functional limitation), hypothesizing the possible impairments causing this activity or functional limitation, and then testing the body systems and subsystems to identify the nature and extent of the impairments. Consistent with the International Classification of Functioning, Disability and Health (ICF) model, the client's strengths are often emphasized as the foundation for this process. The approach is proactive and collaborative, truly capitalizing on the client's potential and goals, and highlights the therapist-client partnership.

TESTS OF ACTIVITY AND FUNCTIONAL PERFORMANCE

As mentioned previously, the therapist typically starts with the examination of functional activities. This step will allow the therapist to understand the specific functional tasks that the patient can do, as well as those activities or functions that the patient is unable to perform. It is important to observe the client during the performance of these tasks and to note the motor patterns used. Many functional assessment tools have been developed to provide a more objective assessment of everyday skills and tasks. Each tool is designed to measure and score a specific type of functional ability. Several tools test a range of skills from balance skills to walking ability during the performance of functional tasks. Some tests are quick and easy to set up and perform, such as the Functional Reach Test and Timed Up and Go (TUG) Test, whereas other tools may take longer to administer, such as the Berg Balance Scale or Fugl-Meyer Assessment. There are advantages and disadvantages to both of these types of tests. Those that are the quickest to administer tend to measure fewer functional skills and do not supply information on the total functioning of a client. However, if the clinician properly identifies the client's problems and is able to focus on the most efficient way of measuring them, a quick functional test can be the most beneficial one to use. Tests that take a bit longer to administer typically assess multiple skills and supply the user with a more comprehensive picture of the client's functional abilities including those in various domains such as gross mobility, self-care, cognitive ability, and communication ability, among others. Often the decision on the complexity of the assessment tool used is based on the client and family's objectives and long-term goals.

Outcome scales for functional tests may be found in ordinal format (e.g., Functional Independence Measure [FIM], Barthel Index, Katz Index of Independence in Activities of Daily Living). Each has its own unique point value and range, varying from a two- to three-point scale (e.g., Tinetti Performance-Oriented Mobility Assessment [POMA]) to a seven-point

scale (e.g., FIM). A few tools supply ratio scale data (e.g., the TUG, Functional Reach Test, and measures of gait velocity). Test data presented in ratio scale format will more clearly show incremental changes, thereby facilitating the comparison of pretherapy to posttherapy performance.

TESTS OF BODY FUNCTIONS AND STRUCTURES

After identifying problems with functional performance of activities, the clinician then focuses on the performance of appropriate tests for body functions and structures. Consistent with the ICF model, the intent is to identify which body systems or subsystems are intact and functioning normally and could be optimized as the patient works on regaining the ability to perform functional tasks or participate in life. In this step, it is also important to identify which body systems and subsystems are not normal. These body system impairments may be the cause of the functional loss.

Impairment (ICF; International Classification of Impairments, Disabilities, and Handicaps [ICIDH]; Nagi)¹¹ is defined as the loss or abnormality of physiological, psychological, or anatomical structure or function at the organ system level.¹² The clinician needs to make the distinction between primary impairments, which are a direct consequence of the client's specific disease or pathological condition, and secondary impairments, which occur as sequelae to the disease or rehabilitation process or as the result of aging, disuse, repetitive strain, lifestyle, and so on. Moreover, the clinician must remember that, although functional limitations are usually caused by a combination of specific impairments, it is possible that impairments may not contribute to specific functional problems for a particular client. If this is the case, the clinician should make a determination regarding whether these impairments, if left uncorrected, will result in the development of activity limitations at a later time. Simultaneously, the patient needs to be a part of this discussion because the therapist may not have the time to address all impairments. The correction of particular impairments may have more meaning or value to the patient. To the consumer some impairments may lead to limitation of functions that are important to them, whereas other impairments may restrict an activity in which the patient would never want to participate.

The ultimate goal of any therapeutic intervention program is to attain the highest level of health and wellness possible. Measurement tools that the clinician chooses to use also need to reflect this end result. For example, "traditional" impairment measurements may indicate that a client demonstrates shoulder range of motion (ROM) that is decreased by 25 degrees. The more important question should be how this decrease in ROM affects the client's ability to perform a functional task such as dressing or any other activity that the client perceives as important. The clinician is therefore encouraged to consider the functional implications of these measurements to obtain results that are more meaningful for the client.

The clinician is always faced with the challenge of identifying and administering examination tools that will not only reflect the client's level of health and wellness but also reflect the client's functional improvement as a result of the intervention provided. Functional measurement tools can be used as a baseline measure for those functional skills.

However, these tools typically require a large improvement in a client's functional performance for a clinically significant change to be seen. Results obtained from impairment tests can fill in the large gaps between numerical scores on functional scales, demonstrating objective measurements and trends in the direction toward improvement before any change is demonstrated on the functional examination.

Box 8-1 illustrates impairments that may be seen in patients/clients with movement disorders caused by neurological dysfunctions. These impairments are further classified as those that are within the central nervous system and those that are outside the central nervous system and result from interaction with the environment. These impairments are further discussed in detail in various sections of this book.

Range of motion testing is one example of a common neuromusculoskeletal system examination procedure. Clinicians depend heavily on ROM measurements as an essential component of their examination and consequent evaluation process. It is imperative that the data obtained from this procedure be reliable. It has been suggested that the main source of variation in the performance of this procedure is method and that reliability can be improved by standardizing the procedure.¹³

An impairment in ROM can be the result of other body system impairments. ROM measurements may be used to

BOX 8-1 ■ IDENTIFICATION AND CLASSIFICATION OF IMPAIRMENTS

IMPAIRMENTS WITHIN THE CENTRAL NERVOUS SYSTEM

1. Tone, reflexes, and abnormal state of the motor neuron pool
2. Synergies (volitional or reflexive)
3. Sensory integration and organization
4. Balance and postural control
5. Speed of movement
6. Timing
7. Reciprocal movement
8. Directional control, trajectory or pattern of movement
9. Accuracy
10. Emotional influences
11. Perception
12. Cognition, memory, and ability to learn
13. Levels of consciousness

IMPAIRMENTS OUTSIDE OF THE CENTRAL NERVOUS SYSTEM AND INTERACTION WITH THE ENVIRONMENT

1. Range of motion
2. Muscle strength or power production
3. Endurance
4. Cardiac function
5. Circulatory function
6. Respiratory function
7. Other organ system interactions
8. Hormonal and nutritional factors
9. Psychosocial factors
10. Task content
11. Environmental construct

determine the effect of tone, balance, movement synergies, pain, and so forth on the neuromuscular system and ultimately on behavior. Most important, the clinician needs to remember that the ROM needed to perform a functional activity is more critical than “normal,” anatomical, biomechanical ROM values and must be considered when labeling and measuring impairments. For example, full ROM in the shoulder is seldom needed unless activities of daily living, work, or leisure activities require it, such as performing a tennis serve or reaching overhead to paint a ceiling. When needed for specific tasks, goniometric measurements of ROM are appropriate, but at other times a functional range measurement may be sufficient.

Muscle strength testing is another commonly used examination procedure. Clinicians use various methods of quantifying strength including “traditional” manual muscle testing (MMT) and the use of a dynamometer. As with ROM, strength should be correlated with the patient’s functional performance. Again, the clinician may find a client to have 3/5 strength in the shoulder flexor muscle groups or find grip strength to be 35 kg, but the more important question should be “What does this mean in terms of the client’s ability to perform activities of daily living, and/or can he use that power in a functional activity?” The clinician is also advised to make the distinction between muscle strength and muscular endurance as it relates to function. A client may have sufficient lower-extremity strength and power to get up from the seated position; however, this does not necessarily mean that the client has muscular endurance to perform the task repeatedly during the day as part of normal everyday activities.

The status of the cardiac, respiratory, and circulatory systems significantly affects a client’s functional performance (see Chapter 30). Blood pressure, heart rate, and respiration give the clinician signs of the patient’s medical stability and the ability to tolerate exercise. The clinician may also obtain the results of pulmonary function tests for ventilation, pulmonary mechanics, lung diffusion capacity, or blood gas analysis after determining that the client’s pulmonary system is a major factor affecting medical stability and functional progress. Various exercise tolerance tests also attempt to quantify functional work capacity and serve as a guide for the clinician performing cardiac and pulmonary rehabilitation.

A client who has difficulty performing activities of daily living and who has neurological impairments in the central motor, sensory, perceptual, or integrative systems needs to undergo examination procedures to establish the level of impairment of each involved system and to determine if and how that system is contributing to the deficit motor behaviors. Functional evaluation tools used may include the FIM, the Barthel Index, the Tinetti POMA, or the TUG test. The results of these tests will help to steer the clinician toward the most useful impairment tools to use to evaluate limitations in the various body systems. Impairment tools may include the Modified Ashworth Scale for spasticity, the Upright Motor Control Test for lower-extremity motor control, the Clinical Test of Sensory Interaction on Balance (CTSIB), or the Sensory Organization Test (SOT) for balance and sensory integrative problems, or computerized tests of limits of stability on the NeuroCom Balance Master, among others (see [Appendices 8-A, 8-B, and 8-C](#)).

The clinician is also advised to investigate the interaction of other organs and systems as they relate to the patient’s functional limitations. For example, electrolyte imbalance, hormonal disorders, or adverse drug reactions (see Chapter 36) may explain impairments and activity limitations noted in other interacting systems.

TESTS FOR PARTICIPATION AND SELF-EFFICACY

In ICF terminology, *participation* is defined as an individual’s involvement in a life situation. Domestic life, interpersonal interactions and relationships, and community, social, and civic life are some examples of aspects of participation that can be examined for each individual. *Participation restriction* is the term used to denote problems that individuals may experience in involvement in life situations. When considering participation it is important to obtain the individual’s perception of how the medical condition, impairments, and activity limitations affect his or her involvement in life and community. Therefore many of the tests for participation and self-efficacy are in self-report format. The Activities-specific Balance Confidence Scale (ABC), Short Form 36 (SF-36), and Dizziness Handicap Inventory (DHI) are examples of tests that can be used to gather information under this domain. These tests allow an individual to assess his or her health quality of life after an incident that affected activity and participation. [Appendices 8-A, 8-B, and 8-D](#) include tools that measure participation and quality of life.

CHOOSING THE APPROPRIATE EXAMINATION TOOL

The ability to choose the appropriate examination tool(s) for a particular client will depend on several factors:

1. The client’s current functional status (ambulatory vs nonambulatory)
2. The client’s current cognitive status (intact vs confused or disoriented)
3. The clinical setting in which the person is being evaluated for treatment (acute hospital, rehabilitation, outpatient, skilled care, or home care)
4. The client’s primary complaints (pain vs weakness vs impaired balance)
5. The client’s goals and realistic expectation of recovery, maintenance, or prevention of functional loss (acute injury, chronic problem, or progressive disease process)
6. The type of information desired from the test (discriminative or predictive)

The evaluator should select examination tools that will measure the client’s primary problems (activity limitations, impairments, and participation restrictions) and supply outcome values that are needed to set realistic treatment goals in accordance with those of the client and family and to plan efficient and effective intervention strategies. The clinician is advised to select functional tools that contain component skills that the particular client is having difficulty performing. Skills the client performs poorly will disclose the activity limitations. Skills the client performs well determine the client’s strengths and abilities. The evaluator must then focus on the client’s functional activity limitations as determined by the test(s) to determine the impairment tests that will be performed next. For example, if the client

demonstrates difficulty in rising from a chair during a functional test and scores low on this skill on the outcome measure (the Tinetti POMA or Berg Balance Scale), the clinician must then closely examine the skill of coming to stand to determine the cause of the mobility limitation. The problem may be that the client cannot generate adequate muscle power to push up from the chair, does not have adequate ROM in the hip or the ankle joints to rise from the chair, or no longer sees a reason to get out of the chair, or that it hurts too much to even try. It may be a problem with dynamic balance during or after the transitional movement. Any impairment that is hypothesized by observing performance of the functional skill needs to be measured more specifically. It is up to the examiner to determine the next best steps to take to target the client's problems as efficiently as possible, to measure and record the needed outcomes as objectively as possible, and then to set treatment goals in consultation with the client to design the best intervention to remediate or manage the problems.

Many of the examination tools that measure a client's ability to perform functional activities have been accepted as valid, reliable, and useful for the justification of payment for services rendered. The number of activity limitations and the extent of the client's participation limitation are often reasons why an individual either has accessed therapy services directly or was referred by a medical practitioner. For this reason, the third-party payer expects to receive reports concerning positive changes in the client's functional status for therapeutic services to be justifiable (see Chapter 10). The initial list of functional or activity limitations or participation restrictions helps the therapist determine the extent of, expectations for, and direction of intervention, but it does not determine why those limitations exist. This is the question that is critical to answer as part of the evaluation process. Examination tests and procedures that identify specific system and subsystem impairments help the therapist determine causes for existing participation and activity limitations. These tools need to be objective, reliable, and sensitive enough to provide needed communication to third-party payers to explain the subsystem's baseline progress during and after the intervention. These tools should also supply explanations for residual difficulties in the event that the functional problems themselves do not demonstrate significant objective change or show progress within the time frame estimated.

USING THE EVALUATION PROCESS TO LINK BODY SYSTEM PROBLEMS, ACTIVITY LIMITATIONS, AND PARTICIPATION RESTRICTIONS TO INTERVENTION

After objective measures have been obtained for activity limitations, body system and subsystem impairments, and participation restrictions, clinicians must determine whether the impairments or the functional problems are changeable to a more independent, safe, and functional level. In certain situations a mobility limitation may be remediated and become more functional, although the contributing component impairments may remain unchanged. In other situations, impairment measures may significantly improve but the functional problem may remain unaltered. This is especially true when one impairment is significantly improved but functional progress is masked by the contribution of

other impairments. The examiner must be able to come to a conclusion regarding the relationship between the client's activity limitations and the existing body systems impairments. Without an understanding of this relationship, it is difficult to assess the effect of the treatment intervention(s) on an individual.

The interactions and interrelationships of the identified functional problems and impairments provide the clinician with an initial status or problem list specific to that individual. That list helps the clinician formulate a diagnosis for the movement dysfunction. Through consideration of the objective values obtained during the examination process, a target status to be reached at the conclusion of therapeutic intervention can be estimated. That target status is both impairment and function driven and traditionally would be considered a list of outcome goals. The interactions between impairments and their related activity and participation limitations make up the unique problem map of that individual and direct the clinician toward selecting optimal interventions.

The prognosis made by the clinician is based on the assessment of the likelihood that the patient will achieve the target outcome in a given time frame and estimated number of visits needed to reach the treatment goal. Once the clinician has measured and identified specific activity limitations and their respective impairments, he or she then has an excellent opportunity to conceptually understand how various impairments affect multiple functional problems and which impairments are activity specific.

The following case scenario synthesizes the clinical examination and evaluation process used by physical and occupational therapists.

Assume that a clinician has been called in to examine a client who has sustained an anoxic brain injury during heart surgery. The client's cognitive ability is within normal limits, and he is highly motivated to get back to his normal activities. He is retired; he loves to walk in the park with his wife and to go on birdwatching experiences in the mountains with their group of friends. The clinician must select which functional tests to use to obtain an objective initial status and target the client's problems. Currently the client requires assistance with all gross mobility skills and is demonstrating difficulty balancing in various postures and performing activities of daily living. Results of functional testing reveal that the client demonstrates significant limitations, requiring moderate assistance in the activities of coming to sit, sitting, coming to stand, standing, walking, dressing, and grooming. Assume that the client also displays impairment limitations in flexion ROM at the hip joints caused by both muscle and fascia tightness and hypertonicity within the extensor muscle groups. He has compensated to some degree and is able to perform bed mobility independently. Upper-extremity motor control is within normal limits, and thus the client is capable of performing many activities of daily living as long as his lower trunk and hips are placed in a supportive position and hip flexion beyond 90 degrees is not required. The client has general weakness from inactivity, and power production problems in his abdominals and hip flexor muscles owing to the dominance of extensor muscle tonicity. Once he is helped to stand, the extensor patterns of hip and knee extension, internal rotation, slight adduction, and plantarflexion are present. He can

actively extend both legs after being placed in flexion, but he is limited in the production of specific fine and gross motor patterns. Thus a resulting balance impairment is present owing to the inability to adequately access appropriate balance strategies caused by the presence of tone, limb synergy production, and weakness in the antagonists to the trunk and hip extensors. Through the use of augmented intervention (see Chapter 9) the client is noted to possess intact postural and procedural balance programming; however, both functions are being masked by existing impairments. The decision is made to perform impairment measures, including assessments of ROM at the hip, knee, and ankle joints; the ability to produce strength in both the abdominal and hip flexor muscle groups; and volitional and nonvolitional synergic programming, balance, and posture, and volitional control over muscle tone. The demand on ROM, power production, and specific synergic programming will vary according to the requirements of the functional activities performed.

Using a clinical decision-making process, the clinician will conclude that the impairments that are being targeted to measure will vary from one functional activity to the next. For instance, if this client is demonstrating difficulty rising from a chair, the target impairment may be a ROM measurement. This same ROM impairment may also contribute to problems with moving about the base of support in functional sitting. The clinician makes the determination as to the extent to which the impairment interferes with each functional problem for that particular client.

These objective measurements help the clinician explain which outcomes would be expected to be achieved first and why. These measurements are recorded as part of intervention charting and help to objectively demonstrate that the client is improving toward functional independence. They also give an indication of what the client still needs to reach the desired outcome, the rate of learning that is taking place, and an estimation of recovery time that is still required. These objective measurements give to the clinician and the client a better avenue to discuss expectations with family members, other medical practitioners, and third-party payers. In this example, assume that, after intervention, functional ROM in the hip was achieved. However, this improvement did not result in an improvement in the activity problems because synergic programming prevented adequate hip flexion during one or more functional activities. Understanding and measuring the difference between lack of ROM as a result of muscle or fascia tightness versus lack of range from abnormal synergic patterning helps the clinician communicate why a client is successful in one activity and may still need assistance in another.

Scores obtained from tests of activity, participation, and impairments supply statistically important measurements that can then be used to discuss the limitations placed on the therapeutic environment by fiscal intermediaries. Therapists must be clear when documenting the initial status and the target status for clients so that the recommended intervention and length of stay may be justified (see Chapter 10).

When making a determination of the potential impact of an intervention on improving a client's problems, clinicians must remember that a key factor in this process of examina-

tion and evaluation is the acceptance of the movement dysfunction or impairment by the client. A mobility problem or impairment may be clearly identified by a functional test or impairment test; however, the client may deny that the problem even exists. Acceptance of the problems by the client and a willingness to change are critical to the client's adherence to the intervention strategy.

As mentioned earlier, the identification of potential impairments was done after functional testing to streamline the examination process. After performing the functional examination, the therapist postulated that the client might have impaired motor control, muscle weakness, sensory deficits, pain, and decreased endurance that may have been causing the functional limitations. MMT revealed lower-extremity strength of 1/5 in both ankle motions, 2/5 in both knees, and 3–/5 in both hips. Upper extremities tested as 1/5 finger flexors (incomplete grip), 2/5 wrist motions, and 3+/5 in both elbow motions. Shoulder and trunk strength were within functional limits for all motions. Sensory testing indicated absent touch and proprioceptive sensations from the foot to the knee of both lower extremities, with impaired sensation from the thighs to the hips. Both hands and wrists tested absent to touch and proprioception, with the elbows and shoulders testing intact. The client's endurance was limited to short bouts of activity (3 to 5 minutes), with rapid muscular and cardiovascular fatigue. The presence of these impairments helped to explain the resultant functional limitations tested earlier.

In terms of standardized functional tests, the multidisciplinary FIM could give insight into this patient's ability to function in multiple domains and categories. Baseline scores on the Tinetti POMA and the Berg Balance Scale could be collected because this client is expected to regain further function in balance and postural control as recovery from the condition occurs. As the client regains strength and peripheral sensory ability, he may be able to perform the TUG and the 10-Meter Walk Test. These functional assessments paint a better picture of what the client can and cannot do, as well as providing a way to measure functional progress in various activities throughout rehabilitation.

When determining an appropriate tool to examine a client's functional status, the clinician must also consider the "ceiling and floor effect" of the functional tools. In this particular case, the patient is probably unable to perform the Functional Gait Assessment (FGA) but may be appropriate for beginning the balance portion of the Tinetti POMA. As the patient progresses, the predictive and discriminative properties of some of these tests could provide information regarding the patient's likelihood of falling, or ability to safely perform selected functional tasks.

CASE STUDY 8-1*

The patient is a 30-year-old man who was referred to outpatient physical therapy after a 1-week stay in an acute care facility following an exacerbation of relapsing-remitting multiple sclerosis (MS). His height was 2.05 m (6 feet 9 inches) and his weight was 133.81 kg (295 pounds). The patient was first diagnosed with MS 4 years ago. He developed optic neuritis during the exacerbation and was treated with corticosteroid pulse therapy. The patient's past medical history included depression, gastroesophageal reflux disease (GERD), migraine headaches, and hyperlipidemia. After being diagnosed with MS, the patient had to stop working. Before the most recent hospitalization, the patient lived with his sister in a single-story home with five stairs to enter with a railing. At that time he was able to ambulate independently without an assistive device and to complete all activities of daily living without any assistance.

An outpatient physical therapy initial examination was conducted 1 week after the patient was discharged from the hospital. He reported that he was using a wheelchair to get to and from appointments, and inside his home. He was alert and oriented to person, place, and time, although responses were delayed and speech was slightly slurred. There were no complaints of pain, and the patient stated that fatigue and temperature had not affected him.

Several tests of functional movement activities were performed first. The patient was able to roll to the right and left with minimal assistance, with rolling to the right being less difficult for the patient. He needed supervision to move from supine to sitting.

The patient required moderate assistance to perform a sit-to-stand transfer. He was able to ambulate five steps with a front-wheeled walker (FWW) and moderate assistance of one person.

After examination of the patient's functional movement activities, several tests of body function and structures were then administered. Passive ROM for all joints in both upper and lower extremities was within normal limits. The patient presented with 3/5 (fair) strength of the right upper and lower extremities and good (4/5) strength of the left upper and lower extremities during MMT. Light touch and superficial pain sensations tested intact from C4-S2 dermatomes bilaterally.

Sitting balance was scored as 3/4 (good), as the patient was able to accept moderate challenges. Standing static balance was 1+/4 (poor plus); the patient was able to maintain balance with handheld support and occasional minimal assistance.

Observational gait analysis was performed, and impairments in gait included the following: decreased step length bilaterally, wide base of support, decreased weight bearing through the right lower extremity, and lack of toe-off. It was also noted that ataxic type movements were present with ambulation.

The Gait Abnormality Rating Scale (GARS) was performed, and the patient scored a 32/48, indicating increased fall risk. The Tinetti POMA was also administered. The patient scored 8/28, indicating a high risk for falls. Several tests were performed using the NeuroCom Balance Master. The sit-to-stand test showed that the patient had difficulty maintaining balance immediately after rising and had more weight on his left lower extremity. The results were abnormal, based on the norms for the patient's gender and age. Next, the weight-bearing squat test was done. During this test the patient was not able to maintain equal weight through bilateral lower extremities, with the patient bearing weight more on the left side. The patient then performed the limits of stability test, which revealed an inability to lean his center of gravity (COG) over his right lower extremity, or forward onto his toes. The patient then performed the rhythmic weight-shift test; he was not able to complete the forward-backward component of the rhythmic weight-shift test without falling, and he also had difficulty with directional control and velocity during lateral weight shifting.

Last, tests for participation and self-efficacy were administered. The Activities-specific Balance Confidence (ABC) Scale questionnaire was given to the patient to assess the patient's balance self-efficacy. The patient had a score of 20%, indicating a low level of physical functioning. He scored 10% on being able to bend down, pick a slipper up off the floor, and reach for a can on a shelf at eye level with the use of a FWW.

The data collected at initial examination revealed limitations in functional performance resulting from impairments in balance, gait, strength, and motor control, giving the therapist the various movement diagnoses that reflected problems. The *Guide to Physical Therapist Practice* was used to classify the patient in the neuromuscular practice pattern E (impaired motor function and sensory integrity associated with progressive disorders of the central nervous system). The *Guide* indicates a range of 6 to 50 visits needed to reach anticipated outcomes for patients who are classified in this practice pattern. Intervention frequency and duration was set at three times per week for 8 weeks. The prognosis that the patient would be able to ambulate independently in the community with an assistive device in 8 weeks was good, given the patient's willingness to participate in physical therapy, positive outlook, family support, and positive response to medical interventions. The plan of care that was developed focused on improving activity limitations such as transfers and gait and impairments such as weakness and imbalance. The long-term goals were set to be achieved in 8 weeks, and short-term goals were set to be achieved in 4 weeks.

*Case study modified from Larsen-Merrill J, Lazaro R: Use of the NeuroCom balance master training protocols to improve functional performance in a person with multiple sclerosis. *J Stud Phys Ther Res* 21:1-16, 2009.

APPENDIX 8-B ■ Sample Outcome Measures According to the Examination Areas in the Guide to Physical Therapist Practice, from: Neurologic Practice Essentials: A Measurement Toolbox*

Body Structures and Functions—

List of Measures

Cognition

- Ability to follow multistep commands
- Alert, oriented × 4
- Kokman Short Test of Mental Status
- Mini-Mental State Examination (MMSE)
- Montreal Cognitive Assessment
- Scales to detect behavioral and cognitive impairments often seen in patients with brain injury:
 - Agitated Behavior Scale
 - Apathy Evaluation Scale
 - Awareness Questionnaire
 - Cognitive Log
 - Coma Recovery Scale–Revised
 - Coma/Near Coma Scale
 - Confusion Assessment Protocol
 - Disorders of Consciousness Scale
 - Glasgow Coma Scale (GCS)
 - Glasgow Outcome Scale (GOS)
 - JFK Coma Recovery Scale–Revised
 - Neurobehavioral Cognitive Exam
 - Neurobehavioral Functioning Inventory
 - Patient Competency Rating Scale
 - Rancho Los Amigos Levels of Cognitive Functioning
- Tests for depression
 - Beck Depression Inventory
 - Geriatric Depression Scale (GDS)
- Tests for inattention and neglect
 - Behavioral Inattention Test
 - Clock Drawing Test
 - Line Bisection Test
 - Motor-Free Visual Perceptual Test
 - Star Cancellation Test

Fatigue

- Fatigue Severity Scale
- Modified Fatigue Impact Score

Joint Integrity and Mobility

- Glenohumeral joint positioning
- Palpation of subluxation

Muscle Performance and Motor Control

- Reflexive motor and involuntary responses
 - Babinski
 - Clonus (ankle, wrist)
 - Deep tendon reflexes (DTRs)
 - Modified Ashworth Scale (tone, spasticity)
 - Motor Control Test (MCT) on force platform
 - Penn Spasm Frequency Scale
- Automatic motor
 - Adaptation Test (ADT) on force platform
 - Nudge-push test (postural reactions to perturbations)
 - Shoulder tug test (STT) (Parkinson disease)

- Voluntary motor
 - American Spinal Injury Association (ASIA) Scale (spinal cord injury)
 - Coordination tests
 - Detection of tremor
 - Finger-to-nose and rapid alternating movement tests (and other nonequilibrium coordination tests)
 - Fregly-Graybiel Ataxia Test Battery
 - Tandem walking (and other equilibrium coordination tests)
 - Five-Times Sit-to-Stand Test (FTSST)
 - Hand-held dynamometry
 - Manual muscle testing (MMT)
 - Motor Assessment Scale (MAS)
 - Motricity Index
 - Rivermead Motor Assessment
 - Stroke Rehabilitation Assessment of Movement (STREAM)
 - Tests of endurance
 - 2-Minute Walk Test
 - 3-Minute Walk Test
 - 6-Minute Walk Test
 - Borg Scale of Perceived Exertion
 - Maximum distance ambulated or propelled in wheelchair
 - Trunk Control Test
 - Trunk Impairment Scale

Posture

- Observational description of posture

Range of Motion

- End feel assessment
- Goniometry
- Neural tension tests

Sensory Integrity

- Sensory organization
 - Modified Clinical Test of Sensory Interaction on Balance (mCTSIB)
 - Sensory Organization Test (SOT)
- Somatosensory
 - Exteroception
 - Monofilament testing
 - Superficial pain (sharp or dull)
 - Superficial touch (light touch)
 - Temperature (can be left out if pain is normal per Goodman and Snyder)
 - Two-point discrimination
 - Vibration
 - Proprioception
 - Joint position sense testing
 - Kinesthesia Test (Mirroring Test)
 - Thumb-finding test
 - Rivermead Assessment of Somatosensory Performance
 - Cortical Sensory Tests
 - Graphesthesia
 - Stereognosis

APPENDIX 8-B ■ Sample Outcome Measures According to the Examination Areas in the Guide to Physical Therapist Practice, from: Neurologic Practice Essentials: A Measurement Toolbox*—cont'd

- Vestibular system testing
 - Dix-Hallpike Test (for benign paroxysmal positional vertigo [BPPV])
 - Fukuda Step Test—50-step protocol
 - Head-Shaking Nystagmus Test
 - Head Thrust Test
 - Motion Sensitivity Quotient (MSQ) (positional testing)
 - Vibration-Induced Nystagmus
- Visual system testing and vestibuloocular reflex (VOR) tests
 - Dynamic visual acuity (DVA) (clinical or computerized)
 - Gaze stabilization test (GST) (clinical or computerized)
 - Oculomotor tests (saccades, smooth pursuit, vergence)
 - Perception time test (computerized)
 - Static visual acuity
 - Visual field test (i.e., confrontation testing)

Pain

- FACES Pain Scale
- Visual Analog Pain Scale (0 to 10 numerical scale versus line bisection)
- Wheelchair User's Shoulder Pain Index (WUSPI)

Multi-Categorical Measures of Body Structure and Function

- ALS Functional Rating Scale
- Canadian Neurological Scale (stroke)
- Chedoke-McMaster Stroke Assessment Scale
- Fugl-Meyer Assessment of Motor Recovery After Stroke
- Hoehn and Yahr Staging of Parkinson's Disease
- Kurtzke Expanded Disability Status Scale (multiple sclerosis)

- NIH Stroke Scale
- Stroke Impact Scale (also addresses activity and participation on ICF)
- Unified Huntington's Disease Rating Scale (UHDRS)
- Unified Parkinson's Disease Rating Scale (UPDRS)

Activity—List of Measures

Balance and Mobility

- Berg Balance Scale
- Dynamic Gait Index (DGI)
- Functional Gait Index (FGA)
- Tinetti Performance-Oriented Mobility Assessment (POMA) (balance and gait)
- Gait speed—10-meter walk test

Participation—List of Measures

- Activities-specific Balance Confidence Scale (ABC)
- Craig Handicap Assessment and Reporting Technique (CHART)
- CHART-19—SF
- Dizziness Handicap Inventory (DHI)
- Geriatric Depression Scale
- Modified Fatigue Impact Scale (mFIS)
- Multiple Sclerosis Quality of Life-54 (MSQOL-54)
- Parkinson's Disease Quality of Life Questionnaire-39 (PDQ-39)
- Satisfaction With Life Scale (SWLS)
- Short Form 36 (SF-36)
- Stroke Impact Scale (SIS)
- Stroke Impact Scale-16 (SIS-16) Physical Performance Short Form
- Tinetti Falls Efficacy Scale (FES)
- Vestibular Activities of Daily Living Scale (VADL)

CHAPTER 9

Interventions for Clients with Movement Limitations

DARCY A. UMPHRED, PT, PhD, FAPTA, NANCY N. BYL, PT, MPH, PhD, FAPTA,
ROLANDO T. LAZARO, PT, PhD, DPT, GCS, and MARGARET L. ROLLER, PT, MS, DPT

KEY TERMS

augmented intervention
evidence-based practice
functional training
impairment training
neuromuscular retraining

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Appreciate the complexity of motor responses, and discuss methods used to influence body systems and their effects on functional behaviors.
2. Outline the differences in recovery related to healing, compensation, substitution, habituation, and adaptation.
3. Analyze the similarities and differences among impairment training of specific body systems, functional training, augmented feedback training, and learning-based sensorimotor retraining.
4. Select appropriate intervention strategies to optimize desired outcomes.
5. Analyze variables that may both positively and negatively affect complex motor responses and a patient's ability to participate in functional activities.
6. Identify procedures and sequences required to attain the most successful therapeutic outcome that best meets the needs and goals of the client and the family.
7. Consider the contribution of the client, the client's support systems, research evidence, neurophysiology, and the best practice standards available to optimize outcomes.

Before discussing therapeutic intervention procedures, the therapist must identify the learning environment within which the client will perform. As discussed in Chapter 1, that environment is made up of the therapist and the client, all internal body control mechanisms of the client, and the external restraints and demands of the world. Although this text focuses on relearning functional movement, the reader must always consider all aspects of the client including how other organs or body systems will be affected by or will affect the therapeutic outcome both during rehabilitation and in relation to long-term quality of life. An examination and evaluation (see Chapter 8) are performed before intervention to establish movement diagnoses. These examinations lead to movement diagnoses that must link to functional limitations or restrictions in activities and their causations (body system problems). Movement diagnoses and the degree and extent of the system or subsystem dysfunction or impairments determine prognosis of the outcomes on the basis of the client's potential for functional improvement. Factors such as motivation, family support, financial support, and cultural biases must be considered as part of the prognosis.¹ This process guides the selection of intervention strategies. Although it could be assumed that some of these impairments would be directly correlated to the central nervous system (CNS) trauma experienced by the client, it must also be determined whether some or most of these impairments have developed over a lifetime as a result of small traumas and adjustments to life. This insidious cause of impairments needs to be differentiated from acute causation of activity limitations because goal setting and expectations related to prognosis and recovery can be different.

Both the American Occupational Therapy Association (AOTA) and the American Physical Therapy Association (APTA) have developed guides to practice that help to direct therapists entering the professions and should help to guide practice throughout their working lives.^{2,3} APTA, through the initiation of the California Physical Therapy Association, has been collecting and classifying evidence-based articles through the Hooked on Evidence project.⁴ Through the use of current evidence-based practice; sensorimotor processing, motor control, motor learning, and neuroplasticity theories (see Chapter 4); and body systems models, the therapist must determine the flexibility or inherent motor control the client demonstrates while executing functional activities and participating in life. This chapter or other chapters in the book cannot establish for the reader the exact treatment sequence that should be used for every patient, but an example of a decision-making pathway has been given in [Box 9-1](#). Functional goals must be established that lead to the client's ability to participate in life within his or her environment and whenever possible lead to or maintain the quality of life desired by the client. Similarly, the therapist must differentiate whether the observed motor problems are based on acute or longstanding impairments before establishing timelines for prognosis.

Before beginning any intervention, the therapist must determine the treatment strategies that will be used to help the client attain the desired functional outcomes. The specific environment used by the therapist to optimize patient performance will depend on the functional level and amount of motor control exhibited by the patient. The following

BOX 9-1 ■ TREATMENT STRATEGY CATEGORIES**COMPENSATION TRAINING**

Use of an assistive device or orthotic to compensate for a permanent impairment or lost body system function.

SUBSTITUTION TRAINING

Teaching the client to use a different sensory system or muscle(s) group to substitute for lost function of another system. An example of sensory substitution might be teaching the client to use vision to substitute for an impaired vestibular system or somatosensory system for balance function. Substitution within the motor system might be teaching hip hiking to substitute for lack of dorsiflexion of the ankle during swing phase of gait.

HABITUATION TRAINING

Activity-based provocation of symptoms with the goal of symptom reduction with repetitive practice. An example would be teaching head movement to a patient who has a chronic labyrinthitis and severe nausea with any head movement.

NEURAL ADAPTATION

Driving changes in structure and function of the central or peripheral nervous system with repetitive, attended practice. This category would be considered neural plasticity. This category of treatment strategy takes the greatest repetition of practice and requires a strong desire by the individual to gain the functional ability and realize the potential of the central nervous system to change.

classifications can be used to document the specific role of the therapist within the training session (refer to Chapter 4 for additional detail):

Functional training: Practice of a functional skill that is meaningful, goal directed, and task oriented. Patient will experience errors and self-correct as the program becomes more automatic and integrated. An example would be gait training on a tile surface, rugs, inclined surfaces, compliant surfaces such as grass, and so on to practice ambulation.

Body system or impairment training: Treatment focus is on correcting a body system problem during an activity (e.g., pure muscle strengthening, stretching, sensory training, endurance training).

Augmented feedback training: Patient needs external feedback (auditory, visual, kinesthetic) and control over the motor program running the target task. This will limit the response patterns (e.g., reducing degrees of freedom, reduction or enhancement of tone) for successful performance of the desired movement (e.g., handling techniques, body-supported treadmill training, constraint-induced training).

Learning-based sensorimotor retraining: Treatment focus is placed on improving sensory discrimination dysfunction as a consequence of somatosensory, premotor, and motor cortical disorganization resulting from trauma, degeneration, or overuse.

Clients with CNS damage often benefit from combining interventions from the above categories. An example of this might be the early phase of partial body-weight supported treadmill training. In the early phases, a therapist or assistant is guiding the client's leg during swing and stance phases while the body harness supports a proportion of the client's total weight (augmented feedback) to assist the postural system in running appropriate programs to maintain balance and decrease the power needed to generate a more normal gait pattern. This augmented intervention is being done in a functional pattern within an environment that perturbs the client's base of support under the normal center of gravity.

Thus, this perturbation moves each foot reciprocally backwards and the body forward, triggering a stepping reaction. In the case of an individual after a cerebrovascular accident (CVA), one leg will still respond normally, thus helping to trigger a between-limb reciprocal stepping action of the involved leg. In the case of bilateral involvement, both legs may need placement, requiring two people to assist. The activity may be classified as impairment training, with the focus on appropriate power production or cardiovascular fitness, leading to functional training to trigger normal motor programs necessary for gait. Simultaneously, augmented training done by a therapist includes manual assistance in the direction, rate, and placement of the involved leg throughout the gait cycle. In this previous example, therapists need to make sure they are aware of the patient's center of gravity and do not move the foot before it should be at "push off" during the gait cycle. This activity would not be considered functional training until the client could reciprocally move both legs during the gait pattern without the need of the harness for postural support and the therapist to guide the movement.

When selecting from a variety of treatment interventions (neuromuscular retraining, functional training, impairment training, and augmented feedback training), it is important for the therapist to consider that each one is based on different strategies and rationales that contribute to the expected outcome. All interventions should address the needs of the patient and must consider any emotional and cognitive restraints. Although these intervention methods can be used simultaneously or in various combinations, the clinician needs to consider which aspect of the intervention falls into which treatment classification. Although various treatment outcomes can be measured, if classification of each treatment variable is not identified, the determination of how and why the outcomes were influenced by the intervention becomes confusing and difficult to distinguish. Without understanding the interactions of intervention methods and the outcome, treatment effectiveness and future clinical decision making remain unpredictable, and unique practice

patterns and pathways are hard to identify with consistency. A master clinician who is effective with all patients but does not know how and why the decisions are made along the intervention pathway cannot leave a legacy of effectiveness that will ever lead to efficacy. Although not all graduates or inexperienced clinicians may have the innate aptitude or potential to become master clinicians, if professionals understand the verbal, spatial, cognitive, fine and gross motor, and emotional sensitivity variables that play a role in the evolution toward mastery, educational experiences might be able to nurture future colleagues along this pathway and help those with mastership potential reach that level of function earlier in their professional careers.

The reader must also remember that intervention encompasses multiple interactive environments where intervention decisions are often made moment by moment during any treatment period. The challenge to the educated clinical professional is to determine what is being done, why it is working, how to continue its effectiveness, and how to determine the progress of the successful intervention. The clinician must also determine how to empower the client (emotionally, cognitively, and motorically) to take over the intervention with inherent, automatic mechanisms that lead to fluid, flexible, functional outcomes independent of both the therapist and the environment within which the activity is occurring. It is not until clinicians can determine effective treatment outcomes from various interventions that efficacy within a research laboratory can be studied without speculation and hypothesis formation based on speculation.¹ Effectiveness is the first way to determine evidence-based practice. Once effectiveness has been established through case studies and larger controlled studies within the clinical environment, researchers can begin to tease out separate variables and establish efficacy as part of evidence to justify clinical decision making.

HISTORY OF DEVELOPMENT OF INTERVENTIONS FOR NEUROLOGICAL DISABILITIES

In the mid 1900s the interventions by physical therapists (PTs) and occupational therapists (OTs) were separate. Generally, PTs worked on gross motor activities with specific emphasis on the lower extremities and the trunk, whereas OTs worked on the upper extremities and fine motor activities. Both professions focused on daily living skills, with those involving the arms falling within the domain of the OT and those involving the legs falling within the domain of the PT. Activities that required gross motor skills such as sitting, coming to stand, walking, walking with assistive devices, and running fell within the purview of the PT, whereas grooming, hygiene, and eating were the responsibility of the OT. Today, this approach is considered ridiculous owing to our understanding of motor learning, neuroplasticity, and motor programming and control. In the past it was also accepted that the PT worked on specific system problems such as weakness, inflexibility, lack of coordination, and voluntary control, whereas the OT worked on functional activities integrated within the environment (such as dressing) and the patient's emotional needs and desires (occupational expectations). According to the terminology of the mid to late twentieth century, PTs were trained to identify and correct impairments that caused functional limitations,

whereas OTs were trained in activity analysis and treatment that identified and optimized the functional activities that resulted from the impairments. Few clinicians seemed to focus on the sequential or interactive aspect of lack of function with specific impairments. Thus after the onset of a stroke the PT would strengthen and evaluate range of motion (ROM) of the leg and trunk, whereas the OT would encourage the patient to try to functionally use the arm. The PT would be preparing the patient to transfer out of bed and get into and out of a chair and then helping the patient walk, whereas the OT would be preparing the patient to use the arm in functional activities such as grooming or eating. Both therapists hoped the patient would accept responsibility for continued improvement through practice. What both professions discovered was that the patient generally did not regain normal motor control. He or she might be able to walk and might be able to move the shoulder, but the movement strategies were generally stereotypical, were abnormal in patterns, and took tremendous effort by and energy from the patient to perform. Over time, clients lost the motivation to even try, and thus what had been gained through therapy may have been lost from lack of practice once they got home. There was also minimal recovery of functional hand use, often because of the tremendous effort a patient had to use to move the shoulder to place the hand somewhere. Once that effort had been used the tightness and increased tone in the hand prevented functional use. Although functionally independent skills as measured on the Functional Independence Measure were achieved, normal movement patterns and normal motor control were rarely restored, and quality of life was clearly affected for the patient and family.

During the decade or two before the 1960s, some talented and intelligent clinicians began to question the traditional intervention strategies used by the OT and PT. These pioneers⁵⁻²⁹ in neurological rehabilitation set the stage for the development of new concepts that allowed basic science to infiltrate the clinical arena. The intervention strategies of Jean Ayers, Berta Bobath, Signe Brunnstrom, Margaret Johnstone, Susanne Klein-Vogelbach, Margaret Knott, Dorothy Voss, Margaret Rood, and others became popular. Colleagues observed these master clinicians and could easily see that the "new" interventions were much more effective and provided better outcomes than previous interventions. Each approach focused on multisensory inputs introduced to the client in controlled and identified sequences. These sequences were based on the inherent nature of synergistic patterns^{5,21,30,31} and motor patterns observed in humans^{5,7,32} and lower-order animals³³ or a combination of the two.^{19,21} Each method focused on the individual client, the specific clinical problems, and the availability of alternative treatment approaches within an established framework. Some of these approaches focused on specific neurological medical diagnoses. The treatment emphasis was then on specific patients and their related movement disorders. Children with cerebral palsy and head injuries^{7,23,28} and adults with hemiplegia^{8,9,21,32} were the three most frequently identified medical diagnostic categories. In 1968 at Northwestern University a large conference was held and laid the foundation for the first STEP conference (Northwest University Special Therapeutic Exercise Project [NUSTEP]). Most of these master clinicians, along with research scientists of the day, came together to try to (1) identify the commonalities

and differences between these approaches, and (2) integrate and use the neuroscience of the day to explain why these approaches worked.³⁴ Since the 1970s, substantial clinical attention has also been paid to children with learning and language difficulties.^{5,13,35} Now these concepts and treatment procedures have been applied across the age spectrum for all types of medically diagnosed neurological problems seen in the clinical setting (refer to Section II of this text). This expansion of the use of any of the methods for any pathological condition manifested by insults from disease, injury, or degeneration of the brain seems to be a natural evolution given the structure and function of the CNS and commonalities in system problems and activity limitations that take the individual away from participating in life.

Fortunately, most dogmatism no longer persists with respect to territorial boundaries identified by clinicians using some specific intervention methods. A conference in 1990³⁶ played a significant role in challenging the relevance of these territorial boundaries and stressed the adoption of a systems model when looking at impairments, activity limitations, and participation in life interactions.³⁷ As the boundaries for interventions began blurring, intervention approaches such as proprioceptive neuromuscular facilitation (PNF) were then integrated into the care of clients with orthopedic problems and patients with neurological impairments. Today, few universities within the United States teach separate sections or units on specific approaches, but rather teach students to identify problems, when they are occurring in functional programs, and what bodily systems might be the cause of those activity limitations.

For example, assume that a client with hemiplegia exhibited signs of a hypertonic upper-extremity pattern of shoulder adduction, internal rotation, elbow flexion, and forearm pronation with wrist and finger flexion. Brunnstrom⁸ would have identified that pattern as the stronger of her two upper-extremity synergies. Michels,²¹ although using an explanation similar to Brunnstrom's to describe the pattern, would have elaborated and described additional upper-extremity synergy patterns. Bobath would have asserted that the client was stuck in a mass-movement pattern resulting from abnormal postural reflex activity.³⁰ Although the conceptualization of the problem certainly determined treatment protocols, the pattern all three clinicians would have worked toward was shoulder abduction, external rotation, elbow extension, forearm supination, and wrist and finger extension. The rationale for the use of this pattern within an intervention period would vary according to the philosophical approach. One clinician might describe the pattern as a reflex-inhibiting position (Bobath).³¹ Another would describe the pattern as the weakest component of the various synergies (Brunnstrom),⁸ whereas still another might identify the pattern as producing an extreme stretch and rotational element that inhibited the spastic pattern (Rood).²⁵ How those master clinicians sequenced treatment from the original hypertonic pattern to the opposite pattern and then to the goal-directed functional pattern would vary. Some would facilitate push-pull patterns in the supine and side-lying positions and rolling. Others would look at propping patterns in sitting clients or at weight-bearing patterns of clients in the prone position, over a ball or bolster, or in partial kneeling. All have the potential of improving the functional pattern of the upper extremity and modifying the

hypertonic pattern. One method may have been better than the others given a particular patient, but in truth improved patient performance may have stemmed not from the method itself, but rather from the preferential CNS biases of the client and the variability of application skills among the clinicians themselves. That is, when a therapist intentionally uses specific augmented feedback to modulate the motor system's response to an environment but does not identify the other external feedback present within that environment (e.g., lighting, sound, touch, environmental constraints), therapeutic results will vary. Because of variance, efficacy of intervention is often questionable, although the effectiveness of that therapist may be easily recognized.

Because of the overlap of treatment methods and the infiltration of therapeutic management into all avenues of neurological dysfunction, various multisensory models were developed during the early 1980s.^{13,38-41} These have continued to evolve into acceptable methods in today's clinical arena. Although these models attempted to integrate existing techniques, in reality they have created a new set of holistic treatment approaches. In July 2005 the III STEP conference⁴² was held in Utah to again bring current theories and evidence-based practice into today's clinical environment. The history of the three STEP conferences demonstrates the evolution of evidence-based practice from the first conference, where basic science was the only evidence to justify treatment, to the second conference, where evidence in motor learning and motor control began to bring efficacy to intervention. By the time the third conference was held, the research in neuro/movement science regarding true efficacy within practice and the reliability and validity of our examination tools set the stage for standards in practice.⁴³ Where the next conference will take the professions and how soon that will occur is up to colleagues in the future. No proceedings from that third conference were published, but over the preceding years articles covering most of the presentations had been published in the *Journal of Physical Therapy*. The ultimate goal would be to develop one all-encompassing methodology that allows the clinician the freedom to use any method that is appropriate for the needs and individual learning styles of the client as well as to tap the unique individual differences of the clinician. Although intervention today is based on an integrated model, the influence of third-party payers, the need for efficacy of practice, and time constraints often factor into the therapist's choice of intervention. Visionary and entrepreneurial practice ideas that have the potential to be effective will always be a challenge to future therapists. Those ideas generally originate within the clinical environment and not the research laboratory. For that reason, clinicians need to communicate ideas to the researcher, and then those researchers can develop research studies that test the established efficacy or refute that effectiveness. Few researchers are master clinicians, and few clinicians are master researchers; thus collaboration is needed as the professions move forward in establishing evidence-based practice.

Today's therapists have replaced many of the existing philosophical approaches with patient-centered therapeutic intervention. Patient performance, available evidence, and the expertise of the clinician often play a key role in the specific decision regarding an intervention. When confronted with an abnormal upper-extremity pattern, today's

therapist may choose to work on improving the movement pattern using a functional activity. Control of the combination of movement responses and modulation over specific central pattern generators or learned behavior programs will allow the patient opportunities to experience functional movement that is task oriented and environmentally specific. With goal-directed practice of the functional activity, neuroplastic changes, motor learning, and carryover can be achieved.⁴⁴ With a better scientific basis for understanding the function of the human nervous system, how the motor system learns and is controlled, and how other body systems, both internal and external to the CNS, modulate response patterns, today's clinicians have many additional options for selection of intervention strategies.⁴⁵⁻⁵⁴ Whether a patient would initially benefit best from neuromuscular retraining, functional retraining, or a more traditional augmented or contrived treatment environment is up to the clinician and is based on the specific needs identified during the examination and evaluation process.

No matter what treatment method is selected by a clinician, all intervention should focus on the active learning process of the client. The client should never be a passive participant, even if the level of consciousness is considered vegetative, nor should the client be asked to perform an activity when the system problems only create distortion or demonstrate total lack of control of the desired movement. With all interventions requiring an active motor response, whether to change a body system impairment such as by increasing or reducing the rate of a motor response, modulate the tonal state of the central pattern generators and learned motor behaviors, or influence a functional response during an activity, the client's CNS is being asked to process and respond to the external world. That response needs to become procedural and controlled by the patient without any augmentation to be measured as functionally independent. In time, the ultimate goal is for the client to self-regulate and orchestrate modulation over this adaptable and dynamic integrated sensorimotor system in all functional activities and in all external environments.

A problem-oriented approach to the treatment of any impairment or activity limitation implies that flexibility and neural adaptation are key elements in recovery. However, adaptation should not be random, disjointed, or non-goal oriented. It should be based on methods that provide the best combination of available treatment alternatives to meet the specific needs of the individual. Development of a clinical knowledge bank enables the therapist to match treatment alternatives with the patient's impairments, activity limitations, objectives for improved function, and desired quality of life. A professionally educated therapist no longer bases treatment on identified approaches, although specific aspects of those approaches may be treatment tools that will meet the client's needs and assist him or her in regaining functional control of movement. Treatment is based on an interaction among basic science, applied science, the therapist's skills, and the client's desired outcomes.^{49-52,55,56} In most cases, multiple intervention strategies must be included, but the therapist needs to be able to identify why those selected treatments will lead to system improvement as well as documenting those findings using reliable standardized and acceptable clinical methods and terminology. These intervention strategies must be dynamic yet also

understandable and repeatable. As new scientific theories are discovered, new information must be integrated to continue to modify treatment approaches.

INTERVENTION STRATEGIES

Functional Training

Functional training is a method of retraining the motor system using repetitive practice of functional tasks in an attempt to reestablish the client's ability to perform activities of daily living (ADLs) and participate in specific life activities such as golfing, fly-fishing, basketball, or bridge. This method of training is a common and popular intervention strategy used by clinicians owing to the fact that it is a relatively simple and straightforward approach to improving deficits in function. A system problem such as weakness in the quadriceps muscle of the leg can be treated by muscle strengthening in a functional pattern that can be easily measured. Because of its inherent simplicity, functional training is sometimes misused or abused by clinicians. Most patients with neurological deficits have multiple subsystem problems within multiple areas, which forces the CNS to use alternative movement patterns in order to try to accomplish the functional task presented. If the therapist accesses a motor plan such as transfers but allows the patient to use programs that are inefficient, inappropriate, or stereotypical, then the activity itself is often beyond the patient's ability. The patient may learn something, but it will not be the normal program for transfers. This activity often leads to additional problems for the client.

In Chapter 8 the steps involved in the examination process are explained in detail. The intricate relationship of body system problems, impairments, and functional limitations that decrease participation in the rehabilitation process are discussed. Functional training can be implemented once the clinician has identified the client's activity limitations. The clinician must first answer the questions "What can the client do?" "What limitations does the client have when engaging in functional activities?" "Are there motor programs that are being used to substitute for normal motor function?" and "Can the therapist use functional training to improve body system problems within the context of the functional skill?" Once the therapist has an understanding of the reasons for any activity limitation and can alleviate substitution and compensation for the deficit, functional tasks should be identified and practiced.

The Effect of Functional Training on Task Performance and Participation

The main focus of functional training is the correction of activity limitations that prevent an individual from participating in life. However, through repetitive practice of functional tasks and gross motor patterns, many of the client's impairments can also be affected. For example, if a therapist practices sit-to-stand transfers with a client in a variety of environments and performs multiple repetitions of each type of transfer, not only can learning be reinforced, but the client can also gain strength in the synergistic patterns of the lower extremities that work against gravity to concentrically lift the client off of the support surface and eccentrically lower him or her down. Weight bearing through the feet in a variety of degrees of ankle dorsiflexion during transfer training

will effectively place the ankles in functional positions. The act of standing also helps the trunk and neck extensors to engage in postural control. Varying the speed of the activity during the treatment can stimulate cerebellar adaptation to the movement task. Moving from one position to another with the head in a variety of positions stimulates the vestibular apparatus and may assist in habituating a hypersensitive vestibular system, allowing the client to change body positions without symptoms of dizziness, resulting in a higher quality of life. Repetitive practice also affects the vasomotor system and may assist in habituating postural hypotensive responses.

A good example of the misuse of functional training is the “nag-and-drag” method of gait training in the parallel bars. This method finds the therapist literally dragging the client through the length of the parallel bars in an attempt to elicit some sort of movement response from the client. The therapist then labels this procedure “gait training.” Clearly, this approach will result in the client eventually learning dysfunctional, inefficient motor programs. Before long, as the client learns to run these dysfunctional programs procedurally, the clinician will realize that he or she has created a bigger problem, and a considerable amount of time and resources may be required to undo the damage that was created by limiting the available movement strategies, limiting the variability within practice, and ultimately restricting the plasticity of the nervous system. Similarly, forcing the axial trunk musculature to compensate for lack of motor control within the elbow and wrist will result in dysfunctional upper-extremity movement patterns.

Functional training is the best method of intervention when the client can run normal programs that have some limitation such as poor ROM or inadequate muscle power from disuse. In that way, functional training will run normal programming until fatigue sets in, which may be after only one or two repetitions. Increasing the repetitions and/or the power necessary to run the programs will lead to functional improvement. In using functional training, accurate standardized measurement tools that clearly illustrate change will quickly tell the therapist whether the change is in the direction of more functional control or additional limitation.

An intervention approach in the early 1990s that evolved as an offshoot of functional training was labeled *clinical pathways*. These pathways were established by health care institutions to improve consistency of management of patients who met specific medical diagnostic criteria. It has been proven that the implementation of these pathways reduces variability in clinical practice and improves patient outcomes.⁶⁷ Health care practitioners also became aware that some individuals do not fall into these pathways and need to be treated according to the specific clinical problems that the patients were presenting.

Selection of Functional Training Strategies

What is the “ideal” procedure for effectively and efficiently using functional training as a treatment intervention? First, it is suggested that the clinician identify and select procedures that will use the client’s strengths to regain lost function and correct system limitations—“What can the client do?” The clinician is also advised to avoid activities that may be too difficult and elicit compensatory strategies that

may result in the development of abnormal, stereotypical movement and potentially create additional impairments. An example of this is using transfer training when the patient is unable to keep the program within the limits that define it as a transfer. What instead happens is that the patient would begin to fall. Once in that situation, the patient is then working on approaches to prevent from falling, not activities that allow the patient to safely transfer. The therapist’s decision regarding what functional patterns or activities to practice, and in what order, will depend on several factors. The therapist must choose functional activities that are necessary for the client to perform independently or manage with less help before being discharged home. For PTs, safe transfers and ambulation are generally the focus of functional training. For OTs, independent bathing, dressing, and feeding are major foci. Yet both PTs and OTs also need to be sensitive to the activities that the patient or the patient’s family want to improve to enhance the quality of life for everyone involved in the person’s case. The ability to get in and out of a car might be the most important activity for the client to learn because he or she needs to make frequent trips to the physician’s office and the primary caregiver has cardiac problems and is unable to assist the patient in transferring without placing his or her own cardiac system at extreme risk.

It is suggested that the clinician modify or “shrink” the environment to allow normal motor programs to run. An example of this might be to limit the ROM an individual is allowed while performing a rolling pattern. The therapist may opt to start this movement with the patient in a side-lying position. The amount of patient movement may be even further limited by the therapist stabilizing the patient’s hips by using the therapist’s one leg in kneeling position against the patient’s posterior pelvis and the therapist’s other leg in half-kneeling position with the top leg of the patient over the therapist’s half-kneeling leg. In this way the individual’s body can be totally controlled by the therapist; the patient can be encouraged to roll the upper part of his trunk both backward with the arm reaching back and then forward with the arm coming across the body toward a weight-bearing pattern on the hand. The therapist can change the rate of movement and also use his or her knees to control the range that the patient is allowed. The environment can be progressively “enlarged” to allow the client to perform the activity in a functional context. Although this narrowing of the functional environment would be considered a contrived environment and must not be recorded as functional as defined in a functional or activities-based examination, it may allow the nervous system the opportunity to control and modify the motor programs within the limitations of its plasticity at the moment. Therefore this therapeutic technique could be used within a functional training environment or may fall into an augmented treatment approach category, given an individual who has neurological problems that prevent normal movement.

The goal of therapy is to move toward functional training as quickly as the client’s motor system can control the movement. As learning and repetition assist the CNS in widening the response pattern during a functional activity, the client’s ability to respond to variance within the environment will enlarge and assist in gaining greater independence.

An example of this application of functional training might be asking a client to perform a stand-to-sit transfer. The client is first guided down to sitting onto a large gym ball, a high-low table, or a stool that allows the client to sit only one fourth to one half of the way down before returning to stand. As the client develops increased strength and balance and improved control over abnormal limb synergies and tone in this pattern, then a smaller gym ball or a lower point on a high-low table can be used. Finally, the client is asked to sit down onto a ball/mat or chair that results in the patient sitting with the hips and knees at 90 degrees. Once the client can sit down and return to a vertical position, the next task will be to sit down, relax, and then stand up. Once that activity is done easily, the client will be functionally able to stand to sit and to reverse the movement pattern to sit to stand.

Although many clinicians understand the importance of running motor tasks within an appropriate biomechanical, musculoskeletal, and sensorimotor window in which the client has the ability to perform procedures functionally, it may be argued that in many cases this particular type of treatment strategy is simply not possible in a real-world situation. For example, given the current health care environment, if the client is given a limited number of visits to achieve the desired outcome, the clinician may conclude that there is no choice but to “allow as many degrees of freedom as possible” or, in other words, to “force the window open” no matter the abnormal movement patterns used or the limitations in independent functional control that they may produce.

In summary, the clinician should first identify and emphasize the client’s strengths (“What can the client do?”) and use those strengths to efficiently and effectively achieve functional change. Next, the clinician must prioritize what systems or activities the client truly needs to change. The choice of what activities to emphasize during therapeutic training always poses a dilemma to therapists. Although it may be ideal for the client to eventually be able to ambulate independently on all surfaces without any assistance or reach for any object in and from any spatial position, it may be more important initially for the client to be able to safely transfer from the bed to the wheelchair, sit independently while someone assists with dressing, or walk and transfer onto and off of the commode independently at home. One should keep in mind that although several skills may be learned by training them simultaneously, it may make more sense to concentrate on the safe performance of one or two necessary functional tasks rather than having the client end up being able to perform multiple tasks that require considerable outside assistance for safety. The need to work functionally on additional activities may also be an opportunity for the clinician to request additional therapy visits for the client, arguing that there is a reasonable expectation that more intervention would result in a greater increase in function and a greater decrease in the risk for potential injury than if the intervention were not continued. The use of valid and reliable functional outcome measures becomes critically important in case management. These tools objectively measure the effect of the intervention, help predict the potential risks if the therapy is not continued, and ultimately aid in the justification to continue therapeutic intervention.

CASE STUDY 9-1 ■ FUNCTIONAL TRAINING: AMBULATION

Teaching a client to ambulate can be approached in many ways. Assume that the objective for a particular session is ambulation. First, the client may be asked to ambulate in the parallel bars using the upper extremities to assist in forward progression of the movement to decrease fear and to assist in maintaining balance. Once the patient can perform this ambulatory activity, the therapist might decide to progress the patient’s ambulation by introducing a walker, which has four points of support. Ambulating with the walker will again increase power production in the legs and create an environment of safety for the client. Once walking with the walker can be performed at various speeds and distances, the therapist may advance the activity to using two canes, then one cane depending on the client’s balance, coordination, and need. While the patient is practicing ambulating with cane(s), he may also be walking on a treadmill to increase endurance, velocity of gait, and power. Once the patient can ambulate safely with a cane, the therapist may decide to transition to walking without any assistive devices. Again the patient may first be asked to walk on a treadmill while holding on with his arms until he feels safe walking and no longer needs an assistive device. The therapist could transition to ramps, obstacles, uneven ground, and so on. All these activities would require the individual to begin with functional control over the program for ambulation. All the activities are focused on regaining independence in the functional activity of walking, using repetitive practice. These therapeutic devices assist the patient in successfully practicing the entire gait cycle on both legs. In time, the patient is asked to continue walking without the need of the assistive devices and will continue to practice that activity as functional movement or is considered functionally independent with the use of an assistive device. The therapist must also remember that when introducing an assistive device, that device itself will usually limit the environments within which a patient can ambulate independently.

Conclusion

One important variable that has clearly been identified with respect to functional training is “task specificity.”^{47,68-76} Although it is important that a patient be independent in as many ADLs as possible, often the therapist, the patient, and the family need to prioritize which activities are most important to the quality of life of the patient. If walking into the mountains to do “birdwatching” is one important goal to the patient, then creating an environment that would closely resemble the environment of that activity is crucial. Similarly, practice within that environment is a key to successful carryover (see Chapter 4). If the patient wants to walk into the mountains and the family expects the patient to walk into his or her old job, a therapist must accept that motivation will drive behavior and task specificity will drive learning. Carryover into any other functional activity such as walking into the office building in order to go back to work may not be the motivating factor that will guide that individual’s desire to perform that motor task. Whether the patient ever goes back to work is not the variable that should be used as

part of the motivational environment for task-specific gait training geared to walking in the mountains and is not a decision for which the therapist is responsible. Therapists need to allow the patient to tell them what will be the most important task and the specificity of that task to optimize motor learning and functional recovery.

Body System and Impairment Training

As mentioned in Chapter 8, the therapeutic examination results in the identification of activity limitations and possible body system and subsystem impairments that are causing the functional movement disorders. Impairment training is another intervention strategy that involves the correction of impairments with the expectation that improving these impairments will result in a corresponding improvement in function. For example, when a client has the inability to stand up without assistance (activity limitation) and the clinician determines the cause to be lower-extremity weakness, an appropriate approach may be to strengthen the lower extremities (impairment training). Numerous studies have shown the effectiveness of impairment training in improving the functional performance of individuals with neurological conditions such as cerebral palsy,^{77,78} stroke,⁷⁹⁻⁸⁷ multiple sclerosis,⁸⁸⁻⁹³ Parkinson disease,⁹⁴⁻⁹⁸ and other neuromuscular diagnoses.⁹⁹⁻¹¹⁰ The strengthening intervention selected should reflect the task and the environment within which the impairment was identified. The clinician should attempt to create a training situation so that the client may be able to run the necessary motor programs with all the required subsystems in place. For example, training sit to stand with weakness in the hip and knee extensors is much less likely to automatically result in the improvement of sit-to-stand function if the therapist begins the activity in sitting where generation of extension is most difficult, than if the strengthening training was performed with repetition of practice starting in standing and going to sit and back again to stand. By decreasing the degrees of freedom of the eccentric control of the hips and knees when going from stand to sit, the functional training activity has turned into specific impairment training. The therapist can ask the patient to eccentrically lengthen the extensors only in a limited range and then concentrically contract back to standing. As the power increases, the degrees of freedom can also be enlarged until the patient is able to complete the task of stand to sit while simultaneously regaining the sit to stand pattern. In pure impairment training a patient might also be asked to straighten the knee when sitting or to extend the hip when prone. These three exercises have the potential of training impaired strength, but only the first example forces the training within a functional pattern. Similarly, the therapist could train the sit-to-stand pattern using various seat heights that encompass many of the components that force the use of normal movement synergies and postural control, using the environment in which that activity is typically performed, versus performance of strengthening exercises against resistance in an open chain exercise program.

The decision to treat the impairments causing the activity limitations or to correct the functional problems themselves is influenced by myriad factors. It would appear that for certain tasks to be completed the client must possess the “threshold amount” of basic movement components required for the task. Task specificity within this limited

environment will result in more meaningful changes in function. Impairment training can be a very effective treatment approach. It can lead to functional gains after an improvement in a specific body system problem. This can lead to improved participation in not only normal functional activities but also activities that should lead to a better quality of life.

Often, clients with neurological trauma or disease cannot begin therapy with functional or impairment training because of the degree and extent of impairments within the entire CNS. Therapists must then choose augmented therapeutic interventions that externally guide the client’s learning through hands-on and environmentally controlled techniques such as a body-weight–supported treadmill training (BWSTT). It is cautioned that the therapist should not consider these interventions as functionally independent until the individual’s success is based on internal self-regulation of movement. The clinician must continually strive to transfer control to the client by widening the window of independence and limiting the manual or verbal guidance used during therapy.

Augmented Therapeutic Intervention

As discussed in the previous section, some treatment alternatives require little if any hands-on therapeutic manipulation of the client during the activity. For example, the patient practices transfers on and off many support surfaces with standby guarding only. Thus the client self-corrects or uses inherent feedback mechanisms to self-correct error to refine the motor skill. This ultimate empowerment of the client allows each individual to adapt and succeed at self-identified and self-motivated objectives first with augmented intervention and finally without any assistance. Often, allowing the client to try to succeed without assistance enables the therapist to evaluate what components of the task the client can control and what components are not within the client’s current capabilities, especially if normal, fluid, efficient, and effortless movement is the desired outcome. In some cases the therapist may use hands-on skills or augmented aids such as BWSTT, which would substitute for many aspects of the environment and allow the client to succeed at the task—but the control and feedback during the activity would be considered augmented feedback and fall into that classification.

These augmented techniques make up a large component of the therapist’s specific interventions tool box. The difference between augmented and functional training might be the need for the therapist or piece of equipment to be part of the client’s external environment for the client to succeed at the task. For example, in BWSTT a harness is used to take away the demand of gravity on the limbs during gait and the demand of the postural trunk and hip muscles for stability. Before the therapist or the patient can consider the movement as independent, those aspects must be removed from the environment. In the previous example, the individual needs to transition from maximal body weight support during ambulation to not needing any external support during ambulation. The client must assume *total ownership* of the functional responses. Then and only then has independence been achieved. At that time, functional retraining can be used with the intent of enlarging the environmental parameters to allow for maximal independence. [Figure 9-1](#) illustrates this concept of functional versus contrived

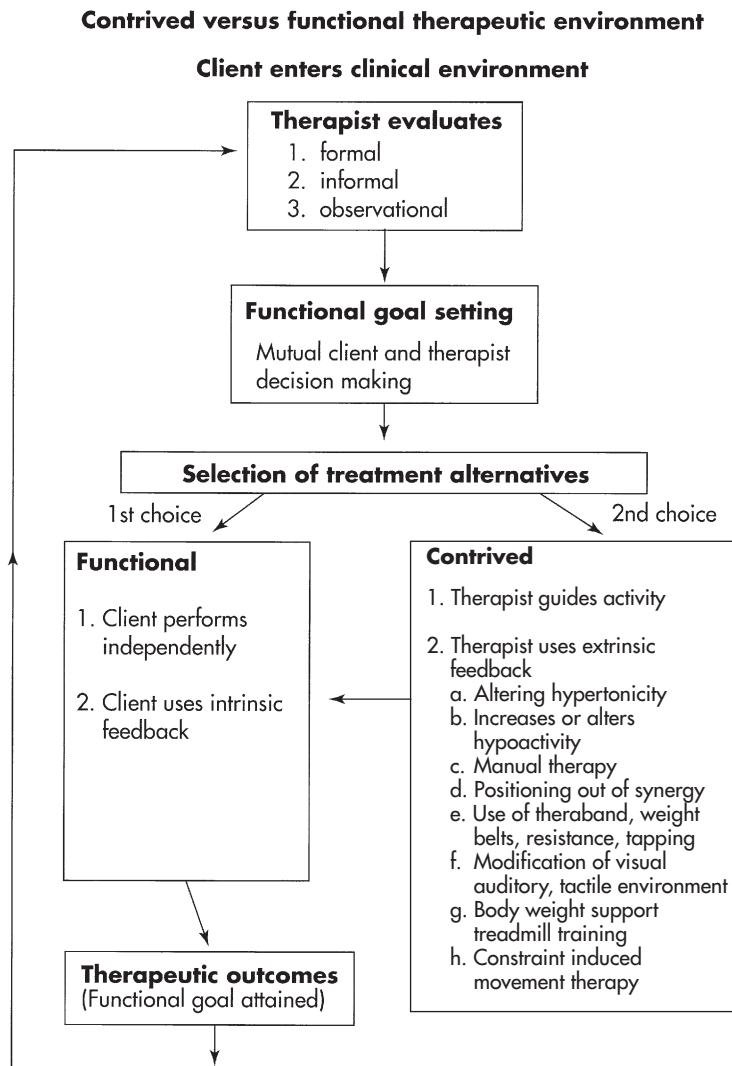

Figure 9-1 ■ Contrived versus functional therapeutics. (Modified from the original work of Jan Davis, OTR, San Jose State University.)

intervention, which must be constantly considered throughout any treatment session. Augmented techniques are often the early choices for treatment of patients who have neurological insults. It cannot be emphasized enough that once the client has the ability to perform without augmented methods and does so in functional, efficient ways, those augmented techniques need to be selectively eliminated.

Once a clinician has chosen to augment the clinical environment, the client needs to learn efficient motor behaviors within the limitations of that environment. The client influences the therapist's decision-making strategies by selecting inefficient or ineffective motor responses to a given task demand. If the response is effortless, efficient, and noninjurious to any part of the body and meets the client's expectations and goals, then the therapist knows the strategies selected were effective even if the therapist augmented the intervention. If the movement itself is available to the client, then there is a high probability that the client will be able to regain that movement control, regardless of the need for early augmentation to achieve the skill. If the response does not meet the desired goal for any reason, then the therapist

must determine why. Often, it is because the therapist did not identify the correct body system problems. Many correct solutions may answer the question. Which solution is best may be more client than approach dependent. Yet if flexibility means that the therapist selects any component of any method that helps the client reach an objective, then the therapist is confronted with hundreds—if not thousands—of various treatment choices. If the treatment procedures used introduce information to the client through sensory systems, then from a neurological perspective a limited number of input systems or modalities are available. The myriad treatment procedures are transformed into neurochemical and electrophysiological responses that must travel along a limited number of pathways in the nervous system. Thus, many different treatment procedures may produce similar types of neurotransmission. The temporal and spatial sequencing or timing of the input will vary according to the technique and the specific application. The clinician has little basis for decision making without a comprehensive understanding of the neurophysiological mechanisms of (1) the various techniques introduced to modify input, (2) where that

information will be processed and how that might affect motor output, (3) prior learning and the ability for new learning, and (4) the client's willingness and motivation to adapt. The reader is referred to Chapter 1 (Figure 1-1); Chapter 4 on motor control, motor learning, and neuroplasticity; and Chapter 5 for a discussion on motivation.

The number of available contrived or augmented feedback techniques is almost infinite. This section presents an overview of a classification system that can be used to help the reader develop a greater understanding of why certain responses occur and why the selection of certain techniques is appropriate and should positively affect the desired motor responses. This section focuses on intervention strategies that have been accepted, have been used within the traditional Western health care model, and are efficacious. Some alternative approaches to intervention that are not necessarily classified as traditional within this chapter are introduced in Chapter 39. There are other classification systems a clinician might use when analyzing movement problems seen in patients with neurological dysfunction. For example, a therapist may see in a patient a problem primarily with tone, such as hypertonicity, hypotonicity, rigidity, dystonia, flaccidity, intentional and nonintentional tremors, ataxia, and combinations of or fluctuations in the total movement strategies. Given this specific classification schema, one still uses the available treatment strategies or uses an input modality that may modify the specific tone problem that was causing the movement dysfunction.

The primary goal of this section is to help the reader develop a classification system based on the primary input modality used when introducing an augmented treatment technique to facilitate a sensory system and provide feedback to the CNS in order to help a client learn or relearn motor control. The reader has been provided with an in-depth reference to the specific neurophysiological approaches in the past also discussed in Chapter 1, and only a brief overview has been included within this chapter. In-depth discussion of some basic treatment strategies, explanations of less familiar techniques, and current approaches gaining popularity within the clinical area of movement analysis are found within the body of this section.

When the primary input system for a technique is identified, at no time do we suggest that it is the only input system affected. For example, when a proprioceptive technique is introduced, tactile cutaneous receptors are also simultaneously firing. If there is a "noise" component (such as with vibration or tapping with the fingers), then auditory input has been triggered as well. There is evidence that a given sensory modality may "cross over" or fuse with a completely different modality, helping in the synthesis of motor responses. In addition, there is evidence that the principles of neuroplasticity are applicable across modalities (e.g., auditory, visual, vestibular, somatosensory). Sometimes responses occur in a modality that does not appear to be related. For example, olfaction may improve tactile sensitivity of the hand. This concept is called *cross-modal training* or *stimulation*.^{111,112} Yet a classification schema based on a primary modality promotes logical problem solving because the therapist can select from available treatment procedures that theoretically provide similar information to the CNS and help in the organization of appropriate motor responses. The motor system and its various motor programmers adapt

to the environment to achieve functional motor output toward a goal. Both external and internal feedback are critical for adaptation and change. External feedback in this chapter is considered a mechanism to help the client's CNS optimally learn and adapt. Obviously, as the patient learns, internal feedback will allow the person to run feed-forward motor programs without the need for external feedback for control. External feedback will, it is hoped, be used only when the outside surrounding needs the feed-forward program to change to adapt to a new environment (refer to the Chapter 4 section on motor learning). Therapists must realize that even if the primary goal may be to facilitate or dampen a motor system response, diverging pathways may also connect with endocrine, immune, and autonomic systems. According to motor control theory, the clinical picture is a consensus of all interacting body systems (see Chapter 4). Research tools are not yet available to measure those systems interacting simultaneously, although functional magnetic resonance imaging (fMRI) studies are beginning to help researchers and clinicians identify what happens to the nervous system with input from the environment and how that information is processed. Efficacy using reliable and valid measurement tools must then be based on outcomes, with an understanding of the best available scientific knowledge as a rationale for why the outcome is present.

This classification system is based on identified input, observed responses, current research on the function of the CNS, and the various systems involved in the control and modification of responses. An understanding of normal processing of input and its effect on the motor systems helps the clinician evaluate and use the intact systems as part of treatment. Research with fMRI is now allowing greater insight into specific brain regions that are being used during various cognitive and motor activities.¹¹³⁻¹²⁸ Yet the specific interactive nature of multisensory input, memory, motivation, and motor function is still unknown. When the response to certain stimuli does not help the client select or adapt a desired motor response, then the classification schema for augmented input provides the clinician with flexibility to select additional options. This can be done by spatially summing input, such as using stretch, vibration, and resistance simultaneously, or temporally summing input, such as increasing the rate of the quick stretch or increasing the time between inputs to give the system ample time to respond.

Many factors can influence motor behavior, such as the methods of instruction, the resting condition of the nervous system, synaptic connections, cerebellar or basal ganglia or cortical processing, retrieval from past learning, motor output systems, or internal influences and neuroendocrine balance. Figure 9-2 illustrates and simplifies this total system. Its clinical implications become clearer if the therapist retains a visual image of the client's total nervous system, including afferent input, intersystem processing, efferent response, and the multiple interactions on one another. At any moment in time, multiple stimuli are admitted into a client's input system. Before that information reaches a level of primary processing, it will cross at least one if not many synaptic junctions. At that time the information may be inhibited, excited, changed or distorted, or allowed to continue without modification. If the information is at the first synapse, the patient will have no sensation. If it is inhibited at the thalamus, again the patient will not perceive sensation,

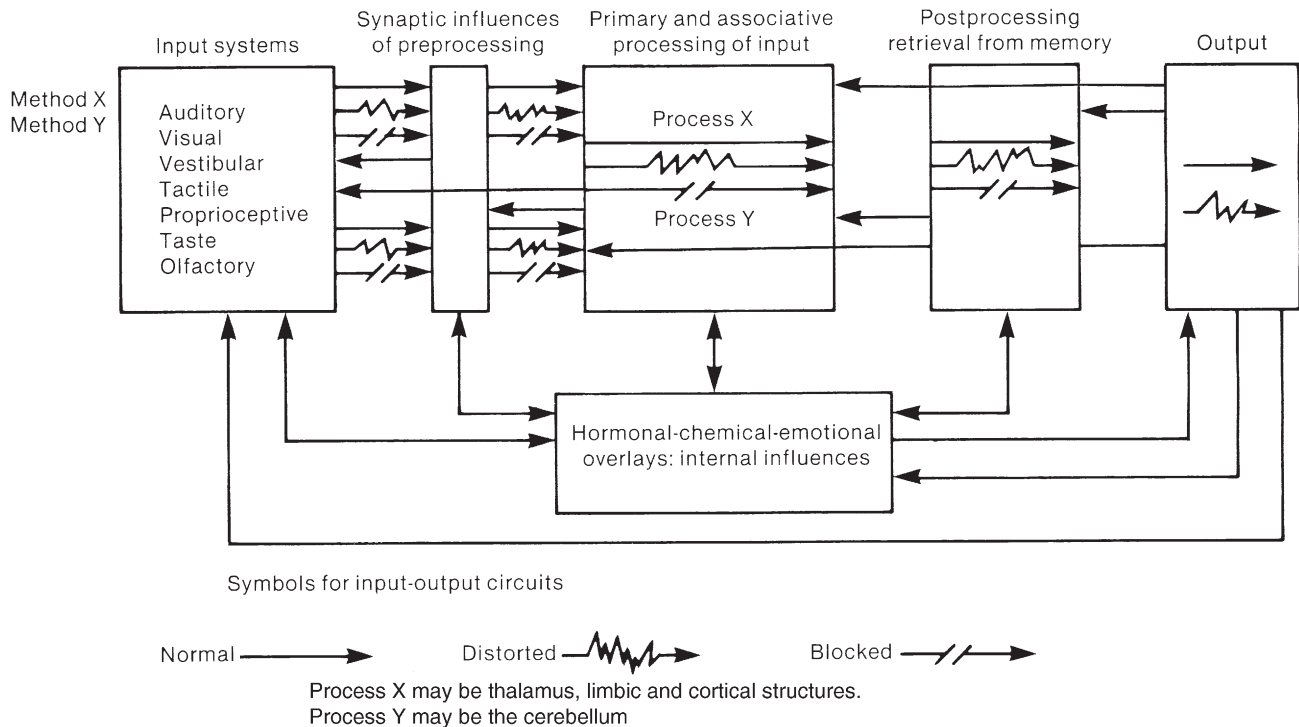

Figure 9-2 ■ Model of possible interactive effects among methods of treatment, input systems, processing and output systems, internal influences, and feedback systems.

but that does not mean other areas of the brain will not be sent that information, because sensory information is also sent to a variety of areas after that initial synapse. Research studies have found that sensory input information may even affect gait and other movement patterns even if the patient has no perception of the input.^{129,130} If the input is changed, then the processing of the input will vary from the one normally anticipated. The end product after multiple system interactions will be close to, will be farther away from, or will seem to have no effect on the desired motor pattern. Furthermore, sensory processing can take place at many segments of the nervous system. Although the CNS is not hierarchical, with one level in total control over another, certain systems are biased to affect various motor responses. At the spinal level the response may be phasic and synergistic. Brain stem mechanisms may evoke flexor or extensor biases, depending on various motor systems and their modulation. Cerebellar, basal ganglia, thalamic, and cortical responses may be more adaptive and purposeful.¹³⁰⁻¹³³ Thus the therapist must try to discern where the input or the feedback is being affective or short circuited.

Remembering input as a possible option for intervention will always allow the therapist to differentiate the same five alternatives—no response, facilitating (heightening), inhibiting (dampening), distorting, or normal processing. These alternatives can occur anywhere in the system at synaptic junctions. Finally, motor output is programmed and a response is observed. If the response is considered normal, the clinician assumes that the system is intact with regard to the use and processing of the inputs. If the response is distorted or absent, little is known other than there is a lack of the

normal processing somewhere in the CNS or an insufficient amount of input was used. One way to differentiate motor problems from problems with other systems is to use other functional activities that have programs similar to the body system program identified as impaired. If a program, such as posture, demonstrates deficiencies in one functional pattern, then the therapist must determine if it is also deficient in other patterns. If the postural motor problem affects all motor performance, then the therapist had determined that a motor program deficit exists and will have to determine how to correct that problem. If, on the other hand, the program runs smoothly and effortlessly when certain demands are taken away, such as resistance from gravity, position in space, need for quick responses, and so forth, then it may be that the problem is within another subsystem such as cognition, perception, the biomechanical system, or the cardio-pulmonary system or is a power-production problem that can be corrected by slowly increasing the demand on the postural system through repetitive practice using various additional input interventions. Differentially screening motor impairments as pure CNS motor problems (muscle recruitment, firing rate, balance) versus problems with another system (perception of vertical) becomes critical in a managed-care system that funds only a certain number of treatment sessions. Internal influences also need to be considered because they affect each aspect of the system. Once normal processing has been identified, understanding of deficit systems and potential problems can be analyzed more easily. To reiterate, this requires awareness of the totality of the individual—that is, the client's personal preference of stimuli and the uniqueness of processing and internal influences.

A systems model requires simultaneous processing of multiple areas, with interactions being relayed in all directions. A client's CNS and peripheral nervous system (PNS) are doing just that, and the therapist must develop a sensitivity toward the client as a whole while interacting with specific components (see Chapters 1, 4, 5, 6, and 39 for additional information). With input from the client and family, it is the therapist's responsibility to select methods most efficacious and effective for each client's needs in relation to that person's specific neurological problems. (See all clinical chapters in Section II.) This viewpoint, based on a variety of questions, leads to a problem-oriented approach to intervention. Because the output or response pattern is based on alpha motor neuron discharge and thus extrafusal muscle contraction, the *first question* is posed: what can be done to alter the state of the alpha motor neuronal pool or motor generators? *Second*, what input systems are available, either directly or indirectly, that will alter the state of the motor pool? *Third*, which techniques use these various input systems as their primary modes of entry into the CNS? *Fourth*, what internal mechanisms need modification or adaptation to produce a desired behavior response from the client? *Fifth*, which input systems are available to alter the internal mechanism and what outcomes are expected? *Sixth*, what combination of input stimuli will provide the best internal homeostatic environment for the client to learn and rehearse a more optimal response pattern? For example, assume that a client with a residual hemiplegia resulting from an anterior cerebral artery problem has a hypertonic lower extremity that produces the pattern of extension, adduction, internal rotation of the hip, extension of the knee, and plantarflexion inversion of the foot. The answers to the first two questions are based on the knowledge that the proprioceptive and exteroceptive systems can drastically affect spinal central pattern generators and that these input systems are intact at spinal, brain stem, cerebellum, and thalamic levels and may even project to the cortex.

Appropriate selection of specific techniques—such as prolonged stretch using the tendon organ to modulate the hypertonic pattern, quick stretch or light touch to the antagonistic muscle, or any other treatment modality within the classification schema—will provide viable treatment alternatives. Awareness that a client's response pattern is an inherent synergistic pattern and that it is further elicited by pressure to the ball of the foot leads to a better understanding of the clinical problem. Knowing that the client is unable to combine the alternative patterns, such as hip flexion with knee extension needed for the late stage of swing phase through the early aspects of stance phase during gait, the therapist can use the other inherent processes to elicit these and other patterns. BWSTT is an example of an augmented treatment intervention in which the clinician assists the patient to place the leg and foot with each step while the apparatus controls balance and posture to provide an experience of normal gait while requiring the patient to have only the strength to manage partial body weight.¹³⁴⁻¹³⁹ Finally, techniques such as combining standing and walking with the application of quick stretch, vibration, or rotation, or having the client reach for a target or follow a visual stimulus while walking, provide a variety of combinations of therapeutic procedures to help the client learn or relearn normal response patterns. Furthermore, combining techniques gives

the clinician a choice of various procedures and promotes a learning environment that is flexible, changing, and interesting. The therapist must, again, make the transition from applying contrived therapeutic procedures during functional tasks to allowing the client to practice the task without the therapist interceding and without external feedback.¹⁴⁰ In that way the client uses inherent feedback to self-correct feed-forward motor programming and then to continue running the appropriate movement strategies. This self-correction leads to independence, adaptability, and long-term learning (see Figure 9-2).

To avoid confusion about which peripheral sensory nerve fiber coming from the surface of the body or extremities is being discussed, the two primary methods of classifications (Gasser-Erlanger and Lloyd), along with a description of the functional component, have been included in Table 9-1 for easy referral. The other sensory systems will be presented separately to help the reader establish an appropriate classification scheme. The primary sensory input systems presented include proprioception, exteroception, vestibular, vision, auditory, taste, and smell. These sensory inputs have the potential to influence CNS structures including the thalamus, sensory and motor cortices, the cerebellum, the reticular formation, and the basal ganglia and thus to affect the descending fibers under their control.

Proprioceptive System Integration of Stretch, Joint, and Tendon Receptors

Proprioception as an input system has a direct effect on program generators at the spinal level.¹⁴¹ Because of its importance in motor learning and motor adaptation to new or changing environments, however, proprioception also has significant connections to the cortical and cerebellar neural networks. Its divergent pathways have synapses within the brain stem, diencephalon, and spinal system. Proprioceptive input can potentially influence multiple levels of CNS function, and all those levels can potentially modulate the intensity or importance of that information through many different mechanisms.^{141,142} Proprioceptors are found in three peripheral anatomical locations: the stretch receptors, the tendon, and the joint. The afferent receptors responsible for relaying sensory information through those sites are discussed in the following subsections.

Muscle Stretch Receptors

Stretch. Stretch, quick stretch, and maintained stretch are all sensory input systems that use the stretch receptors in the muscles and heighten the motor pool.¹⁴³⁻¹⁴⁵ Stretch simultaneously heightens both the muscle response to that stretch and potentially heightens the sensitivity of the agonistic synergy. It will also lower the excitation of the antagonistic muscle and those muscles that are part of the antagonistic synergy. Stretch information will be sent to higher centers for sensory integration and perception. The cerebellum uses this incoming feedback to maintain and/or regulate motor nuclei in the brain stem that will influence the state of the alpha and gamma motor neurons. This allows for cerebellar feed-forward regulation (refer to Chapter 21). There are many ways to apply stretch to the muscles. The therapist can use (1) the hands and their respective muscle power to apply a stretch, (2) a manual weight system of some sort that maintains the stretch through the range, (3) a suspension system such as used in Pilates exercises (see

TABLE 9-1 ■ CLASSIFICATIONS OF PERIPHERAL NERVES ACCORDING TO SIZE

GASSER-ERLANGER	LLOYD	MOTOR (FUNCTIONAL COMPONENT)	SENSORY (FUNCTIONAL COMPONENT)
<i>A fibers</i> : large myelinated fibers with a high conduction rate			
A alpha	Ia	Large, fast fibers of alpha motor system (large cells of anterior horn to extrafusal motor fibers)	Muscle spindle; primary afferent endings (primary stretch or low threshold stretch; Ia tonic fibers respond to length, Ia phasic fibers respond to rate)
	Ib		Tendon organ for contraction; respond to tendon stretch or tension
A beta	II		Muscle spindle; secondary afferent endings; tonic receptors responding to length
			Exteroceptive afferent endings from skin and joints; respond to light or low threshold stretch
A gamma 1 and 2	II	Gamma motor system (small cells of anterior horn to intrafusal motor fibers)	Bare nerve endings; joint receptors, mechanoreception of soft tissues; exteroceptors for pain, touch, and cold (low threshold)
A delta	III		
<i>B fibers</i> : medium-sized myelinated fibers with a fairly rapid conduction rate			
B beta		Preganglionic fibers of autonomic system (effective on glands and smooth muscle; motor branch of alpha): unknown function	
<i>C fibers</i> : small, poorly myelinated or unmyelinated fibers having slowest conduction rate; augmentation and recruiting occur within the nervous system after stimulation of these fibers has ceased			
	IV	Postganglionic fibers of sympathetic system	Exteroceptors; pain, temperature, touch

Chapter 39), (4) the patient's own body weight against gravity, (5) a complex robotic system that computerizes the amount of stretch depending on the individual's specific data (see Chapter 38), or many other creative ways to apply stretch to muscle fibers within the belly of the muscle tissue. As stated previously, stretch can also be applied to the antagonist muscle or muscle synergy in order to dampen agonist function. Thus stretch can be used to enhance tone in the agonist or to decrease tone of the agonist through the antagonist. The therapist should always remember that even though a response may not look obvious, as long as the peripheral nerves and motor neurons within the spinal system are intact, these approaches will change the state of the motor pool.

Table 9-2 lists a variety of treatment procedures believed to use proprioceptive input from the muscles as a primary mode of sensory stimulation. The varying intensity, amount of tension, or rate of the stimuli, in addition to the original length of the muscle before application of the stimulus, will determine its firing. Remember, afferent information is projecting to many areas above the spinal system, and the result will be regulation or modulation, ultimately affecting activity.¹⁴¹

Resistance and Strengthening. Resistance is often used to facilitate intrafusal and extrafusal muscle contraction. Resistance can be applied manually, mechanically, and by the use of gravity. Resistance recruits more motor units in the target muscles. Although muscles can contract both in an isometric and an isotonic fashion, most contractions consist of a mixture of the two. Certain muscle groups, such as the

flexors, benefit from isometric exercise, as well as isotonic exercise in both eccentric and concentric modes. Under normal circumstances, the flexors are used for repetitive or rhythmical activities. The extensors, on the other hand, usually remain contracted in an effort to act against the forces of gravity. Therefore the extensor groups benefit best from isometric and eccentric resistance.¹⁴⁶

When resistance is applied to a voluntary muscle, spindle afferent fibers and tendon organs fire in proportion to the magnitude of the resistance. Resistance is more facilitative to an isometrically contracted muscle than in an isotonic contraction.³⁵ As isometric resistance is increased or continued, more motor units are recruited, thereby increasing the strength of extrafusal contraction.²⁶ Eccentric isotonic contraction refers to the lengthening of muscle fibers with resistance added to the distal segment, as in lowering the arms while holding a heavy weight. Eccentric contraction uses less metabolic output and promotes strength gains in less time.²⁶ However, all types of muscle contraction will promote increased strength. Resistance is an important clinical treatment and has been used and will continue to be used by clinicians within multiple treatment philosophies over the next millennium.^{8,19,25,29,77,147-153} The complexity of neural adaptation after resistive exercises may lead to a different training environment depending on age, athletic status, and specific body system deficits.¹⁵⁴ Combining resistive training with guided imagery or other types of adjunct interactions has conflicting results.¹⁵⁴⁻¹⁵⁶ Yet there are still questions regarding optimal resistive training and

TABLE 9-2 ■ PROPRIOCEPTIVE STRETCH RECEPTORS

RECEPTOR	STIMULUS	NATURE OF RESPONSE
Ia tonic	Length	Monosynaptic and polysynaptic facilitation of agonist
Ia phasic	Rate of change in length	Polysynaptic inhibition of antagonist and antagonistic synergy Polysynaptic facilitation of agonistic synergy Input to cerebellum Input to opposite parietal lobe <i>Specific parietal lobe responses open for question</i>
II	Length	Monosynaptic facilitation of agonist Polysynaptic facilitation of specific muscle groups, depending on muscle function of tissue where II fibers originate Transmittal of information to higher centers

POSSIBLE TREATMENT ALTERNATIVES

1. Resistance
2. Quick stretch to agonist
3. Tapping: tendon and/or muscle belly
4. Reverse tapping: gravity stretches; tapping agonist into shortened range
5. Positioning (range)
6. Electrical stimulation
7. Pressure or sustained stretch
8. Stretch pressure
9. Stretch release
10. Vibration: facilitatory frequency for small vibrator, relaxation for total body vibration
11. Gravity as a prolonged stretch
12. Active motion

whether one resistive technique is better than another.^{157,158} Research certainly has shown that resistance training does enhance functional abilities across age groups,^{150,159,160} but again the specifics regarding resistive training techniques are often not identified. The terms *resistive training*, *weight training*, and *strength training* are often used synonymously, and thus specifics are yet to be identified in the research. How all these uses of resistive exercises will play out in the future is up to future researchers in the field of movement science. Very costly high-technology tools have been added to aid in resistive training (see the discussion of Pilates in Chapter 39 and robotics in Chapter 38).^{161,162} Given the needs of individuals after neurological insults, cost becomes a major factor, and finding creative and cost-efficient ways to apply resistance may become a common research question in the future.

Tapping. Three types of tapping techniques are commonly used by therapists. Tapping of the tendon is a fairly nondiscriminatory stimulus. Physicians use this technique to determine the degree of stretch sensitivity of a muscle. A normal response would be a brisk muscle contraction. Because of the magnitude of the stimulus and the direct effect on the alpha motor neuron, this technique is not highly effective in teaching a client to control or grade muscle contraction.¹⁶³ Instead, tapping of the muscle belly, a lower-intensity stimulus, is more satisfactory. Reverse tapping is a less frequently described technique, but it can be used. The extremity is positioned so gravity promotes the stretch, instead of the therapist manually tapping or actively inducing muscle stretch. Once the muscle responds, the therapist taps or passively moves the extremity to help the muscle

obtain a shortened range. An example of reverse tapping would be tapping the triceps muscle when the client is bearing weight on the extended elbow and actively trying to achieve full elbow extension. Gravity quickly stretches the triceps. Timing of this technique is important. If the therapist taps the elbow toward extension when the flexors' motor neurons are sensitive, then those flexor muscles may respond to the stretch and contract, taking the arm farther into flexion. If the timing follows the quick stretch to the extensor, then the flexors will be dampened and active extension more likely a motor response.

Positioning (Range). The concept of submaximal and maximal range of muscles is highly significant to clinical application. Bessou and colleagues¹⁶⁴ monitored the neuronal firing of muscle spindles at different ranges of motion. Upper motor neuron lesions can alter the sensitivity of the spindle afferent reflex arc fibers by not using presynaptic inhibition to normally dampen incoming afferent activity.¹⁶⁵ Therefore ROM should be carefully assessed on an individual basis, particularly in a patient with an upper motor neuron lesion, to determine the maximal or submaximal range for an individual. Therapists always need to determine whether the difference between optimal range and functional ROM is different. If a patient will never need to use full ROM, then spending long periods of time trying to stretch a shoulder or hip may not be the best decision with regard to intervention. As well as the ROM itself, therapists need to carefully evaluate excessive range resulting from hypermobility and hypotonicity. In those situations, external support of the affected joint or limb needs to be considered in all functional positions in order to prevent complications such as pain.¹⁶⁶⁻¹⁶⁸

Electrical Stimulation. For an in-depth discussion of the use of electrical stimulation both as an evaluation and a treatment modality, see Chapter 16 and Chapter 33. Electrical stimulation has the potential to be an excellent muscle spindle facilitatory technique, especially if additional therapeutic tools, such as resistance, are included. Electrical stimulation delivered to create muscle contraction is beneficial, but electrical stimulation as a sensory stimulus is less effective as a learning tool because there are no sensory receptors for electrical currents and thus they are not represented as a unique stimulus on the somatosensory cortex. Functional electrical stimulation (FES) is a technique that applies electrical stimulation during functional movement. Chapter 16 discusses this technique with traumatic spinal cord injury, but the application has gone beyond those individuals diagnosed with spinal injury. Individuals poststroke have also been studied using FES. The results were inconsistent. Some studies showed there was no difference in the stroke groups during or directly after intervention but that the long-term effect remained with those individuals who received FES, whereas those who did not regressed in function.^{169,170} Studies have shown that FES training increased walking ability and speed during and after the training.^{171,172} Studies that have looked at other neurological problems have also used FES and certainly are showing that this type of intervention may become a standard of practice in the future.¹⁷³⁻¹⁷⁵ Combined modulation of voluntary movement, proprioceptive sensory feedback, and electrical stimulation might play an important role in improving impaired sensorimotor integration by power-assisted FES therapy.¹⁷⁶ The use of FES over acupressure points has been shown to significantly reduce pain.¹⁷⁷

Stretch Pressure. The muscle belly is the stimulus focus of stretch pressure. The therapist slowly applies pressure to the muscle belly. It is used to decrease or release tone in the target muscle, allowing for the (temporary) recovery of voluntary movement.^{111,178} Generally this type of stimulus is applied and maintained for a period of time (e.g., 5 to 10 seconds). It is not a quick stimulus and may be using the tendon organ to dampen tone. This type of pressure technique is also used in a variety of complementary approaches (see Chapter 39).

Stretch Release. This technique is performed by placing the fingertips over the belly of larger muscles and spreading the fingers in an effort to stretch the skin and the underlying muscle. The stretch is done firmly enough to temporarily deform the soft tissue so the cutaneous receptors and Ia afferent fibers may produce facilitation of the target muscle. It is easy to determine quickly whether the response is efficacious by just feeling and looking at the response of the patient.

Manual Pressure. Manual pressure can be facilitatory when it is applied as a brisk stretch or friction-like massage over muscle bellies. The speed and duration at which the manual pressure is applied determine the extent of recruitment from receptors. Paired with volitional efforts, manual pressure can lead to motor function, and with repetition, motor learning.

Vibration. There are two types of vibratory methods used therapeutically. The first deals with the use of a hand-held vibrator to facilitate Ia receptors to enhance agonistic muscle contraction in hypotonic muscles or to facilitate Ia receptors of antagonistic muscle fibers to inhibit hypertonic agonists. Currently the use of vibration to facilitate Ia

responses within specific muscle function has been used to show how proprioception can be used to alter upright standing.^{179,180} The second type of vibratory method is a total-body vibration to facilitate postural tone and balance and is applied through the feet in a standing position.¹⁸¹⁻¹⁸⁴

Bishop^{185,186} wrote an excellent series of articles on the neurophysiology and therapeutic application of vibration in the 1970s. High-frequency vibration (100 to 300 Hz or cycles per second) applied to the muscle or tendon elicits a reflex response referred to as the *tonic vibratory response*. Tension within the muscle will increase slowly and progressively for 30 to 60 seconds and then plateau for the duration of the stimulus.¹⁸⁷ Some researchers found that at cessation of the input the contractibility of the muscle was enhanced for approximately 3 minutes.^{187,188} The discrepancy in the research may reflect the way the individual is using the input, both from a direct effect on the motor generator and from supraspinal modulation over the importance of the input, which may affect the overall learning and plasticity of the CNS. To facilitate hypotonic muscle, the muscle belly is first put on stretch, and then vibratory stimuli are applied.¹⁸⁹ To inhibit a hypertonic muscle, the antagonistic muscle could be vibrated.^{185,189} The use of vibration can be enhanced by combining it with additional modalities such as resistance, position, and visually directed movement. Vibration also stimulates cutaneous receptors, specifically the Pacinian corpuscles, and thus can also be classified as an exteroceptive modality.¹⁹⁰ Because of its ability to decrease hypersensitive tactile receptors through supraspinal regulation, local vibration is considered an inhibitory technique (it is also discussed later in the section on exteroceptor-maintained stimulus). Therapists have reported that vibration over acupressure points can modulate localized pain syndromes. It seems to trigger A delta exteroceptive fibers, which in turn dampen the effect of C fibers. (See Chapter 32 for more information on the treatment of pain.)

Farber¹¹¹ summarized the use of vibration and clearly identified precautions that must be taken. Frequencies greater than 200 Hz can be damaging to the skin. We have found frequencies greater than 150 Hz to cause discomfort and even pain. Therefore it is recommended that vibrators registering 100 to 125 Hz be used. Most battery-operated hand vibrators function at 50 to 90 Hz.¹¹ Frequencies less than 75 Hz are thought to have an inhibitory effect on normal muscle,¹⁸⁷ although a study showed that some muscle groups, especially the lateral gastrocnemius, do respond positively to frequencies of 40 to 60 Hz.¹⁹¹ Another researcher¹⁹² studying vibration found similar results that frequencies of 50 Hz generated more neuromuscular facilitation than lower frequencies (30 Hz) when studying improvements in upper body resistance exercise performance. Cutaneous pressure is also known to cause inhibition, so if it is combined with a vibration technique that is being used to augment a muscle contraction, it can only serve to cancel the desired effects.

Amplitude or amount of displacement must also be considered when vibration is analyzed as a modality. It has been reported that high amplitude causes adverse effects, especially in clients with cerebellar dysfunction.¹⁸⁶ Vibration is not recommended for infants because the nervous system is not yet fully myelinated and the vibration might cause too much stimulation. The reader is also cautioned about using

vibration over areas that have been immobilized because of the underlying vascular tissue potential for clotting. Vibration on or near these blood vessels could dislodge a clot, causing an embolism. Vibration also needs to be used cautiously over skin that has lost its elasticity and is thin (e.g., that in older persons) because the friction itself from the vibration can cause tearing. The therapist must always keep in mind the environment and the functionality of an intervention procedure. The use of vibration may assist the client in contractions and somatosensory awareness, but it is an unnatural way to facilitate either system and thus needs to be removed as part of an intervention as soon as the patient demonstrates some sensory awareness and/or volitional control over a movement component.

Within the last decade the use of vibration of specific muscle groups of the neck has been studied in order to determine its effect on upright standing and the interaction with and without eyes open.^{179,180} These studies showed that by vibrating specific muscle groups, those muscles would actively contract and change the position of the head in space but that with eyes open the effect was minimized in relation to global postural control. A similar study examined the effect of vibration on various muscles within the lower extremities and how that affected various postural responses.^{191,193} These researchers found that different frequencies affected different muscle groups. The one consistent thing all studies have shown is that vibration does facilitate Ia muscle fibers, which in turn affect muscle contraction of the agonist receiving the vibration. Other sensory systems can assist or override the effect of vibration, but that is because of superspinal influence over motor generators.

Total-body vibration is currently being used to determine if it affects motor performance. Studies have shown that whole-body vibration can enhance motor performance in high-level athletes performing sprints and jumps,^{181,182} as well as improve trunk stability, muscle tone, and postural control in individuals after stroke while in geriatric rehabilitation.¹⁸⁴ Its application for individuals with neurological dysfunction is inconclusive.^{194,195} Studies specifically directed toward the elderly again show promise, but further research is needed for specificity.^{196,197} Future research will need to determine the effect of total-body vibration when introduced to all populations of individuals with neurological dysfunction. At that time both amplitude and magnitude will need to be identified in order to replicate studies. Total-body vibration certainly falls under primarily proprioception but also could be classified under combined proprioceptive techniques or multisensory classification techniques because the input affects the muscle spindles, the joints, the vestibular system, and possibly the auditory system with the low frequency noise. And every time vibration is applied, the skin receptors will initially fire although most will adapt quickly to prolonged use of any stimuli.

The Tendon. The tendon receptors are specialized receptors located in both the proximal and the distal musculotendinous insertions. In conjunction with the stretch receptors, the tendon plays an important role in the mediation of proprioception.^{141,142,198-203}

The principal role of the tendon is to monitor muscle tension exerted by the contraction of the muscles or by tension applied to the muscle itself. Research has demonstrated that the tendon is highly sensitive to tension and acts conjointly

with the stretch receptors to inform higher centers of continuing environmental demands to modulate or change existing plans; these higher centers in turn regulate tonicity and the state of the motor pool.^{43,141} The tendon (Ib) signals not only tension but also the rate of change of tension and provides the sensation of force as the muscle is working.¹⁹⁸ A fundamental difference between the tendon organ and the stretch receptors is that the stretch receptors detect length, whereas the tendon monitors tension and force. Sensory input from the stretch receptors and the tendon are mostly opposites.^{43,202} The stretch receptors regulate reciprocal inhibition, whereas the tendon modulates autogenic inhibition. Table 9-3 lists a variety of known treatment approaches that use the tendon to inform higher centers regarding needed change and regulation over spinal generators.

Maintained Stretch to the Tendon Organ. Maintained stretch to a muscle has the potential for triggering the tendon organ if tension is great enough. Once the maintained stretch fires the tendon organ, autogenic inhibition of the same muscle occurs. A therapist will feel a release of the agonist muscle, allowing for elongation of the contractile components. Simultaneously, the tendon organ's sensory neurons will facilitate motor neurons to the antagonist muscle, thus heightening its sensitivity and potential for activity. This is the technique used when a joint has developed range restriction. The clinician always needs to differentiate whether the tightness found within the joint is caused by compensatory muscles considered *movers* protecting injured postural muscles beneath or by tightness just from positioning, disuse, or fear.

Inhibitory Pressure. Pressure has been used therapeutically to alter motor responses. Mechanical pressure (force), such as from cones, pads, or the orthokinetic cuff developed by Blashy and Fuchs,²⁰⁴ provided continuously is inhibitory. That pressure seems most effective on tendinous insertions. It is hypothesized that this deep, maintained pressure activates Pacinian corpuscles, which are rapidly adapting receptors. A variety of researchers have studied these receptors and their relationship to regulating vasomotor reflexes,²⁰⁵ modulating pain,²⁰⁶⁻²¹⁰ and dampening other sensory system influence on the CNS.^{188,209}

This inhibitory pressure technique also works when pressure is applied across the longitudinal axis of a tendon. The pressure is applied across the tendon with increasing pressure until the muscle relaxes. Constant pressure applied over the tendons of the wrist flexors may dampen flexor hypertonicity and elongate the tight fascia over the tendinous insertion (see Chapter 39 for additional information).

Pressure over bony prominences has modulatory effects. A common example is pressure on the medial aspect of the calcaneus, which dampens plantarflexors and allows contraction of the lateral dorsiflexor muscles. Pressure over the lateral aspect of the calcaneus also dampens calf muscles to allow for contraction of the medial dorsiflexor muscles.²⁵ Localized finger pressure applied bilaterally to acupuncture points has been shown to relieve pain and reduce muscle tone.²¹⁰⁻²¹⁴ This technique has also been found to be particularly effective when used in a low-stimulus environment and when combined with deep breathing.

This combination of pressure (manually applied), environmental demands (low), and parasympathetic activity (slow, relaxed breathing) illustrates various systems interacting

TABLE 9-3 ■ PROPRIOCEPTIVE RECEPTORS OF TENDONS AND JOINTS

RECEPTOR	STIMULUS	RESPONSE
TENDON		
Tendon organ Ib	Tension on extrafusal muscle	Polysynaptic inhibition of agonist, facilitation of antagonist spinal level circuitry; supraspinal regulation
Possible Treatment Suggestions		
<ol style="list-style-type: none"> 1. Extreme stretch 2. Deep pressure to tendon 3. Passive positioning in extreme lengthened range 4. Extreme resistance: more effective in lengthened and shortened range 5. Deep pressure to muscle belly to put stretch on tendon 6. Small repeated contractions with gravity eliminated 		
TYPE OF JOINT		
I (6-9 μ)	Static and dynamic joint tension: muscle pull	Thought to facilitate postural holding and joint awareness
II (9-12 μ)	Dynamic: sudden change in joint tension	Thought to facilitate agonist and awareness of joint range of motion
III (13-17 μ)	Dynamic: linked to Golgi tendon organ traction; activates in extreme range	Thought to inhibit agonist
IV (5 μ > 2 μ)	Pain	Thought to inhibit agonist
Possible Treatment Suggestions		
<ol style="list-style-type: none"> 1. Manual traction (distraction) to joint surfaces to facilitate joint motion 2. Manual approximation (compression) to joint surfaces to facilitate co-contraction or postural holding 3. Positioning: gravity used to approximate or apply traction 4. Weight belts, shoulder harnesses, and helmets to increase approximation 5. Wrist and ankle cuffs to increase traction 6. Wall pulleys, weights, manual resistance 7. Manual therapy²⁰ 8. Elastic tubing to provide compression during movement 		

together to create the best motor response. The real world requires the client to respond to many environmental conditions while relaxed or under stress. Thus, once a client begins to demonstrate normal adaptable motor responses, the therapist needs to change the conditions and the stress level to allow the client to practice variability. That practice should incorporate motor error, especially error or distortions in the plan, yet still achieve the desired goal. As the client self-corrects, greater demand and variability should be introduced.²¹⁵

Joint Receptor Approximation. Approximation of the joint mimics weight bearing and facilitates the postural extensor system. Gravity creates approximation and its greatest force is produced down through the body in vertical postures. Approximation should help to stabilize any joint that is in a load-bearing situation by eliciting coactivation of the muscles around the joint in question. In standing, gravity creates approximation down through the entire spine, hips, knees, and ankles. When in a prone position on elbows, the load goes down again through the upper spine while simultaneous going down through the shoulder girdles of both arms. If a therapist increases that load by adding pressure down through the joints in question, then an augmented intervention has been added to the therapeutic environment. Using weight belts around the waist or a weighted vest on the trunk

can facilitate the postural coactivation needed during standing or walking.²¹⁶⁻²¹⁸ At times, approximation can be used to heighten normal postural tone while simultaneously dampening excessive tone in the other leg. For example, clients who have CNS insult often have an imbalance in function within the two lower extremities. This can be very frustrating for the therapist because bringing the patient to standing to assist in regaining normal postural extension of one leg triggers the other into a strong extensor pattern, causing plantarflexion and inversion of that foot. One way to use approximation in treating both legs simultaneously might be to first bring the patient from sitting onto a high-low mat. Then the therapist can raise the mat high enough that the patient can be lowered into standing on the normal-functioning leg. At the same time the patient's other leg can be bent at the knee, and that knee placed on a stool or chair. This allows approximation down through the entire leg that is in standing position while approximating the trunk, hip, and knee of the other leg in the kneeling position. The therapist can work on standing and weight shifting in one leg while dampening abnormal tone in the kneeling leg. As the kneeling leg starts to regain postural coactivation in its hip, postural function will often be felt in the knee and ankle.

One very effective way to apply approximation and resistance simultaneously is to use the product similar to a cut

large elastic rubber band: Thera-Bands. The rubber material is attached under the heel on the right and left side; both ends of the band are brought up across the ankle and then crossed over the lower leg, once more over the back of the thigh, and then anchored onto a belt around the patient's waist. A similar pattern can be used for the arm; the band is first placed across the palm and then crossed in the forearm and then the arm. Finally one end is brought across the upper chest and the other comes around from the back of the arm. Then the two ends of the band are tied together across the neck. These techniques can be graded by the elasticity of the material.²¹⁹⁻²²¹

Traction and Distraction. One or more joints are distracted by a force that causes it or them to separate or pull apart, similar to the swing phase of the leg during ambulation or the arms in a reciprocal pattern to each leg. This distraction of the joint receptors also puts stretch on the muscles, which combines to facilitate the pattern into which the limb is moving. Simultaneously, distraction dampens the antagonistic movement pattern, which allows the agonist movement to continue. A therapist will often use manual traction to get relaxation of hyperactive extensor muscles or for limited mobility.²²² Often therapists do not think of the traction when applying resistance to a limb. For example, a mistake made is placing ankle weights to facilitate limbs that are ataxic. Ataxia is an imbalance in coactivation and smooth movement of both agonist and antagonist muscle groups.²²³ The weight itself slows down the excessive movement by the resistance. However, weight on the ankle creates traction that will facilitate only the flexor group and often creates an additional imbalance in the ataxic leg.²²⁴ When the weights are removed, the patient often is more ataxic.

Combined Proprioceptive Input Techniques. Many techniques succeed because of the combined effects of multiple inputs. Some of these combined techniques include jamming; ballistic movements; total-body positioning; PNF patterns; postexcitatory inhibition (PEI) with stretch, range, rotation, and shaking; heavy work patterns; Feldenkrais (see Chapter 39)²²⁵⁻²²⁷; and manual therapy.^{20,208,228}

Jamming. Jamming is usually applied to the ankle and knee with the intent of dampening plantarflexion while facilitating postural co-contraction around the ankle. The client can be placed in a side-lying position, can sit on a chair or mat, or can be positioned over a bolster with the hip and knee in some degree of flexion. This flexion dampens the total extension pattern, including the plantarflexor muscles. With release of plantarflexion these muscles are placed on extreme stretch to maintain the modulation. In this position, intermittent joint approximation and compression of considerable force is applied between the *heel* and *knee*. If the client is sitting, this approximation can easily be applied by pounding the heel on the floor and controlling a counterforce at the knee. Once coactivation is minimally palpated, the clinician should initiate a movement pattern such as partial weight bearing to further encourage the CNS to readapt with postural control. This technique can also be used to dampen flexion of the wrist and fingers by applying force to the appropriate upper-extremity patterns, modulating flexor reflex afferent activity, and applying a large amount of joint approximation between the heel of the hand and the elbow. To augment functional outcomes, the

technique should be incorporated into functional training to achieve better sensorimotor responses, improved cortical representation of the involved body part, and greater functional carryover.

Ballistic Movement. Ballistic movements are effective because of their combined proprioceptive interaction. The client is asked to initiate a movement, such as shoulder flexion while prone over a table with the arm hanging over the side. This component is volitional, but the client then maintains a passive role. As the patient relaxes, the movement patterns become automatic. The physiology behind the automatic movement is easy to understand. As the muscle approaches the shortened range, the amount of ongoing gamma afferent activity decreases. Thus both the agonist alpha motor neuron bias and the inhibition of Ia and II receptors of the antagonistic alpha motor neurons decrease. Simultaneously, the antagonistic muscle is being placed on more and more stretch. This stretch, as well as the lack of inhibition on the antagonistic alpha motor neurons, will encourage the antagonistic muscle to begin contraction and reverse the movement pattern. The tendon organs also play a key role in ongoing inhibition. As the muscle approaches the shortened range and tension on the tendon becomes intense, the tendon organ increases its firing, thus inhibiting the agonistic muscle in the shortened range while facilitating the antagonistic muscle. This technique is highly movement oriented, and the traction applied by gravity to the shoulder joint while swinging the arm further facilitates the movement. These ballistic movements are part of the program generators within the spinal system that facilitate reciprocal movements of the limb. As the client performs the movement, there is little need for conscious attention to drive the movement; it will run automatically. The role of the Ib fibers during this open chain or movement pattern is definitely different from its role in a closed chain or weight-bearing environment.¹⁹⁹ Supraspinal influence over programmed activity also plays a role in the effectiveness of this treatment.²²⁹ The specific rationale for why ballistic movements have functional carryover may be explained by recent research into cerebellar function and the importance of mechanical afferent input in regulation of movement (see Chapter 21).

The clinician using this technique must exercise caution. ROM can easily be obtained through ballistic movement. Consequently, the clinician must always determine before therapy the reasons for specific clinical signs and whether the total problem will be corrected through an activity such as a ballistic movement. This is the diagnostic responsibility of the professional. If one component of the problem is alleviated, such as limitation of range, while other components are ignored, this can be a dangerous technique. If the lack of range is a result of muscle splinting because there is lack of postural tone or joint stability, then ballistic movement has the possibly increasing the problem. For example, assume that the rotator cuff muscles are slightly torn and the movers of the shoulder are superficially splinting to prevent further tearing. Instructing the client to perform ballistic movement that causes relaxation of more superficial muscles will then place more responsibility for shoulder stabilization on the rotator cuff muscles. If those stabilizers are torn, traction along with relaxation of muscles that are splinting may increase the tear on the rotator cuff muscles and thus increase

the problem. The patient may never return to therapy, but if he does, he will complain of more pain than before.

Total-Body Positioning. Total-body positioning implies the use of positioning and gravity to dampen afferent activity on the alpha motor neurons and thus cause a decrease in tone, or relaxation.²³⁰ Today, the rationale for why relaxation of striated muscle occurs after this treatment implies that the effect of the flexor reflex afferents is being dampened by a combination of input and interneuronal activity. These changes in the state of the muscle tone will not be permanent and will revert to the original posturing unless motor learning and adaptation within the central programmer occur simultaneously. Thus for this treatment to effect permanent change, a large number of systems need modification. This modification can be augmented by techniques that facilitate autogenic inhibition, reciprocal innervation, labyrinthine and somatosensory influences, and cerebellar regulation over tone.²³¹ Changing the degree of flexion of the head also alters vestibular input and the state of the motor pool. But again, the CNS of the client needs to be an active participant and will ultimately determine whether permanent learning and change are programmed.

Proprioceptive Neuromuscular Facilitation. To analyze and learn the principles, techniques, and patterns that constitute PNF, a total approach to treatment, refer to the texts by Adler,²³² Voss,²³³ and Sullivan and colleagues.²⁹ This approach is being used extensively for patients with musculoskeletal and neuromuscular problems, with research on this method encompassing more populations with lower motor neuron and musculoskeletal problems than upper motor neuron lesions.^{154,228,234-242} When proprioceptive techniques are packaged in specific movement patterns, it may be referred to as PNF. When individual proprioceptive techniques are discussed alone, the specific sensory function is being acknowledged, and these techniques can be integrated into many rehabilitation intervention strategies.

Postexcitatory Inhibition with Stretch, Range, Rotation, and Shaking. The concept of PEI is based on the action potential or electrical response pattern of a neuron at the time of stimulation and on the entire phase response until the neuron returns to normal. At the time of stimulation, the action potential will build and go through an excitatory phase. The neuron then enters an inhibitory phase or refractory period during which further stimulation is not possible. This is referred to as the *PEI phase* or *postsynaptic afferent depolarization*.¹¹¹ These phase changes are extremely short and, in normal muscle, asynchronous with respect to multiple neuronal firing. In a hypertonic muscle more simultaneous firing occurs. When the muscle is lengthened, and thus tension is created, more fibers will be discharged. It is hypothesized that if the hypertonic muscle is placed at the end of its spastic range and a quick stretch is applied and held, then total facilitation followed by total inhibition will occur because of PEI. As the inhibition phase is felt, the therapist can passively lengthen the spastic muscle until the facilitatory phase sets in repolarization. At that time the clinician holds the lengthened position. Increased tone will ensue, followed by inhibition and continued lengthening. Holding the range (not allowing concentric contraction during the excitatory phase) is critical. If the muscle is held as the tone increases, the resistance and stretch are then maximal and probably further facilitate the inhibitory phase.

At a certain point in the range, if the muscle is not limited by fascial tightness, the hypertonic muscle will become dampened and tone will disappear. It is thought that at this time either the tendon organ activity takes over and maintains inhibition or flexor reflex afferents are modified, thus creating an inhibitory range in which antagonistic muscles can be more easily initiated and controlled by the client. If this technique is performed in a pure plane of motion, the clinician will find it a time-consuming procedure. Range can be achieved quickly by integrating a few additional techniques, that is, incorporating rotational patterns of movement. For example, if the spastic upper extremity is positioned in the pattern of shoulder adduction, internal rotation, elbow flexion, forearm pronation, and wrist and finger flexion, then a pattern in the opposite direction can be incorporated to include external rotation of the shoulder and supination of the forearm. Every time the clinician begins to lengthen the spastic extremity, those rotational patterns should be used. This should be done both on initial stretch and when resisting movement during excitation and then lengthening (allowing movement) during the inhibitory phase. Rotation seems to lengthen the inhibitory phase and allows additional range. If the clinician adds a quick stretch to the antagonistic muscle during the inhibitory phase of the agonistic muscle, then further facilitation of the antagonistic muscle will occur. Because the agonistic muscle is in an inhibitory phase, movement in and out of its spastic range should not affect it. Yet the quick stretch facilitation of the antagonistic muscle inhibits the spastic agonistic muscle and again lengthens the inhibitory phase. This entire procedure occurs very quickly. An observer might say that the clinician “shakes the hypertonicity out of the arm.” The shaking action is thought to be the quick stretch as well as joint oscillations. The degree of success depends on the therapist’s sensitivity to the tonal shifts or phase changes occurring in the client. These tonal shifts are automatic at the hundredth-of-a-millisecond level and not under the client’s conscious control. But the sensitivity of the Meissner corpuscles are at approximately 2 hundredths of a millisecond and provide adequate input to the therapist. If a master clinician responds to each inhibitory phase, it will look like the tone melts away. Most clinicians do not have that keen sensitivity, and the interventions will look more jerky because not every inhibitory phase is sensed and thus there will be a lot of stop-and-go movement in very small ranges of movement out of synergy until the hypertonic muscles finally relax.

Rood’s Heavy Work Patterns. Rood’s concepts of co-contraction in weight-bearing positions such as on elbows, on extended elbows, kneeling, and standing blend with today’s concepts of motor learning. Concepts explain why postural holding in shortened range for periods of time are valid treatment procedures. Rood stressed the need for patients to work in and out of those shortened ranges in order to gain postural control as well as to practice directing the limbs during both closed and open chain activities.

Feldenkrais. The Feldenkrais concepts^{225,226} of sensory awareness through movement place emphasis on relaxation of muscles on stretch, and distracting and compressing joints for sensory awareness. Both techniques reflect combined proprioceptive techniques. Taking muscles off stretch slows general afferent firing and thus overload to the CNS. Compression and distraction of joints enhance specific input

from a body part while simultaneously facilitating input of a lesser intensity from other body segments. This combined proprioceptive approach enhances body schema awareness in a relaxed environment. It also integrates empowerment of the client by use of visualization and asking for volitional control. (See Chapters 27 and 39 for additional information.)

Manual Therapy, Specifically Maitland's. “The peripheral and central nervous systems need to be considered as one because they form a continuous tissue tract.”^{208,225,243-246} Manual therapy or mobilization of joint or soft tissue structures is not specific to orthopedic conditions, nor are neurological treatment principles ineffective on orthopedic patients. Regardless of the diagnosis or pathological body system leading to joint immobility, the functional consequences can be synonymous. Joint immobility can cause the peripheral nerves to lose their adaptability to change in the length of the nerve bed. This change in neural elasticity then creates additional problems in connective tissue function, which in turn may affect the function of the motor system's control over the musculoskeletal component.^{228,247} For this reason alone, discussion of musculoskeletal mobilization needs to be included in this section as a component of classification.

“Pathological processes may interfere with both of these mechanisms: extraneural pathology will affect the nerve/interface relationship and intraneural pathology will affect the intrinsic elasticity of the nervous system.”²⁴⁷ Patient complaints of pain that limits functional movements constitute the primary reason clients are referred to a therapist for a musculoskeletal evaluation. During the physical examination, tension tests can be used to determine the degree of pain and joint limitation, to differentiate between somatic and radicular symptoms, and to identify adverse neurophysiological changes in the PNS.²⁴⁷ “The increased muscle tone (in a peripheral injury) is considered to be a protective mechanism for the inflamed tissue.”²⁴⁸ This increase in tone may be caused by a dampening of presynaptic activity of the flexor reflex afferent by supraspinal mechanisms. This same mechanism may be triggered by a CNS injury. The difference between the orthopedic patient and the neurological patient may be the trigger to the CNS. In a central lesion the motor generators are often not adequately maintained after injury, which results in hypotonicity. The hypotonicity causes peripheral instability, stretches peripheral tissue, and potentially causes peripheral damage. In both orthopedic and neurological cases, there is peripheral instability, the first the result of peripheral damage and the second the result of hypotonicity. The CNS response to the instability may be the same: an increase in muscle tone by dampening of presynaptic inhibition. A decrease in presynaptic inhibition on incoming afferents would cause an increase in spinal generator activity. With an isolated musculoskeletal problem and an intact CNS, the motor system would have the adaptability and control to modulate the spinal generators and isolate only those components in which an increase in tone might directly affect the problems. The client with CNS involvement may lose some of the flexibility of the motor system's control over the pattern generators, and thus high-tone synergistic patterns may develop.

In either case, the peripheral system needs to be evaluated and intervention provided when necessary. Tension

tests look for adverse responses to physical examination of neural tissues. These adverse responses are muscle tone increases as a result of painful provocation of sensitized neural tissue nociceptors attempting to prevent further pain by limiting the movement of the neural tissue.²⁴⁸ Pain increases tone and leads to limited range of passive movement.^{248,249} Pain-free range suggests CNS sensitivity to the large, highly myelinated alpha fibers and functions in a discriminatory manner. Pain range encompasses the degree of joint motion where neural length, as well as nociceptors in the skin, fascia, muscles, and joints, plays a primary role in CNS attention and protection. Inflammation of neural tissue can also cause the nociceptors to become hypersensitized or more reactive to mechanical or chemical changes. This is particularly true in the joint when the nociceptors react significantly to movement at the end ranges.²⁴⁸

Treatment will be based on the degree of immobility, the pain range, the site of the irritability, and the degree of pain. Butler²²⁸ not only looks at joint problems but also considers many joint problems as having adverse neural dynamics (tension on the PNS). Treatment still incorporates Maitland's grades of passive movement, but with consideration across the length of the neural tissue across multiple joints.

Butler^{247,250} divides treatment of the joint into three categories: limitations, pain, and adverse mechanical tension. When analyzing selective nervous system mobilization as identified by Butler, the therapist needs to mobilize the nervous system and its surrounding fascia rather than stretching it. These techniques may be either gentle (grade I) or strong (grade IV), through the range (grades II and III), or at end range only (grade IV). Different disorders (irritable compared with nonirritable) will require different treatment approaches (Figure 9-3).

Treatment must interface with related tissues. When joint immobility is interfaced with muscle and fascia tightness, all components must be treated simultaneously. If the focus of treatment is the correction of joint and muscle signs, then constant reassessment of the effect on the nervous system is crucial. This aspect would seem even more crucial in clients with CNS and PNS injuries. The treatment may be direct or indirect. Direct intervention involves procedures aimed at rebalancing the neuromusculoskeletal system through strengthening and increasing ROM to improve motor control. Indirect treatment includes the use of movement patterns, especially posture-based patterns. When individuals have nervous system changes, static and dynamic postural patterns often emerge as compensatory reactions to the problem state. Pain posturing, tension, or stiffness from prolonged positioning, and forced postures that are the result of synergy patterns, to name a few, all seem to respond well to indirect treatment with or without passive CNS mobilization. The use of posture-based movement patterns during functional activities also provides for variability and repetition and thus should lead to greater carryover in motor learning.

Many manual therapy approaches affect and use the proprioceptive system as a means to change motor responses. The reader is again reminded that the proprioceptive system affects all systems within the CNS and vice versa. The end effect of all system interactions will be intrinsic reinforcement of existing behavior or changes in and adaptations of behavior to meet intrinsic and extrinsic demands. The

Grades of Movement

- Grade I** A small amplitude movement performed near the beginning of range.
- Grade II** A large amplitude movement carried well into range. It's a movement that occupies any part of the range that is free of pain or resistance.
- Grade III** A large amplitude movement that moves up to the limit of range or into resistance.
- Grade IV** A small amplitude movement performed near the end of range or slightly into resistance.

Maitland has also been using the pluses (1) and minuses (2) in his grades of movement for many years now. It enables the therapist to communicate better with other therapists as well as treat the patient with accuracy and skill.

Grade IV--: just nicking resistance

Grade IV-: touching resistance

Grade IV: into resistance about 25%

Grade IV+: into resistance about 50%

Grade IV++: into resistance about 75%

Figure 9-3 ■ Grades of movement. (Modified from Maitland's theory of joint and tissue mobilization by John Sievert, PT, GDMT. From Course notes, Graduate Diploma in Manipulative Therapy, Curtin University of Technology, Perth, Western Australia, 1990; and from Maitland GD: *Peripheral manipulation*, ed 3, Boston, 1991, Butterworth Heinemann.)

behavior observed by the therapist as the client initiates motor strategies in response to functional goals will be a consensus of all these interactions.

Exteroceptive or Cutaneous Sensory System

Differentiation of Receptor Site as Augmented Intervention. Humans have many different types of tactile receptors. Some are superficial, and others are deep within the layers of the skin. These receptors have been identified within the chapter on motor learning. Their use as augmented intervention strategies is discussed in the following section.

A list of treatment techniques using the exteroceptive (tactile) input system as their primary mode of entry can be found in [Table 9-4](#).

Treatment Alternatives Using the Exteroceptive System. The function of the exteroceptive system is to inform the nervous system about the surrounding world. The CNS will adapt behavior to coexist and survive within this environment. Although many protective responses are patterned within the motor system, these patterned responses can be changed or modulated according to momentary inherent chemistry, attitude, motivation, alertness, and so on. Different from some of the other treatment approaches, the function of the exteroceptive input system is not reflexive but rather informative and adaptable.

Quick Phasic Withdrawal. The human organism reacts to painful or noxious stimuli at both conscious and unconscious levels. If the stimulus is brief and of noxious quality, it will elicit a protective reaction of short duration with use of the long-chain spinal reflex loops. Simultaneously, afferent impulses ascend to higher centers to evoke prolonged emotional-behavioral responses. Stimuli such as pain, extremes in temperature, rapid movement, light touch, and hair displacement are the most likely to cause this reaction by activating free nerve endings. These stimuli are perceived as potentially dangerous and communicate directly with the reticular-activating system and nonspecific thalamic nuclei. These structures have diffuse interconnections with all regions of the cerebral cortex, ANS, limbic system, cerebellum, and motor centers in the brain stem. Research has shown that children who exhibit hyperactive withdrawal reactions also develop negative emotional reactivity and show significantly more avoidance behavior and in time show right frontal asymmetry.²⁵¹ These alerting stimuli have been linked to motor seizures in critically ill patients.²⁵² As indicated by these research studies, therapists need to be aware of these potential responses, especially in patients with severe neurological insult that has resulted in a lower level of consciousness. These low-functioning clients cannot express their feelings nor how their nervous system is reacting to the input. Thus therapists need to be very aware of any motor response a patient may express and try to avoid using stimuli that might trigger these avoidance behaviors. From observance of the behavior of clients with chronic pain, these responses seem to become habitual and may lead to somatosensory remapping, making it hard to differentiate protective from discriminatory information. Thus, any movement or touch triggers pain. Patients need to be taught to discriminate between tightness and true pain, and therapists need to feel when the muscle response has shifted from muscle gliding to muscle restriction. Therapists need to gain trust, and one way is to not elicit a lot of pain. For example, if a therapist tells a patient to say something when it hurts, and the patient says, "Now," the therapist should never respond with "Well, just a little more." In that instant the patient has learned that the therapist lied (because the patient was told to tell the therapist when it hurt, suggesting that the therapist would stop then) or that the therapist is a masochist. If the therapist had stopped when the patient said that it hurt, the patient would then know that he does not need to tell the therapist to stop 10 degrees before it hurts because the therapist is not going to range him that 10 extra degrees. Often the therapist will find that without any effort the patient now has that extra range and has no need to splint the limb because it is not going to hurt to have therapy.

TABLE 9-4 ■ EXTEROCEPTIVE INPUT TECHNIQUES

RECEPTORS	STIMULI	RESPONSE*
Free nerve endings: C + A fibers	Pain, temperature, touch	Seem to protect and alert, perception of temperatures, protective withdrawal
Hair follicles	Mechanical displacement of hair receptors	Increased tone of muscle below stimulus site
Merkel disk	Touch: pressure receptors	Touch identification
Meissner corpuscles	Discriminative touch	Postural tone; two-point discrimination
Pacinian corpuscles	Deep pressure and quick stretch to tissue, vibration	Position sense, postural tone and movement
Ruffini corpuscles	Touch mechanoreceptor	Touch and spatial discrimination

SUGGESTED TREATMENT PROCEDURES USING CUTANEOUS STIMULI**Quick Phasic Withdrawal**

1. Stimulus
 - a. Pain
 - b. Cold: one-sweep with ice cubes, Rood's quick ice
 - c. Light touch: brush (quick stroking), finger, feather
2. Response
 - a. Stimulus applied to an extensor surface: elicits a flexor withdrawal
 - b. Stimulus applied to flexor surface: may elicit flexor withdrawal or withdrawal from stimulus into extension

Prolonged Icing (Repetitive Icing Should Be Used with Caution Because of Rebound Effect)

1. Stimulus
 - a. Ice cube
 - b. Ice chips and wet towel
 - c. Bucket of ice water
 - d. Ice pack
 - e. Immersion of body part or total body
2. Response: inhibition of muscles below skin areas iced

Neutral Warmth

1. Stimulus
 - a. Air bag splints
 - b. Wrapping entire body or individual body part with towel
 - c. Tight clothing such as tights, fitted turtleneck jerseys, Lycra clothing
 - d. Tepid water or shower
2. Response: inhibition of area under which neutral warmth was applied

Light Touch, Rapid Stroking

1. Stimulus
 - a. Light intermittent tactile stimulus to an identified dermatome-myotome interaction area
2. Response: facilitation of muscle(s) related to the stimulus area

Maintained Pressure or Slow, Continuous Stroking with Pressure

1. Stimulus
 - a. Slowly rubbing the target area with a towel
 - b. Wearing Lycra or spandex clothing
2. Response: sensory receptor adaptation and decrease in afferent firing

*Response: adaptation of many cutaneous receptors to stimulus, thus decreasing exteroceptive input, decreasing reticular activity, and decreasing facilitation of muscles underlying stimulated skin.

There are some real therapeutic limitations to using stimuli that “load” the spinothalamic system. A painful stimulus will be excitatory to the nervous system and produce a prolonged reaction after discharge. According to Wall's gate-control theory,²⁵³⁻²⁵⁷ all sensory afferent neurons converge and synapse in the dorsal horn in an area called the *substantia gelatinosa*. Curiously, the large, more discriminatory fibers do outnumber the small fibers.²⁵⁸ Therefore, physical activity, frequent positioning, deep pressure, and proprioceptive and cutaneous stimulation should cause enough impulses to converge on cells within the substantia

gelatinosa to close the gate and thus block transmission of pain messages to the brain. Studies have demonstrated that physical activity (types of physical stress) stimulates the production of endorphins, which in turn release opiate receptors and act as the body's own morphine for pain control^{20,212,259-262} (see Chapters 18 and 32).

Because light touch has both a protective and a discriminatory function, techniques such as brushing or stroking the skin with a soft brush have the potential of informing the CNS about (1) texture, object specificity, and error in fine motor responses or (2) danger (eliciting a protective

response). If a protective response is triggered, the specific withdrawal pattern will depend on a variety of circumstances. If the stimulus is applied to an extensor surface, then a flexor withdrawal will be facilitated. If the stimulus is placed on a flexor surface, one of two responses occurs. First, the client might withdraw from the stimulus, thus going into an extensor pattern. Second, the stimulus may elicit a flexor withdrawal and cause the client to go into a flexor pattern. Which pattern occurs depends on preexisting motor programming bias as a result of positioning and the predisposition of the client's CNS. Both responses would be considered normal. The condition or emotional state of the nervous system and whether the stimulus is considered threatening also determine the sensitivity of the response, again reinforcing the systems' interdependence. These responses are protective and do not lead to repetition of movement or motor learning. For that reason, along with the emotional and autonomic reactions, a phasic withdrawal to facilitate flexion or extension is not recommended as a treatment approach unless all other possibilities have been eliminated.

Short Duration, High-Intensity Icing. Cold is another stimulus that the nervous system perceives as potentially dangerous. The use of ice as a stimulus to elicit desired motor patterns is an early technique developed by Rood. Her technique was referred to as *repetitive icing*. An ice cube is rubbed with pressure for 3 to 5 seconds or used in a quick-sweep motion over the muscle bellies to be facilitated. This method activates both exteroceptors and proprioceptors and causes a brief arousal of the cortex. This method can produce unpredictable results. Although initially a phasic withdrawal pattern generator response will be activated immediately after the reflex has taken place, the "rebound" phenomenon deactivates the muscle that has been stimulated and lowers the resting potential of the antagonistic muscle.²⁶³ Therefore a second stimulus to the same dermatome-myotome neural network may not elicit a second response. But, because of reciprocal innervation, the antagonistic muscle may effect a rebound movement in the opposite direction. Icing may also cause prolonged reaction after discharge because of the connections to the reticular system, limbic system, and ANS. Thus the ANS would be shifted toward the sympathetic end. Too much sympathetic tone causes a desynchronization of the cortex.²⁶⁴ Although the resting state of the spinal generator may be altered briefly, if the heightened state persists the cause is most likely fear or sympathetic overflow (see Chapter 5). This state is destabilizing to the system and most likely will not lead to any motor learning. Because of unpredictable response patterns to Rood's repetitive icing, this technique is seldom used.

The therapist is cautioned not to use short-duration, high-intensity icing to the facial region above the level of the lips, to the forehead, or to the midline of the trunk. These areas have a high concentration of pain fibers and a strong connection to the reticular system.^{10,265}

Ice should not be used behind the ear because it may produce a sudden lowering of blood pressure.²⁶⁶ The therapist should also avoid using ice in the left shoulder region in patients with a history of heart disease because referred pain from angina pectoris manifests itself in the left shoulder area, indicating that the cold stimulus might cause a reflexive constriction of the coronary arteries.²⁶⁷ In addition, the

primary rami located along the midline of the dorsum of the trunk have sympathetic connections to internal organs. The cold stimulus may alter organ activity and perhaps produce vasoconstriction, causing increased blood pressure and reduced blood supply to the viscera.^{268,269}

Brief administration of ice can have beneficial effects if the nervous system's inhibitory mechanisms are in place. For instance, in children with learning disabilities or adults with sensorimotor delays, the application of ice to the palmar surface of the hands will cause arousal at the cortical level because of the increased activity of the reticular activating system. This arousal response presumably produces increased adrenal medullary secretions, resulting in various metabolic changes. Therefore icing should be used selectively. If the patient has an unstable ANS, icing should be eliminated as a potential sensory modality.²⁷⁰

Prolonged Use of Ice. Physicians have used therapeutic cold for the treatment of individuals with high fever and/or intracranial pressure with the intent of reducing the body temperature or brain swelling to prevent brain damage.²⁷¹ This procedure is done with cooling pans or blankets. Whole-body cryotherapy has been used to reduce inflammation and pain and overcome symptoms that prevent normal movement. This type of therapy consists of the use of very cold air maintained for 2 minutes in cryochambers. A recent study looked at this type of therapy for injured athletes. It was found that the procedure did not cause harm to the individual.²⁷² This approach does not seem realistic for use in occupational or physical therapy clinics.

A variety of approaches that incorporate prolonged icing techniques have been used in therapy clinics for decades. The PNF approach may be the most common.¹⁹ Inhibition of hypertonicity or pain is the goal for the use of any of these methods. With prolonged cold the neurotransmission of impulses, both afferent and efferent, is reduced. Simultaneously the metabolic rate within the cooled tissue is reduced (see Chapter 32). Caution must be exercised with regard to the use of this modality. However, for effective treatment results, the client (1) should be receptive to the modality, (2) should be able to monitor the cold stimulus (sensory deficits should not be present), and (3) should have a stable autonomic system to prevent unnecessary adverse effects of hypothermia. Research of the last decade has consistently shown that cryotherapy is an effective tool for reducing pain and has helped individuals regain integration of axial musculature after neurological insults.²⁷³⁻²⁷⁶ Individuals of all ages seem to respond similarly, which allows therapists to use this therapeutic tool across generations.²⁷⁷

Ice immersion of the contralateral limb was used decades ago in order to get a reflexive decrease in temperature in the affected limb. It was believed that this intralimb reflex was an effective way of treating pain without directly treating the limb. Recent research has validated that belief.²⁷⁸

Ice massage is another form of prolonged icing and is often used to treat somatic pain problems.²⁷⁹ It is also used over high-toned muscles to dampen striated muscle contractions. Caution must be used when eliminating pain without correcting the problem causing pain. For example, if instability causes muscle tone and pain, then icing might decrease pain while causing additional joint instability and potential damage. The end result would be an increase, not a decrease, in pain and motor dysfunction.

Neutral Warmth. Like icing, neutral warmth alters the state of the motor generators, either directly or indirectly through afferent input. According to Farber,¹² the length of application depends on the client. A 3- to 4-minute tepid bath may create the same results as a 15-minute total-body-wrapping procedure. As with any input procedure, the effects should be incorporated into the therapeutic session to maximize the results and promote client learning. The Johnstone approach uses air splints effectively as a neutral warm treatment intervention while clients work on functional activities.¹⁷ If neutral warmth is applied as an isolated intervention, the client may feel relaxation or a decrease in discomfort, but neuroplastic CNS changes are unlikely, owing to the lack of repetition, attention, and error correction by the client during activities. A recent study looked at blood pressure, heart rate, and other autonomic mechanisms in subjects using compression hose. The researchers did not look at neutral warmth as a mechanism to maintain a homeostatic state of the nervous system. Yet the use of compression hose does create a state of neutral warmth, and the link to homeostasis can easily be made.²⁸⁰

Maintained Stimulus or Pressure. Because of the rapid adaptation of many cutaneous receptors, a maintained stimulus will effectively cause inhibition by preventing further stimuli from entering the system. This technique is applied to hypersensitive areas to normalize skin responses. Vibration used alternately with maintained pressure can be highly effective. It should be remembered that these combined inputs use different neurophysiological mechanisms. It is often observed that low-frequency maintained vibration is especially effective with learning-disabled children who have hypersensitive tactile systems that prevent them from comfortable exploration of their environment. When children themselves use vibration on the extremities, their hypersensitive systems seem to normalize and they become receptive to exploring objects. If that exploration is accompanied by additional prolonged pressure, such as digging in a sandbox, the technique seems to be more effective because of the adaptive responses of the nervous system.

Maintained pressure approaches using elastic stockings, tight form-fitting clothing (e.g., wet suits, expanded polytetrafluoroethylene [Gore-Tex] biking clothing), air splints, and other techniques can be incorporated into a client's daily activity without altering lifestyle. The use of TheraTogs in children with various hyperactivity conditions has become an accepted therapeutic tool. They add some resistance, some support, and maintained pressure.²⁸¹ TheraTogs have also been shown to be effective in assisting individuals with hemiplegia to regain abductor control.²⁸²

In this way clients can self-regulate their systems, allowing greater variability in adapting to the environment. Owing to the multisensory and multineuronal pathways used when peripheral input is augmented, traditional linear, allopathic research on human subjects is extremely difficult to design or measure with control. But outcome studies demonstrating efficacy are possible. Initially, efficacy confirmed by observation was acceptable. Now it is time to repeat studies and use objective measures to demonstrate the same outcome.

Light Discriminatory Touch. Once an individual can discriminate light touch both for protection and for discriminatory learning, a lot of therapeutic tools become available to

the therapist. Using boxes with an opening so the individual can insert a hand and arm but cannot see what is inside, a patient can work on discriminating textures, objects, letter, numbers, and so on while working on higher-order processing. Once this touch has been integrated, the patient can also use light touch to determine balance, position in space, and various other types of perceptual tasks.²⁸³

Vestibular System (Refer to Chapter 22B)

Vestibular Treatment Techniques. The vestibular system is a unique sensory system, critical for multisensory functioning, making it a viable and powerful input modality for therapeutic intervention (see Chapter 22B). Any static position and any movement pattern will facilitate the labyrinthine system; therefore vestibular function and dysfunction play a role in all therapeutic activities. To conceptualize vestibular stimulation as spinning or angular acceleration minimizes its therapeutic potential and also negates an entire progression of vestibular treatment techniques.^{12,41,284-286} Linear movements in horizontal and vertical postures and forward-backward directions occur early in development and should be considered one viable treatment modality. These movements seem to precede side-to-side and diagonal movements, which are followed by linear acceleration and end with rotational movements. All these movements can be done with assistance or independently by the client in all functional activities. It is important to remember that the rate of vestibular stimulation determines the effects. A constant, slow, repetitive rocking pattern, irrespective of plan or direction, generally causes inhibition of total-body responses via the alpha motor neuron but not the spindles,²⁸⁷ whereas a fast spin or fast linear movement tends to heighten both alertness and the motor responses. Again, the vestibular mechanism is only one of many that influence the motor system. Thus, the system interaction must be constantly reassessed.

As already indicated, constant, slow, repetitive rocking patterns, irrespective of plane or direction, generally cause inhibition of the total-body responses. Yet any stimulus has the potential of causing undesired responses, such as increased or decreased tone. When this occurs, the procedure should be stopped and reanalyzed to determine the reason for the observed or palpated response. For example, assume that a client, whether a child with cerebral palsy, an adolescent with head trauma, or an adult with anoxia, exhibits signs of severe generalized extensor hypertonicity in the supine position. To dampen the general motor response, the therapist decides to use a slow, gentle rocking procedure in supine position and discovers that the hypertonicity has increased. Obviously, the procedure did not elicit the desired response and alternative treatment is selected, but the reason for the increased hypertonicity needs to be addressed.

It is possible that the static positioning of the vestibular system is causing the release of the original tone and that through increasing of the vestibular input the tone also increases. It may also be that the facilitatory input did indeed cause inhibition, but the movement itself caused fear and anxiety, thus increasing preexisting tone and overriding the inhibitory technique. Instead of selecting an entirely new treatment approach, a therapist could use the same procedure in a different spatial plane, such as a side-lying, prone, or sitting position. Each position affects the static position of

the vestibular system differently and may differentially affect the excessive extensor tone observed in the client. The vertical sitting position adds flexion to the system, which has the potential of further dampening extensor tone. This additional inhibition may be necessary to determine whether the slow rocking pattern will be effective with this client. It would seem obvious that if a vestibular procedure was ineffective in modifying the preexisting extensor tone, then use of a powerful procedure, such as spinning, would be inappropriate. Selection of treatment techniques should be determined according to client needs and disability. Clients either with an acoustic tumor that perforates into the brain stem or with generalized inflammatory disorders may be hypersensitive to vestibular stimulation, whereas other clients, such as a child with a learning disability, may be in need of massive input through this system. Heiniger and Randolph⁴¹ and Farber^{12,111} present in-depth analyses of various specific vestibular treatment procedures commonly used in the clinic. A general summary of the treatment suggestions is summarized in Table 9-5.

The literature clearly establishes the causation of one vestibular imbalance, dizziness, for all age groups.²⁸⁸⁻²⁹¹ Certainly individuals can have vestibular problems and will present themselves as being dizzy or hyperactive to movement of the head. There is a lot of literature discussing treatment of dizziness, and only a few publications are listed here.²⁹²⁻²⁹⁴ There is certainly evidence to show how the vestibular system links to the autonomic nervous system and especially the sympathetic pathways.²⁹⁵ In Chapter 22B the reader will be able to find in-depth discussion of vestibular rehabilitation and the role movement scientists play in that rehabilitation.

General Body Responses Leading to Relaxation. Any technique performed in a slow, continuous, even pattern will cause a generalized dampening of the motor output.²⁹⁶ During handling techniques, these procedures can be performed with the client in bed, on a mat while horizontal, sitting at bedside or in a chair, or standing. The movement can be done passively by the therapist or actively by the client. Carryover into motor learning will best be accomplished when the client performs the movement actively, without therapeutic assistance. In a clinical or school setting, a client who is extremely anxious, hyperactive, and hypertonic may initiate slow rocking to decrease tone or feel less anxious or hyperactive. The reduction of clinical signs allows the client to sit with less effort and to be more attentive to the environment, thus promoting the ability to learn and adapt.

It is the type of movement, not the technique, that is critical. The concept of slow, continuous patterns is used in Brunnstrom's rocking patterns⁸ in early sitting, in PNF mat programs, and in therapeutic ball exercise programs; the use of these patterns can be observed in every clinic. Although the therapist may be unaware of why Mr. Smith gets so relaxed when slowly rocked from side to side in sitting, this procedure elicits an appropriate response. The nurse taking Mr. Smith for a slow wheelchair ride around the hospital grounds may do the same thing. Once the relaxation or inhibition has occurred, the groundwork for a therapeutic environment has been created to promote further learning, such as learning of ADL skills. The technique in and of itself will relax the individual but not create change or learning.

Pelvic mobilization techniques in sitting use relaxation from slow rocking to release the fixed pelvis. This release allows for joint mobility and thus creates the potential for pelvic movement performed passively by the therapist, with the assistance of the therapist, or actively by the client. This technique often combines vestibular with proprioceptive techniques, such as rotation and elongation of muscle groups, which physiologically modify existing fixed tonal response through motor mechanisms or systems interactions. Simultaneously, slow, rhythmic rocking, especially on diagonals, is used to incorporate all planes of motion and thus all vestibular receptor sites to get maximal dampening effect, whether directly through the vestibulospinal system or indirectly through the cerebellum and reticular spinal motor system. The same pelvic mobility can be achieved by placing the patient (child or adult) over a large ball. The ball must be large enough for the patient to be semiprone while arms are abducted and externally rotated and legs relaxed (either draped over the ball or in the therapist's arms). Again, this position allows for maintained or prolonged stretch to tight muscles both in the extremities and in the trunk while doing slow, rhythmical rocking over the ball. The pelvis often releases, and the patient can be rolled off the large ball to stand on a relaxed pelvis preliminary to gait activities. A word of caution must be given regarding use of a large ball for relaxation. It is much easier to control the ball when someone is assisting that control from the opposite direction (in front of the patient). If slow rocking is done and the therapist is keeping his or her voice monotonous for further relaxation, the individual assisting will also relax. One author has had family members fall asleep and slowly or quickly fall to the floor.

Techniques to Heighten Postural Extensors. Any technique that uses rapid anteroposterior or angular acceleration of the head and body while the client is prone will facilitate a postural extensor response. Scooter boards down inclines, rapid acceleration forward over a ball or bolster, going down slides prone, and using a platform or mesh net to propel someone will all facilitate a similar vestibular response of righting of the head with postural overflow down into the shoulder girdle, trunk, hips, and lower extremities. Rapid movements while on elbows, on extended elbows, and in a crawling position can also facilitate a similar response. Depending on the intensity of the stimulus, the response will vary. In addition, the client's emotional level during introduction to various types of stimuli may cause differences in tonal patterns. Clinical experience has shown that facilitatory vestibular stimulation promotes verbal responses and affects oral-motor mechanisms. Children with speech delays will speak out spontaneously and respond verbally.

Because facilitatory vestibular stimulation biases the sympathetic branch of the ANS, drooling diminishes and a generalized arousal response occurs at the cortical level. Therefore the appropriate time to teach adaptive rehabilitative techniques is after vestibular stimulation.²⁹⁷

Facilitatory Techniques Influencing Whole-Body Responses. Tactile, vestibular, and proprioceptive inputs also assist in the regulation of the body's responses to movement.^{35,111} As stated previously, the vestibular system, when facilitated with fast, irregular, or angular movement, such as spinning, not only induces tonal responses but also causes massive reticular activity and overflow into higher centers.

TABLE 9-5 ■ COMBINED INPUT SENSORY SYSTEMS: TREATMENT MODALITIES

TECHNIQUE	PROPRIOCEPTIVE: JOINT, TENDON SPINDLE	EXTEROCEPTIVE	VESTIBULAR	GUSTATORY	OLFACTORY	AUDITORY	VISUAL	ANS	INHERENT RESPONSE	
									LABELED	NOT LABELED
Sweep tapping ⁶²⁰	X	X								
Brunnstrom rolling (hand) ⁴⁰	X	X							Automatic extension of hand

2. Postural activities in front of mirror	X		?			X			
3. Therapist using voice command to assist client with movement	X		X		X				
High-level movement									
1. Walking balance beam	X		X		?	? If visually corrected	X		Labyrinthine righting and equilibrium; possible OLR
2. Trampoline activities	X		X			If visually corrected	X		OLR and equilibrium
3. Running, jumping, skipping	X		X						

OLR, Optic and labyrinthine righting reactions; PNF, proprioceptive neuromuscular facilitation; TLR, tonic labyrinthine reflex.

Thus increased attention and alertness are often the outcome. The tracts going from the spinal cord, brain stem, and higher subcortical structures must be sufficiently intact to permit the desired responses from this type of input. If a lesion in the brain stem blocks higher-center communication with the vestibular apparatus, then massive input may cause a large increase in abnormal tone. The therapist needs to closely monitor any distress or ANS anomalies.²⁹⁵

Total-Body Relaxation Followed by Selective Postural Facilitation. The use of the inverted position in therapy has become very popular as a way to relax postural muscles and decrease compression between vertebrae.²⁹⁸ Not only does this decrease pain, but it also causes relaxation. Earlier research on the labyrinth's influence on posture and the influence of the inverted position showed that total inversion (angle of 0 degrees) produced maximal postural extensor tone, and the normal upright position elicited maximal flexor tonicity.²³⁰ There seems to be confusion in the literature about the clinical effects of inversion. The initial research was performed on anesthetized animals and cannot be representative of how the human CNS responds to inversion as a system. Kottke²⁹⁹ reports that the static labyrinthine reflex is maximal when the head is tilted back in the semireclining position at an angle of 60 degrees above the horizontal. Conversely, minimal stimulation occurs when the head is prone and down 60 degrees below the horizontal position. Stejskal²⁹⁷ studied the effects of the tonic labyrinthine position in hypertonic patients. This study failed to show labyrinthine reflexes in subjects with hypertonia. The problem with use of the inverted position is its lack of permanency. It is a contrived technique used to relieve pain or to achieve total relaxation. The effectiveness of this approach comes with the next set of therapeutic activities that allow the CNS to maintain that relaxation for a period of time and hopefully indefinitely over a series of multiple treatments.

The explanation for the incongruity in the literature over decades seems to be one of interpretation. Any time a subject is put on a tilt table or even a scooter board, the weight bearing of the body on the surface must cause firing of the underlying exteroceptors while gravity pulls on the proprioceptors. This position also has the potential to create fear.³⁰⁰ As the body shifts and presses onto the underlying surface, stretch reflexes associated with posture and movement must contribute some bias to muscle tone.³⁰¹ In addition, if the subject is in supine and the neck flexors are activated eccentrically (being lowered to supine) or concentrically (being pulled toward sitting or actively lifting the head), or if the subject is in prone and the neck extensors are activated eccentrically (lowering the head toward the ground) or concentrically (holding the head up in prone), the proprioceptors of the neck could alter the muscle tone of the limbs.³⁰²

Another factor that contributes to tonal changes in the extremities is the cervicoocular reflex.^{303,304} Reflex eye movements to center the eyes as the body or neck rotates also exert influences on the muscles of the limbs. Because all the influences brought about by gravity and postural mechanisms in a clinical situation cannot be controlled, the inverted position appears to be an interplay of cutaneous receptors, proprioceptors, and tonal changes in the labyrinthine system.³⁰⁵

Several highly recognized therapists have reported using the inverted position as a therapeutic modality.^{12,28,41} Generally

the inverted position produces three major changes. First, because of the gravitational forces on circulation, the carotid sinus sends messages to the medulla and cardiac centers that ultimately lower heart rate, respiration, and resting blood pressure through peripheral dilation, creating a parasympathetic response pattern. This position may be contraindicated for certain patients with a history of cardiovascular disease, glaucoma, or completed stroke. Clients with unstable intracranial pressure—for example, those with traumatic head injuries, coma, tumor, or postinflammatory disorders—and many children with congenital spinal cord lesions would also be at high risk for further injury if the inverted position were used. However, this position has been used with some success for adult patients with hypertension. In any case, scrupulous recording of blood pressure and other ANS effects should be taken before, during, and after positioning.

Another benefit of the inverted position is generalized relaxation. Farber¹² recommends its use as an inhibitory technique. Because the carotid sinus stimulates the parasympathetic system, the trophotropic system is influenced and muscle tonicity is reduced. This has been found to be beneficial to patients with upper motor neuron lesions and also to children who exhibit hyperkinetic behavior. Heiniger and Randolph⁴¹ report that severe hypertonicity in the upper extremities is noticeably reduced.

The third benefit of the inverted position is an increased tonicity of certain extensor muscles. This phenomenon is not purely a function of the labyrinth; it is also a result of activation of the exteroceptors being stimulated by the body's contact with the positioning apparatus.³⁰⁵ Therapists have capitalized on this reaction to activate specific extensor muscles of the neck, trunk, and limb girdles.^{27,297,299}

Because the inverted position decreases hypertonicity and hyperactivity and facilitates normal postural extensor patterns, the responses to the technique should be incorporated into meaningful functional activities. For example, if the position of total inversion over a ball is used, then postural extension of the head, trunk, and shoulder girdles and hips should be facilitated next. Additional facilitation techniques, such as vibration or tapping, could help summate the response. Resistance to the pattern in a functional or play activity would be the ultimate goal. If the inverted position is used in a squat pattern, then squatting to standing against resistance would probably be a primary goal. This can be accomplished by the therapist positioning his or her body behind and over the child, not only to direct the child initially into the inverted position but also to resist the child coming to stand. If the inverted position is used in sitting, activities of the neck, trunk, and upper extremities would be the major focus after the initial responses.

Because the inverted position elicits both labyrinthine and ANS responses, this technique needs to be cross-referenced within the classification schema. Because of its ANS influence, close monitoring is important for all clients placed in an inverted position. As with all labyrinthine treatment techniques, this approach, considered a normal, inherent human response, is used outside the therapeutic setting. For example, standing on one's head in a yoga exercise causes the same physiological state as that observed in the clinic. In many respects the yoga stance is done for the same reasons: decreasing hypertonicity (generally caused by

tension), achieving relaxation, and increasing postural tone and altered states of consciousness. Clients can certainly be taught to control their own ANS activity and hypertonicity by placing their hands between their legs when they need a generalized dampening effect on motor generators. Thus, when accessing and incorporating other approaches, the therapist analyzes each specific technique with use of a critical neuroscientific frame of reference.

This section has described procedures that use the vestibular system as a primary input modality to alter the client's CNS. If the client's vestibular system itself is dysfunctional, this dysfunction has the potential to alter the functional state of the motor system. See Chapter 22A for additional information on balance and Chapter 22B for information on the vestibular system.

The therapist must always remember that in combining vestibular and proprioceptive input or asking the CNS to process this information, a variety of results can develop. When the two input systems are congruent, the response will be summated and the CNS will not need to make a lot of adjustment. However, if the inputs are in conflict, then the CNS needs to update the differences and weigh which stimulus is more relevant. Then the updating and response will be in direct proportion to how both inputs were weighted.³⁰⁶

Autonomic Nervous System

The ability to differentiate tone created by emotional responses versus tone resulting from CNS damage is a critical aspect of the evaluation process. Emotional tone can be reduced when stress, anxiety, and fear of the unknown have been reduced. This is true for all individuals. The client with brain damage is no exception. Six treatment modalities³⁰⁷ that normally produce a parasympathetic or decreased sympathetic (flight or fight) response are as follows:

1. Slow, continuous stroking for 3 to 5 minutes over the paravertebral area of the spine
2. Inversion, eliciting carotid sinus reflex along with other somatosensory receptors (refer to the discussion of vestibular system earlier in the chapter).
3. Slow, smooth, passive and active assistive movement within a pain-free range (refer to Maitland's grade II movements (see Figure 9-3)²⁰
4. Deep breathing exercises (see Chapter 18)
5. Progressive muscle relaxation
6. Cranial sacral manipulation (see Chapter 39)

When pressure is applied to both the anterior and posterior surfaces of the body, measurable reductions may be recorded in pulse rate, metabolic activity, oxygen consumption, and muscle tone.^{266,308} These pressure techniques are identified as an intricate part of the many intervention approaches such as therapeutic touch,^{24,267} Feldenkrais,^{225-227,309} Maitland,²⁰ massage,^{310,311} and myofascial release.^{6,212,312-314} Although not verbally identified, other techniques (e.g., neurodevelopmental treatment (NDT),^{31,32} Rood,^{29,41,111} Brunnstrom,⁸ and PNF²⁹) also place an important emphasis on the response of the patient to the therapist's touch.

Treatment Alternatives Using the Autonomic Nervous System

Slow Stroking. Slow stroking over the paravertebral areas along the spine from the cervical through lumbar components will cause inhibition or a dampening of the

sympathetic nervous system. The technique is performed while the client is in the prone position. The therapist begins by stroking the cervical paravertebral region in the direction of the thoracic area, using a slow, continuous motion with one hand. Usually a lubricant is applied to the skin, and the index and middle fingers are used to stroke both sides of the spinal column simultaneously. Once the first hand is approaching the end of the lumbar section, the second hand should begin a downward stroking at the cervical region. This maintains at least one point of contact with the client's skin at all times during the procedure. The technique is applied for 3 to 5 minutes—and no longer—because of the potential for massive inhibition or rebound of the autonomic responses.^{35,296} It is also recommended that at the end of the range of the last stroking pattern, the therapist maintain pressure for a few seconds to alert both the somatic and visceral systems that the procedure has concluded. Eastern medicine recognizes the importance of the ANS in total-body regulation to a greater extent than Western medicine does. The concepts of meridians and acupressure and acupuncture points are all intricately intertwined with the ANS (see Chapter 39). For that reason, a technique such as slow stroking would potentially interact with meridians and does extend over the row of acupuncture points referred to as *shu points* and relates to visceral reflexes connecting smooth muscle and specific organ systems. It is believed that this continuous, slow, downward pressure modulates the sympathetic outflow, causing a shift to a parasympathetic reaction or relaxation. Whether a result of the pressure on the sympathetic chain, some energy pressure over meridian points, a pleasant sensation, or something unknown, slow stroking does elicit relaxation and calming.^{41,111} Clients with large amounts of body hair or hair whorls are poor candidates for this procedure because of the irritating effect of stroking against the growth patterns and the sensitivity of hair follicles.

Slow, Smooth, Passive Movement within Pain-Free Range. Increasing ROM in painful joints is a dilemma frequently encountered by therapists caring for clients with neurological damage. Having the client communicate the first perception of pain and then moving the limb in a slow, smooth motion toward the pain range elicits a variety of behaviors. First, the client generally gestures or verbalizes that pain is present 10 to 15 degrees before it may, in reality, exist. This behavior may occur because the patient during previous treatment interventions learned that therapists often responded to the client's statement of pain by saying, "Let's just go a little farther." That additional range is usually 10 to 15 degrees. If the therapist stops at the stated point of pain, retreats back into a pain-free area, and approaches again, possibly with a slight variation in rotation or direction, the client will often relinquish the safety range and a true picture of the pain range will be obtained. The second finding is that if the motion toward the pain range is slow, smooth, and continuous, then frequently much of the range that was initially painful becomes pain free. The hypothesis is that slow, continuous motion is critical feedback for the ANS to handle imminent discomfort. The slow pattern provides the ANS time to release endorphins, thus modifying the perception of pain and allowing for increased motion. If the therapist stabilizes the painful joint and prevents the possibility of that joint going into the pain range, rapid,

oscillating movements can often be obtained within the pain-free range. This maintains joint mobility and often, as an end result, increases the pain-free range. This technique is not unique to the treatment of clients with neurological problems; it is often used as a manual therapy procedure.^{212,253,315} Furthermore, one can move slowly into a range that actually shortens muscles. If held for 30 seconds, the muscle that is too short can relax, promoting greater motion in the opposite direction. This can be called *strain-counterstrain*—inhibiting firing by maintaining a position of active insufficiency, making the muscle too short.

Manual therapy^{20,148,316-319} can be used to describe the pain and joint changes occurring at the joint level. As the fields of orthopedics and neurology merge into one system,²²⁸ with the brain acting as an organ controlling the entire system and its components, the question of whether the pain reduction is centrally or peripherally triggered may be an important one. The answer is probably both. For example, thumb pain can increase the sensation of the nervous system to the point that even cutaneous and proprioceptive receptors act as nociceptors.

Maintained Pressure. Farber¹² discusses a variety of techniques that facilitate a reduction of tone or hyperactivity. Pressure to the palm of the hand or sole of the foot, to the tip of the upper lip, and to the abdomen all seem to produce this effect. The pressure need not be forceful, but it should be firm and maintained.³²⁰ This same technique is defined as inhibitory casting when applied through the use of an orthosis (see Chapter 34).

Progressive Muscle Relaxation. Progressive muscle relaxation is practiced during both meditation and treatment approaches such as Feldenkrais.^{309,320,321} These methods of relaxation tend to trigger parasympathetic reactions, which in turn slow down heart rate and blood pressure and trigger slow, deep breathing (see Chapters 18 and 39). The Alexander technique has also been shown to cause relaxation while simultaneously increasing postural tone.³²²

Cranial Sacral Manipulation. Summarizing the complexity of cranial sacral theory is not within the scope of this book. The reader is referred to references to gain a global understanding of the treatment interactions and the ANS response to cranial therapy as well as a brief discussion in Chapter 39.^{307,312} This treatment approach needs to be more intensively researched in terms of physiological effects and clinical effectiveness.

Olfactory System: Smell

The complexity of the olfactory system and how it interacts with nuclei that direct emotion in humans is still not totally understood. Yet quality of life in patients without smell (dysosmic) is often impaired. How the neuroanatomy and neurophysiology of human smell lead to a decreased quality of life is still under investigation.³²³⁻³²⁶

Smell evokes different responses by means of the limbic system's control over behavior. Pleasant odors, such as vanilla or perfume, can evoke strong moods. Unpleasant odors can facilitate primitive protective reflexes, such as sneezing and choking. Sharp-smelling substances such as ammonia can elicit a reflex interruption of breathing.^{327,328}

As a result of arousal, protective reflexes, and mood changes caused by odors, the use of smell as a treatment modality has been implemented, especially during feeding

procedures. Odors such as vanilla and banana have been used to facilitate sucking and licking motions.^{329,330} Ammonia and vinegar have been used clinically to elicit withdrawal patterns and increase arousal in semicomatose patients.³³¹ When odors are used as a stimulant, the therapist must be aware of all behavior changes occurring within the client. Arousal, level of consciousness, tonal patterns, reflex behavior, and emotional levels all can be affected by odor. Because of limited research in this area, caution must be exercised to avoid indiscriminate use of the olfactory system. Odors such as body odor, perfumes, hairspray, and urine can affect the client's behavior although the smell was not intended as a therapeutic procedure. Some clients, especially those with head traumas and inflammatory disorders of the CNS, often seem to be hypersensitive to smell. In these cases the therapist needs to be aware of the external olfactory environment surrounding the client and to make sure those odors that are present facilitate or at least do not hinder desired response patterns.³³²

Many clinical questions arise regarding smell as a therapeutic modality. If the choice of odors is between pleasant and noxious, a pleasant odor will theoretically be perceived in a way that should be enjoyable, relaxing, and thus potentially tone reducing. On the other hand, noxious odors should cause a sympathetic reaction and, although producing alertness, may also create a fight-or-flight internal reaction that if repeated frequently could cause an adverse response to the client's perception of the world. This has the potential for having a profound effect on her or his feelings toward the therapist and the therapeutic environment. The effect may not be observable until the client reaches a level of consciousness or motor skill in which there is some ability to react.

Individuals' perception of smell is not correlated to their actual olfactory ability.³³³ Because of the complex neuronetwork of the olfactory system, the specifics between emotional responses and olfactory environment cannot be established, and determining which olfactory input will drive a pleasant, unpleasant, or neutral response is variable. There may be a cultural sensitivity to various smells that would suggest a cultural learning linked with emotional responses to smell.³³⁴⁻³³⁶ Therefore if a therapist is going to use smell as part of therapy, identification of the individual's prior likes and dislikes is very important. Family members and close friends will be the best people to consult in order to get this information.

Without a sense of smell an individual may not be able to respond appropriately to various olfactory environments, which may increase a client's feeling of isolation and lack of social interactive skills.³³⁷⁻³³⁹ Smell is intricately linked to the sense of taste. Without these sensory systems, individuals tend to stop eating, thus creating an entirely different health care issue.^{340,341}

Gustatory Sense: Taste

Gustatory input is generally used as part of feeding and prefeeding activities. As already mentioned, the oral region is sensitive not only to taste but also to pressure, texture, and temperature. For that reason feeding would be classified as a multisensory technique that uses gustatory input as one of its entry modalities. Specific input modalities are based on the combined taste, texture, temperature, and affective

response pattern—that is, both a banana and an apple may be sweet, yet the textures vary greatly. When mashed, both fruits may have a pudding-like texture, yet the client's emotional response may differ. Disliking the taste of banana but enjoying apple may cause startling differences in the client's response during a feeding session. Thus the importance of the clinician's sensitivity to the client's response patterns within each sensory modality cannot be overemphasized.¹¹¹ Similarly, a therapist needs to take into consideration normal changes with taste and smell that occur as a result of aging and adjust the input threshold appropriately.^{342,343} The interrelationship of taste and smell leads to the perception of flavor. Current research has shown that the role of taste may be guided more by taste than by smell, but with each client will not be able to differentiate flavors of food.³⁴⁴ Understanding this sensory system will lead to a greater understanding of some patient problems that follow CNS damage.³⁴⁵

Auditory System

Treatment Alternatives with Use of the Auditory System. Because of the complexity of the auditory system, a potentially large number of types of input modalities exists. Although some of them might not be considered traditional therapeutic tools, they are nonetheless techniques that affect the CNS. Some treatment alternatives focus on the following:

- Quality of voice (pitch and tone)³⁴⁶
- Quantity of voice (level and intensity)³⁴⁷
- Affect of voice (emotional overtones)^{348,349}
- Spatial and temporal sound (how fast a stimulus occurs, and how frequently)³⁵⁰⁻³⁵⁴
- Extraneous noise (sound)³⁵⁵
- Auditory biofeedback³⁵⁶⁻³⁶²
- Language³⁶³
- Volume, level, and affect of voice³⁶⁴⁻³⁶⁶
- Auditory perception³⁶⁷⁻³⁶⁹

The therapist's voice can be considered one of the most powerful therapeutic tools. Even constant sound has the ability to cause adaptation of the auditory system and thus inhibition of auditory sensitivity.^{141,355} Similarly, intermittent, changing, or random auditory input can cause an increase in auditory sensitivity.^{346,370} Because of auditory system connections, an increase or decrease in initial input or auditory sensitivity has the potential for drastically affecting many other areas of the CNS.³⁷¹ The connections to the cerebellum could affect the regulation of muscle tone. The collaterals projecting into the reticular formation could affect arousal, alertness, and attention, in addition to muscular tone. The importance of voice level has been acknowledged by colleagues for decades with respect to encouraging clients to achieve optimal output or maximal effort. The use of voice levels is a critical aspect of the entire PNF approach.²⁹ Yet the volume or intensity of a therapist's voice is only one aspect of this important clinical tool. Through clinical observation, it has been observed that clients respond differently to various pitches.³⁴⁶ The response patterns and specific range of comfortable pitch seem to be client dependent. The concept that each individual may have a range within the musical scale or even a specific note that is optimal for biorhythm function has been proposed by one composer-musician.³⁷² This concept needs research verification but

may prove to relate to one of those innate talents some therapists have that distinguish them as gifted therapists.

The emotional inflections used by the clinician certainly have the potential to alter client response.^{348,349} For example, assume the therapist asks Tim, a child with cerebral palsy, to walk. The specific response from the child may vary if the clinician's voice expresses anger, frustration, encouragement, disgust, understanding, or empathy. Knowing which emotional tone best coincides with a client's need at a particular moment may come with experience or sensitivity to others' unique needs.

Extraneous Noise. The varying level of sound or extraneous noise in a clinical setting can at times be overwhelming. Dropping of foot pedals, messages over loudspeakers, conversations, computers, printers, telephones, moans, a jackhammer outside the clinic, water filling in a tank, a drip in a faucet, whirlpool agitators, a burn patient screaming, and a child crying all are encountered in the clinical environment, and all could be occurring simultaneously. A therapist whose CNS is intact usually can inhibit or screen out most of the irrelevant sound, although his or her voice may rise according to the surrounding noise and the therapist may not even be aware of the vocal change.³⁴⁷ Clients with CNS damage may not have the ability to filter sensitivity to all these intermittent noise sensations.³⁶¹ The protective arousal responses these sounds might produce in a client could certainly elevate tone, block attention to the task, heighten irritability, and generally destroy client progress during a therapy session. Awareness of the noisy environment and the client's response to it not only is important for treatment modalities but also is critical to the problem-solving process.

Decreasing auditory distracters or sudden noises can drastically improve the client's ability to attend to a task or to succeed at a desired movement.^{343,373} The therapist is reminded that if the environment has been externally adapted for a client to procedurally and successfully practice the goal, then independence in that functional skill has not been achieved. Reintroduction of the noises of the external world must be incorporated into the client's repertoire of responses so that the individual can feel competent in dealing with any auditory environment the world might present.

Music. Music as an adjunct to therapy has been suggested as a viable way to help clients develop timing and rhythm in a movement sequence (see Chapter 20 for a discussion of basal ganglia disorders and Chapters 5 and 39 for a discussion of music therapy). Consistent sound waves and tempos, such as soft music, allow the patient to develop a neuronal model or an engram for the stimulus. The use of background music during therapy sessions enables the patient to make an association to the sounds, producing an autonomically induced relaxation response to a particular musical composition.³⁷⁴⁻³⁷⁶ Therapists must remember that music has a very strong emotional link to all other areas of the nervous system.³⁷⁷ For that reason, the use of music needs to be discriminative and not randomly introduced because the therapist likes the sound. Similarly, the music selected should be a piece that assists the patient and does not become a deterrent to succeeding at the current motor task. The clinician will easily tell the difference by the tone the music creates (increase or decrease) and the success made toward achieving the desired task.

Music is used for encouraging not only motor function but also memory^{378,379} and socialization.³⁸⁰⁻³⁸² Rhythmic sound perceived as an enjoyable sensation certainly has the effect of creating motor patterns in response to that rhythm. Individuals, young and old, will tap their fingers or feet to a beat. If the beat has words, people will often sing along, recalling from memory the appropriate words. The movement, memory, and willingness to interact are all critical aspects of the therapeutic environment. Having clients dance with a significant other twice a day to music they have enjoyed in the past encourages both the physical function and the social bonding so important for quality of life.³⁸³ Music affects heart rate, blood pressure, and respiration.^{384,385} It has even been suggested that easy listening music may bolster the immune system.³⁸⁶⁻³⁹⁰

Auditory Biofeedback. Biofeedback as a total therapeutic modality is discussed under the treatment sections in Chapters 33 and 39. Auditory biofeedback is generally thought of as a procedure in which sound is used to inform the client of specific muscle activity.^{360,362} The level or pitch may change in relation to strength of muscle contraction or specific muscle group activity. Yet auditory biofeedback also encompasses feedback as simple as a foot slap that communicates that a client's foot is on the floor or verbal praise after a successful therapeutic session.³⁵⁹ The importance of the auditory feedback system as a regulatory mechanism between internal and external homeostasis cannot be overlooked. However, the clinician should not assume that this system is intact and can automatically be used as a normal feedback mechanism for clients with CNS damage.^{112,361,391}

Language. Although most therapists thoroughly appreciate the complexity of the language system as a whole, they have little if any in-depth background to help them understand the components or the sequences leading to the development of language.^{364,392,393} Thus many therapists are extremely frustrated when confronted with clients who show perceptual or cognitive deficits involving the auditory processing system.

Therapists easily identify language comprehension difficulties with adults who have first language differences and with young children because of their age and lack of language experience. Nevertheless, many clients have a language processing dysfunction that leads to communication difficulties, both in reception and appropriate expression.³⁵¹ The elderly often can understand a conversation in a quiet room but have difficulty in rooms that are noisy.^{371,394,395} The environment within which communication occurs can drastically affect both reception and the ability to express to the world inner feelings and thoughts.³⁸⁷ Creating an environment conducive to that exchange will dramatically affect the motivation and drive of a patient within the therapeutic setting.³⁸⁸ The complexity of auditory reception, processing, and responses is extremely extensive and could be overwhelming to a PT or OT, but developing an understanding of how auditory information affects motor performance will certainly enhance the therapist's analysis of movement problems.^{396,397}

Visual System

Treatment Alternatives with Use of the Visual System. Because light is an adequate stimulus for vision, any light, no matter the degree of complexity, has the potential

to affect a client's CNS. That input not only reaches the optic cortex for sight recognition and processing but also projects to the brain stem and to the cerebellum through the tectocerebellar tract. Simultaneously, these afferents activate the reticular-activating and limbic spinal generators through the tectospinal tract.^{296,398} Thus, as long as light is entering a client's CNS, it has the potential to alter response patterns either directly—through the tectospinal system or the corticospinal system through occipitofrontal radiations—or indirectly through the influence of the ANS and limbic system on muscle tone resulting from emotional responses to light.³⁹⁹

The five categories of visual-system treatment alternatives should not be considered fixed, all-inclusive, or without overlap. The first three categories (color, lighting, and visual complexity) are common everyday visual stimuli. Combined, they make up the visual world.

Colors. When colors, hues, tones, the type of lighting, and the degree of complexity of the combined visual stimuli are varied, the treatment modality and the way the CNS processes it change.⁴⁰⁰⁻⁴⁰⁷ Because the visual system tends to adapt to sustained, repetitive, even patterns, any input falling under those parameters should elicit visual adaptation.^{141,408,409} This adaptation response will lead to decreased firing of sensory afferent fibers and have an overall effect of decreasing CNS excitation. A clinician would expect to see or palpate a decrease in muscle tone, a calming of the client's affective mood, and a generalized inhibitory response. Cool colors, a darkened room, and monotone color schemes all seem to have an inhibitory effect. What a therapist might look for is a change in a patient's behavior. For example, four days ago Patient A was placed on the green mat for therapy and he seemed interactive, calm, and involved in producing motor function. On the next day, he came to therapy and the red mat was available. When Patient A got on the mat he became agitated and inattentive. The next day again Patient A was placed on the red mat and again was agitated and distracted. On day four, Patient A was placed on the green mat and had a great therapy session. On this fourth day he was calm, interactive, and involved in regaining motor function. It would be easy for a therapist to miss behavioral changes occurring when a patient is placed on a green or a red mat. These problems should be anticipated when treating patients with emotional instability (see Chapters 5, 14, 23, 24, and 26).

In contrast, intermittent visual stimuli, bright colors, bright lights, and a random color scheme seem to alert the CNS and have a generalized facilitatory effect.⁴¹⁰⁻⁴¹² Research in the 1980s in the area of criminology has produced evidence to suggest that specific shades of colors can produce either a sedating response (such as certain pinks) or general arousal (certain blues).⁴¹³ Although a tremendous amount of research is required to substantiate these results if the clinician is to apply them with confidence, research is beginning to show that specific shades of colors and hues may drastically affect a client's general response to the world and specific response to a therapy session.^{403,404,407,414} Within the next few years, many facts regarding the reaction of the CNS to specific visual stimuli may be uncovered, and the clinician will be responsible for integrating this new information into the present categorization scheme.⁴¹⁵ Although a person without body system problems may react

in specific ways to color, intensity, and visual distracters, individuals with CNS may not respond with the same behavior.⁴¹⁶ In the Netherlands at the Institut de Hartenbuer, playrooms have been designed in different colors.¹⁴ Except for color, all rooms are exactly the same and originate from a central hub or core.¹⁴ Children are allowed to select which room they wish to play or be treated in. Children seem to pick the color room that most suits their moods and alertness and creates an environment in which they can learn.¹⁴

Lighting. Two types of lighting are found in a clinical environment. Fluorescent or luminescent lighting comes by definition from a nonthermal cold source. This type of lighting is generally emitted by a high-frequency pulse. Umphred (clinical observations, 1967 to 2005) has found that many individuals within a normal population complain that this high-frequency flutter is irritating and causes distraction. For this reason, it is recommended that each clinician observe clients' responses to various types of lighting to determine whether fluorescent visual stimuli cause undesirable output.⁴¹⁷ This is especially true with clients who already have an irritated CNS, such as those with inflammatory disorders (see Chapter 26), head trauma (see Chapter 24), or seizure disorders.^{418,419} The clinician should also remember that clients frequently lie supine and look directly at overhead lighting, whereas the therapist looking at the client is unaware of that particular visual stimulus. The types of visual stimuli that may cause seizures and are seen by clients within rehabilitation settings include computers, videogames, television, and venetian blinds.⁴¹⁷ For that reason, any change in lighting should alert the clinicians to watch for changes in their clients' behavior.

Incandescent lights by definition come from hot sources and emit a constant light without a frequency. The brightness of this type of lighting has the potential to alter CNS response. The visual system quickly responds to bright lights with pupil constriction. After prolonged exposure to a bright environment, the visual system adapts and becomes progressively less sensitive to it.^{141,408} Similarly, when exposed to darkness the retina becomes more sensitive to small amounts of light. Because of the response of the visual system to incandescent lighting, it is recommended that a therapist monitor the brightness of the lighting, especially before any type of visual-perceptual training or visually directed movement.

Although the sun is a natural source of light, it is not generally the primary source in a clinical setting. The sun can effectively be used as indirect lighting, thus eliminating the problems produced by artificial lighting. Sunlight is also more acceptable psychologically. Some clinics have designed the buildings to allow for maximum use of natural light.¹³

Visual Complexity. The visual system is the primary spatial sense for monitoring moving and stationary objects in space.^{420,421} An infant continually refines the ability to discriminate objects in external space until capable of identifying specific objects amid a complex visual array.⁴⁰⁹ When brain damage occurs, the ability to identify objects, localize them in space, pick them out from other things, and adapt to their presence may be drastically diminished.²⁶⁸ Because of the distractibility of many clients, reducing the visual stimuli within their external space can help them cope with the stimuli to which they are trying to pay attention.

Using rooms that have been stripped of such stimuli as furniture and pictures can reduce not only distractibility but also hyperactivity and emotional tone. If this method of reduction of stimuli is used, the clinician must remember that this procedure has a sequential component. The client must once again adapt to extraneous visual stimuli. Thus as the client's coping mechanisms improve, the therapist needs to monitor and change the visual environment. The therapist can monitor the amount of input according to the response patterns of the client but in time needs to have the client function in everyday environments and practice adaptation.

Cognitive-Perceptual Sequencing with the Visual System. In sighted individuals the visual system is important for integrating many areas of perceptual development, such as body schemes, body image, position in space, and spatial relationships.^{268,422,423} Vision as a processing system is so highly developed and interrelated with other sensory systems that when intact it can be used to help integrate other systems.^{395,424} Conversely, if the visual system is neurologically damaged, it can cause problems in the processing of other systems.

For example, assume that a child is asked to walk a balance beam while fixating on a target. The child is observed falling off the beam. On initial assessment vestibular-proprioceptive involvement would be primarily suspected. On further testing the therapist might discover that the child, while looking at the target, switches the lead eye in conjunction with the ipsilateral leg. As the child switches from right to left eye, the target will seem to move. Knowing the wall is stationary, the child will assume the movement is caused by body sway, will counter the force, and will fall off the beam. The problem is a lack of bilateral integration of the visual system in contrast to other sensory modalities. The visual system deficit is overriding normal proprioceptive-vestibular input to avoid CNS confusion. Unfortunately, the client is attending to a deficit system and negating intact ones. This visual conflict would be overriding the normal processing of intact systems.⁴²⁵

An intact visual system can be overridden by deficits in other systems. This can be seen in clients who are trying to relearn the concept of verticality. Clients with hemiplegia who demonstrate a "pusher" syndrome illustrate this conflict. This clinical problem originates from a posterior thalamic stroke and less frequently with extrathalamic lesions.^{426,427} An intact visual system can often be used to help reintegrate other sensory systems. First teaching clients to attend to vestibular-proprioceptive cues while vision is occluded or visual stimuli tremendously reduced will help present a kinesthetic conflict. Individuals feel straight at 20 degrees or more to the ipsilesional side yet when not supported they fall. This conflict does not need to be verbally discussed. The patients' nervous systems will interpret the conflict. The intent of the CNS is not to fall. If the patient does not automatically self-correct, the therapist can add reaching patterns across midline to assist. Then vision can be reintroduced to assist orientation to vertical or upright posture. The pusher syndrome is not just a posterior thalamic problem and can be combined with neglect. When additional perceptual problems are added, the testing results and direction of the backward push can change.⁴²⁸ Once the orientation has been reestablished, visual input will often be perceived in a more normal fashion. This syndrome has been

linked to the posterior thalamus as well as other integrative cortical areas within the brain.^{427,429-432}

Familiarity with the visual-perceptual system and its interrelationships with all aspects of the therapeutic environment is crucial if the clinician is to have a thorough concept of the client's problem. (See Chapter 28 for specific information regarding visual deficits and treatment alternatives.)

Mental Imagery. As is mentioned in the discussion of neuroplasticity in Chapter 4, and as is discussed further in the section on somatosensory retraining within this chapter, having patients visualize the sensory awareness of input from the environment has a positive effect on treatment outcomes. Similar positive effects have been shown to be effective when having patients practice motor imagery as part of the treatment protocol.^{137,433-436} It is known today that using mental imagery to retrieve past information or experiences does use a variety of pathways within the CNS, depending on the specific task.⁴³⁷ Having some cognitive understanding of the correlation between cortical deficits in specific patients and their visual-spatial problems helps the clinician avoid task-specific activities that will lead to failure while introducing task-specific mental imagery that will lead to success.⁴³⁸ Having the patient practice mental imagery of the functional activity practiced during a therapeutic session can be an excellent way to empower patients to practice when they cannot perform the activity itself independently, without extreme effort and abnormal movement strategies.^{155,439} A therapist will know whether the patient has mentally practiced the movement strategies by the carryover within the next session. The neurophysiological reason for this perceived contradiction may lie in neuroanatomy, site of the lesion, specificity of the individual client.^{156,439,440} Although imagery usually insinuates visualization, there are also other forms of imagery that can be used as part of intervention.^{155,437,439,441-443} Refer to the music therapy section in Chapter 39 for information on mental imagery.

One extension of mental imagery that came into common usage in the 1990s as a result of videogame popularity was "virtual reality." Over the last two decades the interface between virtual reality and medical education has included the use of a virtual environment to teach surgeons fine motor skill without having them practice on a live subject.⁴⁴⁴ An inevitable link has currently been identified between virtual reality and motor rehabilitation.⁴⁴⁵⁻⁴⁴⁸ Today the literature certainly reflects the potential advantage virtual reality may have with regard to not only motor learning but also the use of these environments as an adjunct to therapy in individuals with CNS damage.⁴⁴⁹⁻⁴⁵⁵ The future realization of the potential of this type of augmented intervention will be up to visionary thinkers who "push the envelope" of traditional therapeutic interventions.

Compensatory Treatment Alternatives with Use of the Visual System. The visual system can be used effectively as a compensatory input system if the sensory component of the tactile, proprioceptive, or vestibular system has been lost or severely damaged. The procedure for using vision in a compensatory manner should not be attempted until the clinician is convinced the primary systems will not regain needed input for normal processing. Although vision can direct and control many aspects of a movement, it is not extremely efficient and seems to take a tremendous amount

of cortical concentration and effort.^{418,456,457} Vision was meant to lead and direct movement sequences.^{297,420,458} If it is used to modify each aspect of a movement, it cannot warn or inform the CNS about what to expect when advancing to the next movement sequence. Thus, using vision to compensate eliminates one problem but also takes the visual system away from its normal function. For example, if a hemiplegic man is taught to use vision to tell him the placement of his cane and feet, his need to attend to proprioceptive cues will decrease. When advancing to ambulatory skills such as crossing the street, the client may be caught in a dilemma. As he is crossing the street, if he attends to the truck coming rapidly down the road, he will not know where his cane or foot is and thus will become anxious and possibly fall. If, on the other hand, he attends to his foot and cane, he will not know if the truck is going to hit him. That may increase emotional tone and make it difficult to move. If normal sensory mechanisms could be reintegrated, this client would have freedom to respond flexibly to the situation. Thus caution should be exercised to avoid automatic use of this high-level system to compensate for what seem to be depressed or deficit systems.^{225,226,309,459,460}

Visual input should be used to check or correct errors if other systems are not available. Movement should be programmed in a feed-forward mode unless change is indicated. Vision often recognizes the need for that change. If a client is taught a motor strategy in which vision is used as feedback to direct each component of the pattern, the pattern itself will generally be inefficient and disorganized and will lack the automatic nature of feed-forward procedural motor plans. If the client is too anxious to practice the procedure physically without overusing vision, then visual mental practice can be introduced.

Internal Visual Processing: "Visualization Techniques."

A previous section discussed mental imagery as a substitute in the presence of a sensory deficit or as a practice method for when a patient cannot perform a motor task. The use of visualization of some aspect of bodily function goes far beyond just mental practice. Visualization has been and continues to be used in many forms of therapy.⁴⁵⁹ In a randomized controlled study that looked at normal bone healing versus the use of a specific type of yoga that involves breath control, chanting, and visualization as an adjunct treatment, the individuals who practiced this yoga-based approach had accelerated fracture healing.⁴⁶¹ It has been shown that individuals can modulate their immune responses and that others can change that response through visualization.^{460,462} Smith and colleagues⁴⁶⁰ showed that individuals could exercise through their thoughts and visualization various degrees of control over what had been thought to be mindless internal processes. These concepts have been used therapeutically but usually when the client is resting or totally relaxed.^{225,226,309}

More recently, technology in neuroscience has allowed for the measure of tissue metabolism (positron emission transaxial tomography [PET])⁴⁶³ and changes in blood flow (fMRI) while the brain is engaged in functional mental tasks.^{464,465} All areas of the brain except the cerebellum appear to be activated during intense goal-directed mental imagery. Given that the task is not motorically executed, errors in rhythm and accuracy are not made, and thus the cerebellum is not recruited for correction. This suggests that mental imagery can be used to restore a function that might

have been lost as the result of a stroke or other type of injury because the individual may be able to use kinesthetic memory to facilitate learning even if current kinesthetic recognition is impaired.⁴⁶⁶ Visual imagination has the benefit of allowing correct task performance when physical limitations may prevent normal task completion. This could prevent abnormal learning (e.g., like that developing from abnormal posturing in gait in a stroke patient who lacks the voluntary control to ambulate and integrate a primitive synergy). For additional information, see the section on somatosensory discrimination.

Today these concepts can be integrated during active treatment in a variety of ways. Before a client begins to initiate a plan of movement, the therapist could ask the client to close the eyes and imagine the movement and what it felt like in that functional activity before the CNS injury. In this way, the patient is using prior memory and visualization to access the motor systems and hopefully initiate better motor plans. Similarly, if during a movement plan the state of the motor generators builds to such a level that the client is becoming dysfunctional, the therapist can stop the movement; ask the client to visualize a calm, quiet place; and then continue with the movement pattern when the tone is reduced or extraneous patterns cease.⁴⁶⁷ The client can be asked to practice mental imagery of the task until she or he can accomplish it normally and then finally carry it over to the real environment.^{468,469} For example, a client may have practiced transferring during an intervention session in which the therapist, using augmented treatment, kept the patient within a biomechanical window or limits of stability. During the interval between sessions, the patient is asked to visualize performing transfers initially from the same surface practiced and later to other surfaces at least a couple of times an hour. At the follow-up session, the therapist will often be able to tell if the patient has done the visualization. If the patient did practice, there is often carryover into the skill performance. If the patient forgot to practice, often the skill has reverted back to the initial level of learning, with little carryover from the last intervention.

Another way to use the visual system to access the processing strategies of the client is to observe eye gaze. Neurolinguistic theory postulates that the eyes gaze in the direction of brain processing.^{264,468} Figure 9-4 illustrates the eye gaze direction along with the suggested processing activity. For example, a client who needs to access and process motor plans through the frontal lobe will look down. A client who needs to visually construct an idea of something new will look up and to the right. Various cortical lobes and hemispheres serve specific global processing functions. There are many ways to apply and interpret this theory. By observing the patient's eye gaze, the therapist can determine whether processing is conducted in what would be believed to be the appropriate areas. Even more clinically relevant is observing where the eyes are gazing before and during successful functional activities. It may be that the area once used in processing is no longer available to do the function. If gazing to the right and down always leads to motor success, then the therapist can empower the patient to look down and right before dressing or transferring. Similarly, if a patient always looks down at the feet during ambulation, the reason may not be "to look at the feet" but instead may

Figure 9-4 ■ Eye gaze: correlation with lobe and hemispheric processing based on right-handed individuals. (Modified from a handout from *New Learning Pathways*, Denver, 1988. Illustrations by Ben Burton.)

be to access the motor cortex to gain better motor function. If the client is asked to visualize the movement before and during the activity, the head often comes to a posturally correct position as the eyes gaze upward toward the occipital lobe and the body automatically orients to vertical. If the client is asked to walk while visualizing the movement, again the result may be a more upright, posturally efficient pattern. Once the program is set and practice scheduling begun, the patient may no longer need to look down and into the frontal lobe. Thus in this case the client not only learned the procedure but also avoided practicing and learning a posturally incorrect ambulation strategy.

Combined Multisensory Approaches. Although all techniques have the potential to be multisensory, the specific mode of entry may focus on one sensory system, as already described, or it may target two or more input modalities along with automatic motor programming. As stated before, Table 9-5 categorizes a variety of treatment techniques that are clearly multisensory. The therapist, analyzing how the summated effect of the combined input and automatic responses influences client performance, gains direction in anticipating treatment outcomes in terms of the problem-solving process. Because the potential combinations of multisensory input classification are enormous, only a few examples of combinations are included in the text to illustrate the process a clinician might use when classifying a new technique or a new approach to intervention. When clinicians select augmented treatment interventions to help a client as part of somatosensory retraining or functional retraining or to establish a procedural program, the basic science understanding behind the clinical decision helps develop questions for future research, determine a prognosis regarding outcomes, and rationally explain why or why not an intervention was effective. Clinical decisions must ultimately be made regarding which techniques or component of an approach should be eliminated first as the patient progresses. These decisions must be based on understanding and integration of neurophysiological mechanisms, learning environments, concepts of motor learning and control, and what motor impairment or body system problems are affecting functional performance and on the client's and family's

needs, motivations, and goals. A simple rule a therapist might follow would be to take away the least natural technique first. That technique would be the most artificial or contrived. An example using only one sensory system might help to clarify this point. For example, a therapist might assist a client with elbow flexion during a feeding pattern by (1) vibrating the biceps, (2) quickly tapping the biceps, or (3) quickly stretching the biceps a little beyond midrange by using gravity. The first option would be the least natural and obviously the least socially acceptable at a dinner party. The third option is the most natural and closest to what might occur in the real environment in which the client will need to function. Remember, these contrived techniques are used to assist clients who cannot control or perform the motor programs or functional activities without assistance or who need assistance in learning to modulate motor control for greater functional adaptability. If the therapist added verbal feedback or music as well as asking the patient to visually look at the target, the example would become multisensory.

Within the following section are examples of combined multisensory approaches that might be used to augment sensory feedback to obtain a better environment for regaining functional control.

Sweep Tapping. Sweep tapping is usually used to open a hypertonic flexor-biased hand. Many isolated techniques, such as sweep tapping¹¹¹ or rolling,⁸ would be considered primarily proprioceptive-tactile in sensory origin. During sweep tapping the clinician first uses a light-touch sweep pattern over the back of the fingers of one of the hands. This stimulus is applied quickly over the dermatome area that relates to muscles the client is being asked to contract. Second, the therapist applies some quick tapping over the muscle belly of the hypotonic muscle. The first technique is tactile and believed to stimulate the reflex mechanism within the cord to heighten motor generators and increase the potential for muscle contraction of the hypotonic muscle or to dampen the hypertonic flexors. The second aspect, tapping, is a proprioceptive stimulus used to facilitate afferent activity within the muscle spindle of the extensors, thus further enhancing the client's potential for muscle contraction. At the same time the client will be asked to voluntarily activate the extensor motor system, which then automatically augments tactile, proprioceptive, and auditory input with functional control.

Rolling of the Hand. Before Brunnstrom's rolling pattern is implemented, the client's upper extremity is placed above 90 degrees to elicit a Souque's sign. This decreases abnormal, excessive tone in the arm, wrist, and hand.⁸ This phenomenon may well be a proprioceptive reaction of joints and muscle. The rolling technique consists of two alternating stimulus patterns. The wrist and fingers are placed on extensor stretch. The ulnar side of the volar component of the hand is the stimulus target. A light-touch sweeping pattern is applied to the hypothenar aspect, which has the potential to elicit an automatic opening of the hand beginning with the fifth digit.⁸ Immediately after the light touch, a quick stretch is applied to the wrist and finger extensors. These two techniques are applied quickly and repeatedly, thus giving the visual impression that the therapist is rolling his or her hand over the ulnar aspect of the dorsum of the client's hand. In reality, tactile and proprioceptive stimuli are being effectively combined to facilitate the central

pattern generators responsible for the extensor motor neurons controlling the wrist and finger musculature. Because the tone is felt in the client's extensors and thus induces relaxation of the hypertonic flexors, the therapist can more easily open the client's hand. As the client obtains volitional control, some resistance can be added by the therapist to further facilitate wrist and finger extension. A hemiplegic client can also be taught to use this combined approach to open the affected hand and give it increased range. This technique is a noninvasive, relaxing approach to opening the hand stuck in wrist and finger flexion hypertonicity. The technique itself also seems to trigger spinal generator patterns that dampen the existing neuron network. It does not teach the patient anything unless that individual begins to assist or take over control of the extensor pattern. This usually occurs first when the therapist feels the flexors relax while the patient is trying to extend the wrist and fingers even if no active extension is palpated. Encouraging the patient at this time, confirming that he or she is thinking correctly, and urging him or her to continue doing it provide important motivation for continued practice.

Withdrawal with Resistance. A therapist could combine the technique of eliciting a withdrawal with resistance to the withdrawal pattern. This can be an effective way to release hypertonicity, especially in the lower extremities. The withdrawal can be elicited by a thumbnail, a sharp instrument, a piece of ice, or any adequate light-touch stimulus to the sole of the foot. As soon as the flexor withdrawal is initiated, the therapist must resist the entire pattern. Once the resistance is applied, the input neuron network changes and the flexor pattern is maintained through the proprioceptive input caused by resistance to the movement pattern. The one difficulty with this technique is the application of resistance. The withdrawal pattern directly affects alpha motor neurons innervating those muscles responding in the flexor pattern and simultaneously suppresses alpha motor neurons going to the antagonistic muscles. If the antagonistic muscles are hypertonic, then initially the hypertonicity is dampened within the alpha motor neurons' neuronal pool. Because of the pattern itself, as soon as the flexor response begins, a high-intensity quick stretch is applied to the extensor muscles. If resistance is not applied to the flexors to maintain inhibition over the antagonistic muscles, the extensors will respond to the stretch. The client will quickly return to the predisposed hypertonic pattern and may even exhibit an increase in abnormal tone. This extensor response is a complex reaction within the spinal generators. The therapist should instruct the patient if appropriate to assist with the flexor pattern to recruit other components of the motor system to enhance the system's modulation over the spinal generators. This can be a way to generate the early component of rolling when leading from the lower extremity and can get the patient out of an extreme extensor pattern in the supine position.

Touch Bombardment. Another example of a proprioceptive-tactile treatment technique is modification of a hypersensitive touch system through a touch-bombardment approach. The goal of this approach is to bombard the tactile system with continuous input to elicit light-touch sensory adaptation or desensitization. Deep pressure is applied simultaneously to facilitate proprioceptive input and conscious awareness. Proprioceptive discrimination and tactile-pressure

sensitivity are thought to be critical for high-level tactile discrimination and stereognosis. A hypersensitive light-touch system elicits a protective, altering, withdrawal pattern that prevents development of this discriminatory system and the integrated use of these systems in higher thought. This method of treatment can be implemented by having an individual dig in sand or rice. The continuous pressure forces adaptation of the touch system, and the resistance and deep pressure enhance the proprioceptive-discriminatory touch system by a complex adaptation process that most likely affects all areas involved in light and discriminatory touch, as well as the complex interaction of all motor system components. Whereas sand is often used in the clinic or outside, rice can be used inside and vacuumed easily whether in the clinic or in a patient's home.

Pool therapy can be used effectively for the same purpose, with the added advantage of neutral warmth, as long as the temperature is in the neutral warmth parameters. Heat increases the sensitivity of light touch, whereas cold initially heightens the nervous system. In time cold can suppress the state of the motor pool (refer to the section on cold). Any client perceiving touch as noxious, dangerous, and even life-threatening will not greatly benefit from any therapeutic session in which touch is a component. Touch includes contacts such as touching the floor with a foot, reaching out and touching the parallel bar railings, and touching the mat. The client may not respond with verbal clues such as "Don't touch me" or "When I touch the floor it hurts" but will often respond with increased tone, emotional or attitude changes, and avoidance responses. Nevertheless, this treatment approach has application in many areas of intervention with clients having neurological deficits. As an adjunct to this method, a clinician should cautiously apply light touch when in contact with the client. Deep pressure or a firm hold should elicit a more desirable response for the client even if the light-touch system is functional.^{212,320} The use of Gore-Tex material for clothing can greatly enhance the client's ability to tolerate the external world, where light-touch encounters cannot be avoided. Similarly, socks can decrease the hyperactive tactile system in the foot and may allow the patient to stand or transfer without the feeling that he is standing on pins or that it is a noxious stimulus.

The therapist may also consider systematic desensitization as a strategy to integrate the touch system. By allowing patients to apply the stimuli to themselves, they can grade the amount that they can tolerate. In this respect they are empowered to control their own environment. They can practice adaptation in many situations. When the environment seems overwhelming, they have learned techniques to dampen the input both from within their own systems and by controlling the external world. For example, the therapist may place a box containing objects of different textures before the patient and encourage exploration and active participation to learn which textures are acceptable or offensive. A gradual exposure to the offensive stimuli will raise the threshold of the mechanoreceptors in the skin. There are also the benefits to the patient of being in control of the stimulus and having awareness of the treatment objectives. In addition, vibratory stimuli through a folded towel provide proprioceptive input to desensitize the touch system.^{188,268,320} Desensitizing the touch system from a need

to protectively withdraw is an important process within the CNS if normal stereognosis is to develop.

Taping. Taping procedures normally used in peripheral orthopedic muscle imbalances and pain have the same potential for patients with neurological problems. This adaptation would be a modification of both splinting and slings. Research has been done to demonstrate efficacy of taping to offset peripheral instability in individuals with neurological system impairments.^{282,470-474} The concepts and ideas remain that taping has implications when treating individuals with neurological problems. Taping hypotonic muscle groups into a shortened range should effectively reduce the mechanical pull of gravity on both the muscle groups and joints and prevent the CNS from developing the need for compensatory stabilization or hypertonicity. If hypertonicity is the result of peripheral instability, then taping a hypertonic muscle into its shortened range should stabilize the peripheral system and eliminate the need for the CNS to create the hypertonic pattern. On the other hand, taping can also be used to heighten information about proprioception and joint position, providing feedback to avoid hyperextension or hypermobility of a joint. This is especially true when there is an imbalance of intrinsics and extrinsics in the hand.

Oral-Motor Interventions. There are more research articles available on specific oral-motor dysfunctions in patients with neurological problems⁴⁷⁵⁻⁴⁸⁰ than on intervention. These are studies using fMRI of the CNS during oral-motor activity, but the transition to intervention again is limited.^{481,482} Systematic reviews of potential oral-motor interventions are even fewer.⁴⁸³

When dealing with oral-motor intervention, the complexity of combined proprioceptive-tactile input becomes enhanced by adding another sensory input, such as taste. Implementation of one of a variety of feeding techniques clearly identifies the complexity of the total input system. When taste is used, smell cannot be eliminated as a potential input, nor can vision if the client visually addresses the food. The following explanation of feeding techniques is included to encourage the reader to analyze the sensory input, processing, and motor response patterns necessary to accomplish this ADL task. The complexity of the interaction of all the various systems within the CNS is mind-boggling, but if the motor response is functional, effortless, and acceptable to the client and the environment, then the adaptation should be facilitated after attended repetitive behaviors.

Several feeding techniques have been developed in the past by master clinicians such as Mueller,³⁰¹ Farber,¹¹¹ Rood,²⁵ and Huss.²⁹⁶ These techniques were not easily mastered or understood through reading alone. Competence in feeding techniques is best achieved through empirical experience under the guidance of a skilled instructor. Today, some evidence base for implementation of feeding techniques or related motor activities can be found in the literature.^{52,484,485}

The facial and oral region plays an important role in survival. Facial stimulation can elicit the rooting reaction. Oral stimulation facilitates reflexive behaviors, such as sucking and swallowing. Deeper stimulation to the midline of the tongue elicits a gag reflex. These reactions and reflexes are normal patterns for the neonate. When these reactions and reflexes are depressed or hyperactive, therapeutic intervention is a necessity. Oral facilitation is an important treatment

modality for infants and children with CNS dysfunction. Therapeutic intervention during the early stages of myelination can be crucial to the development of more normalized feeding and speech patterns.

Similarly, adults with neurological impairment often have difficulty with oral-motor integration. Problems with swallowing, tongue control, and hypersensitive and desensitized areas within the oral cavity and also with mouth closure and chewing are frequently observed in adults with CNS damage.^{475,476}

Before basic feeding techniques are implemented, clinicians need to understand how the CNS and PNS work collaboratively with the musculoskeletal system to control and perform these complex oral-motor functional movements.^{141,486,487} Feeding therapy is preceded by observation and examination. With a pediatric client the therapist should observe breathing patterns while the client is feeding to determine whether the child can breathe through the nose while sucking on a nipple. In addition, the child's lips should form a tight seal around the nipple. Formal assessments should include functional assessments, developmental milestones, and behavioral manifestations. Medical charts and results from neurological examinations should be consulted for baseline data.

Postural mechanisms can influence feeding and speech patterns in clients with neurological dysfunction.^{28,485,488} A client with a strong extensor pattern may have to be placed in the side-lying, flexed position to inhibit the forces of the extensor pattern. The ideal pattern for feeding is the flexed position, which promotes sucking and oral activity. Basic reflexes such as rooting, sucking, swallowing, and bite and gag reactions should be elicited and graded in children and evaluated in adults. The head needs to be in slight ventroflexion to pull in the postural stabilization of the neck and tongue. This is necessary to effectively facilitate programs that provide functional swallowing and control of foods by the tongue.

The facial region and the mouth have an extraordinary arrangement of sensory innervation. Therefore oral techniques must be used with utmost care. Anyone who has visited the dentist can attest to the feeling of invasiveness when foreign objects are placed in the mouth. With this in mind, the therapist should begin each treatment session by moving the autonomic continuum toward the parasympathetic end. Activation of the parasympathetic system should lower blood pressure, decrease heart rate, and, more important, increase the activity of the gastrointestinal system. Neutral warmth, the inverted position, and slow vestibular stimulation should help to promote parasympathetic "loading." Another approach that is applicable to feeding techniques is the application of sustained and firm pressure to the upper lip. An effective inhibitory device is a pacifier with a plastic shield that applies firm pressure on the lips. Perhaps this is why a pacifier is a "pacifier." Adults can acquire resistive sucking patterns with a straw and plastic shield and achieve the same results.

Sometimes children or adults are not cooperative and will not open their mouths.^{489,490} Rather than the mouth being pried open, the jaw is pushed closed and held firmly for a few seconds. On release of the pressure, the jaw reflexively relaxes. The receptors in the temporomandibular joint and tooth sockets may be involved in the production of this response.

A common problem seen in neurologically impaired infants and adults with head trauma is the "hyperactive tongue," which is often accompanied by a hyperactive gag reflex. To alleviate this problem, the receptors have to be systematically desensitized. The technique called *tongue walking* has met with clinical success.^{12,41} It entails using an instrument such as a swizzle stick or tongue depressor to apply firm pressure to the midline of the tongue. The pressure is first applied near the tip of the tongue and progressively "walked back" in small steps. As the instrument reaches the back of the tongue, the stimulus sets off an automatic swallow response. The instrument is withdrawn the instant the swallow is triggered. This technique is repeated anywhere from five to 30 times a session, depending on individual responses.

Another technique, which might be called *deep stroking*, is used to either elicit or desensitize the gag reflex. Again, an instrument such as a swizzle stick is used to apply a light stroking stimulus to the posterior arc of the mouth. The instrument should lightly stretch the lateral walls of the palatoglossal arch of the uvula. Normally, the palatoglossal muscle elevates the tongue and narrows the fauces (the opening between the mouth and the oropharynx). Just behind the palatoglossal arch lies another arch, called the *palatopharyngeal arch*. Normally, this structure elevates the pharynx, closes off the nasopharynx, and aids in swallowing. Touch pressure to either arc incites the gag reflex. This touch pressure should be carefully calibrated. A hyperactive gag reflex may be best diminished by prolonged pressure to the arcs, whereas light, continuous stroking may be more facilitatory in activating a hypoactive gag reflex. A child or adult who has been fed by tube for extended periods of time will often have both hypersensitive reactions in various parts of the oral cavity and hyposensitive areas in other locations. This problem needs to be assessed to formulate a complete picture of the client's difficulties.

The use of vibration over the muscles of mastication appears to be physiologically valid. Muscle spindles have been identified in the temporal and masseter muscles.³⁹ Selected use of vibration on the muscles of mastication enhances jaw stability and retraction. For protraction to be facilitated, the mandible is manually pushed in.¹¹¹

To promote swallowing, some therapists use manual finger oscillations in downward strokes along the laryngopharyngeal muscles and follow up with stretch pressure. Ice is beneficial as a quick stimulus to the ventral portion of the neck or the sternal notch. In addition, chewing ice chips provides a thermal stimulus to the oral cavity and a proprioceptive stimulus to the jaw and teeth; it also increases salivation for swallowing.

It is recommended that a therapist work closely with a colleague who has experience working with functional feeding before independently beginning to work with clients. The possible complications that might develop with individuals aspirating food cannot be overemphasized.⁴⁹¹

The therapist can quickly realize that feeding as a proprioceptive, tactile, and gustatory input modality is extremely complex and often incorporates other sensory systems. Breaking down the specific approaches into finite techniques helps the clinician categorize each component and then reassemble them into a whole. The job of dividing and reassembling the parts becomes more and more difficult as the number of input systems enlarges.²⁶⁷

Head and Body Movements in Space. Proprioceptive and vestibular input is one of the most frequent combination techniques used by therapists. In fact, client success in almost all therapeutic tasks depends on the coordinated input of these two sensory modalities.

If the head is moving in space and gravity has not been eliminated from the environment, vestibular and proprioceptive receptors will be firing to inform the CNS whether it should continue its feed-forward pattern or adapt the plan because the environment no longer matches the programmed movement. Depending on the direction of the head motion and the way gravity is affecting joints, tendons, and muscles, the specific body response will vary according to the degree of flexibility within the motor system. Bed mobility, transfers, mat activities, and gait all incorporate these two modalities. Although all these functional movements can be performed without these feedback mechanisms, the CNS cannot adapt effectively to changing environments without input from these systems. For that reason alone, a thorough examination of the integrity of both systems and the effect of their combined input seems critical if any ADL is to be used as a treatment goal.

The use of a large ball or a gymnastic exercise ball can be classified under the category of proprioceptive-vestibular input. Many activities can be initiated over a ball. When a child or adult is prone on a ball, righting of the head can often be elicited by quickly projecting the child forward while the therapist exerts control through the feet, knees, or hips. If the weight of the head is greater than the available power, then a more vertical and less gravitationally demanding position can be used. As the head begins to come up, approximation of the neck can be added. Vibration of the paravertebral muscles might also assist. Rocking forward or bouncing the client who is weight bearing on elbows or extended elbows will facilitate postural weight-bearing patterns through the two identified sensory input systems. Having a client sitting on a therapy ball doing almost any exercise will require vestibular and proprioceptive feedback for appropriate adaptive responses to be made. The combination seems to play a delicate role in the maintenance of normal righting and the equilibrium response so important in functional independence.

A trampoline, balance board, or similar apparatus has the potential to channel a large amount of vestibular-proprioreceptive input into the client's CNS. In fact, a trampoline is so powerful it can often overstimulate the client and cause excitation or arousal in the CNS.

The trampoline and balance board are generally used to increase balance reactions, orient the client to position in space and to verticality, and increase postural tone. A client with poor balance, poor postural tone, or inadequate position in space and verticality perception may be justifiably fearful of these two apparatus because of the rate, intensity, and skill necessary to accomplish the task. Because fear creates tone and that tone may be in conflict with the motor response from the client, caution must be exercised with either modality. (See Chapter 22A for further discussion of the interactions of sensory systems and balance.)

Gentle Shaking. A specific technique of gentle shaking can be listed under a combined vestibular, muscle spindle, and tendon category. This technique is performed while the client is in a supine position and the head ventroflexed in

midline. The head is flexed 35 to 40 degrees to reduce the influence of the otoliths and unnecessary extensor tone through the lateral vestibulospinal tract. This flexed position should be maintained throughout the procedure. The therapist places one hand under the client's occiput and the other on the forehead. Light compression is applied to the cervical vertebrae. This technique activates the deep-joint receptors (C1 to C3) and muscle spindles in the neck along with the vestibular mechanism, which in turn connects with the cerebellum and motor nuclei with the brain stem. If the technique is performed slowly and continuously in a rhythmical motion, total-body inhibition will occur. If the pattern is irregular and fast, facilitation of the spinal motor generators will be observed.

Any one of these techniques can be implemented as a viable treatment approach in considering vestibular-proprioreceptive stimuli. The selection of an approach or a method will depend on client preference, client response, the clinician's application skills, and the need for therapeutic assistance.

Summary of Techniques Incorporating Auditory, Visual, Vestibular, Tactile, and Proprioceptive Senses

Most therapeutic activities activate five sensory modalities: auditory, visual, vestibular, tactile, and proprioceptive. Auditory and visual inputs are used as the therapist talks to the client, asks the patient to look, and/or demonstrates the various movement or response patterns to be accomplished during an activity. As the client moves, vestibular, tactile, and proprioceptive receptors are firing as inherent feedback systems. Thus the complexity of any activity with respect to analysis of primary input systems is enormous. Even a sedentary activity such as card playing requires a certain amount of proprioception for postural background adaptations, tactile input from supporting body parts and limbs, and visual input for perception and cognition. When treating an individual with CNS damage, one or a number of sensory systems may not be processing at all or may be processing incorrectly, which confounds the clinical problem even farther.

Thus when the categorization of techniques—such as a PNF slow reversal,¹⁹ a Brunnstrom marking time,⁸ marking time with music,⁴⁹² Feldenkrais's sensory awareness through movement,^{225,226} NDT,^{31,493} Rood's mobility on stability,^{25,28} or any mat or ADL activity—is considered, the therapist must observe the sensory systems being bombarded during the activity. At the same time, if the therapist has determined which sensory systems are intact, which are suppressed or dysfunctional, and which seem to be registering faulty data, then altering duration and intensity of the input environment through any one system and the combined input through multiple systems creates tremendous flexibility in the clinical learning environment. Understanding this diagnostic process leads to more accurate prognosis and selection of appropriate interventions. Highly gifted therapists seem to instinctively go through this diagnostic process. One skill that seems consistent among master clinicians is a highly developed sensitivity to the client's responses, which represents a summation of expression of all systems within the CNS. Simultaneously, they adjust the quantity and duration of combined input to best meet the needs of the client. These

masters release external control and encourage the client to use normal, inherent monitoring systems to adapt to changing environments as soon as the client is able to function independently, no matter if that is only 5 degrees of motion or an entire functional pattern made up of many motor programs. Control may begin within a part of the range of a functional skill and not necessarily the entire functional activity itself. Therapists must remember that when the control comes from the clinician and not the patient, it is then augmented. The key to carryover will be the client's empowerment over the motor control system and the degree of practice, self-monitoring, and adaptation available to the client. By analyzing and categorizing input and patient responses, many therapists may develop skills that were initially considered out of reach. Today, clinicians have the examination tools to validate changes in their patients' motor behavior (refer to Chapter 8).

Innate Central Nervous System Programming

The responses of the PNS and CNS to various external stimuli determine the individuality of an organism and its survival potential within the environment. As organisms become more and more complex, the types of external stimuli and the internal mechanisms designed to deal with that input also increase in complexity. As the CNS develops structurally and functionally, inherent control over responses to certain common environmental stimuli seems to be manifested. Different areas of the motor system play different roles in the regulation of motor output. No area is dominant over another. Each area is interdependent on both the input from the environment and the intrinsic mechanisms and function of the nervous system.

As mentioned earlier, the PNS is intricately linked to the CNS and vice versa. Damage to one could potentially alter the neuropathways, their function, and ultimately behavior anywhere along the dynamic loops. Nevertheless, although researchers today emphasize the dynamic interactions of all components,⁴⁹⁴⁻⁵⁰¹ clinicians have observed for decades different motor problems when different areas of the brain are damaged. Thus, when clients with neurological damage are discussed, it seems paramount to identify inherent synergy patterns available to humans, especially if those patterns become stereotypical and limit the client's ability to adapt to a changing environment.

The authors do not recommend or discredit the use of any stereotypical or patterned response as a treatment procedure. Acknowledging the presence and stressing the importance of knowing how these motor programs affect clients' functional skills are important. Without this knowledge, therapists working with either children or adults with CNS dysfunction limit their understanding of the normal CNS, the normal motor control mechanism and its components, and the interactive effect of all systems on the end product: a motor response to a behavioral goal.

To conceptualize a systems model, the reader must replace the hypothesis of a stimulus response–based concept of reflexes³⁰⁸ with a theory of neuronnetworks that may be more or less receptive to environmental influences (see Chapter 4).⁵⁰² That sensitivity is modulated by a large number of interconnecting systems throughout the CNS and by the internal molecular sensitivity of the neurons themselves. Specific motor patterns seem to be organized or programmed

at various levels or areas within the CNS. These synergies or patterned responses are thought to limit the degrees of freedom available to programming centers such as the basal ganglia and cerebellum^{11,231} and to enable more control over the entire body. Having soft-wired, preprogrammed, patterned responses allows organizing systems to activate entire sequences of plans and modify any components within the total plan. Modification and adaptation then become the goal or function of the motor system in response to both internal and external goal-directed activities. The specific location of soft-wired programs is open to controversy, as is the complexity of programming at any level within the CNS. Recognizing that these neuronnetworks exist with or without external environmental influences would suggest that patterns can and will present themselves without an identified stimulus. In the past, when an external influence was not correlated with an identifiable stereotypical motor pattern, it was referred to as a *synergy*. When a stimulus was identifiable, the entire loop was called a *reflex*. Reflexes and preprogrammed, soft-wired neuronnetworks such as walking are interactive or superimposed on one another to form the background combinations for more complex program interactions. This superimposed network may encompass spinal and supraspinal coactivity, which makes it difficult to specify a level of processing. The exact control mechanisms that regulate the specific pattern may again be a shared responsibility throughout the nervous system, thus providing the plasticity observed when disease, trauma, or environmental circumstances force adaptation of existing plans, as discussed in the neuroplasticity section (see Chapter 4).

One way to conceptualize this complex neuronnetwork is to picture a telephone system linking your home to any other home in any city in any country on the planet. If the relay between a friend in New York and you in California develops static, the system may self-correct, relay through another area, or even route through a nonwired mechanism such as a satellite. The options are infinite, but priorities for efficiency and adaptability exist within both the telephone network and the brain. If the wires to your home are cut, the phone will not ring. If your peripheral nerve is cut or the alpha motor neuron damaged, the muscle will not contract. If the relay centers at one end of your block are short-circuited and not working properly, then your phone and those of your neighbors may still function, but not in a fluid or specific manner. That is, someone may be calling your neighbor but both your phone and your neighbor's phone might ring. Spinal involvement can create a similar problem. The muscles are innervated and the input from the environment is accurate, but the neuronnetwork is faulty. Regulation or modulation may be less efficient or controlled, but the system will use all available resources to try to respond to internal and external environmental requirements. This rule seems consistent throughout the nervous system, and the degree of plasticity is tremendous.⁵⁰³

When specific patterned responses are observed, the reader must always hold simultaneously the interaction of all other motor programming options. In this way the therapist can easily conceptualize the variations within one response and the reason why, under different environmental and internal constraints, the motor response pattern may show great variations within the same general plan. Similarly, the expected motor response may not be observable,

although it would seem appropriate and anticipated. The clinician must remember that the more complex the action (e.g., rolling compared with dressing compared with playing hockey), the greater the need for integration and coordination over pattern generators. Similarly, the more complex the desired action (especially in new learning), the greater the potential for needed perceptual-cognitive and affective interactions and the greater the potential for gratification and also for failure.

Certain patterned responses or neuronetworks might be considered more simplistic or protective in function. These patterns were once thought to be hard-wired spinal reflexes. It is now known that these reflexes, as well as complex pattern generators, exist at the spinal level and that their responses affect brain stem, cerebellar, and cortical actions. These centers simultaneously affect the specifics of the spinal neuronetwork responses.^{129,130,504} With clients who have low functional control over the spinal or brain stem motor networks, identifying existing patterns, optional patterns as a response to environmental demands, and obligatory patterns not within the control of the client's intentional repertoire of patterns becomes a critical evaluative component before prognosing or identifying the most appropriate interventions.

Recognizing specific patterns and how those patterns and others might affect functional movement or positional patterns has clinical significance. A child with spastic cerebral palsy, for instance, shows extension and "scissoring" when the pads of the feet are stimulated. Sometimes the extension pattern is so strong that the child will arch backward. Sustained positions that oppose pathological patterns are believed to elicit autogenic inhibition. Contraction-relaxation techniques also work on the autogenic inhibition principle.¹⁹

Just as afferent input can be used to alter tone and elicit movement, it can also become an obstacle when the therapist tries to coordinate complex movement patterns. The human palmar and plantar grasp patterns are often thought of as reflexive patterns, as seen in a newborn.⁵⁰⁵⁻⁵⁰⁷ A persistent grasp pattern is a common occurrence in children and adults with a CNS insult. This dominant grasp is often reinforced by the client's own fingers and frequently prevents functional use of the hand. If a withdrawal pattern is elicited every time a client is touched, the client not only will be unable to explore the environment through the tactile-proprioceptive systems but also will experience arousal by the influence of the cutaneous system over the reticular activating system. Severe agitation could likely be a behavioral outcome from such a persistent reflex.

As with any treatment procedure, a clinician should determine whether the technique will help the client obtain a higher level of function. The clinician must learn to recognize not only specific patterns but also what combinations of responses of pattern generators would look like. If the reader overlaid the map of the pattern generators for any combination of programs, a complex neuronetwork would result. To some it would verify chaos theory, and to others it would verify the end result of multiple systems interacting. The neuronetwork complexity of multiple input can be overwhelming. Thus a therapist must always be observant of the specific behavioral response and the moment-to-moment changes in behavior during a treatment session, even if the specific neuronetwork is not understood.

The clinician needs to observe whether the specific patterned response is (1) triggered by afferent input, (2) triggered by volitional intent, or (3) activated without environmental input including position in space or cortical intent. In the third case, the entire motor system needs to be evaluated to determine which portion might be modulating the observable behavior. Differentiating these motor components will help in selecting appropriate examination tools, making the movement diagnosis, prognosing, and selecting interventions.

Holistic Treatment Techniques Based on Multisensory Input

As already mentioned, a variety of accepted treatment methods exist. Each approach focuses on multisensory input introduced to the client in controlled and identified sequences. These sequences are based on the inherent nature of synergistic patterns,^{5,30} the patterns observed in humans^{5,7,249} and lower-order animals,³³ or a combination of the two.^{19,28} Each method focuses on the total client, the specific clinical problems, and alternative treatment approaches available within each established framework. Certain methods have traditionally emphasized specific neurological disabilities. Cerebral palsy in children^{7,23,28,508-510} and hemiplegia in adults^{8,9,21,31,511,512} are the two most frequently identified. In the past two decades, substantial clinical attention has been paid to children with learning difficulties.^{12,35,513-515} Yet the concepts and treatment procedures specific to all the techniques have been applied to almost every neurological disability seen in the clinical setting. This expansion of the use of each method seems to be a natural evolution because of the structure and function of the CNS and commonalities in clinical signs manifested by brain insult. Literature in occupational and physical therapy management of individuals with various other neurological problems has also enriched therapists' identification of efficacious interventions as well as those that should be removed from the toolbox.^{519,516-521}

Additional Augmented Interventions: Today's Focus

Four augmented therapeutic intervention approaches that have become accepted over the last decade are (1) BWSTT, (2) constraint-induced movement therapy (CIMT), (3) imagery (discussed in the section on the visual system) and virtual reality, and (4) robotic training. Each is discussed as a separate intervention philosophy, but the reader must remember that these are *augmented intervention* programs. Before an individual would be considered functionally independent, the patient must be able to perform the functional activity in a natural environment, such as ambulation within a home setting or eating using the more involved extremity without having the unaffected extremity restrained. A fourth augmented intervention approach, robotics, will also be presented briefly within this chapter in order to illustrate how therapists and patients have the capabilities to interface with new and sophisticated technology. The reader is also referred to Chapter 38 for more in-depth detail. One additional augmented approach, the Accelerated Skill Acquisition Program (ASAP), has been described here. This approach is currently undergoing, and research is still needed to establish efficacy. This approach is impairment

oriented, emphasizes bimanual activities, and focuses on active, patient-centered collaboration reinforced with self-management and self-efficacy.⁵²²⁻⁵²⁵ This approach emphasizes attended, repetitive task practice progressing in difficult situations and meets the principles for neuroplasticity.

Body-Weight-Supported Treadmill Training. Over the last decade BWSTT has been accepted within the therapeutic community as an alternative approach to teaching gait training for individuals with CNS damage and residual motor dysfunction. Students are introduced to the treatment procedures and potential sequences from total dependence to independence of the patient. Colleagues take continuing education courses to learn to position and drive the various motor components of the gait program while using BWSTT. Both a vertical support (harness) or air-distributed positive pressure to unweight the body and a treadmill are combined for BWSTT. The treadmill perturbs the feet backward or shifts the center of gravity forward, and the ground reaction forces are reduced by the support. The clinical environment unloads the CNS's need to (1) provide protection from falling; (2) trigger and control an effective and efficient postural system reaction; (3) reflexively drive the power stepping reaction necessary to perform upright ambulation; (4) control the balance strategy of stepping to prevent falling; (5) facilitate rhythmic, symmetrical, bilateral stepping; and (6) have a cognitive interface with the various motor programs necessary to run this functional activity. The treadmill perturbation of the lower limb into extension facilitates the transfer of weight to the forefoot. This forward translation forces the feet backward and optimizes the stepping reaction forward. If the moving treadmill is not a sufficient stimulus to trigger a step, this component can be controlled by one or two therapists depending on whether it is a unilateral or bilateral problem. If the patient does not step, has a delayed stepping response, or steps effectively with only one foot, the therapist(s) can help to initiate the desired response at the patient's feet. The rate of movement or speed of the treadmill can also be controlled, as well as the length of time spent on the affected leg. This treadmill strategy may encourage more symmetrical and faster gait speed in patients after stroke⁵²⁶ and with Parkinson disease⁵²⁷⁻⁵²⁹ compared with standard physical therapy. This control by the therapist helps to facilitate a patient's response even if it is slow or inadequate for normal over-ground ambulation. The question remains whether this type of augmented therapeutic intervention does create the best environment to empower the patient to learn or relearn normal locomotion after a neurological insult.

The literature is mixed with regard to this question. The literature supports BWSTT for individuals with incomplete spinal injury,⁵²⁰ the elderly with Parkinson disease,⁵²¹ and some individuals after stroke,^{138,522} but other literature suggests that BWSTT is equivalent to or maybe less effective than over-ground gait training with a PT,^{533,534} and still other researchers report that there is no difference among different forms of ambulation training.⁵³⁴ With the literature so inconsistent, the clinician could be confused as to the effectiveness of BWSTT and whether this type of augmented intervention should even be considered. One primary problem with the research literature is the great variance in training and the identified variables selected by researchers within their

respective studies.^{136,532,535-537} The following are examples of potential variables:

- Walking speeds
- Frequency of training
- Length of training
- Aerobic levels of training
- Type of unweighting
- Endurance
- Type and severity of the patient's neurological dysfunction
- Presence of hypertonicity
- Age of patient
- Time since injury
- Level of independence
- Assistance needed during ambulation

There have been some excellent systematic reviews of BWSTT in the literature that help identify many of the reasons the literature seems so inconsistent.^{136,538} The research indicates that the two populations of individuals who most often benefit from use of BWSTT are people with incomplete spinal cord injuries and individuals poststroke. Another problem in BWSTT research is that the harness systems can be uncomfortable at 20% to 30% unweighting.⁵³⁹ Thus, as stated, the huge number of possible variables and functional ways to measure outcomes using BWSTT or other types of training along with BWSTT has led to confusion in the literature.^{532,534,537,540,541} Even with all the confusion regarding these variables, this form of augmented intervention seems to show promise as a protocol for gait training. Future research studies will still need to determine which patients, their degree of motor involvement, the optimal dosage, the time after insult, the best combination of other interactive interventions (e.g., pharmacological, robotic), the specific type of gait impairments, and where within the gait cycle the clients would most likely benefit from this type of augmented intervention. It is important to continue to obtain evidence to more precisely define the practice guidelines for BWSTT. As has been shown in the past, new treatment ideas gain popularity and become standards of practice without the rigor of establishing an evidence-based practice.^{35,36,42,542} Physical therapy and occupational therapy need to establish that evidence as proof of the evolving effectiveness of clinical practice.

Constraint-Induced Movement Therapy. CIMT (or CI therapy) is a type of treatment of clients with motor system limitations that combines constraint or immobilization of the unaffected arm with forced use of the affected limb. A hand mitt or sling is used to constrain the use of the unaffected upper limb while the affected limb is engaged in a forced-use, mass practice meaningful motor task. The treatment focus of CIMT is on shaping behavior to improve functional use of the impaired upper limb.^{543,544} CIMT is based on the theory that impairment in hand and arm function in clients after a stroke is compounded by learned nonuse of that affected upper extremity, which leads to a physical change in the cortical representation of the upper limb in the primary sensory cortex.⁵⁴⁵ Learned nonuse develops in the early stages after a stroke in humans as the patient compensates for difficulty using the impaired limb by increasing reliance on the intact limb. This compensation has been shown to hinder recovery of function in the impaired limb.⁵⁴⁶

CIMT and the learned nonuse theory are based on deafferentation experiments in monkeys done by Dr. Edward Taub.^{547,548} Early primate studies demonstrated that if the upper limb was surgically impaired by dorsal rhizotomy to disrupt afferent input to the sensory cortex, the animal stopped using the limb for function. Active mobility was restored by immobilizing the intact upper limb for several days while training the animal to use the affected limb.⁵⁴⁶ The first report of CIMT for hemiparesis in humans was by Ostendorf and Wolf in 1981.⁵⁴⁹ Since then, investigations have demonstrated the effectiveness of CIMT with individuals who have residual upper-extremity weakness as the result of an upper motor neuron lesion.⁵⁴⁹⁻⁵⁵⁹ CIMT has been shown to be an effective therapy in persons with chronic stroke who have sufficient residual motor control to benefit from the exercises,^{550-552,557,560-565} in brain-injured patients,^{566,567} in children with hemiplegic cerebral palsy,^{543,568-573} and in patients with Parkinson disease.⁵⁷⁴ The CI therapy approach has also been used successfully for the lower-limb rehabilitation of patients with stroke hemiparesis, incomplete spinal cord injury, and fractured hip.⁵⁵³ Other diverse chronic disabling conditions, including nonmotor disorders such as phantom limb pain and aphasia, may also benefit from CIMT.⁵⁵³

The criteria for the inclusion of subjects in most CIMT research studies have focused on voluntary movement ability in the involved upper extremity.^{549,543-560,565} These criteria included the ability to start from a resting position of forearm pronation and wrist flexion and actively extend each metacarpal-phalangeal and interphalangeal joint at least 10 degrees and extend the wrist at least 20 degrees through a ROM.⁵⁶¹ It is estimated that approximately 20% to 25% of the population of patients with chronic stroke with residual motor deficit meet this motor criterion.⁵⁷⁵

Not all patients with hemiparesis have been found to benefit from CIMT. It has not been shown to be beneficial for clients with severe chronic upper-extremity hemiplegia after a stroke.⁵⁷⁶ Attempts to include individuals who did not meet the minimal motor criteria (at least 10 degrees of finger extension and 20 degrees of wrist extension) have failed to demonstrate significant or lasting functional improvements in the involved upper extremity after CIMT.^{553,576}

The criteria associated with successful therapeutic components of CIMT therapy are (1) restraint of the unaffected arm with a mitt, sling, or glove for 90% of waking hours for a 2- to 3-week period; and (2) therapeutic sessions with physical and occupational therapy in which patients concentrate on intense, repetitive task training of the more affected upper extremity for 8 hours a day.*

Clients typically participate in 6 to 7 hours of therapy a day; in addition, clients must reinforce this training in home activities and ADLs.^{546,564,572,575} The therapist-client ratio is typically 1:1, with the therapist present to give tactile and verbal feedback and instruction, along with assistance for the desired skill training. Clients also typically keep a daily treatment diary to document the amount and intensity of therapeutic intervention and the amount of time spent wearing the mitt or sling each day for the duration of the intervention.⁵⁷²

Subjects with chronic stroke hemiparesis who have participated in CIMT rehabilitation programs have demonstrated significant gains in functional use of the stroke-affected upper extremity as measured by the Motor Activity Log,⁵⁷⁵ significant reductions in motor impairment on the upper-extremity motor component of the Fugl-Meyer Test,⁵⁷⁶ and more efficient task performance as measured by the Wolf Motor Function Test.⁵⁷⁷⁻⁵⁸¹ Fine motor improvements have also been measured with use of the Grooved Pegboard Test and other dexterity tests.^{545,546} These improvements in impairment and function have been shown to persist at follow-up evaluations up to 2 years after training.^{545,559,573,580} Individuals participating in CIMT studies have demonstrated improvements in the amount of use and quality of movement in the more involved upper extremity and carryover of skills from the clinic to real-world activities.^{549-551,572} This functional improvement may be significant even if the patient has previously participated in a conventional rehabilitation program.⁵⁸²

The question of when to begin CIMT after a stroke has not yet been definitively answered. CIMT has been applied to clients with subacute strokes. This early use of CIMT is based on the hypothesis that earlier intervention may prevent learned nonuse and may have a greater impact on overall function. Investigators have found no adverse effects of CIMT in the subacute phase and only slightly greater improvement in motor function of the affected upper extremity.⁵⁸³ There is some evidence from animal studies to suggest that if CIMT is introduced too early (e.g., 24 hours poststroke), it may be detrimental and potentially harmful to humans. It may cause an increase in the size of the cortical lesion. This is based on studies of “forced overuse” in animals.⁵⁸⁴⁻⁵⁸⁷ Kozlowski and colleagues⁵⁸⁷ found that early forced overuse of the affected limb within the first 7 days after a sensorimotor cortex lesion impeded motor recovery of the affected limb and enlarged lesion volume. Bland and co-workers⁵⁸⁴ also forced overuse of the affected forelimb immediately after a focal cortical middle cerebral artery stroke, which increased the lesion size and impaired motor recovery. The relative risks and benefits of “acute” CIMT, and its optimal timing, remain to be determined.⁵⁴⁶

The neurophysiological mechanisms that are believed to underlie the treatment benefit of CIMT include overcoming learned nonuse and plastic brain reorganization.^{582,588} Studies have confirmed that CIMT produces use-dependent cortical reorganization in humans with stroke-related paresis of an upper limb.^{551,559,588,589} There is some question, however, as to whether the improvements in upper-extremity motor function after CIMT are a result of the reduction of learned nonuse or of overcoming a sense of increased effort during movement.⁵⁴⁵ Thus, task-specific, goal-oriented training with the affected limb might be similarly beneficial, even without the constraint of the less affected side.

Neuroimaging studies such as transcranial magnetic stimulation (TMS), fMRI, and electroencephalography^{411,545} have been used to provide cortical evidence of neuroplasticity and cortical changes after CIMT.^{554,559,572,590} These studies have validated that massed practice of CIMT produces a massive use-dependent cortical reorganization. This change increases the area in which the cortex is involved during voluntary movements of an affected limb, even in patients with chronic stroke.^{546,591}

*References 550, 551, 554, 555, 557, 558, 560, 565, 573, 574.

The application of CIMT to real-life clinical environments presents some challenges, including the time and physical demands on therapists, the cost to the patient, and the resources required during rehabilitation. This limits its cost-effectiveness and overall effect.⁵⁴⁶ Many patients in the acute rehabilitation setting do not qualify for CIMT on the basis of limited motor function.⁵⁴⁶ CIMT, by its nature, can prove to be difficult, frustrating, and intense, and progress can be slow. It will create beneficial effects only if all participants put in the time and effort to make it successful.⁵⁷² Many subjects who have been presented with the opportunity to participate in CIMT programs and studies have refused because of the intense practice schedule and the necessity of the restrictive device.⁵⁹² Therapists have also voiced concerns about patient adherence and safety.⁵⁹² Although it has been shown to be effective in laboratory research, CIMT may have limited practicality in some clinical environments.⁵⁹²

The future success of CIMT will depend on its ability to be modified according to disease factors, economic considerations, limitations of the practice setting, and the cognitive and physical status of the patient. Less intense practice schedule models^{590,593,594} and combining CIMT with pharmacological interventions or robotic assistance may help increase its effectiveness and decrease costs without sacrificing the benefits.^{546,595} Studies are now underway to determine if massed task-specific practice without constraint can be equally beneficial.^{596,597} Patient satisfaction, overall cost, and the impact on quality of life are other areas that require further evaluation.⁵⁹⁸

Robotics, Gaming, and Virtual Reality (See Chapter 38). The most recent augmented intervention procedures involve the use of technology to regain control over functional movement and are the third and fourth approaches mentioned in the first sentence in this section. The use of robotics,⁵⁹⁹⁻⁶⁰² virtual reality,⁶⁰³⁻⁶⁰⁶ and gaming⁶⁰⁷⁻⁶¹⁰ in the clinical environment continues to gain popularity as such technology continues to be more affordable, and their applications are becoming more widespread. A thorough discussion of these technologies can be found in Chapter 38.

Summary of Augmented Intervention Strategies.

As with many interventions, the therapist may need to start with augmented approaches to reduce impairments and/or gain functional movement in a controlled environment. As the patient demonstrates improvement in this narrow window of movement or function, the clinician could then increase the challenge with the goal of optimizing functional performance and improving quality of life. A summary of the augmented intervention strategies that facilitate neuroplasticity can be found in [Box 9-2](#).

Case Examples: Using Augmented Intervention Strategies to Optimize Functional Performance

Case Study 1: Client with Lack of Head Control.

There is a potential for lack of head control in young, developmentally delayed children or in individuals who have sustained a severe injury to the CNS. For that reason it is a common clinical problem. Furthermore, because of the importance of head and neck control, virtually all functional activities are affected by its absence.

The client is Timothy, a 16-year-old adolescent male with a closed-head injury. He had a lesion in his CNS 3 months

ago and currently demonstrates the following attributes regarding head control:

- Mild extensor hypertonicity is present in the supine position, and Timothy is unable to flex and rotate his head off the mat.
- In prone position, extensor hypertonicity is absent and hypotonicity prevails. The client is able to briefly bob his head off the mat in a hyperextension pattern. Mild tonal shifts occur to either side when the head is turned and when it is symmetrically flexed or extended.
- Timothy is unable to roll or perform any functional activity in the horizontal plane.
- When placed in a long sitting position, he is unable to hold the position or sit with flexed hips and extended knees. His head remains in total flexion with his chin on his chest.
- When placed in a short sitting position on a mat table, he is unable to hold the position. General hypotonicity prevails, although slightly more flexion is palpable. His head remains flexed. When asked to pick up his head, he extends into a hyperextension pattern followed by extensor relaxation into flexion.
- He is unable to hold the head in a neutral postural coactivation pattern in a vertical position.
- Timothy does not mind being touched and responds well to handling techniques.

From the analysis of these clinical signs, the following clinical interpretations are presented:

1. In the horizontal position, Timothy has persistence of a motor program that is enhanced by the spatial position and its influence on the vestibular system. The result might be considered persistence of a tonic labyrinthine reflex (TLR). In this client the dominant synergic pattern is extension. While he is supine, extension prevails. While he is prone, extension is inhibited, although flexion tone is not dominant. Because of the persistence of hyperactivity among the extensor motor generators, the ability to initiate rolling using a neck-righting pattern is prevented. The presence of a mild, asymmetrical tonic neck reflex to both sides and a symmetrical tonic neck reflex has been noted. Because of his instability and low tone, Timothy seems to be using these stereotypical patterns volitionally to assist in gaining some control over his motor patterns. In prone position, Timothy has the ability to move into a neck extension or optic and labyrinthine righting (OLR) pattern but is unable to hold it. Thus movement and range are present but postural holding is missing.
2. As a result of ventroflexion of the head in sitting, the vestibular apparatus is placed in a position similar to that when prone. In a like manner, the total patterns remain fairly consistent. The increase in flexor tone may result from the positioning of hip and knee flexion and kyphosis of the back. The inability to flex the hips with knee extension suggests that total tonal patterns or synergies are dominant. The client is unable to break out of those dominant patterns. Dominant OLR is not present.
3. When asked, Timothy carries out the command to the best of his motor ability. This suggests the presence of

BOX 9-2 ■ SUMMARY OF INTERVENTION STRATEGIES TO FACILITATE NEUROPLASTICITY

There are many different intervention strategies to use when working with patients with neurological problems. These interventions need to be matched to the needs of the individual patient and be consistent with the patient's goals and objectives. All the intervention strategies should be goal directed and repeated with attention to both the input mechanisms (motivation, sensory) and the output mechanisms (movement). The input and output mechanisms are multifactorial, and they also involve all components of the sensory, emotional, sensorimotor, and motor systems. Although evidence is increasing about the benefit of learning-based activities, research is still needed to help define more precisely when intervention should occur, how intense the intervention should be, how much repetition is needed, how long the learning-based activities need to be continued and spaced, how specific the training needs to be, how quickly behaviors can be progressed and the magnitude of gradation needed, how to keep patients interested, motivated, and compliant in learning, and the magnitude of interference in learning relative to depression, stress, and loss of self-esteem. The intervention strategies can be broadly classified as follows:

1. General body responses leading to quieting of the nervous system^{8,296}
 - a. Slow rocking in a rocking chair or hammock.
 - b. Slow anterior-posterior, horizontal, or vertical movements (chair, hassock, mesh net, swing, ball bolster, riding in a carriage, glider chair).
 - c. Rotating equipment such as a bed, chair, stool, hammock, or therapeutic or gymnastic ball (e.g., rhythmical bouncing).
 - d. Slow linear, undulating movements, such as in a carriage, stroller, wheelchair, or wagon.
 - e. Wrapping up tightly before rocking (e.g., roll self in sheet; put both arms inside tight tee shirt).
 - f. Listening to quiet music or natural environmental sounds (e.g., waves).
 - g. Repeating activities listed above first with eyes open and then closed.
2. Techniques to heighten postural righting reactions¹⁴¹
 - a. Rapid or unexpected anterior-posterior or angular acceleration.
 - i. Scooter board: pulled or projected down inclines.
 - ii. Prone over ball: rapid acceleration forward.
 - iii. Platform or mesh net: prone.
 - iv. Slides.
 - v. Any proprioceptive input that heightens postural extensors (e.g., quick stretch, tapping, resistance, vibration, joint compression). Remember to use the most natural first, such as quick stretch versus vibration.
 - b. Rapid anterior-posterior motion in prone position, weight-bearing patterns such as on elbows or extended elbows while rocking and crawling.
 - c. Weight-shifting in kneeling, half-kneel, or standing positions (first in vertical and then off vertical within limits of stability by an activity itself [reaching]).
 - d. Do activities with eyes closed.
 - e. Create dual-task activities such as walking and talking, stepping over obstacles while on unstable surfaces, reading while maintaining balance in a confusing environment.
 - f. Challenge balance in distracting environments (e.g., moving surround, multisensory stimuli in visual surround).
3. Facilitatory techniques to influence whole-body responses^{30,111,295}
 - a. Movement patterns in specific sequences.
 - i. Rolling patterns.
 - ii. Prop on elbows (prone and side-lying positions) and extend and flex elbows as well as crawling (e.g., side by side, or linear and angular motion).
 - iii. Coming to sit (side-lying to sit [using upper trunk and head rotation], prone to four-point position to sit [four-point position to lower trunk rotation to side sit to sit], adult sit [full flexion leading with head]).
 - iv. Coming to stand (squat to stand, half-kneel to stand, standing from a chair or stool).
 - b. Spinning.
 - i. Mesh net.
 - ii. Sit and spin toy.
 - iii. Office chair on universal joint.
 - c. Any activity that uses acceleration and deceleration of head.
 - i. Sitting and reaching.
 - ii. Walking.
 - iii. Running.
 - iv. Moving from sit to stand.
 - v. Doing activities with eyes closed, head still, and then eyes closed, head turning.
 - d. Performing activities that require attention, memory, and cognitive processing at the same time.
4. Combined facilitatory and inhibitory technique: inverted tonic labyrinthine activities
 - a. Inverted tonic labyrinthine activities.
 - i. Semiinverted in-sitting (head between the legs).
 - ii. Squatting to stand (head below heart).
 - iii. Thirty degrees to total inverted vertical position beginning in supine.

BOX 9-2 ■ SUMMARY OF INTERVENTION STRATEGIES TO FACILITATE NEUROPLASTICITY—cont'd

- b. Somatosensory and sensorimotor stimulation (refer to earlier in this chapter).
 - i. See detailed progressive learning-based sensorimotor training (Appendices 9-B and 9-C).
 - ii. Proprioceptive stimulation.
 - (a) Vibration over joints.
 - (b) Vibration in opposite direction of movement.
 - (c) Wear weights around ankles or on belt.
 - (d) Position the limbs and the trunk to match a position visually presented.
 - (e) Move slowly to the count of a metronome and then change speeds.
 - (f) Look at pictures and position the body to match the pictures.
- c. Auditory discrimination (localization).
- 5. Techniques to facilitate specific task performance
 - a. Forced use.
 - i. Create training activities in which patients must use the affected extremity.
 - ii. Minimize the need to use the unaffected side.
 - iii. Use bilateral activities in which both hands and upper extremities are required.
 - b. Constraint-induced movement therapy (CIMT) (forced use)^{550-552,591,631,632} emphasizes the repetitive use of an impaired limb in regular functional activities by restricting the movement of the less affected or unaffected side.
 - i. The patient is constrained from using the unimpaired limb on a concentrated task basis.
 - ii. The impaired limb is used on a concentrated basis.
 - iii. The theory is to reduce motor deficits early in the recovery period (learned disuse).
 - iv. The assumption is that the nervous system is adaptable and training for recovery should begin as soon as possible.
 - v. If the good arm is constrained, the patient must use the affected limb.
 - vi. Set time limits to use the constraint; in one large randomized clinical trial the patients were asked to wear a protective safety mitt on the less affected upper limb for a goal of 90% of the waking hours for 14 consecutive days.
 - vii. During constraint, the individual works under supervision on designated functional tasks for 6 hours a day.
 - viii. The patient is encouraged to try to use the affected limb during waking hours.
 - ix. The constraint is paired with motor or behavioral objectives.
 - x. Tasks are practiced and progressed in difficulty or speed.
 - c. Mass task practice (see Chapter 4).
 - d. Mental imagery.
 - e. Mental practice.
 - f. Body-weight–supported treadmill training (BWSTT)^{524-527,633}
 - g. Integration of robotics and technology (see Chapter 38)
 - h. Use of gaming (Wii Fit, Brain Fit)^{604,607-610}

some intact verbal processing, which is translated into appropriate motor acts. Similarly, when asked to pick up his head, he does just that, suggesting some perceptual integrity of body image, body schema, and position in space. Knowing where his head is in space and where to reposition it also suggests that some proprioceptive-vestibular input and processing are occurring.

- 4. Timothy's enjoyment of being moved in space as related to handling techniques suggests proprioceptive-vestibular integrity. Similarly, his tactile systems seem to be functioning in a discriminatory manner and modifying negative responses of withdrawal and arousal. However, specific tactile perception would need a great deal of further testing. Thus he demonstrates functional strengths in cognition and perception, in limbic motivation, in some areas of sensory integrity, and in control over available but limited motor programming. Yet performance on any functional test would result in identification of an individual whose functional limitations prevent him from independence in any activity. Prognosis must be guarded

until the therapist has had an opportunity to augment the environment to determine how quickly he will regain control and retain the learning. The initial plan of care is assumed to focus on development of head control as a preliminary and necessary motor program for all functional daily living activity. The estimated time it will take to regain this function will not be identified until after the first intervention session.

Movement Diagnosis. The client is unable to functionally control his head in any position in space, which limits independence in all functional activities. Lack of postural coactivation and adequate control over the motor generators has led to imbalances in the tonal characteristics of flexor and extensor patterns with the compensatory development of stereotypical patterns of movement.

Goal of Intervention Program. The goal is development of independent head control, initially in a vertical midline posture with the intent of enlarging that biomechanical window to include all positions in space.

Now that the clinical problem has been analyzed and the goal of development of head control set, an intervention

sequence or protocol must be established. Timothy lacks head control in all planes and in all patterns of movement. Thus, flexors and extensors must be facilitated to develop a dynamic coactivation or postural holding pattern of the neck. The categorization scheme can now be of some assistance. The therapist can ask, “Are there any inherent mechanisms that enhance flexors or extensors in a holding pattern?” The optic and labyrinthine righting (OLR) reaction should elicit the desired response. Similarly, the clinician can ask, “Are there any inherent motor programs that would prevent righting of the head to face vertical OLR?” The TLR would block or modify the facilitation of OLR. Knowing that the TLR is most dominant in horizontal and least dominant (if at all affected) in vertical is of clinical significance. It is also important to know that the OLR is most frequently tested in a vertical position and seems most active in that position. Awareness that the client is sensitive to total patterns (e.g., flexion facilitates flexion or extension facilitates extension) gives additional treatment clues.

After all this information has been assimilated, the following treatment could be established.

For enhancement of neck flexors, the client will be placed in a totally flexed position in vertical, with the head positioned in neutral. The client will be rocked backward toward supine, allowing gravity to quick stretch the flexors (Figure 9-5, A). As soon as the neck flexors are stretched, the head should be tapped forward and then back to vertical but not beyond. This avoids hyperextension, extreme stretch to the proprioceptors, and the horizontal supine position of the labyrinths, all of which dampen the flexors and facilitate the extensors. The quick stretch and position should optimally facilitate OLR, which should activate the neck flexors. The total flexion of the body similarly facilitates the neck flexors. Once the neck flexors respond, Timothy can be rocked farther and farther backward while maintaining the head in vertical or ventroflexion (Figure 9-5, B). Once Timothy can be rocked from vertical to horizontal and back to vertical while maintaining good flexor neck control, his CNS has demonstrated inherent control and modification over the stereotypical patterns, such as the TLR in supine with respect to its influence over the neck musculature. This rocking maneuver can be done on diagonals to practice

flexion and rotation (Figure 9-5, C), the key to eliciting a neck-righting, rolling pattern from supine to prone. The total flexed pattern can also be altered by adding more and more extension of the extremities. This decreases the external facilitation to the flexors and demands that Timothy’s CNS take more and more control (internal regulation). Additional treatment procedures can be extracted from a variety of sensory categories. To add additional proprioceptive input, any one of those listed techniques might be used. The rotation and speed of the rocking pattern affect the vestibular mechanism. Auditory and visual stimuli can be used effectively. If the therapist takes a position slightly below the client’s horizontal eye level, the client (to look at the therapist) will need to look down and flex his head, thus encouraging the desired pattern. Any type of visual or auditory stimulus that directs the client into the desired pattern would be appropriate. The therapist must remember that neck flexion is one of the identified goals. Rotation was added to incorporate and set the stage for inherent programming that will lead to rolling, coming to sit, and reaching while sitting. Because the postural extensor component still needs integration, total head control has not been attained. To facilitate neck extension, a procedure similar to the one for flexion can be established. A vertical position, thus eliminating the influence of the TLR, would again be the starting position of choice. For additional visual feedback on the development of flexor head control, refer to Chapter 3, Figures 3-15 through 3-18.

With extension facilitating extension, the client should be placed in as much extension as possible without eliciting excessive extensor tone. An inverted labyrinthine position, a kneeling position, or a standing position would be viable spatial patterns to facilitate OLR of the head and coactivation of postural extensors. The vestibular system sensory category can be checked to identify the treatment procedure for use with an inverted labyrinthine position. The kneeling or standing position places the client in a vertical position with hip and trunk extension. Kneeling rather than standing is used first because of the influence of the positive supporting reaction in standing and the massive facilitation of total extension. Kneeling avoids total extension while maintaining a predominant extensor pattern. As a result of the gravitational pull of body weight through the joints,

Figure 9-5 ■ Development of flexor aspect of head control. **A**, Vertical position: head at midline and midrange (total-body flexion) to optimally facilitate neck flexors. **B**, Facilitating symmetrical neck flexion, using position, gravity, and flexor positions. **C**, Facilitating flexion and rotation to develop pattern necessary for neck-righting pattern.

approximation to facilitate postural extension is constantly maintained. The upper extremities can be placed in shoulder abduction and external rotation, which tends to inhibit abnormal upper-extremity flexor tone and facilitate postural tone into the shoulder. This extensor tone has the potential through associated spinal reactions to facilitate neck and trunk extension. The arms can be placed in this position over a bolster or ball or by the therapist handling the client from the rear (Figure 9-6, A). The head should begin again in a neutral position. The client is rocked forward (Figure 9-6, B) to facilitate OLR of the head and to elicit a quick stretch to the postural extensors. If the head begins to fall forward, the therapist can tap the client's forehead immediately after the quick stretch. This tapping action is the reverse tap procedure described under the proprioceptive stretch receptors category. The tapping is done to passively move the head back to vertical.

A variety of additional procedures can easily be combined to summate facilitation to the postural extensors. Tapping, vibration, and approximation through the head to the shoulders are only a few of the proprioceptive modalities. All would be facilitatory. A variety of auditory and visual stimuli could be used to orient the client to a position in space and thus righting of the head. Techniques listed under the exteroceptive and vestibular systems could also be part of the treatment protocol. The therapist would want to sequence the client toward prone while the head remained in a vertical postural holding pattern. As the therapist rocks the client toward prone again, a rotational component should be added (Figure 9-6, C). The client will extend and rotate to counterbalance the movement, thus incorporating the neck-righting pattern of extension and rotation necessary when rolling from prone to supine. Resistance to neck extension with or without rotation is an important element in regaining normal functional control. The client is alert and has some functional use of the arms and legs. This rocking pattern in kneeling can be done as a functional activity. The therapist asks the client to assist in reaching toward an object with one upper extremity. The therapist can guide the client in the reaching pattern in a forward, sideward, or cross-midline direction. While reaching, the client can be rocked forward to elicit right and equilibrium reactions. In incorporating an activity into the treatment of head control, the client not only is entertained but also attends to the task rather than

cognitively trying to keep his head up. In this way automatic head control is facilitated, and often postural patterns follow. In a partial kneeling pattern the client can be sequenced to on-elbow over a bolster or ball or on a chair. These activities should be sequenced from vertical to prone to ensure both total postural programming in prone and optimal integration of OLR, as well as to let the client experience control of various motor strategies in many different environmental contexts. For more analysis of the development of extensor head control, refer to Chapter 3, Figures 3-19, 3-21, and 3-22.

Once the client can maintain good flexor, extensor, and rotational components of head control, the activity should, if possible, be practiced with the client's eyes closed. If the client can still maintain head control, labyrinthine righting would be adequate for any functional activity. If the client loses head control, then additional labyrinthine facilitation would be indicated. If a client uses only vision to right the head, then any time vision is needed to lead or direct another activity, head control might be lost. Because symmetrical vestibular stimulation plays a key role in activating the neck muscles to hold the head in vertical, it also is a key element leading to the perception of vertical and all the directional activities sequencing out of the concept of verticality. The postural extensor programming for head control needs to be practiced in a standing position and a sitting position. The client needs to be able to stand quietly without excessive extension to run both postural and balance programs. Similarly, he needs to be able to sit with hip flexion while coactivating postural extension in the trunk and neck.

Head control is a complex motor response. A therapist can facilitate inherent mechanisms to assist a client in regaining function. Simultaneously, multitudinous external input techniques classified under the various sensory modalities and combined modalities can be used to give the client additional information. Awareness of one technique and the ability to categorize it appropriately allow easy identification and implementation of many additional approaches. The therapist always needs to remember that the client must practice the behavior (head control) in a variety of spatial positions during various functional activities. This practice must be functional and no longer contrived.

The reader is referred to Chapter 3 in order to understand the normal development of head control and how the nervous system demonstrates motor learning and control.

Figure 9-6 ■ Development of extensor aspect of head control. **A**, Vertical position: head midline with long extensor in midrange and postural extensors in shortened range; body in postural weight-bearing pattern. **B**, Facilitating symmetrical extension of head, trunk, and hips while inhibiting abnormal upper-extremity tone. **C**, Facilitating head and trunk extension and rotation to encourage neck righting pattern; client reaches for an object, which is then placed on the opposite side.

Case Study 2: Initial Augmented Intervention Transitioning to Independence in Bed Mobility. Teaching the client to roll in bed can be approached in a variety of ways to accomplish the goal. The entire rolling pattern may be practiced with enough assistance for the client to be able to accomplish the goal, but also limiting help so that the client must use the maximum amount of power and ROM available within the key movement pattern.

Rolling. The patient is a 73-year-old man, status post-ischemic infarct in the frontoparietal cortex with resultant left hemiplegia, hemisensory deficit, and left homonymous hemianopia. The patient demonstrates visual-spatial inattention to the left environment. The client must learn to roll independently in bed for comfort and function. An example of a treatment session aimed at reaching the goal of independent rolling to the right and left may include the following sequence of activities: (1) begin in side-lying on one side; (2) ask patient to tip back a few degrees and then return to the side-lying position (impairment training within limited ROM); and (3) progressively increase the degree the patient must roll backward, assisting (augmenting) him as needed. By the end of several repetitions the patient may be rolling from supine to side lying and the movement is functional because he is performing independently. The client will need to practice many times to relearn the activity before that activity would be considered functional training within the environment practiced. Rolling on a therapeutic mat table is not the same as rolling on a soft mattress at home. There may or may not be carryover. That needs to be identified by the therapist and appropriate steps taken to ensure that independence in all environments is obtained.

Refer to the video for a demonstration of handling while working on rolling for bed mobility.

Case Study 3: An Individual post Stroke. A 66-year-old man after a stroke has mild extensor synergic hypertonicity within the right lower extremity and hypotonicity within the right upper extremity except within the shoulder girdle, which has weak but functional movement patterns. His stroke was medically considered mild and his prognosis good in relation to the potential of the CNS regarding function. It has been agreed that the therapeutic goals after physical rehabilitation are to ambulate independently and use the right upper extremity to fly-fish, an activity that he loves and has done daily since he retired.

In terms of occupational and physical therapy intervention, the patient would be taught to regain independent functional skills in dressing, feeding, hygiene, transfers, and other ADLs. To facilitate the patient's goal of fly-fishing, his family is asked to bring in the rod and reel to augment a real situation with the functional skill he possessed within his right shoulder girdle.

Specific Physical Therapy Task Training: Fly-fishing. In addition to ADL training, it is decided to use BWSTT as a training tool for his right lower extremity. Manual assistance is used to guide the placement of the right foot into dorsiflexion at heel strike. The training begins with a 30% weight reduction, and the patient is relaxed into the gait pattern. His right arm is suspended with the use of a shoulder harness and a robotic aid that swings through the arm in a reciprocal pattern to the left leg. This intervention is performed twice daily for 3 weeks. During weeks 2 and 3, the patient's body weight support is reduced to 15%. By the end of the second week the

patient is actively assisting the therapist with the entire gait cycle of both legs. By the end of week 3, the patient is able to walk on the treadmill independently. During the second week, over-ground ambulation is begun to transfer the treadmill learning into a functional activity. By the end of the fourth week, the patient is independent on noncompliant surfaces. Over the next month the patient is in an outpatient environment with the primary goal of independent ambulation on compliant surfaces such as sand, dirt hills, and gravel environments.

Specific Occupational Therapy Intervention with Regard to Fly-Fishing. It is determined that the OT will work on postural endurance of the trunk and lower extremities while facilitating the right upper extremity to practice fly-fishing. Initially the training is done in sitting to create a stable environment for the right upper extremity. The arm is placed over a ball that the patient can roll back and forth as he visualizes fly-fishing. His right hand is placed in a glove that has a wrist support and is fastened to the rod with Velcro. The rod is placed in a bucket with a hinge joint that allows for anterior and posterior movement of the rod attached to its base of support. Using this adaptation of the ball, rod brace, and wrist support and glove, the patient is able to mimic one half of the range needed to fly-fish. He so enjoys the activity that his family takes it up to the room to allow him to practice between therapy visits. After a week, the patient is brought to stand, and the apparatus is adjusted for height. The ball is still used but placed on an adjustable bedside table. As normal motor programs begin to be generated within the right upper extremity, modifications in size of the ball, angle of the wrist and hand, and range allowed within the hinge joint are made to allow for error and self-correction. Within the 3-week period of inpatient rehabilitation, the patient becomes able to perform the activity normally with only the use of the ball for postural support within the shoulder girdle. The apparatus is taken home and the patient adjusts all components depending on his fatigue level. Within a 2-month period of the patient working at home, he goes from a totally augmented intervention program to functionally being able to stand by a river or lake and fly-fish independently. His endurance for this activity improves as he continues to practice.

SOMATOSENSORY RETRAINING

Somatosensory retraining is a multisensory approach to retraining target-specific skills for patients with movement dysfunction that manifests with measurable levels of sensory impairments. This type of therapy is based on the principles of learning and plasticity and progresses from a strong sensory emphasis to sensorimotor practice to motor learning. This approach has been used with patients with various types of hypertonicity resulting from congenital deficits (see Chapter 15) to degeneration (see Chapters 13, 17, 19, and 20) and disease (see Chapters 21, 23, 25, and 26). It has been most commonly used in patients with dystonia and chronic pain. This approach combines a variety of the strategies summarized in the augmented intervention section as well as [Box 9-3](#). The principles for retraining can be found in [Appendix 9-A](#). The progression of specific learning-based sensorimotor training is summarized in [Appendix 9-B](#). Additional ways to enhance sensorimotor training can be found in [Appendix 9-C](#).

BOX 9-3 ■ CONCEPTUAL GUIDELINES FOR CLINICAL DECISION MAKING: HOW TO SELECT TREATMENT OPTIONS FOR PATIENTS WITH NEUROLOGICAL IMPAIRMENTS

After performing examination procedures in which you identify problems with activities and participation, you will then be able to classify these into clusters or syndromes (i.e., the physical therapy diagnosis). You then need to formulate a prognosis and determine the intervention options.

In order to determine the *best* treatment options for a patient with a neurological condition with movement problems, you must simultaneously consider non-physical therapy-based as well as non-neurological system-based limitations along with the specific neurological impairments.

Assume the *best case scenario* (which never exists) in which there are no limitations in health benefits, from cultural beliefs or family, caused by conflict with other care providers, or in systems other than motor such as cognitive, emotional, vascular, integumentary, pulmonary, cardiac, and so on.

First, what does the patient want to do compared with what his or her motor system can do? Can you work on improvement of impairments and function within activities the patient is motivated to do? *If so, do it!*

Second, without altering the patient's normal feedback (intrinsic) mechanisms, can he or she perform the functional activity without causing program adaptations that are so stereotypical that those programs may limit future movement functions and carryover?

For example: can you create an activity that will do the following without contriving the environment and while still running flexible, malleable motor programs?

1. Improve range of motion (ROM) or
2. Improve power or
3. Improve coordination or
4. Improve balance or
5. Improve endurance or
6. Any or all of the above
7. Have any similar effect

If so, do it!

If not, you will need to contrive the environment in order to create functional change through treatment intervention.

ASK YOURSELF

1. Where in the activity can you optimize biomechanics, and where are biomechanics deoptimized? If the body was placed at a better biomechanical advantage:
 - a. Would the client be able to run and power the program?
 - b. Would the motor program run more fluidly and procedurally?
 - c. Would there be greater endurance?

If your answer is *yes*, then try running the program that way initially and then increase the range and challenge all components of the program.
2. Throughout the activity, where would the least and greatest power be needed? Does the program run differently at different points throughout the activity depending on power production? Optimize what power you have, while maintaining fluid, relaxed program generators. Hypertonicity will often be observed if you ask for more power than the generators can create in a normal fashion.
3. Look at the program itself.
 - a. What central nervous system (CNS) components are missing (impairments or functional problems)? These are usually your neurological diagnoses (physical therapy diagnoses).
 - b. Can you elicit through treatment intervention corrections of the impairments in any aspect of the program? *If so, how?*
 - Caused by biomechanical advantage
 - Caused by musculoskeletal advantage
 - Caused by the program advantage itself

Optimize:

- Synergistic advantage
- Balance synergies
- Sensory processing
- And so on

These treatment answers will lay the foundations for your specific intervention strategies.

- c. Can you elicit those components in any other movement programs? If so, these are treatment alternatives, although they will not be task specific and have less immediate carryover.
4. Select movement activities that use existing components procedurally and facilitate or elicit function from impairment component of subsystems.
5. Prioritize functional activities by identifying daily living needs of the patient, goals of the patient, and functional skill of the patient. Determine which impairments affect the greatest number of functional activities. Similarly determine which impairments can be quickly changed in order to gain functional skill. Decide within the limits of the environment which activities to focus on first.

BOX 9-3 ■ CONCEPTUAL GUIDELINES FOR CLINICAL DECISION MAKING: HOW TO SELECT TREATMENT OPTIONS FOR PATIENTS WITH NEUROLOGICAL IMPAIRMENTS—cont'd

For example: Assume the patient has poor balance in sitting and standing. He plans to sit in the lounge chair most of the day but walk to the toilet when necessary. Although range, power, and postural control would need to be considered, you might decide to work on standing balance and balance during walking before sitting balance owing to task specificity and functional need. This is not stating that sitting balance is not important; it is prioritizing the activities according to need. Power, range, posture, and so on may determine the specific intervention strategies used to work on standing and walking balance.

6. If normal programming cannot be elicited, look at adaptations and determine alternative interventions such as the following:
 - a. Adaptive equipment: biofeedback, orthotics, canes, and so on
 - b. Adaptive environments: ramps, rails, lights, changing walkways, changing surfaces (e.g., removing shag carpets)
 - c. Encouraging stereotypical and inflexible programs
 - d. Combination of a, b, or c

Make sure that when selection of alternative approaches or adaptations is made, consideration is given to what will be given up by adapting the environment and CNS. Consider whether that decision is truly cost efficient and the best alternative to meet the needs and goals of the patient, his or her family, and the physical and cultural environment within which he or she will function.

Neural Mobilization

Neural mobilization is often needed as an intervention strategy before somatosensory retraining is begun. Often there is increased sensitivity in a limb from pain,⁶¹¹ neurovascular restrictions, or soft tissue adhesions limiting the ability of the peripheral nerve to move through the tissue (see Chapter 18). This sensitivity can increase hypertonicity and further interfere with retraining motor control. In order to address this, it is important to quiet the nervous system and then gently mobilize the neural tissue. One way to quiet the nervous system is by “swaddling.” This is often used in newborns to quiet their nervous system. For an older child or an adult, the patient is wrapped similar to the way a baby would be; then gentle rocking in a rocking chair or a swing is added. Patients can do this themselves by putting on a t-shirt with the arms tight to the trunk and then wrapping even further with a blanket. This technique can be used periodically on days that the nervous system appears to be responding primarily to adrenaline rather than purposeful heightened activity. There are a variety of ways to mobilize the PNS. Detailed examples of this can be found in textbooks on the hand.⁶¹²

NATURAL ENVIRONMENTS AND QUALITY OF LIFE

Research has already been identified in the discussions of the various sensory input systems that recognizes that changes in external sensory input such as decreasing sound, light, tactile contact, or color of mats can change the processing of CNS of the clients. The present and future research will recommend that therapists apply changes that affect not only the patient’s inherent sensory systems, but also the environments within which the therapy is done. Therapists are going to have to adapt to change. At this time it is unrealistic to think that acute management of patients after a neurological insult will occur anywhere but in a large medical institution, but treatment needs after that acute stage may better be served in a more natural environment of the individual needing service.⁶¹³⁻⁶¹⁸ Not only has this conclusion been accepted conceptually in postacute pediatric settings, but federal law has ordered that individuals up to

21 years of age must receive educational experiences in the least restrictive environment. This amendment was made to the Individuals with Disabilities Educational Act (IDEA) in 1997.⁶¹⁹ These changes have been mandated within the school systems and have affected therapy environments for clinicians who work in those situations. It is realistic to assume those changes will in time affect all therapy environments.

As the World Health Organization has moved toward an individual-friendly focus and thus a focus on body system strengths as well as impairments, participation in life, and its quality, the term *patient* may also need to be changed to *participant*. As can be seen in Chapter 8, examination tools have been included that deal with quality of life and not just functional outcomes from therapy. Therapists, if they have not done so already, are going to have to learn to deal with individuals coming to them for assistance as a partner in the process and not a patient who receives services. Change will come. That is one of the exciting aspects of being an OT or PT in the coming decades.

CONCLUSION

There are treatment techniques that are universally applied to the very young and the very old. As discussed in Chapter 4, the CNS is in a constant state of change throughout life. The brain is unique to each individual. Each brain has idiosyncrasies but also has an enormous number of predictable responses. These factors affect the success or failure of a client-therapist interaction. In Box 9-3 the reader will find guidelines that may assist in determining the type of interventions (functional, impairment, augmented, or somatosensory training) that will best match the patient’s functional movement capability. In answering the questions presented, the therapist will gain a better idea of which examination tools will best help objectively measure the progress of the patient toward that patient’s specific goals. From that thorough evaluation process (see Chapter 8), the therapist must decide which treatment is appropriate and the most efficient course of intervention on the basis of the goals of the patient and family, the movement diagnosis, the prognosis, the resources available, and the skills of the therapist. Once a

decision is made regarding whether the interventions should be based on compensation, substitution, habituation, neural adaptation, or a combination of the four, the team must select the best options available given all the resources. The options include functional retraining, impairment training, augmented and contrived interventions, and somatosensory reintegration. No matter the specifics of the intervention selection, the therapist must cognitively organize intervention options in a sequential process, be willing to change direction or options as the patient changes, and develop a greater clinical repertoire of intervention strategies.

When specific augmented interventions are needed, the therapist must select specific treatments according to the needs of the client, the time available for therapy, the level and extent of the functional involvement, the motivation of the client and family, the creativity of the therapist, and, of course, the existing pathology, whether it be stable or an active disease process. A therapist must choose whether somatosensory retraining, functional training, impairment training, augmented treatment interventions,

or any combination of these four will provide the client with the most environmentally effective, cost-efficient, and quickest map to functional independence or maximal quality of life. How each therapist combines the interventions with the client's specific needs will vary according to education, belief, skill, and openness to learning from the total environment itself. Learning should lead to further learning. Answers to unknowns will be found, with new unknowns coming to consciousness. The brain is still more mystery than not, so for most OTs and PTs beginning or ending their practice, the adventure has just begun. *Enjoy the experience.*

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 636 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

APPENDIX 9-A ■ Principles Used by Therapists for Retraining Clients with Pain and Motor Control Problems of the Hand

Nancy N. Byl, PT, PhD, FAPTA, Professor Emeritus, Department of Physical Therapy and Rehabilitation Science, School of Medicine, University of California, San Francisco

A. Positive Foundation for Retraining

1. Carry out a regular exercise program, be well hydrated, eat balanced meals, get adequate sleep, make time to have fun, minimize habitual repetitions, and effectively manage stress.
2. Engage in challenging balance to improve posture and integrating diaphragmatic breathing, neural mobilization, and core trunk strengthening to maintain a healthy posture.
3. Create learning strategies that emphasize sensory input and feedback. You can do this by placing sticky, coarse, or rough surfaces on tools that are used in functional activities (e.g., pen, keyboard, glass, hammer, utensils).
4. Set goals and objectives to guide your training.
5. Think positively about learning to be as good as you can be or to recover after injury; expect to regain function.
6. Analyze and break down the tasks you want to learn or to improve into manageable components.
7. Perform each component of functional tasks without abnormal movements (e.g., pathological synergies, extraneous movements, excessive muscle firing, involuntary movements, strain, pain).
8. Be sure each activity is designed to require attention, repetition, progression of difficulty, feedback regarding accuracy of performance, and positive reinforcement (reward).

B. Stress-Free Hand Use Strategies

1. Strengthen the small muscles inside the hand (intrinsic muscles) to facilitate stability of functional hand use.
 - i. Give resistance to spreading fingers apart (try not to use muscles that straighten the fingers).
 - ii. Try to hold the fingers together while you use your other hand to try and spread them apart.
 - iii. Bend the fingers at the large knuckle (metacarpophalangeal joint) to 90 degrees by placing the back of the hand against the edge of a table. Now, one finger at a time, try to keep the fingers straight as you use the other hand to try and bend the finger, giving resistance at the distal segment of the finger.
2. Concentrate on using the small muscles of the hands in all functional activities.
 - i. Initiate bending the fingers from the base joint (the large metacarpophalangeal joint that joins the finger to the palm); try to do this without bending the fingers at the other joints, especially without using the muscles that bend the distal finger joints.
 - ii. Avoid heavy gripping; squeeze the fingers in a power grip only when necessary. For example, do not (1) squeeze the steering wheel, (2) exercise while holding on to free weights, or (3) squeeze a ball or strengthen the grip in other ways.
 - iii. Practice reaching for common objects with the eyes closed and the hand relaxed. When you contact the object, let the sensation of the surface of the object open the hand. For example, when you reach for your cup, let the cup open the hand (e.g., do not actively spread the fingers first). Do not use the handle of the cup.

3. When practicing tool use, let the sensation of the object teach your hand how hard to squeeze.
 - i. Modify the sensation of the object (e.g., very rough, slightly rough, coarse, smooth, silky).
 - ii. Take practice lifts of the object to determine how heavy it is.
 - iii. Manipulate the object in your hands without visual monitoring before beginning functional use of the tool.
4. Avoid aggressive, precise, rapid, alternating, forceful finger flexion and extension movements of the hand.
 - i. Transfer some of the work of the hand from the fingers to the forearm. For example,
 - Lift the fingers by rotating the forearm into supination (e.g., turn palm up). If forearm rotation is limited, let the shoulder externally rotate if necessary.
 - When the hand needs to be palm down (pronated), let the elbow swing away from the trunk if necessary to keep the hand relaxed (e.g., internal rotation of the shoulder can take the stress off the forearm).
 - ii. Use the hand in a *natural functional position* (e.g., rounded palm from the base of the thumb to the base of the fifth finger and rounded from the tips of the fingers to the wrist). Thus all the finger joints are slightly bent, the palm is round, and the wrist is extended about 15 degrees. When your arms are at your side, this will usually be the position of the hand.
 - iii. Do not let the joints of the fingers collapse or hyperextend when they are down on a surface. This can be difficult if the joints are hypermobile or the intrinsic muscles (muscles inside the hand) are weak.
 - Practice dropping the hand onto a surface and maintaining the roundness of the hand (a small soft ball under the palm may be used for assistance).
 - Lean lightly onto the hand while it is on a flat surface, pronated and keep the round shape of the hand (e.g., may need to initially keep small round ball under palm).
 - Thread the fingers of one hand through the fingers of the other hand to help stabilize the hand when placing weight onto the hand as noted previously.
 - Put a soft, rubber ball about 2 inches in diameter on the table; roll the palm of the hand over the ball while letting the finger pads (not the tips) drop onto the surface.

C. Using the Computer Keyboard Safely

1. Position yourself comfortably to use the computer.
 - i. Sit with feet flat on the floor. Sit tall with hips about 90 degrees (vary this posture throughout the day).
 - ii. Place the computer screen at or slightly below eye level.
 - iii. Keyboard height should be adjusted to maintain elbow flexion at about 80 degrees (positioned in approximately 100 degrees of extension).
 - iv. Forearms should be angled toward the floor and not resting on the table. If it is difficult to let your hands rest lightly on the keyboard with the wrist floating, it may be helpful to have a pillow on your lap (or a lumbar roll around the waist), where the forearms receive positive sensory information to help them relax.

Continued

APPENDIX 9-A ■ Principles Used by Therapists for Retraining Clients with Pain and Motor Control Problems of the Hand—cont'd

- v. Place the screen about 2 feet away from the eyes for most work; pull the screen closer as necessary for close work.
 - vi. Consider getting special antiglare glasses for computer terminal display work or use a screen glare protector.
2. Use your hands in a functional (e.g., round, not flat or angular) position on the keyboard.
 - i. Look at the contour of the hand when it is at your side; maintain that position as the finger pads (not the tips) are dropped on the keyboard.
 - ii. Place a rough surface on the keys (e.g., Velcro) to make it easier to feel the pads on the keys.
 - iii. Avoid placing the tips of the fingers on the keys. This creates an obligatory co-coactivation of the finger flexors and extensors.
 3. Keep the wrist in a neutral position (0 to 10 degrees of extension) while working on the keyboard (e.g., a floating wrist).
 - i. Do not rest the wrist on a “wrist rest.” Resting the wrist and forearm on the work surface will increase the pressure in the carpal tunnel and force all the work to be done with the fingers.
 - ii. If there is a wrist pad on the computer keyboard tray, think of the pad as a “sensory tickle” to let you know that your wrists should be floating above the rest.
 4. Have all the fingers resting on the keyboard.
 - i. Do not let any of the fingers fly up.
 - ii. Continue to keep the fingers resting down even when one finger is engaged in depressing a key.
 - iii. Avoid allowing the adjacent fingers to extend to get them away from the finger actively pressing down.
 5. It is not necessary to actively lift the fingers after pressing down. Usually it is sufficient to release the pressure without actively lifting up the digits.
 6. Avoid resting the fingers on the keyboard with the finger tips. This leads to a contraction of the fingers and the wrist.
 - i. Do not keep your fingers excessively curled. In that position it is impossible to keep the fingers on their pads.
 - ii. Initiate the movement down from the base joint of the fingers.
 - iii. Imagine that you are using the muscles inside your hand and not the long muscles that bend the fingers.
 - iv. Avoid reaching one finger out in isolation from the others.
 7. In general, change the primary fulcrum of movement from the fingers of the hand to the elbow and shoulder.
 - i. Allow the elbow to move freely in flexion, extension, and rotation.
 - ii. Use the trunk with a little shoulder movement when reaching for an object or a paper or to move closer to or away from the computer keyboard or screen.
 8. Use the mouse by using forearm rotation rather than individual finger movements.
 - i. Do not squeeze the mouse; drape your hand on the mouse.
 - ii. Keep your wrist in neutral position.
 - iii. Avoid clicking the button by lifting and bending the index finger.
 - iv. Use rotation of the forearm to activate the button on the mouse.
 - v. Make sure the mouse is close to you and that the arm is not extended to the side. Place a cover for the mouse over the number keys, if necessary, to keep the arm closer to your trunk.
 - vi. Consider interfaces other than a mouse (e.g., roller ball, a movement-sensitive pad, pen).
 - vii. If it is not possible to use the hand in a stress-free way when on the computer, then consider voice-activated software to use your computer.
 - Use your voice carefully and without excessive force or strain (e.g., loudness).
 - Be careful to prevent co-contractions and stressful use of the vocal cords.
 9. Take regular breaks (e.g., every 15 minutes).
 - i. Consider obtaining the software that forces a computer breakthrough screen reminder.
 - ii. Do diaphragmatic breathing continually while working on your computer to minimize tension and facilitate good oxygen exchange.
 - iii. When taking a break and staying at the desk, get your hands off the computer and change your sitting posture while doing gentle range-of-motion exercises. Occasionally place the arms on the desk and bend the trunk over the arms.
 10. At least every 20 minutes, stand up for a few minutes and stretch.
- ### D. Writing
1. The fulcrum for the movement of writing should be the shoulder and elbow, not the fingers.
 2. The hand should be round and relaxed.
 3. Try putting a sticky or a rough surface on the pen or pencil before you begin to practice.
 - a. A sticky surface (e.g., tape with the sticky side facing out) can be strong enough to hold the pen in place without any squeezing.
 - b. A fatter pen is not as helpful as a sticky or a rough surface. It is possible to excessively grip a large pen.
 4. Practice writing when you are not at work or at a store when you have to write your name.
 5. Practice writing non-work-related words and sentences and then progress to meaningful writing.
 6. Try holding the pen by different fingers or using different movements.
 - i. Try to hold the pen between the second (index) and third (middle) finger rather than the thumb (D1), index finger (D2), and middle finger (D3). The hand should be open, thumb resting down.
 - ii. If you must hold the pen in the traditional way, try to hold the pen lightly among D1, D2, and D3, with D1 and D2 moving toward the thumb from the base joint with all joints of the digits extended.
 - iii. With a sticky surface on the pen, it is possible to control the pen with minimal squeezing.
 7. Practice picking up the pen and putting it down without feeling any tension in your hand.
 8. Control the movement of the pen primarily from the elbow and shoulder; keep wrist and fingers quietly positioned on the pen.
 - i. Let the arm rest lightly on the table and comfortably on the ulnar (fifth finger) side of your hand. Avoid resting the elbow on the surface. If there is inadequate pronation (e.g., it is uncomfortable to have the hand be palm side down), allow the shoulder to move out away from the trunk (e.g., shoulder abduction or rotation).

APPENDIX 9-A ■ Principles Used by Therapists for Retraining Clients with Pain and Motor Control Problems of the Hand—cont'd

- ii. Let all fingers rest down on the pen or the support surface. Do not hold any fingers up off the pen or the support surface.
 - iii. Mentally review relaxed writing before beginning to write with a new technique.
 - iv. Practice making circles, loops, large numbers, and letters. Consider practicing by writing in shaving cream, finger paints, or water.
 - v. If you see your fingers moving and your knuckles turning white, you are squeezing too hard and you are using only your fingers.
9. Use a mirror to get some feedback to retrain your style of writing.
 - i. Place a mirror in front of your affected hand as you write and notice whether it appears relaxed.
 - ii. Place the unaffected hand in front of the mirror and the affected hand behind the mirror. Look at the image of the unaffected hand (e.g., looks like the affected side), and then have the affected hand behind the mirror copy the mirror image.
 10. Put the pen down if any signs of stress develop.

E. Daily Activities in the Kitchen

1. Use two hands to hold a pot or a frying pan.
2. Use an electronic can opener and jar opener.
3. Use an electronic blender rather than hand stirring.
4. Use a chopper to avoid heavy cutting.
5. Stand close to the sink and the work surface so you do not have to have your arms out too far in front of you.
6. Get close to the table for setting the table; avoid having to lean over; bend at the knees.
7. If you are short, stand on a stool to work at the sink.
8. If you are tall, consider raising the refrigerator up higher so you do not have to lean over.
9. Concentrate on eating and using utensils without stress in your hands.
 - i. Consider putting a sticky or a rough surface on the utensils (e.g., Velcro or flooring with a sticky back).
 - ii. When eating, hold the utensils lightly, even when trying to cut.
 - iii. When cutting, move the whole arm from the shoulder; use the weight of the trunk to assist putting force down on the knife.

F. Driving

1. Use a lumbar roll in the back of your seat to support your lower back. Also consider placing a wedge in your seat (varying the placement of the wedge with the high side in front and then toward the back).

2. Pull the seat close to the steering wheel so that you do not have to reach out so far for the gas pedal.
3. Sit tall to ensure good visibility, and try to drive without stress.
4. Consider putting a rough surface on the wheel so you do not tend to squeeze it (you can buy ergonomic steering wheel covers).
5. When you need to look behind you, shift your weight in the opposite direction that you want to look. This will allow you to turn your whole trunk in the desired direction and avoid the isolated neck strain that occurs when you only turn your head.
6. Mentally rehearse and review calm, alert driving.
7. Do not squeeze the wheel in a death grip. Hold the steering wheel by gently pushing your arms together. You only need to hold the wheel with a palmar squeeze when turning.
8. Keep your arms comfortably at your sides.
9. Do not grip the shift knob; press the palm of your hand down on the shift bar to change gears. You may even want to allow your trunk to move with your arm while shifting.
10. If you continue to experience stress with driving, practice braking and turning the wheel in your garage and imagine different scenarios.
11. Also, if you need a diversion to avoid emotional confrontation with rude drivers, bring a plastic bag of buttons that you can manipulate and match to decrease your stress.

G. Other Household Activities

1. As before, do not grip objects too firmly; keep hands open and work with your arms close to the trunk.
2. Always bend your knees to pick up objects from the floor.
3. Be careful to avoid leaning over and straightening the bedding (e.g., when making the bed, ask someone to do it with you; otherwise, make one side of the bed at a time).
4. Put items at eye level; avoid putting things over your head for which you have to reach out and up.
5. Walk close to the vacuum cleaner; try to hold it where you do not have to reach your arms out (e.g., step forward and backward with the movement of the vacuum cleaner).
6. Do not lean over from the waist for dusting; if necessary, dust while kneeling or wipe the floor while you are on your knees; hold the dust cloth lightly.

APPENDIX 9-B ■ Specific Learning-Based Sensorimotor Training

A. Instructions

Patients

We use our hands for many skilled fine motor and functional tasks. It is important for these movements to be smooth, efficient, and accurate. When there is dysfunction in the central or peripheral nervous system from congenital anomalies, injury, disease, overuse, degeneration, or chronic pain, skilled and functional movements can be impaired. Although it is still important to strengthen the muscles, increase flexibility, and restore normal motor control, it is critical to improve sensory processing. The purpose of learning-based sensorimotor activities is to place demands on the sensory receptors of the skin, the muscle, and the joints to restore normal sensitivity and accuracy of sensory input and feedback. Your brain can change with training. By improving the accuracy of sensory discrimination under conditions of high levels of attention, repetitive activities progressed in difficulty and reinforced with feedback and reward should improve how the hand is mapped on your brain (e.g., primary sensory cortex). When specific tasks involve motor practice, topographical changes will also occur in other parts of the brain (e.g., thalamus, motor cortex, limbic system, basal ganglia, prefrontal cortex, supplementary motor cortex, brain stem). Although most think about the motor requirements for performing a task, it is essential to have accurate sensory information and feedback, which comes from accurate sensory differentiation of the hand. Dynamic sensory topography and function are requisite for the restoration of fine motor control.

Research also suggests that positive expectations can facilitate recovery and maximize performance.⁶³⁴ Physical impairments can lead to significant handicaps and disability. In these cases it is challenging to maintain a positive attitude and be motivated for recovery and rehabilitation. Depression, anxiety, loss of self-worth, and compromised self-esteem can significantly impair the recovery process, especially when training activities are demanding, intensive, and possibly associated with discomfort or frustration. It is essential to progress activities without causing unnecessary anxiety, apprehension, or pain. With these issues in mind, the initial steps in sensorimotor training may seem unusually simple and involve imagery in lieu of motor practice. Also, although the suggestions here focus on the hand, the principles apply to sensorimotor retraining for other parts of the body as well.

Specific randomized clinical trials have not been carried out on this series of training activities. However, Moseley⁶¹¹ carried out several studies establishing the procedures to perform recognition training of hand laterality, imagined hand movements, and mirror movements. He also carried out a randomized clinical trial for patients with complex regional pain syndrome using these training techniques. He randomly assigned 20 subjects to one of three different groups: hand laterality recognition, imagined movements, mirror training, or imagined movements; hand laterality recognition, imagined movements, or hand lateral recognition; mirror movements or hand recognition laterality. At 6 and 18 weeks after training for 2 weeks on these behaviors, subjects in all groups had a significant reduction in pain and disability ($P < .05$), with the group doing hand laterality recognition, imagined movements, and mirror training making significantly greater gains than the other two groups. Byl and co-workers^{635,636} also reported significant gains in patients with focal hand dystonia after 6 weeks of learning-based training. Candia and colleagues⁶³⁴ also reported

significant gains in performance for musicians with focal hand dystonia after 1 year of training focusing on task practice while controlling the fingers with a splint to improve isolated control of the dystonic fingers. For patients who are stable after a stroke, Byl and colleagues⁴⁴ also reported significant gains in fine motor performance after a sensory retraining program similar to the activities described here.

Therapists and Family Members

When giving these instructions to patients, it is important to supplement the written instructions with pictures or even videos. For patients with significant cognitive impairments, these instructions are almost more important for the family members who are helping reinforce the supervised therapy program.

B. Principles of Learning-Based Sensorimotor Training

1. Learning strategies focus on improving the discrimination of the somatosensory system in a range of tasks that focus primarily on sensory processing during sensory discrimination tasks and fine motor tasks.
2. Successful recovery is contingent on being able to imagine using the hands normally again without abnormal movements, apprehension, or pain.
3. The injured hand (affected limb) needs to recover laterality (right and left).
4. The patient needs to be able to look at a hand and imagine integrating the image of the hand into the movement or positioning of his or her own hand.
5. The hand must be able to interface with the target surface without creating tension, pain, or abnormal movement.
6. It is essential to be able to mentally imagine performing related and target tasks without abnormal movements or pain.
7. Sensory processing must achieve a minimum level of accuracy before functional fine motor movements are integrated.
8. Functional fine motor tasks need to be mentally practiced before they are physically practiced.
9. Tasks must be divided into the smallest components that can be normally executed (e.g., partial task performance), which will serve as the foundation for building skill-based learning on the whole task.
10. Learning requires attention and repetition of behaviors progressed over time.
11. Feedback and reward must be integrated into all learning activities, either by mental imagery, mirror imagery, visual reinforcement, auditory feedback, or objective, accurate task performance.
12. Feedback from error correction may be critical for enhancing learning.
13. Each component of a functional task must be performed as normally as possible before progressing to a more difficult task (e.g., without pathological synergies, extraneous movements, excessive muscle firing, involuntary movements, strain, pain).
14. Repetitive activities must avoid stereotypical movements that occur nearly simultaneously in time.
15. Sensory discriminative retraining should eliminate visual cues to facilitate somatosensory learning (e.g., eyes closed, blindfolded, distorting lenses).

APPENDIX 9-B ■ Specific Learning-Based Sensorimotor Training—cont'd

16. Begin sensory training on nontarget surfaces or with easy tasks that do not trigger abnormal responses (e.g., nontarget tasks).
 - i. Practice on nontarget tasks until sensory processing is improved and the task can be performed without any abnormal movement.
 - ii. Integrate sensory retraining in tasks that historically have been associated with abnormal movement (e.g., writer's cramp, keyboarder's cramp, hand functions associated with abnormal synergies related to hypertonicity, tremors, dystonia).

C. Preliminary Activities to Improve Readiness for Learning-Based Sensorimotor Discrimination Training

1. Restore hand laterality recognition.
 - i. Follow the guidelines developed by Moseley⁶¹¹ to be able to quickly see the hand in different positions and identify whether the hand is right or left.
 - ii. See pictures of the hand in different orientations and different positions of the wrist and fingers and identify whether right or left.
 - iii. See the pictures in random order, faster and faster, and be able to accurately determine the side.⁶¹¹
2. Restore ability to mentally imagine putting the affected hand into different positions.⁶¹¹
 - i. See pictures of the appropriate hand (affected) in different positions.
 - ii. When picture is shown, mentally put your hand into the same position as the one in the picture.
 - iii. Practice doing this while changing the order of the positions and the time the position is visualized.
3. Restore the ability to imagine performing normal movements while observing a video of the hands of someone else performing target and nontarget tasks.
 - i. Record video of different people performing target and nontarget tasks.
 - ii. Watch the videos and imagine that the hands being observed are your hands performing the tasks without pain or abnormal movements.
4. Learn how to copy a mirror image of the affected side.⁶³⁵
 - i. Place the unaffected hand in front of a vertical mirror and the affected hand behind the mirror (out of sight).
 - ii. Look in the mirror and note that the mirror image of the unaffected hand looks like the affected hand.
 - iii. Do simple tasks using the mirror image to guide the movement of the affected side.
 - Take the pictures from the visualization training and assume the position of the hand and wrist.⁶³⁵
 - Put different sensory objects within the reach of both hands; pick up an object and make the object feel the same on both sides.⁶³⁵
 - Do simple functional tasks with both hands simultaneously (e.g., turn hand up and down, tap a finger, bring thumb to each finger, pick up a pen, circle the pen, pick up objects of different size or same size but different surfaces).⁶³⁵

D. Initiate Specific Learning-Based Sensorimotor Training

1. Retrain cutaneous, muscle, and joint receptors at nontarget tasks.
 - i. Develop a variety of active sensory discrimination activities that you can do by yourself (e.g., actively exploring to interpret different object surfaces—stereognosis).
 - Take the opportunity to feel objects in your environment and identify the objects without looking at the object.
 - Put small objects in bowls of rice or beans and reach in and try to find and match the objects.
 - Hang different objects from a string on a door jamb; start the objects swinging and allow them to stimulate your hand. See whether you can differentiate the different objects as they move across your hand.
 - ii. Modify the difficulty of the sensory task.
 - Change the intensity of the sensory stimuli (e.g., make the surfaces less distinct).
 - Increase the challenge or the complexity of the stimuli you are trying to identify.
 - Change the environment in which you are exploring the sensory stimuli (e.g., hand in water, still or agitated; in shaving soap; in whipped cream as you discriminate an object or manipulate a pen).
 - Change the position you assume when discriminating the stimulus (e.g., lie down on your back or your stomach, stand instead of sitting).
 - iii. Palpate objects in water or other media for identification; have the water be still and then agitate the water.
 - iv. Put pairs of coins and objects in your pocket (or a plastic bag) and try to match them or discriminate between them.
 - v. Purchase clay that can be molded and shaped and then heated until firm.
 - Place or draw different shapes on the clay.
 - Always include a pair of designs that can be matched.
 - vi. Paste matched pairs of items on a card and try to find the matched pairs.
 - Paste stickers with shapes on cards and try to find matched pairs.
 - Paste matched pairs of buttons on a card.
 - Paste alphabet soup letters on a card and match letters or spell words.
 - Put magnetic letters and other shapes on a card or a refrigerator and move them to spell words.
 - vii. Take construction paper and create pairs of letters, shapes, or other designs by pressing heavily with the pen; this will create a raised surface on the other side.
 - With eyes closed, palpate and try to find matching pairs.
 - Turn the paper in different directions to make the exploration different.
 - viii. Make a grab bag of items and reach into the bag and identify the objects by gentle touch.
 - ix. Obtain Braille workbooks and learn to read Braille.
 - If you have trouble learning Braille with the affected side, try with the unaffected side.
 - Do not tense your hand as you feel the letters, and do not extend the adjacent digits away.

Continued

APPENDIX 9-B ■ Specific Learning-Based Sensorimotor Training—cont'd

- Work your hands smoothly over the dots. You can improve your skill, getting other workbooks for the blind and ultimately purchasing books in Braille.
 - Obtain “Braille object cards” where the object is described in Braille. Palpate the letters and sentences.
 - x. Place raised numbers and designs on the computer keyboard and try to determine what the number or shape is before striking the key; make some labeled letters match or mismatch the key itself.
2. Practice activities requiring the interpretation of sensory information delivered to the skin (interpretation of sensory inputs without active exploration of the stimulus, graphesthesia).
- i. Ask a friend to stimulate your skin with different stimuli (e.g., hot, cold, sharp, dull, rough) and try to identify the stimuli.
 - ii. Ask this friend to draw numbers, letters, words (upper and lower case or cursive), and designs on your forearm, hands, and fingers when you are not looking.
 - Identify the letters, numbers, words, and shapes verbally (e.g., start with capital letters).
 - When it is easy to be correct on capital letters, have your friend draw lowercase letters, including words.
 - Progress to having designs drawn on your skin; replicate the design by drawing it on a piece of paper or on your own skin.
 - Ask your friend to give you feedback about the drawing to make sure the drawing matches the stimulus.
 - Check the angles where the lines meet.
 - Note accuracy of detection of curves.
 - Note whether all parts of the design are placed in the right relationship and orientation (spatial accuracy).
 - Note whether the design is the correct size.
 - Check whether the drawing has some elaborate components that were not actually drawn on the surface of the skin.
 - Your friend should make the drawings smaller and smaller to increase the challenge of detection (e.g., 2 to 3 mm).
 - The drawing or the stimuli should be delivered two or three times. If the design is still missed, look at the design. After viewing the design, repeat the design at the next trial (or the alternate trial), and before progressing determine whether you can recognize the drawing). Use a friend to check on your accuracy.
3. Use other stimuli to reinforce somatosensory learning.
- i. Develop tasks to improve sound discrimination (either location or determination of whether you hear one or two sounds delivered).
 - ii. Have a visual stimulus provided at the same time an object is touched to the skin (on the affected and unaffected side); the goal is for you to accurately describe the cutaneous stimulus (e.g., sharp, dull, smooth, rough, silky, hard, soft).
4. Develop activities to emphasize proprioceptive and kinesthetic learning.
- i. Where necessary, use tape on the skin, use electrical or auditory biofeedback, or put weights around the wrist and ankle to increase feedback from joint, tendon, and muscle receptors.
 - ii. Create games in which a part of an object has to be accurately placed on a topographical picture.
 - iii. Create games in which objects have to be moved accurately across specific distances on a variable surface.
 - iv. Create objects of the same weight and place different types of surfaces on the object (e.g., Velcro, sandpaper, flooring). Then practice picking up, moving, and putting down the object with minimal effort.
 - v. Assemble puzzles by feeling the matching pieces rather than looking with the eyes.
 - vi. Work with a friend and practice copying movements together (first by looking and then by feeling).
 - Tap one finger while the other fingers are resting down.
 - Bring arms up over head and tap one finger at a time.
 - Bend wrist with one arm and bend elbow with other arm.
 - Circle wrist to the right (right hand) and circle to the left with left hand.
 - vii. Have a friend give you some resistance as you move one finger, the wrist, or the forearm up and down.
 - viii. On a piece of paper, draw hand diagrams with different angles of each finger and different angles of the wrist. Then put up a vertical screen where you cannot see your hand. Look at each picture and try to copy the pictures with your own hand. Look behind the screen to check to see how accurate you are.
 - ix. See if you can rent a continuous passive motion machine.
 - Set the machine at different speeds.
 - Try to follow the movements of the machine.
 - Apply vibration to the skin over the joint in the direction opposite to the movement.
 - Carefully time the movements to enable success.
 - x. Practice grasping objects with a light grip on the object. Use a spherical group (thumb pad to the pads of other fingers). Practice this with objects of different size with minimum graded force.
 - xi. Practice bending and straightening the elbow, wrist, or fingers while applying vibration to the appropriate joint.
 - When bending (flexing) the joint, apply vibration on the extensor surface.
 - When straightening the joint, apply vibration on the flexor surface.

E. Sensory and Fine Motor Activities at Nontarget Tasks

1. Move in normal patterns in desired directions without excessive firing of the muscles.
 - i. Consider a number of strategies to allow you to move the most difficult finger more easily (e.g., stabilize adjacent digits).
 - Use a soft splint to stabilize the fingers adjacent to the finger you want to move.
 - Mold a piece of clay; keep an area clear under the finger you want to move, and place a hole in the clay for the other fingers to rest in.
 - Put a buddy strap on fingers adjacent to most dystonic or painful finger.
 - Put tape on the fingers on the surface that would be most likely to improve movement (e.g., on the flexor surface if the finger extends; on the extensor surface if the finger flexes; on the side of the finger if having difficulty with isolation).
 - Use a finger interphalangeal splint on fingers adjacent to dystonic fingers.
 - ii. Increase sensory feedback on the finger you are trying to move (e.g., use tape on the finger).

APPENDIX 9-B ■ Specific Learning-Based Sensorimotor Training—cont'd

2. With the eyes closed, play games that require discrimination of sensory information through the skin of the fingers.
 - i. Play dominoes.
 - ii. Play pick-up sticks.
 - iii. Play shape games (e.g., match a shape to an opening, such as in *Perfection*).
 - iv. Put together puzzles that have a raised surface.
 - v. Play Scrabble with raised or indented letters.
 - vi. Play games that require orientation in place without the benefit of vision.
 - Play pin the tail on the donkey.
 - Walk through the house with your eyes closed and hands out to feel objects in your way and to catch yourself if needed.
 - vii. Get a Braille deck of cards and play cards (e.g., *Solitaire* can be played alone; play hearts, bridge, pinochle, or poker with others).
 - viii. Create other sensory games that require planning and control and that can be played without vision.

F. Learning-Based Sensorimotor Retraining (Praxis)

1. Feel objects and then define and demonstrate what to do with the objects.
2. Have a friend provide a sensory stimulus and ask you to do something that indicates you felt the stimulus (e.g., “when I tap with this sharp object, I want you to tap once, but when I touch you with this dull object, I want you to tap twice”).
3. Feel a number of items in a bag that are related to performing a task, and put the items together to do the task.
4. Feel a number of objects put together in a specific design; have someone give you a second set of the objects to replicate or match the design.
5. Practice throwing objects of different size; practice throwing them to a particular spot.
6. Get accustomed to grading movements without uncontrollable contractions.
 - i. Place the hand on a moving target and do not stop the movement.
 - ii. Manipulate objects without excessive force.
 - iii. Put your hand on a record player and do not stop the record movement (e.g., do not change the sound).
 - iv. Put your hand on the moving belt of a treadmill and feel the moving belt.
 - Feel the belt moving under the hand.
 - Hold objects under the fingers.
 - Pass objects back and forth between the fingers, and make the objects feel the same.
7. When it is possible to perform the sensory activities in nontarget tasks, begin placing the hand on the target instrument without abnormal movements.
 - i. With the hand on the target instrument, mentally rehearse the movements and the tasks you should perform.
 - ii. Add rough surfaces to the target instrument if necessary to change the interface with the hand.

G. Sensorimotor and Fine Motor Training at Target Tasks

1. Emphasize the sensory aspects of the task even when beginning to perform the target task.
2. Perform a selected component of the task (e.g., drop one finger down on the keyboard).
3. Progress the ability to complete more and more of a target task, emphasizing sensory exploration as long as the tasks can be done normally.

4. Be sure to get reinforcement for performing all tasks normally (e.g., use a mirror, use biofeedback, get verbal feedback).
5. Have someone make a video performing the target task with which you are having trouble. Then try to copy the movements. Watch the movements carefully and imagine that the movements are your hands moving.
6. Perform the target task in different, nontraditional positions (e.g., practice in nontraditional positions such as lying on the back, lying on the stomach, reaching hand behind you or over your head).
7. Do the target task in different media (e.g., if having a problem with writing, draw shapes and letters in shaving soap; draw big letters and then small letters and then words).
8. Provide external support of the affected hand to appropriately position the digits (e.g., a splint if necessary to prevent movement of adjacent digits) while doing sensory and sensorimotor tasks on the target instrument.
 - i. Begin with a single digit adjacent to the most involved digit, but not the most involved digit.
 - ii. When you can do complex sensory exploration with a single finger without abnormal movement, combine sensory exploration with more complete target movements.
 - iii. Add multiple digits to the sensorimotor tasks.
9. Without externally supporting the position of the digits (e.g., all digits free) perform one simple movement on the target task.
 - i. Integrate sensory exploration with the simple movements and do the movements slowly, in time with a metronome.
 - ii. Increase the complexity of the sensory-driven motor tasks (e.g., tapping single note to playing scales and chords to playing new music or performing new keyboard tasks).
 - iii. Increase the speed of the movements on the target task, keeping up with the metronome.
 - iv. Perform the target task normally for brief periods, and progress the practice time slowly with frequent breaks.

H. Reinforcing Sensorimotor Learning with Feedback

1. Biofeedback can include visual, cutaneous, muscle, vibration, auditory, or stretch stimuli.
2. Biofeedback can be supervised by another person, facilitated with robotic movements, controlled by electronic contraction (activation of muscles), or controlled by a physical constraint of a limb; guided repetitive passive movements can be supplemented with active movements to control motor output.
 - i. Put tape on the top of the skin over the extensor surface of the digits to limit motion or emphasize somatosensory input and feedback.
 - ii. Use multichannel biofeedback to learn how to avoid abnormal movement strategies.
 - Practice isolated movements and stop practice of unnecessary co-contractions of agonists and antagonists.
 - Use the small muscles inside the hand (intrinsic muscles) to move the digits instead of the extrinsic muscles.
 - Use imagery with mental rehearsal and practice to help restore the image of performing the task normally (see [Appendix 9-C](#)).

I. Return to Work

1. Try to return to work part time.
2. Discuss other work options if you cannot resume the original job tasks.
3. Make ergonomic modifications at the workplace.
4. Integrate stress-free techniques.
5. Take frequent brief breaks.
6. Walk or do other exercises at lunch time.

APPENDIX 9-C ■ Enhancing Learning-Based Sensorimotor Training: Use of Imagery, Mental Rehearsal, and Mental Practice

A. General Comments about Imagery

It is critical to restore confidence, a sense of wellness, and normal control of the movements of the extremities and trunk. Initially this may be difficult because of pain, lack of accurate sensory information, and difficulty with the control of movement or imagining that the hand or arm could be normal again. One way to begin to restore the accuracy of the information processing system so you can use your hand normally is to begin by changing how the hand and the functional task you are trying to perform are represented on your brain (the internal representation of that injured part).

It is important to be able to restore the normal image of the involved limb, that is, how it used to be and how it will be normal again. In the process of restoring normal control, it is also important to begin to use the hand normally and not increase the pain or repeat the abnormal movements. Thus, visually imagine your hand and how it looks. Making your hand look like the other hand is a good beginning. Then begin to create an image of the hand and the task you want to perform. Imagine using the hand normally to perform all the usual and target tasks. You can start by imaging small parts of a larger task and then finally the whole task and then related skills and activities that would be associated with performing the task.

With advances in magnetic resonance imaging, we can more readily confirm the recruitment of brain processes with imagery. It is possible to activate functional, motor, and sensory representations of the hand with mental imagery. The area of the brain recruited is dependent on the activities imagined by the individual. For example, you have many different maps of your body. Some of the topographical maps may be redundant across different parts of the central nervous system (e.g., motor cortex, sensory cortex, prefrontal cortex, thalamus, basal ganglia). Well-learned functions are also mapped separately from sensory and motor topography. When you visualize a body part, you will activate the somatosensory cortex. When you imagine doing the task (motor imagery), you will also activate the motor cortex. When you can visually and motorically imagine completing the task in your mind, you will activate the cortical areas representing the part of your body that is moving and the part of the brain that is devoted to completing that task (e.g., walking, writing, playing an instrument). The intensity with which the neurons fire when you are imaging is less than the intensity of firing when you are actually performing the task. Try to imagine performing your tasks without mistakes. This will reinforce the positive aspects of the sensorimotor feedback. You must imagine without interruption (e.g., attention), and you must repeat the imaging process with a high level of concentration to help the nervous system learn. If you are imaging and you run into difficulty completing a task normally, try to focus on the source of the difficulty, including asking your inner self what barriers are getting in the way. Once you can get insight into these barriers, you should be able to break them down.

During imaging or mental practice, approximately 30% of the neurons are recruited as would be recruited when the task is physically executed. Furthermore, when learning a new task, more neurons are recruited than when the task is learned. An impairment of structure (e.g., neurological or musculoskeletal) could modify the ability to image performing a task normally. On the other hand, imaging normal function and task performance could be easier than actually executing normal performance. In addition, repetitive imaging could begin to drive neural adaptation and recovery.

When there are conditions of chronic pain, there are changes in the organization and representation of the painful part in the central nervous system (e.g., cortex, thalamus, prefrontal cortex, supplemental motor cortex). Similarly, repetitive, abnormal patterns of movement also can dedifferentiate the representation of the body part. Thus, intervention must focus on restoring the normal representation of the brain. Sometimes it is easier to imagine normal movement or pain reduction than it is to actually change the pattern of movement or turn off the “on cells” for pain.

B. Suggestions for Goal-Directed Imaging

1. Set goals for yourself to specifically improve the function of your hand.
2. Follow a sequence for learning.
 - a. Imagine that you are healthy and fit and have full normal control of all of your extremities.
 - b. Focus on healing the involved tissues, particularly if you have signs of inflammation and pain.
 - i. Focus on diaphragmatic breathing and bringing blood to the tissues.
 - ii. Imagine the blood carrying important elements to the area of injury (e.g., the growth factors and oxygen that are requisites for healing tissues).
 - iii. Imagine that an injury causes inflammation that triggers the healing response (e.g., laying down collagen [scar]). Also imagine that the body modifies the scar tissue and tries to keep it mobile.
 - c. Visualize the anatomy, physiology, and kinesiology of the hand.
 - i. Imagine the bones gliding smoothly on one another.
 - ii. Imagine the muscles being strong, with a balance between the intrinsic and extrinsic muscles that serve the hand.
 - iii. Imagine normal movement patterns.
 - iv. Imagine normal sensation in the hand.
 - d. Imagine pain-free movement.
 - e. Imagine the hand being quiet and relaxed.
 - f. Imagine smooth control of the hand without involuntary extraneous movements.
 - g. Imagine that the affected hand is working just like the unaffected hand.
 - h. Imagine using the hand as you used to use it. Go back in time to when your hand felt good and you did not have any problems.
 - i. When mentally practicing and imaging, there should be no distractions. Spend at least 30 to 60 minutes a day normalizing the hand and imagining how good it feels.
 - j. Mentally practice and perform the target task without any signs of strain or pain.
 - k. Concentrate and mentally review each of the components of the hand working normally.
 - l. Concentrate on the free flow of rhythmic movements of the hand and arm as you walk.
 - m. Recapture the excitement of using your hand while playing your instrument or working at your job without pain or strain.
 - n. Reinforce the image of a normal hand by continuing to progress learning, including more complex tasks and public performances.

 ICD-9-CM
 ICD-10-CM
 Medicaid
 Medicare
 prospective payment system
 reasonable and necessary
 skilled services
 third-party payer

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Value the importance of documentation and its relationship to payment for services.
2. Synthesize different inpatient and outpatient payment systems.
3. Differentiate the continuum of care and documentation needed in different treatment settings.
4. Appropriately assign an ICD-9-CM code to medical and functional diagnoses.
5. Identify and select the CPT codes that best describe therapeutic interventions used in treating patients.
6. Analyze how payment policy can affect patient outcomes.

IMPORTANCE OF DOCUMENTATION

Physical therapists (PTs) and occupational therapists (OTs) are in the business of providing a health care service to improve quality of life. Because of the myriad insurance options available from both private and government-run programs, people rarely pay cash (self-pay) for physical and occupational therapy. Therapists want to be paid a “fair” amount for their skills and knowledge, but they generally rely on a third party to provide this payment. Clinicians must convince the third-party payer, an entity that was not present and did not receive the therapeutic interventions, that the patient received valuable, unique, and worthwhile services. Documentation is one method used to persuade the third-party payers to pay for the professional services provided.

Documentation is a skill a therapist must acquire. Its importance is equivalent to other forms of therapy skills. Documentation creates a lasting impression of the practitioners who represent the profession. Occupational therapy and physical therapy are an imperative and integral part of patient care; the documentation must reflect that. In addition, PTs and OTs are legally responsible for interventions provided by personnel under their supervision. Therapists then depend on other people to interpret their documentation and, on the basis of contracted rates, determine how much should be paid for each service. Third-party payers often submit documentation to peer reviewers to ascertain excessive, useless, or fraudulent treatments.

Securing payment for services rendered is, and will continue to be, a crucial element for the therapist as a professional as well as for the therapist’s livelihood. Documentation, which is a legal and professional responsibility, is the basis for billing and is the proof that treatment was provided.

Documentation is critical for success in the payment appeals process. For these reasons, documentation and payment for services are tightly linked together. This chapter will look at the payer sources at the national level and their required documentation components for payment.

It is important to remember that all the federal programs mentioned in this chapter are constantly changing. The process of legislating health care is dynamic and will be significantly modified in the next several years because there are not enough dollars available to cover the projected total costs. The supply of funds is in direct conflict with both the increased numbers of patients and their need for services. Major changes must occur in the future to enable health care, as expected by the public, to survive. One of the keys to these changes lies in documentation. A new national health policy plan for United States citizens was voted on and accepted in the spring of 2010, and new payment schedules or structure may be the outcome; but the need for documentation will remain constant, and documentation will always be a tool used for evaluating and justifying payment for services.

Why document? Documentation provides baseline status, records pertinent information, measures progress and success, fulfills predictions, and declares the final outcomes. It creates a record of the appointments the patient or client had. It provides data for concurrent or retrospective audits as well as evidence for research. It serves as an itemized bill for services rendered. The medical record may also become evidence in legal proceedings, which can either defend or incriminate the clinician. Documentation provides a snapshot of a period of time that gives the reviewer a full and practical description of the status of patients and the impact care has made on their quality of life.

Who reads the medical record? Although many therapists seem to believe that documenting is a necessary evil with no particular purpose, the information that therapists provide is vitally important. Physical and occupational therapy documentation is read by colleagues in the same or related disciplines to affect or continue the plan of care (POC). It is also read by physicians and discharge planners to assist in determining additional treatment or surgical options or placement opportunities. Insurance case managers rely on documentation for the assessment of proper use of services. OT and PT documentation is read by employees of third-party payers who may be screening for proper dates and codes or for predicted outcomes in a reasonable time frame. Therapists do not want to have payment denied for any reason; therefore it is extremely important that the documentation clearly present all the pertinent information in a manner that is easily understood by all parties.

DEFINITION OF TERMS

There is an entire language of terms regarding payment issues. Please refer to the Quick Reference Guide to Acronyms (Appendix 10-A) for assistance. When therapy services are received, either the person pays the therapist directly or someone else pays the bill. Generally a patient will pay directly for therapy in three circumstances: (1) having a need for skilled services and not having insurance; (2) having had therapy interventions, understanding their value, and wishing to continue beyond what insurance is willing to cover; or (3) having a preference for a specific therapist who accepts only cash payment or who is not a preferred provider of the insurance company. When someone else pays the bill, it is the third-party payer that is billed for the services. Third-party payers are usually insurance carriers who, by contract or written agreement, may determine the maximum amount of money paid and under what circumstances.

Private health insurance is either purchased by a consumer or provided to people as a benefit of employment. People may have additional coverage by paying for it or as a result of being a dependent on someone else's insurance plan. This secondary insurance may pay for the portion of the bill that is unpaid by the patient's primary insurance. In the case of Medicare coverage, Medicare beneficiaries can purchase supplemental insurance that will pay some or all of the charges that are not part of their Medicare benefit. As the federal government is taking on a larger role in making sure individuals are insured by setting up a National Health Insurance System, the payer for the therapeutic services may change, but the fact remains that someone or a group of insurance carriers will pay for services rendered.

Health care services, for purposes of payment, are generally divided into three groups: inpatient, outpatient, and home health services. Inpatient services are delivered to patients staying in a hospital or health care facility. Outpatient services are delivered to patients who receive service by going to a health care provider. Home health agencies (HHAs) deliver services to patients in their own homes. Medicare services are processed and paid for by Medicare Administrative Contractors (MACs). MACs are responsible for administering Medicare programs in 15 jurisdictions comprised of two or more states. MACs are private companies that have been awarded contracts by the Centers for Medicare and Medicaid Services (CMS) for processing all

Part A and Part B claims within their geographical jurisdictions. MACs have the ability to accept or deny claims made to them for payment on the basis of their interpretations of the CMS guidelines. Medicare Parts A and B are discussed in more detail later in this chapter.

COBRA (from the Consolidated Omnibus Budget Reconciliation Act of 1985) refers to short-term interim insurance coverage. It allows people whose employment benefits have been terminated to have continuing employer-sponsored group health coverage temporarily. The American Recovery and Reinvestment Act of 2009 (ARRA) has expanded premium assistance to some people who qualify.

Workers' compensation is coverage for people who have been injured on the job. These regulations are determined at both national and state levels. Workers' compensation is discussed in greater detail later in this chapter.

Correct billing and claims processing are also dependent on accurately communicating treatment diagnoses and interventions to third-party payers. Three primary coding systems are used to communicate diagnoses and interventions in health care. The International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) is a tabular list of medical diagnoses approved for use by CMS based on the World Health Organization's ICD-9, originally published in 1977. Current Procedural Terminology (CPT) (a registered trademark of the American Medical Association [AMA]) is a coding system that describes health care interventions. CMS has developed its own coding system to meet the specific requirements of the Medicare and Medicaid programs. The Healthcare Common Procedure Coding System uses CPT and alphanumeric codes developed by CMS in conjunction with the AMA to describe interventions, procedures, and supplies for the Medicare and Medicaid programs.¹ Use of these coding systems is discussed in greater detail later in this chapter.

FEDERAL PROGRAMS

Medicare and Medicaid

"Medicare is a health insurance program for people age 65 or older, people under age 65 with certain disabilities, and people of all ages with end-stage renal disease . . . (permanent kidney failure requiring dialysis or a kidney transplant)."² The Medicaid program provides medical benefits to groups of low-income people, some of whom may have no medical insurance or inadequate medical insurance.³ Although the federal government establishes general guidelines for the program, the Medicaid program requirements are actually established by each state. Whether or not a person is eligible for Medicaid will depend on the state where he or she lives.

"President Truman was the first President to propose a national health insurance plan."⁴ Congressional debate about federal health care coverage continued for 20 years. In 1965, HR 6675, the "Mills Bill," was introduced. "Congressman Wilbur Mills, Chairman of the House Ways and Means Committee, created what was called the 'three-layer cake' by starting with President Johnson's Medicare proposal (Part A), adding to it physician and other outpatient services (Part B), and creating Medicaid which significantly expanded federal support for health care services for poor elderly, disabled, and families with dependent children. Medicare became Title 18 of the Social Security Act and

Medicaid became Title 19.”⁴ Although HR 6675 passed the House without a single amendment, the Senate version required much more discussion and many amendments. Finally, Medicare Part A, which involves basic hospital benefits and other institutional services for the elderly; Medicare Part B, a voluntary program; and Medicaid were approved by both the House and Senate.

Medicare and Medicaid implementation did not begin until 1966. Initially, “Medicare was the responsibility of the Social Security Administration (SSA), the agency that controlled the retirement social insurance program through which most people became eligible for Medicare. Federal assistance to the State Medicaid programs was administered by the Social and Rehabilitation Service (SRS). SRS oversaw welfare programs including Aid to Families with Dependent Children (AFDC), through which many people became eligible for Medicaid. SSA and SRS were agencies in the Department of Health, Education, and Welfare (HEW). In 1977, HEW Secretary Joseph Califano reorganized the department to create the Health Care Financing Administration (HCFA). HCFA was designed to improve administration of both Medicare and Medicaid by moving both health programs together, to improve the staffing of the Medicaid program, and to create a new administrative structure to implement national health insurance. In 1980, HEW was divided into the Department of Education and the Department of Health and Human Services (HHS). In 2001, Secretary Tommy G. Thompson renamed HCFA to become the Centers for Medicare and Medicaid Services (CMS) as part of his initiative to create a new culture of responsiveness in the agency.”⁴

“Coverage for Medicare Part A is automatic for people age 65 or older (and for certain disabled persons) who have insured status under Social Security or Railroad Retirement. Most people don’t pay a monthly premium for Part A. Coverage for Part A may be purchased by individuals who do not have insured status through the payment of monthly Part A premiums. Coverage for Part B also requires payment of monthly premiums. People with Medicare who have limited income and resources may get help paying for their out-of-pocket medical expenses from their state Medicaid program. There are various benefits available to ‘dual eligibles’ who are entitled to Medicare and are eligible for some type of Medicaid benefit. These benefits are sometimes also called Medicare Savings Programs (MSPs). For people who are eligible for full Medicaid coverage, the Medicaid program supplements Medicare coverage by providing services and supplies that are available under their state’s Medicaid program. Services that are covered by both programs will be paid first by Medicare and the difference by Medicaid, up to the state’s payment limit. Medicaid also covers additional services (e.g., nursing facility care beyond the 100-day limit covered by Medicare, prescription drugs, eyeglasses, and hearing aids). Limited Medicaid benefits are also available to pay out-of-pocket Medicare cost-sharing expenses for certain other Medicare beneficiaries. The Medicaid program will assume their Medicare payment liability if they qualify.”⁵

The Balanced Budget Act of 1997 (BBA) made the most significant changes to the Medicare and Medicaid programs since their implementation. One goal was to shift some of the financial stress to the private sector, which was accomplished

by allowing Medicare beneficiaries options for additional types of health plans. The BBA also reduced hospital payments, which had considerable consequences in the health care industry. This was one reason that the Balanced Budget Refinement Act of 1999 (BBRA) was introduced. The BBA was also designed to address fraud, abuse, and waste in the federal health care programs.

The BBA also created the Children’s Health Insurance Program (CHIP), also known as Title XXI of the Social Security Act. “CMS administers this program, which helped states expand health care coverage to over 5 million of the nation’s uninsured children. The program was reauthorized on February 4, 2009, when President Obama signed into law the Children’s Health Insurance Program Reauthorization Act of 2009 (CHIPRA or Public Law 111-3). CHIPRA finances CHIP through fiscal year 2013. It will preserve coverage for the millions of children who rely on CHIP today and provides the resources for states to reach millions of additional uninsured children. CHIP is jointly financed by the federal and state governments and is administered by the states. Within broad federal guidelines, each state determines the design of its program, eligibility groups, benefit packages, payment levels for coverage, and administrative and operating procedures. CHIP provides a capped amount of funds to states on a matching basis. Federal payments under CHIP to states are based on state expenditures under approved plans effective on or after October 1, 1997.”⁶

At least two other federal laws affect children who may not have sufficient health care coverage. The Elementary and Secondary Education Act of 1965 (ESEA), reauthorized as the No Child Left Behind Act of 2001 (NCLB), is standards-based education reform that is directed at disadvantaged students. IDEA, the Individuals with Disabilities Education Act, provides for early intervention, special education, and related services to children with disabilities.⁷

Health Insurance Portability and Accountability Act of 1996

The Health Insurance Portability and Accountability Act of 1996 (HIPAA) is a legislative effort to improve insurance coverage of the work force and also to improve the continuum of care by switching health care records away from paper and into the computer age.

Title I of HIPAA refers to health insurance reform. This reform increases the opportunities for workers to maintain or acquire insurance coverage when they lose or change jobs.

Title II of HIPAA relates to administrative simplification. These provisions are more closely associated with documentation and payment for services. The purpose of administrative simplification is to create a national database for medical records to ease communication among health care agencies. However, this led to concerns about privacy and security of vital information as a result of easily accessible online medical records. This prompted HHS to also include a privacy rule and a security rule. “The Standards for Privacy of Individually Identifiable Health Information (‘Privacy Rule’) establishes, for the first time, a set of national standards for the protection of certain health information. HHS issued the Privacy Rule to implement the requirement of HIPAA. The Privacy Rule standards address the use and disclosure of individuals’ health information—called protected health information (PHI) by organizations

subject to the Privacy Rule, called covered entities—as well as standards for individuals' privacy rights to understand and control how their health information is used. Within HHS, the Office for Civil Rights (OCR) has responsibility for implementing and enforcing the Privacy Rule with respect to voluntary compliance activities and civil money penalties.

“A major goal of the Privacy Rule is to [ensure] that individuals' health information is properly protected while allowing the flow of health information needed to provide and promote high-quality health care and to protect the public's health and well-being. The Rule strikes a balance that permits important uses of information, while protecting the privacy of people who seek care and healing. Given that the health care marketplace is diverse, the Rule is designed to be flexible and comprehensive to cover the variety of uses and disclosures that need to be addressed.”⁸

“While the Privacy Rule mandates policies and procedures to protect patient information in all forms, the purpose of the Security Rule is to adopt national standards to protect the confidentiality, integrity, and availability of electronic protected health information. This Rule is directed at the covered entities, which are health care providers, health care clearinghouses, and/or health plans, that transmit or maintain protected health information electronically [and] are required to implement reasonable and appropriate administrative, physical, and technical safeguards. The Security standards require that steps be taken to protect this information from reasonably anticipated threats or hazards. Built into the Security Rule, however, is some flexibility that allows covered entities to determine what is reasonable and appropriate based on their size, cost considerations, and their existing technical infrastructure. This built-in flexibility also makes allowances for the rapid changes in technology.”⁹

“On July 27, 2009, Secretary of the Department of Health and Human Services Kathleen Sebelius delegated authority for the administration and enforcement of the Security Standards for the Protection of Electronic Protected Health Information (Security Rule) to [OCR].” This action will improve HHS's ability to protect individuals' health information by combining the authority for administration and enforcement of the federal standards for health information privacy and security called for in HIPAA. The HIPAA Privacy Rule is also administered and enforced by OCR.

“Congress mandated improved enforcement of the Privacy Rule and Security Rule in the Health Information Technology for Economic and Clinical Health (HITECH) Act, part of the American Recovery and Reinvestment Act of 2009. Privacy and Security are naturally intertwined, because they both address protected health information. Combining the enforcement authority in one agency within HHS will facilitate improvements by eliminating duplication and increasing the efficiency of investigations and resolutions of failures to comply with both rules. Moreover, combining the administration of the Security Rule and the Privacy Rule is consistent with the health care industry's increasing adoption of electronic health records and the electronic transmission of health information.”¹⁰

The federal government is helping businesses to achieve the HIPAA-mandated goals of improved and efficient health care while protecting the privacy of the recipients and the

security of their information. The well-being of a person is reflected not only in her or his treatment but also by the integrity of the system to keep personal information confidential. HIPAA and its consequences directly relate to documentation standards and handling of PHI.

Prospective Payment Systems

Years ago, people received therapy in hospitals, Medicare was billed, and the hospital was paid. Physical and occupational therapy departments were among the highest money-makers in the hospital. This, unfortunately, led to excessive billing and resulted in the need for improved accounting. More recently, CMS has established stricter requirements in an effort to control spending and to have money available for future generations. These requirements also benefit patients today by accelerating the establishment of a medical diagnosis, allowing for faster implementation of therapeutic interventions and preventing billing or payment for unskilled services. Currently, under the prospective payment system (PPS), hospitals are paid a set amount per patient. The amount depends on the medical diagnosis and related morbidities. Payments are no longer related to the length of stay or procedures ordered. It is the hospital's responsibility to maximize its income by minimizing the patient's stay.

The Social Security Amendments of 1983 were responsible for the plan to save taxpayers money by creating incentives to improve efficiency in acute-care hospitals. This system applied to Part A Medicare beneficiaries and was designed to give the hospitals a lump sum for patients who fit into certain categories.

“Section 1886(d) of the Social Security Act (the Act) sets forth a system of payment for the operating costs of acute-care hospital inpatient stays under Medicare Part A (Hospital Insurance) based on prospectively set rates. This payment system is referred to as the inpatient prospective payment system (IPPS). Under the IPPS, each case is categorized into a diagnosis-related group (DRG). Each DRG has a payment weight assigned to it, based on the average resources used to treat Medicare patients in that DRG.”¹¹

Use of the IPPS and DRGs, in which Medicare payments are established in advance and determined by the medical diagnosis at discharge, created the opportunity to transform hospitals into more efficient and cost-effective organizations. It also became essential to accurately determine the discharge diagnosis of patients in the hospital. Appropriate “coding” of patients developed in the Health Information Management Departments of hospitals to determine the correct DRG and corresponding payment.

Although the DRG is associated with an average hospital cost per diagnosis and is calculated on a per-case-at-discharge basis, the actual payment is affected by many factors. There are two different paths that contribute to the final payment: the operating, or labor, expenses, and the capital, or nonlabor, expenses. On the operating expenses side, the wage index incorporates local labor costs. Cost of living adjustments are made on the capital side. Also taken into account is the geographical area (rural versus urban) where the hospital is located. To adjust for case mix, each DRG is weighted relative to its complexity against the other individual DRGs. There are several other possible factors contributing to the DRG payments. The indirect medical education adjustment is allocated when the hospital is an approved teaching hospital

for graduate medical education. The new technology adjustment is granted if the hospital is using expensive new technology that significantly improves clinical outcomes. The disproportionate share of the hospital adjustment is provided to hospitals that treat a higher percentage of low-income patients. An outlier is an exceptionally expensive course of treatment that qualifies for additional funding. DRG payments may be reduced if the patient's length of stay is shortened by a transfer to another acute-care hospital or post-acute-care setting. Fiscal year 2009 completed the transition to MS-DRGs, which are based on secondary diagnosis codes and provide more specific information for resource allocation. Medicare Severity (MS) divides cases into three levels. MCC, major complications with comorbidities, is the most severe. CC refers to complications with comorbidities, and Non-CC, or no complications with comorbidities present, is the least likely to require additional hospital resources.

With the success of the IPPS in acute-care hospitals, additional legislation mandated extension into other settings with Medicare Part A beneficiaries. The BBA, the BBRA, and the Benefits Improvement Act of 2000 (BIPA) moved the PPS into skilled nursing and inpatient rehabilitation facilities (IRFs), HHAs, hospice, hospital outpatient, inpatient psychiatric facilities, and long-term care hospitals (LTCHs). Payments for each are based on different classification systems, although therapy services remain included in the lump sum. The basic payment in each facility may also be adjusted by the factors listed in the previous paragraph.

The initial PPS has encouraged the use of modified versions of this payment system by nongovernment third-party payers. Today, most inpatient services are covered by prospectively paid contracts with hospitals and health care facilities. Services not covered by prospective payment arrangements are often covered by per diem contract arrangements that pay a flat rate per day for inpatient services.

Outcome Measures

CMS has developed different methods of determining payment in the PPS for the various settings. In almost every case, the initial status of the patient determines the amount of money the facility will receive. Generally, the more complicated the patient's condition, the higher the reimbursement rate. The facility must then have a system to create a preliminary comprehensive "snapshot" of patients within days of their arrival at that particular setting. To ensure that patients receive the same standard of care and are treated equally, all patients are assessed by use of the Medicare preferred tools, even if they do not have Medicare coverage.

In the inpatient acute rehabilitation facility, the preferred tool is the Inpatient Rehabilitation Facility–Patient Assessment Instrument (IRF-PAI) to assist in determining the payment amount. The Resident Assessment Instrument (RAI) is the primary tool in subacute and skilled nursing facilities, and OASIS (Outcome and Assessment Information Set) is used in HHAs. These tools are discussed in more detail later in this chapter.

With each of these outcome measurement tools and in each setting, therapy documentation in the medical record must validate the tool's ratings. Each tool is completed when the patient is admitted to the program and also at the time of discharge. As the patient progresses, it is very important for

therapy documentation to reflect improvement and goal achievement. Because of the relative insensitivity and ordinal scales of these comprehensive instruments, a significant amount of functional change is often required to document improvement from one level to the next.

It is expected that third-party payers will begin to use the outcome measurement tools as a way of assessing the performance of different facilities. With this information available for comparison, physicians and payers may choose to admit patients to those facilities that provide the best outcomes in the fewest number of days.

The IRF-PAI, RAI, and OASIS were developed with essentially the same goals in mind: (1) to measure patient outcomes and (2) to improve quality of care. These tools are each used in conjunction with the Medicare PPS to determine payments. However, the functional tools themselves are not related and therefore there is no one system available in the United States to provide "standardized, patient-centered outcome data that can provide policy officials and managers with outcome data across different diagnostic categories, over time, and across different settings where post-acute services are provided (p. 13)."¹² For the future, it is hoped that "functional outcome data that [are] applicable to patients treated across different clinical settings and applications, more efficient and less costly to administer, and sufficiently precise to detect clinically meaningful changes in functional outcomes (p. 23)"¹² will be developed.

Recent legislation instructed CMS to investigate this problem. By 2010, CMS had begun addressing the need for a standardized assessment tool that would be applied from the acute-care hospital to four possible post-acute-care settings (IRFs, skilled nursing facilities [SNFs], HHAs, and LTCHs). Named the Continuity Assessment Record and Evaluation, or CARE, tool, it was being used only in Demonstration Projects at the time of this writing. Similar to the other instruments discussed (IRF-PAI, Minimum Data Set 2.0 [MDS], and OASIS), the CARE tool is initiated at admission and completed at discharge. It incorporates demographics, medical status, cognitive status, and functional abilities. With the electronic medical record, a standardized assessment tool across the continuum of care, and Web-based technology, CMS will then be able to determine and compare specific case-mix outcomes and costs relative to the particular discharge status and setting. This will ultimately be able to guide payment policy.

Inpatient Rehabilitation Facility–Patient Assessment Instrument

In an IRF, the IRF-PAI is required by CMS as part of its PPS. On admission to the IRF, the patient is assigned an Impairment Group Code (IGC), which is the condition requiring a rehabilitation stay. "The IRF PPS uses data from the IRF-PAI to classify patients into distinct groups based on clinical characteristics and expected resource needs. These distinct groups are called 'case-mix groups' or 'CMGs.' To classify a 'typical patient,' one who has a length of stay of more than 3 days, receives a full course of inpatient rehabilitation care, and is discharged to the community, into a CMG, the admission IGC, the admission motor and cognitive scores from the FIM,* and the age at admission are required. The CMG and comorbidity tier determine the unadjusted federal prospective payment rate."¹³

The Patient Assessment Instrument is best known for having incorporated the *Functional Independence Measure (FIM)*¹⁴ along with function modifiers, quality indicators, and additional *patient information*. “The FIM instrument is a basic indicator of severity of disability The need for assistance (burden of care) translates to the time/energy that another person must expend to serve the dependent needs of the disabled individual so that the individual can achieve and maintain a certain quality of life. The FIM instrument is a measure of disability, not impairment. The FIM instrument is intended to measure what the person with the disability actually does, whatever the diagnosis or impairment, not what (s)he ought to be able to do, or might be able to do under different circumstances (p. III-1).”¹⁵

Demographic, payer, medical, admission, and discharge information are included in the IRF-PAI. “The function modifiers assist in the scoring of related FIM items and provide explicit information as to how a FIM score has been determined.”¹⁵ These modifiers apply to bowel and bladder control, tub and shower transfers, and distances covered by walking or in a wheelchair. The FIM instrument specifically addresses the amount of assistance required for the functional activities of eating; grooming; bathing; upper body and lower body dressing; toileting; bladder and bowel management; bed, chair, and wheelchair transfers; toilet transfers; tub transfers; shower transfers; locomotion via walking or wheelchair; stairs; comprehension; expression; social interaction; problem solving, and memory. Each has its own algorithm to determine the FIM score. Quality indicators include respiratory status, pain, pressure ulcers, and safety (balance and falls).¹⁵

The FIM instrument has a total of seven levels of assistance. These are divided into two main categories, Independent—No Helper, and Dependent—Requires Helper. The two items in Independent—No Helper consist of Complete Independence—7 and Modified Independence—6. The highest score of 7 indicates that the patient completes the task safely, in a timely manner, and without any assistive devices. A score of 6 means that the patient requires a device or takes extra time or safety is an issue. The Dependent—Requires Helper category is further divided into two sections: the Modified Dependence—5, 4, and 3 scores, in which the patient provides 50% or more of the effort, and the Complete Dependence—2 and 1 scores, in which the patient’s effort is less than 50%. Supervision or setup, 5, denotes no physical contact with the patient; the patient requires coaxing or someone standing by, or a helper may need to set up the equipment. Minimal contact assistance, 4, includes touching; the patient is doing 75% or more of the activity. Moderate assistance, 3, indicates that more than touching is required, with the patient giving 50% to 74% effort. Maximal assistance, 2, has the patient supplying 25% to 49% of the effort. In Total assistance, 1, the patient performs less than 25% of the workload. There

is a training manual available to assist the clinician in completing this form.¹⁵

A similar data or documentation form is used in pediatrics: the WeeFIM II System. “The WeeFIM instrument was developed to measure the need for assistance and the severity of disability in children between the ages of 6 months and 7 years. The WeeFIM instrument may be used with children above the age of 7 years as long as their functional abilities, as measured by the WeeFIM instrument, are below those expected of children aged 7 who do not have disabilities. The WeeFIM instrument consists of a minimal data set of 18 items that measure functional performance in three domains: self-care, mobility, and cognition.”¹⁶

Resident Assessment Instrument

In SNFs, the PPS is designed to cover the costs of providing care on a daily basis. This includes payment for ancillary services. The BBA required that the payments be adjusted for case mix. Case mix refers to the diversity of patients/residents on the basis of their complexity of medical problems or need for resources. This accounts for the increase in costs of complicated or involved cases. It ensures that facilities accept a variety of patients, rather than only those who require the least amount of services. In SNFs, a method of classifying each resident was developed to adjust the payments relative to the staff resources required to care for and to provide therapy to the residents. There is a higher cost associated with residents who require more resources or one-on-one care by staff. The facility should be reimbursed at a higher rate for these residents than for those who are more independent. Facilities are also reimbursed at a higher rate for residents who are receiving skilled services. All this information is acquired in the RAI, which is composed of three parts: the MDS, the Resident Assessment Protocols (RAPs), and the Utilization Guidelines. The RAI provides a structured method for the facility to create individualized care plans, to communicate on an internal and external basis, and to monitor quality performance. The MDS indicators are factored into the calculations for the Resource Utilization Groups, version III (RUG-III). RUG-III is the complex classification system used by CMS to determine the daily payment rate for the SNF PPS. RUG-III, in addition to many other categories, has a Rehabilitation category with five subcategories that describe the intensity of therapy received. The subcategories are determined by the number of minutes of therapy and the number of therapies each week.

The MDS is completed on a set schedule. After the initial 5-day, then 14-, 30-, 60-, and 90-day reports, the MDS is filed on a quarterly and annual basis. The MDS requires input from residents, their families, physicians, therapists, and dietitians. Facility staff from direct care, social services, activities, billing, and admissions is also consulted. The resident’s performance over the entire 24-hour day is reviewed and recorded to create an individual picture of strengths and needs. The MDS includes a complete review of the resident’s health, sensory systems, activity levels, behaviors, continence, activities of daily living (ADLs), physical and functional status, medications, procedures, and discharge plans. Although the MDS assesses activities similar to those of the FIM, the format is quite different. The Functional Status section is composed of Activities of Daily Living Assistance, Bathing, Balance during Transitions and Walking, Functional Limitations in Range of Motion, Mobility

Devices, and Functional Rehabilitation Potential. The Activities of Daily Living Self-Performance subcategory of Activities of Daily Living Assistance includes bed mobility, transfers, walk in room, walk in corridor, locomotion on unit, locomotion off unit, dressing, eating, toilet use, and personal hygiene. The scoring system is based on an activity occurring three or more times. Use code 0 for Independent, no help or staff oversight; 1 for Supervision—oversight, encouragement, or cueing; 2 for Limited assistance if the resident is highly involved in the activity; 3 for Extensive assistance if the resident is involved in the activity and staff members provide weight-bearing support; and 4 for Total dependence if full staff performance is required every time. This section has a separate but related area to record the ADL Support Provided. In this case, the coding is 0 for no setup or physical help from staff; 1 for setup help only; 2 for one-person physical assistance; and 3 for physical assistance from two or more persons. The MDS has a training manual available to assist with completing the instrument.¹⁷

The RAPs are used to identify problems and to create individualized care plans. Certain responses from the RAPs initiate triggers, which identify potential or actual problems. From the triggers, areas of concern are further researched to determine complications and risk factors in addition to noting the need for referrals to appropriate health professionals. Utilization Guidelines are necessary to analyze the information gathered from the RAPs.

In response to providers, consumers, and others, CMS implemented the new and improved MDS Version 3.0 effective October 1, 2010. This redesigned version incorporated many significant changes. Based on a RAND/Harvard team effort, the MDS 3.0 is much easier to read and accomplishes several goals. These include improved resident input, improved accuracy and reliability, increased efficiency, and improved staff satisfaction and perception of clinical utility. A new development with MDS 3.0 is the addition of the Care Area Assessment (CAA) Process to assist with the interpretation of the information gathered from the MDS. As of October 2010, the RAI components are the MDS 3.0, the CAA process and the RAI utilization guidelines. An updated classification system, RUG-IV, was scheduled to be introduced at the same time as the MDS 3.0. However, while Section 10325 of the Affordable Care Act allowed CMS to implement the MDS 3.0 as scheduled, this same Section mandated a delay of the implementation of the RUG-IV classification system by one year. Portions of RUG-IV were implemented on an interim basis on October 1, 2010. The purpose of RUG-IV is to more accurately allocate payments. RUG-III bases payments on predicted therapy minutes from the MDS, causing inaccurate classifications and payments to SNFs in some instances. RUG-IV calculates the average daily number of therapy minutes based on the actual number of minutes provided to assign patients to Rehabilitation categories. The number of minutes of therapy received affects the reimbursement rate. This is why it is very important to correctly document the time spent treating the resident in addition to the resident's functional status.¹⁸

Outcome and Assessment Information Set

The home health PPS, introduced with the BBA, uses a similar system as do the acute-care facilities, IRFs, and SNFs. There is a standard base payment rate adjusted according to

several variables, including geographical differences in wages, outliers, and the health condition and care needs of the patient. The latter, also referred to as the case mix, is determined by items in the Outcome and Assessment Information Set. On January 1, 2010, HHAs began using OASIS-C version 2.00 at the direction of CMS.

“The Outcome and Assessment Information Set (OASIS) is a group of data elements that represent core items of a comprehensive assessment for an adult home care patient and form the basis for measuring patient outcomes for purposes of outcome-based quality improvement. The OASIS is a key component of Medicare's partnership with the home care industry to foster and monitor improved home health care outcomes. The goal was not to produce a comprehensive assessment instrument, but to provide a set of data items necessary for measuring patient outcomes and essential for assessment—which home health agencies (HHAs) in turn could augment as they judge necessary. Overall, the OASIS items have utility for outcome monitoring, clinical assessment, care planning, and other internal agency-level applications.”¹⁹

The OASIS includes sections on patient demographics, clinical record items, patient history and diagnoses, living arrangements, sensory status, integumentary status, respiratory status, cardiac status, elimination status, neuro/emotional/behavioral status, ADLs *and* instrumental activities of daily living (IADLs), medications, care management, and therapy need and POC. The ADL/IADL category is divided into grooming, upper body dressing, lower body dressing, bathing, toilet transferring, toileting hygiene, transferring, ambulation/locomotion, feeding or eating, ability to plan and prepare light meals, ability to use telephone, prior functioning ADL/IADL, and fall risk assessment. In the OASIS format, choices to describe patient function vary with the activity. Grooming, upper and lower body dressing, and toileting hygiene scales are 0 for independent; 1 for setup, no assistance; 2 if someone must help with the activity; and 3 if the patient is totally dependent. With bathing, the range is from 0, or independent, to 6, bathed totally by another person. For transfers, 0 is independent and 5 is bedfast, unable to move self. Ambulation/locomotion scores are from 0, able to independently walk on even and uneven surfaces, and negotiate stairs with or without railings and no device, to 6, bedfast, unable to ambulate or be up in a chair. Feeding or eating starts with 0 for able to independently feed self and extends to 5, unable to take in nutrients orally or by tube feeding. Ability to plan and prepare light meals (make cereal or sandwich or reheat delivered meals safely) ranges from 0 for independent or was able to but did not before this admission to 2 for unable. Ability to use telephone is 0 for able to dial numbers and answer calls appropriately and as desired to 5, totally unable to use the telephone. Prior functioning requests information about self-care, ambulation, transfer, and household tasks. Finally, the fall risk assessment asks if the patient is at risk for falls. A score of 0 means that no multifactor fall risk assessment was conducted, 1 indicates that the fall assessment was completed but does not indicate a risk for falls, and 2 indicates that the patient is at risk for falls. The care management section assesses the level of caregiver ability and willingness to provide assistance if needed in activities ranging from ADL assistance to patient advocacy. Note that although the OASIS is very precise, it also makes it difficult to measure progress. For example, in the ambulation category, a score of 4 indicates “chairfast, unable to ambulate but is

able to wheel self independently”; 3 indicates “able to walk only with the supervision or assistance of another person at all times”; and 2 indicates “requires use of a two-handed device (e.g., walker or crutches) to walk alone on a level surface and/or requires human supervision or assistance to negotiate stairs or steps or uneven surfaces.”²⁰ This is another example of the importance of documentation to report significant improvement in therapy.

DOCUMENTATION RECOMMENDATIONS

Documentation is communication of the professional judgment used to establish a patient’s POC. Documentation should demonstrate the integration of the elements of patient management that determine the services that, in the professional opinion of the therapist, will provide the best possible outcome for the patient.

Medicare guidelines provide the minimum context standards required for adequate documentation. Satisfying minimum guidelines is not sufficient for the therapist who is thinking critically. This therapist should always be asking determinative questions (Box 10-1).

When the answer to whether therapy is necessary is “no,” document the reason why services will not be rendered. This will explain the therapist’s perspective. Generally this is an obvious decision because the therapist is unable to establish any goals.

When the answer is “yes,” the therapist must be able to answer the additional questions in Box 10-1. These important questions justify treatment and payment. The patient may have insurance or may be receiving federal, state, or county aid. Either way, the therapist must not forget that someone is responsible for paying the bill and that someone deserves a meaningful and beneficial product in return.

The American Physical Therapy Association (APTA) has published *Guidelines: Physical Therapy Documentation of Patient/Client Management*.²¹ These guidelines can be found on the APTA website (www.apta.org) under About Us—Policies and Bylaws—Board of Directors Positions and Policies, Section I—Practice. Although the general guidelines in Box 10-2 were written as part of an APTA document, they set a standard for therapists in the health care industry.

In addition to following APTA’s *Guidelines: Physical Therapy Documentation of Patient/Client Management*, the medical record must follow requirements set forth by other agencies and regulating bodies. CMS sets minimum standards for documentation that are implemented on the local level by fiscal intermediaries or Medicare carriers, as

appropriate. Fiscal intermediaries and Medicare carriers are responsible for acceptance or denial of claims made to them by the acknowledged provider of services. The standards pertaining to “reasonable and necessary” are available from individual fiscal intermediaries and Medicare carriers as local coverage determinations (LCDs).

The LCD standards and other helpful information are available through specific websites or through the Medicare Coverage page of the CMS website (www.cms.gov). Non-government third-party payers can follow guidelines of their own design. These may or may not be similar to Medicare guidelines. In general, when a therapist’s documentation meets Medicare requirements, it satisfies the expectations of other third-party payers as well.

There are other regulating organizations, such as The Joint Commission, licensing boards, or state departments of health services, that set documentation standards to protect consumers of health care services. It is important that therapists be aware of all documentation required by the regulatory agencies associated with their patients when documenting in the medical record. Because of the unique requirements of payers at the various state, county, and local levels, this section of the chapter primarily addresses CMS guidelines for inpatient facilities.

Medicare requires specific information with bills that are submitted for payment. Following these rules will facilitate reimbursement for services because any deviation may be used as a reason for denial of payment. Proper documentation is always necessary for the appeals process when a claim has been denied. Medicare billing must include the following, which are appropriate for both inpatient and outpatient settings.

The patient must be eligible for therapy services on the basis of an active written POC. The POC must be ordered or certified by a physician or by another licensed independent practitioner. Time periods for certification and requirements for return physician visits may vary. These requirements may be different in states with direct access to physical therapy.

In addition, therapy must be a reasonable and necessary treatment for the particular illness or injury. Reasonable and necessary allows a broad interpretation, which is why documentation becomes so important. The following are components that establish medical necessity:

1. Intervention, as related to the specific profession, is an accepted standard of care for this diagnosis. There are specific and effective interventions (evidence-based practice) successfully used to treat the condition.
2. The treatments require the skilled services of a professional. Knowledge and judgment are required because of the complexity of the problem and sophistication of the therapist’s unique body of knowledge.
3. Therapeutic intervention creates significant improvement, demonstrated by measurable gains in range of motion, strength, function, level of assistance, and so on.
4. The amount, frequency, and duration of treatment are reasonable. This is clarified by a POC with short- and long-term goals, predicted end of treatment, and reasonable potential to achieve the stated goals. Weekly reassessments or changes in the patient’s condition will require the plan to be modified as necessary.

Reasonable and necessary are key words for therapists to synthesize as part of the critical thinking process. Two examples are given to assist the reader to further analyze the meaning of these words.

BOX 10-1 ■ DETERMINATIVE QUESTIONS

Is there any therapy-related skilled service that this patient requires?

If yes, what is the unique professional contribution to this person’s rehabilitation?

Are therapy services medically reasonable and necessary and able to be correctly administered in a timely and beneficial way?

What are the therapy services and on what schedule will they be administered?

BOX 10-2 ■ GENERAL GUIDELINES

Documentation is required for every visit or encounter. All documentation must comply with the applicable jurisdictional and regulatory requirements.

All handwritten entries shall be made in ink and will include original signatures. Electronic entries are made with appropriate security and confidentiality provisions.

Charting errors should be corrected by drawing a single line through the error and initialing and dating the chart or through the appropriate mechanism for electronic documentation that clearly indicates that a change was made without deletion of the original record.

All documentation must include adequate identification of the patient/client and the physical therapist (PT) or physical therapist assistant (PTA) (or occupational therapist or occupational therapist assistant):

- The patient's/client's full name and identification number, if applicable, must be included on all official documents.
- All entries must be dated and authenticated with the provider's full name and appropriate designation*.
- Documentation of examination, evaluation, diagnosis, prognosis, plan of care, and discharge summary

must be authenticated by the PT who provided the service.

- Documentation of intervention in visit or encounter notes must be authenticated by the PT or PTA who provided the service.
- Documentation by PT or PTA graduates or other PTs and PTAs pending receipt of an unrestricted license shall be authenticated by a licensed PT, or, when permissible by law, documentation by PTA graduates may be authenticated by a PTA.
- Documentation by students in PT or PTA programs must be additionally authenticated by the PT, or, when permissible by law, documentation by PTA students may be authenticated by a PTA.

Documentation should include the referral mechanism by which physical therapy services are initiated. Examples include:

- Self-referral or direct access
- Request for consultation from another practitioner

Documentation should include indication of no shows and cancellations.²¹

*OT or occupational therapist assistant should use the same documentation system and protocol. Space prohibited using all professionals' initials.

CASE STUDY 10-1

A 60-year-old active, independent woman who falls and fractures her humerus may be, understandably, a little wobbly from the trauma, but she will not need therapy to achieve independent mobility. However, the situation changes completely when the same woman has an existing right hemiparesis, requires the use of a cane for balance, and then fractures her left humerus. Now therapy would be appropriate to address ADLs, safety, and gait to assist her in regaining her independence. Both physical and occupational therapists may be treating this patient, and each professional needs to be following similar processes for thorough documentation.

CASE STUDY 10-2

A patient who lives independently and is admitted to the hospital with a ruptured appendix would not usually require therapy services. The patient would need to spend time out of bed and to ambulate in the hallways to regain endurance, but this may be done with nursing staff or family. If the same patient had comorbidities such as multiple sclerosis or Parkinson disease that were exacerbated by the hospitalization, then therapy would be warranted. Therapy would establish a POC to address the issues that prevent a return to the prior level of function.

Recovery Audit Contractors

As part of the Medicare Modernization Act of 2003, Congress initiated a Recovery Audit Contractor (RAC) demonstration project to fight fraud, waste, and abuse in the Medicare system. "The demonstration resulted in over \$900 million in overpayments being returned to the Medicare Trust Fund between 2005 and 2008 and nearly \$38 million in underpayments returned to health care providers."²² The RACs were so effective that Congressional legislation made them permanent in Section 302 of the Tax Relief and Health Care Act of 2006. This Act expanded the RAC program to cover all 50 states in January 1, 2010. These audits were designed with three purposes in mind: first, to protect Medicare beneficiaries; second, to protect taxpayer dollars used to make payments; and third, to ensure that claims were paid only for services that met Medicare requirements. The RAC teams, which are required to include nurses and therapists, are paid on a contingency fee basis in which the fee is returned if the provider wins at any level of appeal.

"The goal of the recovery audit program is to identify improper payments made on claims of health care services provided to Medicare beneficiaries. Improper payments may be overpayments or underpayments. Overpayments can occur when health care providers submit claims that do not meet Medicare's coding or medical necessity policies. Underpayments can occur when health care providers submit claims for a simple procedure but the medical record reveals that a more complicated procedure was actually performed. Health care providers that might be reviewed include hospitals, physician practices, nursing homes, home health agencies, durable medical equipment suppliers and any other provider or supplier

that bills Medicare Parts A and B.”²² Because a complex review requires the medical record, documenting comprehensible reasonable and necessary skilled services is critical.

Skilled Services

People who have experienced trauma or a disease process that affects their ability to move or function would be readily labeled candidates for therapy services. Therapy intervention should be easy to justify. The challenge is twofold. The therapist must (1) be able to identify and then substantiate the need for skilled services and (2) be sure that the documentation allows other parties to follow and understand what has been provided. The following example of documentation compares two sentences that a reviewer might read: “Gait training to facilitate weight shifting onto the affected extremity with minimal assistance required for safety” versus “The patient ambulated down the hall.” The first sentence conveys the need for the unique and necessary skills of a PT. The second fails to even suggest the presence of a therapist. Avoid referring to skilled physical or occupational therapy, which then infers that unskilled therapy is also available. Unskilled therapy, for which a reviewer should deny payment for services, could easily be represented by “The patient ambulated down the hall.” Skilled services, on the other hand, reflect therapy provided by qualified therapists with clinical expertise and knowledge.

A list of the interventions provided does not demonstrate skilled care. A therapist must include the level and type of skilled assistance given, clinical decision making or problem solving involved, and continued analysis of patient progress. An explanation of why specific interventions are chosen and what makes them still necessary is *also required*. Documentation of the therapist’s observations of the patient’s movement and activity before, during, and after an intervention, the patient’s specific response to the intervention, and the relationship of progress to goals are additional examples of skilled service.

Duplication of services is also a concern when there is collaboration across the disciplines. Many patients will benefit from treatments in which both OTs and PTs are present. However, if both therapists document, “Sat patient at edge of bed to work on balance,” reviewers could easily question whether both therapists did the same thing at the same time. The reviewers might then have a problem approving payment for the care provided, with a possibility that both services would be denied payment. There are no questions of duplication when the medical record states that the PT treatment session included “instruction and demonstration of strategies for dynamic postural adjustments” and the OT treatment session was directed toward “ADL training with emphasis on dressing.” The same is true for speech pathologists, OTs, and/or PTs in a multidisciplinary approach. A treatment session may have one therapist facilitating head control and midline orientation, another addressing upper extremity function and coordination, and a therapist from a third discipline focusing on the ability to swallow. Be sure the documentation reflects the specific skills and knowledge related to each therapy.

DOCUMENTATION: A LEGAL DOCUMENT

The medical record is a legal document that is read by many people who are not therapists. Patients have much greater access to and interest in their medical records today than

ever before. The medical record is available to insurance case managers and medical reviewers who are outside the medical facility. Patients may share their records with their families, new physicians and therapists, or even attorneys. Because of the various interests and needs of these diverse groups, it is necessary to be concise, legible, objective, and professional when documenting. Remember that no documentation can be released to others without a patient’s signed release of information form on file in the patient’s medical record.

Therapists should realize that it is very possible that their notes may be subpoenaed in the future as part of a lawsuit. The person who is the keeper of the records at the time of the case may have to go to court and explain, via another’s documentation, what was done for the patient, or it is possible that the therapist may be reading her own notes several years later while sitting in the witness box.

When documenting, be aware of the following important and sensitive areas. Remember that therapists receive a long and expensive education to enable them to write in the official legal record. Reviewers are basing their decision to pay for therapy on what has been recorded; be mindful of the need to meet criteria for skilled services. Patients and their entire medical team appreciate professional interventions and professional documentation.

Patient Advocacy

The therapist is the patient’s advocate. As such, the therapist should champion the best care for the patient. This may mean consulting professionals in other disciplines or facilitating transfers to other facilities. It is the clinician’s responsibility to ensure that the record reflects the patient’s best interests. Do not let therapy notes hinder the patient’s forward progress in any way. Patients with neurological conditions may have deficits that affect their orientation, judgment, initiation, ability to respond or comprehend, or insight. They may have visual-perceptual or other sensory problems that affect their ability to participate in therapy. Their ability to process information may be delayed. None of these components are reasons to withhold treatment, but they may affect the time required to achieve appropriate goals. These patients can and will progress with a creative, patient, and knowledgeable therapist.

Timeliness

Whenever possible, document immediately after seeing the patient. This ensures that the session is recorded accurately. It is better to report the results of consultations, test results, or phone calls rather than writing that the therapist intends to take action. The latter leaves the reader wondering if anything happened until the relevant findings are included in the medical record.

Motivation

A therapist should believe that a patient is motivated to improve. Sometimes there is damage to the brain that affects initiation, insight, or judgment; sometimes there is depression, pain, or another medical reason. It is the therapist’s responsibility to find the key to unlock the patient’s ability to participate. Do not record that the patient is unmotivated. The lack of motivation usually belongs to the therapist. (See Chapter 5 for additional information.)

Personal Opinion

The therapist's documentation must be absolutely objective. The PT or OT may provide direct quotations or accurately record an event that happened during a therapy session to allow the reader to make his or her own judgment. It is very important to never let personal feelings about the patient enter the medical record. Bias and antagonism on the part of the therapist may leave the medical record open to speculation and become a problem if litigation occurs. If the reader of the documentation senses animosity, certainly the patient will too! The validity of the comments and the therapy provided become questionable. Always keep personal opinions out of official documentation.

Abbreviations

Be careful with abbreviations because the individual documenting may be the only one who understands what is being stated. Most facilities have an approved abbreviations list; use it! The meaning of what has been written will change according to the reader's interpretation of the abbreviations used. It is possible that a reviewer will read the medical record and either find it incomprehensible or completely misunderstand the original intent. The purpose of documentation is to provide information. Claims may be denied because the reviewer does not understand the abbreviations used.

Pain

The Joint Commission has brought the patient's pain level to the forefront, making a patient's pain level the "fifth vital sign." It is required that a comprehensive pain assessment appropriate for the patient's age and condition be recorded at regular intervals. The most common pain scale is 0 to 10, with 0 signifying no pain and 10 signifying the worst pain the patient can imagine. To further explain the scale to the patient, the numbers 1 to 3 correspond to minimal pain, 4 to 7 to moderate pain, and 8 to 10 to severe pain. A score of 4 or higher requires immediate attention. It is important to explain to the patient that his or her pain scale response is accepted at face value and belongs only to the patient; the patient's numbers are not compared with those of anyone else. For children ages 3 years and older, the Wong-Baker FACES Pain Rating Scale²³ may be easier to understand. The purpose of a pain scale is to ascertain the effectiveness of pain medication or pain-reducing modalities. It is important to document the pain number at rest and during treatment, whether pain interferes with or prohibits participation in therapy, and what the therapist has done to remedy the painful situation. (See Chapters 5 and 32 for additional information.)

Reassessments

Reassessments are done on a weekly basis or sooner if short-term goals have been met or there has been a change in status. The reassessment should describe the patient's situation and address the short-term goals, either explaining why the goals have not been met or setting new goals when the previous ones have been achieved. In addition to addressing the short-term goals, the reassessment provides the opportunity to clarify the treatment plan, treatment frequency, and duration of treatment.

Patient, Family, and Caregiver Training

The education provided must be appropriate to the patient's abilities. It is important to assess the learning style and barriers to learning, then adjust the teaching accordingly. The

patient or caregivers must be able to understand the information. For example, documenting that the patient is blind and that he was given written handouts would be inappropriate, unless it was also documented that the family was trained with the materials provided. With any teaching, it is important to record what was taught, the response, and how well the new information was comprehended, either by return demonstration or by correct responses to questioning. Indicate whether the patient will be safe alone or with the specified caregivers after the training or whether additional education is necessary.

Patient Rights

Patients have many rights, including the right to be treated with respect and dignity. Use terms that focus on the patient as a person; avoid labeling patients by their diagnosis. Informed consent, risks and benefits of treatment, and confidentiality are extremely important, both ethically and legally. Patients always have the right to refuse treatment. Therapy cannot be forced on individuals against their will. Therapists offer a service that medical and health care professionals know will be beneficial, but patients are responsible for paying for their health care and they must be given a choice.

Accountability

Whenever possible, include references to other health care team members in order to demonstrate an interdisciplinary approach to patient care. Perform a thorough review of the medical record. Information from other team members can aid therapists in their understanding of the patient's situation. Inquire about the patient's goals for therapy treatment to incorporate into the POC. Each case must be examined individually. No two cases should be assumed to have the same problems and the same plans for resolution. What appears to be a routine assessment may present subtle and intricate challenges to both the patient and the therapist. Be sure to take a critical look at what has already been entered into the medical record. Question any findings that do not make sense, especially if previous documentation does not correspond to all the information and clinical symptoms present. Take the initiative to solve problems and investigate inconsistencies. Patients depend on the skills and knowledge of their therapists. Therapists must be accountable for their own documentation.

CONTINUUM OF CARE

Acute Care

Different settings require a change in the focus of documentation. It is important for the therapist to understand this concept and to modify documentation as necessary. In the acute-care setting, discharge planning begins as soon as the patient is admitted. The primary role of the therapist is to assess the patient to determine the next level of care and to introduce therapeutic interventions to expedite that process. Time is of the essence; the therapist may have only one or two visits to make a discharge recommendation and fewer than five visits to achieve initial short-term goals.

Depending on various circumstances, patients may transfer from the acute-care hospital to home either directly or indirectly by way of acute inpatient rehabilitation or an SNF.

Although the primary goal is to return the patient home and continue therapy there or in an outpatient setting, some patients may never leave the SNF. The emphasis is on safety. The patient must be safe in her or his own environment. Caregivers, if necessary, must be capable of safely assisting the patient. It is important to realize that patients may not access every level of care, or they may require a combination of settings. In each location, the treatment techniques may vary and the short-term goals will be different, but the same documentation guidelines apply. The following paragraphs assume that the patient is initially admitted to an acute-care hospital and then describe the possible discharge options.

Subacute Care

A patient who is admitted to the hospital and then requires the use of both a ventilator and a feeding tube may benefit from a subacute setting before moving on to acute inpatient rehabilitation. In the subacute setting, respiratory therapists and the nursing staff have key roles. Patients who have had respiratory failure in addition to their neurological deficits require a much slower pace to achieve their rehabilitation goals (see Chapter 3). These patients, with extremely impaired endurance and low functional levels, may stay in subacute settings for several months before they develop sufficient strength to progress to acute inpatient rehabilitation or return home. Short-term goals are set month to month, in contrast to acute-care hospitals, where short-term goals may be met in a matter of visits or days.

Acute Inpatient Rehabilitation

The Commission on Accreditation of Rehabilitation Facilities (CARF) monitors quality standards for acute inpatient rehabilitation care and is respected at an international level. Patients admitted to rehabilitation facilities accredited by this commission must meet several requirements. First, the patient must be medically stable and able to participate in at least 3 hours of therapy throughout the day. The overall medical stability must still require 24-hour nursing care and physician monitoring for medical diagnoses such as hypertension or diabetes. Second, the physical disability is such that the patient must need at least two of the three rehabilitation disciplines of speech, occupational, and physical therapy. Finally, the patient must have a community discharge plan. The discharge plan is imperative because acute inpatient rehabilitation is a dynamic process and patients will be discharged from this setting. A patient who was living alone before hospitalization but whose long-term goals do not include independence may not be eligible for acute inpatient rehabilitation care.

Skilled Nursing Facility

If the patient does not meet the requirements for acute inpatient rehabilitation or if the patient does not have financial, family, or other resources to enable him or her to live at home with assistance, then an SNF may be a better option. The patient benefits by receiving rehabilitation services and having a place to live. The facility is able to bill the third-party payer at a higher rate than for someone who is not receiving therapy services. The patient is allowed to receive therapy at a slower pace for a longer period of time. As the

patient improves, acute inpatient rehabilitation may then be considered.

Home Health

Patients who are discharged from hospitals and facilities may still require additional therapy. They may not have the ability or the endurance to travel to an outpatient setting and then also participate in the various therapies. In these cases, home health therapists provide the solution. To receive home therapy, a patient must be homebound. According to CMS, the definition of homebound is “Normally unable to leave home unassisted. To be homebound means that leaving home takes considerable and taxing effort. A person may leave home for medical treatment or short, infrequent absences for nonmedical reasons, such as a trip to the barber or to attend religious service. A need for adult day care doesn’t keep you from getting home health care.”²⁴ Documentation must explain why the patient is homebound. As the patient improves, this becomes more difficult and facilitates a decision for outpatient therapy or discontinuation of therapy services altogether.

Transitional Living Centers

Some communities are fortunate to have a transitional living center (TLC) available for clients to move beyond IRFs and into “real-world” situations. TLCs are community-based neurocognitive rehabilitation programs where the standard of care includes occupational, physical, and speech therapy; case management; and neuropsychology services. This treatment team pulls weekly documentation into a combined, goal-oriented individualized rehabilitation plan with summaries prepared for the payer source, physicians, family, and team. TLCs provide “custom-designed” life plans to facilitate reentry into home, school, or vocational settings. TLCs have been extremely successful as a way for older adolescents and young adults with neurological problems to progress from a rehabilitation center back into society.

Outpatient Therapy

Patients who have progressed to a level where they can easily leave home usually prefer to travel to therapy departments or offices for treatment. Once in outpatient therapy, patients receive the fine-tuning necessary to maximize their potential function. Usually these patients benefit from a gradually decreasing frequency with an increasing emphasis on independent home programs. Although the guidelines for outpatient and inpatient documentation are the same, the payment systems for outpatient services are quite different and will be covered in detail later in this chapter.

Therapy and Discharge Planning

Therapists in hospitals have the tremendous responsibility of seeing patients just a few times and making recommendations that may affect the patients for the rest of their lives. These decisions are not made in a vacuum; other members of the health care team are involved and initial plans may be amended. Often, however, the team looks to the therapists to determine the best discharge plan.

When discharge options are considered, there are questions a therapist should ask as part of the critical-thinking process (Box 10-3).

BOX 10-3 ■ CONSIDERING DISCHARGE OPTIONS

The questions a therapist should consider before making a discharge recommendation may include the following:

- Is the patient capable of being successful at home, either alone or with selective assistance?
- If selective assistance is still needed, is outpatient therapy appropriate or would home health care be a better choice?
- Is the patient medically and physically stable enough to proceed to an acute inpatient rehabilitation facility?
- Is the patient's medical condition at a level that warrants a skilled nursing facility?

There are no simple answers to any of these questions, but the questions need to be asked to arrive at the best discharge plan for the patient. When trying to ascertain the best solution, the therapist should remember that cognition is a major concern, as is the length of time expected for the patient to meet the long-term goals. The wishes of the patient and the family must always be involved in the decision-making process because sometimes they do not agree with each other or with the therapist's recommendations.

There are many aspects to consider. The patient's prior level of function is essential information, followed closely by the situation at home. The medical and surgical histories are also pertinent factors. Contemplate the questions listed in [Box 10-4](#).

The therapist should consider the level of responsiveness, the ability to follow commands, the prior level of function, and the patient's support system before making a recommendation. To further challenge the therapist, insurance coverage may affect the discharge plans. There will be cases where particular insurance carriers will contractually mandate the patient's discharge disposition. In rare instances, patients must wait in an acute-care hospital until they become eligible for state or federal funding before moving on to the next level of care.

In situations such as multiple fractures with non-weight bearing on bilateral lower extremities, the patient only needs time to heal before being able to participate in a rehabilitation setting. Although the best-case scenario is for the patient to return home while recuperating, this is not always possible. The patient would then transfer to a facility for custodial care.

Another possible discharge option is that of a retirement housing community. This plan usually includes three levels of care: the independent living setting, assisted living, and a health center or SNF. People purchase a contract for a secure and predetermined health care future in the retirement community. The contract specifies receiving care at any and all of these levels. The members stay in independent living until they require medical intervention. They may slowly decline and move into assisted living for a few years before finally settling into the skilled nursing level of care, or they may have a medical emergency and be admitted to acute care. The hospital will then transfer them back to the community's health center for rehabilitation. These patients may stay in the assisted

BOX 10-4 ■ POINTS TO PONDER ABOUT DISCHARGING A PATIENT**TO HOME**

- Was the home environment safe before the patient entered the hospital?
- Did the patient rely heavily on family, friends, or neighbors for assistance?
- Does the patient have a history of falls? (Some patients know the paramedics by name.)
- Are there stairs with rails or elevators available?
- Are the rooms and halls wheelchair or walker accessible?
- What kind of assistive equipment will need to be in the home?
- Are there healthy and available family members willing to assist on a continuing basis?
- Is there any money available to hire caregivers in the home, and will the patient consent to this?
- Are there cultural factors in the family unit that may affect caregiving?
- Does the patient need dialysis, and if so, how will this be accomplished?
- How compliant will the patient be with an independent exercise program?
- Will it be possible and easy for the patient to travel to an outpatient program?

TO A RETIREMENT COMMUNITY

- How far must the patient walk to reach the dining area, or can meals be delivered to the room?
- Are assistive devices allowed in public areas of this community?
- If not, what options have been provided or recommended by this community?

living facility temporarily before returning to their independent living setting.

Be careful! The therapist may adversely affect a patient's disposition on the basis of the POC. For example, a therapist in an acute-care hospital might routinely treat postoperative patients with orthopedic problems who elect to have surgery. These patients are expected to make major functional changes in just a few days. If a different patient arrives with a new subarachnoid hemorrhage and a maximum assist functional level, that same therapist may underestimate the amount of assistance and the duration of care that will be needed for this severely involved patient. The therapist's short-term goals might project independent mobility within a 2-week time frame. If the therapist does not amend the POC, then the discharge planner, insurance case manager, and physicians may decide that the patient is not making any progress at all. The patient is judged to have little to no rehabilitation potential, when, in reality, the therapist's POC was inappropriate. This kind of error could essentially end the patient's chances for acute inpatient rehabilitation and affect the patient's ultimate recovery level.

Less dramatic and possibly more common is the case of a patient who undergoes total hip arthroplasty for a hip fracture after an unwitnessed fall. The patient does not progress as quickly as the therapist would expect. The therapist must consider the possibility that this patient had

a mild stroke and then fell and fractured the hip. The patient underwent workup for the obvious fracture, but the neurological symptoms went undetected by the orthopedic surgeon. Sometimes the patient's subtle medical problems are realized only during evaluations that identify mismatches between the medical diagnosis and the anticipated functional skills and limitations. Open and clear lines of communication must be established between individuals working within the medical disease or pathology model and therapists working on impairments, activity limitations, and participation restrictions. The therapists have the opportunity to

assist the patient and influence the discharge plan by advocating for a facility that offers both orthopedic and neurological rehabilitation.

The third-party payer also has a say in the disposition of the case. Occasionally the discharge choice of the insurer, on the basis of the case manager's review of the medical records and the patient's coverage, is not the therapist's first choice for the patient. It may be possible to affect the decision regarding the patient's future only if the therapist has been a strong patient advocate and has consistently documented appropriately and thoroughly.

CASE STUDY 10-3

The following case illustrates the interaction of therapy on the continuum of care and the various assessment instruments used in different settings.

Ysabella D. is a 66-year-old woman, independent and healthy, who has been diagnosed with atypical Guillain-Barré syndrome. She is admitted to the acute-care hospital, and subsequently respiratory failure, flaccid quadriplegia, and cardiac arrhythmias develop.

Over the course of 5 months in the acute-care hospital, with more than one visit to intensive care, Ysabella undergoes tracheostomy and receives a feeding tube and a pacemaker. In the meantime, she also acquires pneumonia, dysphagia, and a decubitus ulcer. Although Ysabella receives occupational, physical, and speech therapy while in the acute-care hospital, she remains dependent in all areas. Because of the presence of the tracheostomy and percutaneous endoscopic gastrostomy tubes, Ysabella is transferred to a subacute setting, where she stays for another 8 months. Here she gradually improves in strength, endurance, and function.

After her tracheostomy and feeding tubes are removed, her skin has healed, and she has progressed to a regular diet, Ysabella is strong enough to meet the criteria for an acute inpatient rehabilitation facility and she is transferred there. She stays in the short-term rehabilitation facility for another 6 weeks before she reaches a minimal-assist level of care. At this point, she and her very supportive family have been

trained and she is able to be discharged home. Because she lives in a second-story apartment, is still using a wheelchair, and continues to require occupational and physical therapy, Ysabella is eligible for home health therapy.

Ysabella has Medicare Part A and B insurance coverage. This enables the acute-care hospital to be reimbursed on the basis of her diagnosis-related group. In this case, her long and complicated stay would qualify her for the outlier adjustment, allowing the hospital to receive more money than it would have received for a patient with an uncomplicated Guillain-Barré diagnosis. At the subacute facility, the initial Resident Assessment Instrument Minimum Data Set (MDS) is completed after 5 days. The MDS is again completed after 14 days, 30 days, 60 days, 90 days, and then quarterly until her transfer to the short-term inpatient rehabilitation setting. Here the Inpatient Rehabilitation Facility–Patient Assessment Instrument (IRF-PAI), including the Functional Independence Measure (FIM) score, is completed after 3 days and at the time of discharge. When Ysabella finally returns home, the home health therapist opens the case using the Outcome and Assessment Information Set (OASIS). Each facility will be reimbursed after the submission of the appropriate information gathered from each assessment and outcome instrument, assuming these tools were completed correctly and there was no reason for payment to be denied. Proper documentation by the therapists would justify all her therapy if there were to be an appeals process.

MEDICAL AND FUNCTIONAL DIAGNOSIS AND INTERVENTION CODING: DIAGNOSIS CODING

Payment for rehabilitation services is dependent not only on the quality of the medical record produced during the course of care but also on the accuracy of the codes used to describe medical and functional diagnoses and therapeutic interventions used in treatment. Third-party payers and other health care system stakeholders rely on the accuracy of coding so that the appropriate payment policy can be applied during the claims adjudication process. This section will introduce the reader to the basics of diagnosis coding using ICD-9 codes and intervention coding using CPT codes.

The ICD-9-CM, or ICD-9 for short, is based on the official version of the World Health Organization's Ninth Revision of the International Classification of Diseases. ICD-9 classifies diagnosis, morbidity, and mortality information to

allow systematic codification and standardized naming of diseases and injuries and allows indexing of data for outcome studies and for use in various payment, billing, and electronic information formats. Health care insurance companies and government agencies require the use of ICD-9 for billing and payment processes and for medical records as a result of HIPAA. To track outcomes, especially functional outcomes, standardized diagnosis nomenclature is absolutely essential. In rehabilitation settings the treating therapist is responsible for accurate identification of the physical therapy (treating) diagnosis and any comorbidities that could be factors during the course of care. Accurately identifying these diagnostic codes is an essential part of the advocacy role of the treating therapist because these coding decisions can have significant effects on third-party payer decisions for paying claims for patients and clients with potentially life-altering diseases and injuries.

Organization and Characteristics of ICD-9-CM

ICD-9-CM is organized into two volumes. Volume 1 is the tabular list of ICD-9 codes and five appendices. Codes from Volume 1 are not usually used for medical and functional diagnoses involved with rehabilitation. Volume 2 is an alphabetical list of ICD-9 codes. This listing contains a large number of medical and functional diagnoses that incorporate most of the diagnostic terms currently in use. A group composed of the American Hospital Association, CMS, National Center for Health Statistics, and American Health Information Management Association regularly updates ICD-9 codes, resulting in annual editions that are updated throughout each calendar year. When ICD-9 resources are consulted, it is important to always be sure that the most current edition is used.

ICD-9 codes can be up to five digits long: at least three digits are to the left of the decimal and up to two digits to the right of the decimal. The three digits to the left of the decimal define the diagnosis category, and the two available digits to the right of the decimal define more specific characteristics of the diagnosis by further defining site and location. We will look at several examples to illustrate the coding process (Box 10-5).

BOX 10-5 ■ ICD-9 CODING EXAMPLES

Following are two examples of common neurological conditions. You will need an ICD-9-CM book to do this exercise.

The name of the condition is the best place to begin. For example, code the diagnosis *complete paraplegia*.

- Go to Volume 2 (alphabetical index) and look up “Paraplegia, complete.”
- Review the listings under 344 of Volume 2 under “Paraplegia.” There is no listing that matches the term “complete.”
- Go to “344.1 Paraplegia” in Volume 1 (tabular index). The main entry is “344 Quadriplegia and Paraplegia.”
- Read the entries under 344 and find “344.1 Paraplegia.” Note what conditions are included and excluded by the listed codes. Read the note under “344.1 Paraplegia” that says “paralysis of both limbs.” This represents the closest match to “complete paraplegia.”
- “344.1 Paraplegia” is the diagnostic code.

Coding *nonspecific encephalopathy*:

- Go to Volume 2 (alphabetical index) and look up “Encephalopathy.”
- Review the listings under “Encephalopathy.” There is no listing that matches the term “nonspecific.”
- Go to Volume 1 (tabular index) and look up “348.30 Encephalopathy.”
- Read the notes and descriptions under “348.3 Encephalopathy.” Note what conditions are included and excluded by the listed codes.
- “348.30 Encephalopathy, unspecified” matches nonspecific encephalopathy most closely.
- “348.30 Encephalopathy, unspecified” is the diagnostic code.

Two terms need to be kept in mind when using ICD-9 codes. The first is Not Elsewhere Classified (NEC). This term is used when the ICD-9-CM does not provide a code that may be as specific as the diagnosis the therapist is trying to code, or when the clinician may not have enough information to code to a more specific diagnosis requiring the fourth-digit subcategory. The second term is Not Otherwise Specified (NOS). This term is used when the diagnosis is unspecified. Again, the reader will have an opportunity to look at examples of both abbreviations for illustration purposes.

Assigning ICD-9-CM Codes

In most cases the therapist will start with the name of a medical or functional diagnosis and will have to convert that name to the numerical ICD-9 code. In rare cases the opposite occurs; a diagnostic code is provided and the code will need to be converted to a name. For the purposes of this discussion it is assumed that a codebook is being used; however, readers will find that many software and Internet applications embed ICD-9 information within the application. When using embedded resources, it is important that the reader refer to the text included in the codebook because most of these applications use the “short language” form of the code and do not tell you whether fourth- or fifth-digit modification is required.

ICD-9 Coding Is a Five-Step Process

The following five-step process will guide the reader through the ICD-9 coding process:

- Step 1: Start by consulting the alphabetical index (Volume 2) to identify the diagnostic category before using the tabular index (Volume 1). By identifying the correct name of the diagnostic category in the alphabetical index, therapists will avoid coding errors that will result in denied services.
- Step 2: Identify the main medical or functional diagnostic term or category. The alphabetical index is arranged by condition. Conditions can be expressed as nouns, adjectives, and eponyms. Some conditions have multiple entries under their synonyms. Be sure to read any notes listed with the main term or category because these categories will help the reader identify the specific diagnostic code he or she is trying to identify.
- Step 3: Interpret abbreviations, cross-references, and brackets. Cross-references used are “see,” “see category,” and “see also.” The abbreviations NEC and NOS follow main terms or subterms. Identify a tentative code and locate it in the tabular index.
- Step 4: By reading the entry in the tabular list, clinicians will be able to determine whether the code is at its highest level of specificity. Assign three-digit codes (category code) if there are no four-digit codes within the code category. Assign four-digit codes (subcategory codes) if there are no five-digit codes for that category. Assign five-digit codes (fifth-digit subclassification codes) for these categories where they are available.

Step 5: Assign the code.²⁵

Box 10-5 provides two ICD-9 coding examples.

Depending on the treatment setting, patients/clients may come to the therapist with diagnoses that are already coded. In other situations, such as in acute-care facilities and IRFs, ICD-9 codes will be assigned by certified ICD-9 coders in the medical records department. In many outpatient settings the therapist will be required to “match” ICD-9 codes for Medicare patients with specific CPT codes to establish medical necessity for the rehabilitation interventions according to the Fiscal Intermediary or Carrier Local Coverage Decisions. In any case, the treating therapist should be absolutely clear in the medical record about the treating diagnoses and comorbidities that define the treatment program and POC of the patient or client.

The Future of Diagnosis Coding: ICD-10-CM

In 2013, changes in HIPAA regulations will replace ICD-9-CM with an updated diagnostic coding set: ICD-10-CM. This updated system will enhance accurate payment for services and facilitate evaluation and tracking of medical diagnoses and outcomes. ICD-10-CM will provide improvements through more detailed diagnostic information and increased specificity of location and pathologies and will have expanded ability to capture additional advancements in identification of pathology, diagnoses, and patient problems.

The ICD-10-CM classification system has been used in other countries since the mid-1990s; it has been adapted by the Centers for Disease Control and Prevention for use in the United States. The diagnostic coding under this system uses three to seven alphabetical and numerical characters and full code titles for each entry. Organization and format are very similar to those of ICD-9-CM.

Because of the impact this change will have on electronic data interchange and computer systems, the transitional plan for this significant change is already underway. Therapists and other health care providers should be aware of this impending change and participate in training opportunities as they become available.

INTERVENTION CODING

Just as ICD-9 codes allow therapists to communicate to payers and other health care stakeholders the conditions and injuries being treated, CPT codes allow therapists to identify and communicate the interventions being used in the course of patient care. In a world where most billing information is transmitted electronically, it is essential for therapists to use the most appropriate CPT codes to communicate the breadth, depth, and complexity of the treatment plans required in the care of patients/clients. Appropriate intervention coding is also essential to the billing and claims adjudication process and to maximize the health care benefits available to the patient with complex neurological conditions and injuries.

Current Procedural Terminology

Current Procedural Terminology,²⁶ Fourth Edition, is maintained, updated, and published by the AMA and is a registered trademark of the AMA. It is a code set designed to identify the interventions and other services performed by health care providers. Each intervention or service is described by a five-digit code. CPT is mandated by HIPAA as the appropriate code set for use in health care transactions in the United States.

CPT is used to report health care provider services to public and private or commercial insurance companies and payers. CPT codes are also used to report treatment encounter information to government agencies and private companies for the purposes of research, outcome tracking, and education.

The AMA first published the fourth edition of CPT in 1977. CPT is continually updated to keep the codes current with the community standard of practice by a process led by the AMA CPT Editorial Panel.²⁶ For the rehabilitation disciplines, the Health Care Professional Advisory Committee develops CPT coding changes and updates. The Committee consists of representatives from 16 nonphysician provider groups, including physical therapy, occupational therapy, and speech and language pathology.

The CPT code set is organized into six major sections: Evaluation and Management, Anesthesiology, Surgery, Radiology, Pathology/Laboratory, and Medicine. Each section is divided into subsections based on anatomical, procedural, condition, and descriptor headings as appropriate to that specialty section. The AMA, in publishing the CPT code set, recognizes that there may be significant overlap in the interventions, procedures, and services performed by health care providers and makes the following statement in the introduction:

It is important to recognize that the listing of a service or procedure and its code number in a specific of this book does not restrict its use to a specific specialty group. Any procedure or service in any section of this book may be used to designate the services rendered by any qualified physician or other qualified health care professional.²⁶

Typically, most codes used by rehabilitation professionals to describe treatment of neurological conditions are in the 97000 series of the CPT; however, any code that adequately represents the interventions or services performed by a provider with the appropriate qualifications may be used.

Using the CPT Codes

Selecting the correct CPT code that most adequately describes the intervention performed is often very challenging because most therapists have not had formal CPT training. Although in-depth coding training is beyond the scope of this text, this section will help the reader develop some basic skills in applying sound coding techniques to practice.

Most of the codes used to describe therapy interventions are found in the Physical Medicine section of the CPT code. Although therapists use these codes, so do a large number of other health care professionals and providers. For this reason it is important for therapists to be able to adequately describe their use of interventions using the correct CPT codes so the codes reflect the complex nature of the treatment plans implemented with their patients.

Physical Medicine CPT Codes

The Physical Medicine codes are located in a subsection of the Medicine section of the CPT code set. Some CPT codes in the Physical Medicine section represent interventions that occur in specified time intervals (e.g., 15 minutes) and are considered “timed” codes. Timed codes generally require

constant attendance or direct (one-on-one) patient contact. Other codes are considered “occurrence” codes and do not have a time period associated with them. Some occurrence codes require direct contact, whereas others do not. Occurrence codes are billed only one time during a visit or treatment, but timed codes can be billed in multiple units as justified by the time it takes to provide the intervention. Consult a current CPT codebook for specific details, because these codes and their associated descriptions can change each year.

The Physical Medicine codes are organized into six groups of codes. The codes in these subsections have specific attributes.²⁶

Evaluation/Reevaluation

Evaluation/Reevaluation codes are the evaluation and reevaluation codes for physical therapy, occupational therapy, and athletic training. These codes are occurrence codes requiring direct contact between the therapist and the patient.

Modalities

Modality codes are further divided into two groups: “Supervised” modalities (occurrence codes that do not require direct contact) and “Constant Attendance” modalities (timed codes that require direct contact).

Therapeutic Procedures

Therapeutic Procedure codes require direct patient contact by the therapist. All but one of these codes are timed, so if the time required for the intervention warrants, multiple units of a code can be charged.

Active Wound Care Management

Active Wound Care Management codes are occurrence codes that require direct contact.

Tests and Measures. Tests and Measures codes represent specific assessment and testing interventions that are separate and distinct from evaluations and reevaluations. These interventions require separate written reports.

Other Procedures

The Other Procedures section consists of a single code used to describe any “unlisted” physical medicine service or intervention.

Each year therapists should review the codes and sections commonly used for changes and additions that will better describe the interventions performed with their patients. All therapists should consult the CPT codes directly and avail themselves of training specifically designed to help them accurately describe their interventions. CPT coding resources are available from a number of sources, including the AMA and professional associations such as APTA.²⁷

OUTPATIENT PAYMENT POLICY

The processes involved with billing, payment, and payment policy for outpatient services remains distinctly different compared with inpatient services. Although inpatient rehabilitation services are primarily paid on a prospective basis, outpatient rehabilitation services continue to be paid primarily on a retrospective basis. This means that, although services may have been authorized before delivery of care, the decision to pay for the services is

made after care has been delivered and subject to reviews of medical necessity, appropriateness, and other policies. Financial class largely determines the types of policies and regulations that apply to any particular payer. There are four primary financial classes: Medicare, Medicaid, and government programs; commercial insurance and private coverage; automobile and accident insurance companies; and workers’ compensation. To be effective advocates for patient care, therapists must be vigilant regarding regulations and payment policies that determine how care is approved, billed, and paid.

Medicare and Medicaid

Both the Medicare and Medicaid programs are overseen and regulated by CMS. Medicare, as a federal program, is heavily regulated. These regulations are readily available to providers through a number of resources, but the primary access to information is through the Internet at <http://cms.gov>. As previously discussed, Medicare pays for outpatient services through MACs. Each of these entities must maintain a website for beneficiaries and providers to allow for ready dissemination of pertinent information. MACs use Medicare’s national policies to process and adjudicate claims. Although Medicare has national policies, MACs have some discretion in how these policies are implemented locally. Any MAC regulations or policies specific to particular services, interventions, or provider types are contained in LCDs that must go through a lengthy draft and approval process before they are made available to providers and implemented. Most MACs have LCDs specific to physical rehabilitation providers (physical therapy, occupational therapy, and speech and language pathology) as well as specific services or interventions such as wound care, biofeedback for incontinence, vestibular problems, and cardiac rehabilitation. Because MACs have defined geographic coverage areas, it is advisable for therapists to be sure they are familiar with Medicare’s payment policies in the areas where they practice.

Medicaid, as discussed earlier, is a health program for the economically disadvantaged. Although it is partially funded with federal dollars, it is also funded at the state level. Because Medicaid is implemented at the state level, states have significant leeway in how their programs operate, approve care, and pay for services. Consequently there are large variations in the Medicaid program from state to state. Therapists should be aware within their individual work settings of the regulations and policies that may apply to them as a result of their employer’s possible participation in the Medicaid program.

Medicare and other payers often attempt to mitigate their financial risk for costly episodes of rehabilitation by imposing arbitrary limits on care. These limits are often referred to as “caps.” One example of such a limit is Medicare yearly cap on rehabilitation services. This cap was created as part of the BBA and went into effect in 1999. The cap was \$1500 in payments per year for physical therapy and speech therapy and a separate \$1500 cap for occupational therapy services. The cap applies in all outpatient settings except outpatient hospital rehabilitation units. The therapy cap is adjusted annually as a consequence of changes in the Medicare Economic Index that tracks health care costs and inflation.

Another way Medicare and Medicaid attempt to mitigate their financial risk is to use outpatient service programs that are prospectively paid. These programs operate by use of capitation, a system by which health care providers are paid in advance of rendering care to a defined group of beneficiaries. In this payment system the capitated health care providers provide care out of the prepaid pool of funds. These programs use contracted insurance companies, using large groups of health care providers representing a wide array of specialties, to provide the anticipated health care needs of the covered patients. Capitation agreements must be carefully negotiated. If the negotiated prospective payment is too low, or, if the therapist overtreats, the payment for services rendered will be inadequate to cover the cost of providing care to the covered patient population.

A number of smaller government programs also may have specific regulations and policies similar to those of Medicare. An example of such programs is CHAMPUS/TRICARE. This program provides health care insurance coverage for members of the military and their dependents and for military retirees. Other federal health care programs, such as the Veterans Administration, may vary significantly from Medicare and Medicaid in their policies.

Coverage programs for children with congenital or acquired conditions requiring extensive rehabilitation are financed through a number of federal, state, and local programs. Because of the huge diversity in the payment policies related to these programs, therapists should be aware of the particular program covering the care and should work closely with parents and agencies involved to ensure that proper coverage for services is achieved.

Commercial Insurance and Private Coverage

Commercial insurance coverage is financed by traditional health insurance companies, self-insured employers, and self-paying consumers. Commercial insurance companies are regulated at the state level, and self-insured companies are regulated at the federal level. Cash-paying consumers must rely on their own understanding and self-education to make their purchasing decisions regarding therapeutic care.

Commercial insurance companies operate by charging premiums to the beneficiaries (employers or individual consumers) and then paying for services delivered to their insured. Because these payers bear the risks associated with the health of their beneficiaries, they use a number of strategies to mitigate their risks in this delivery model. Many use preferred panels of health care providers to deliver services. These preferred providers agree to particular business processes, rates of payment, and utilization review and restrictions to have access to the beneficiaries of these payers. Some require the provider to obtain authorization before treatment is provided, whereas others provide strict review of care after delivery to decide whether payment is warranted. These companies also have a number of mechanisms to shift their financial risk to the patient and to the provider, including capitation and case-rate reimbursement. In case-rate reimbursement, a flat rate is paid for the entire course of care for a patient with a particular medical diagnosis.

Insurance companies often require the patient to pay different amounts toward their care on the basis of whether the

patient sees a network provider (preferred provider) or an out-of-network provider (a provider who is not a contracted provider). These amounts can be based on a percentage of the charges, on a flat amount for each treatment (co-pay), or both. The required patient payment can have a significant effect on patients' and clients' financial abilities to participate in their respective treatments. By increasing co-pay amounts, payers know patients will have to make "harder" decisions regarding how much care they can afford. This can play an important factor when a therapist and his or her patient agree on a POC, how much therapy the patient can afford, and when the patient is discharged to a home program. For patients who pay cash for services, these decisions can be even more difficult and come far sooner in the POC. In other situations, especially in long-term management of an individual after central nervous system (CNS) injury, the therapist's role may become consultative. When the patient or family identifies functional changes, the therapist may be asked to establish new goal interventions as a home program to be carried out by the patient's support system.

Payers can also place limitations on the amount of services a patient can receive each year by limiting the number of visits, days, and dollars spent on therapy services. Therapists must be aware of these limitations and how these limitations may affect the potential interactions between long-term care and patient potential. With this understanding, a therapist can help identify the best use of patients' resources and facilitate those individuals' abilities to participate in their own care. The nearly infinite number of ways payers can shift risk and financial responsibility to patients and providers makes it imperative that systems be in place in each clinical setting to check for limitations and alert the patient and therapist to potential financial challenges that can have chilling effects on treatment and the potential for recovery.

Automobile and Accident Coverage and Third-Party Liability

When individuals are injured in automobile and other accidents, financial liability for care may become the responsibility of others who were involved in or responsible for the accidents. In the case of automobile accidents, people are generally required by state law to carry some minimum amount of public liability insurance to cover such costs. Health insurance companies usually have stipulations in their policies that allow them to recover any costs they incur as the result of the liability of others.

To further complicate matters related to accidents, many of these cases end up in lawsuits and litigation. This represents several challenges for the treating therapist. In terms of payment for services, it is not always entirely clear who will be paying for services and when they will pay. Many patients injured from the actions of others may feel that they are not responsible for paying for the care they receive, and they can be unaware of the cost of treatment as it mounts. This can be problematic if the party the patient believed was liable is exonerated or unable to pay.

Nearly all health care facilities have a policy that states that the patient, or his or her parent or guardian, is financially responsible for the treatment received, although the facility may be willing to bill other parties for those services.

Therapists should always be aware of the various possibilities that can occur during the course of care that can affect the ability of the patient to continue therapy. Therapists should also be aware that the medical records could end up being examined by a number of attorneys and end up in open court.

Workers' Compensation

Of all the insurance classes reviewed, workers' compensation has the highest degree of variability in regulation and payment policy. Each state legislates and regulates its treatment of injured workers independently of other states and federal involvement. This variability requires every facility treating workers' compensation patients to maintain a knowledge base of the laws and regulations governing the care of these patients as well as establishing procedures to ensure that they are followed. Many states use fee schedules that are based on CPT codes but are highly modified and have significant variations from "normal" coding. These types of fee schedules may require specific instruction to use so that the therapist can accurately describe the interventions used with patients covered by these fee schedules. In addition, the nature of work-related injuries produces other potential challenges for therapists.

Workers' compensation coverage is provided through purchased insurance or through self-insurance programs set up by employers. Workers' compensation cases are concurrently managed by insurance companies or by third-party administrators who manage self-insured employer programs. Concurrently managed care means that the payer requires the health care provider to preauthorize all proposed care and reviews documentation to ensure compliance with state-mandated fee schedules and use guidelines. Because of the assumed employer liability of work-related injuries, some of these cases progress to lawsuits and litigation as in the case of accidents. Therapists should remain aware, also, of the potential involvement of their patients' medical records in these legal proceedings. In the area of neurological rehabilitation, a workers' compensation package may become very complex. If the injury results in permanent CNS limitations, therapists are often asked to estimate the long-term needs of the patient to establish potential costs of long-term therapeutic management over the lifetime of the patient.

Evolving Health Care Reform Efforts and Effects on Payment Policy

In March 2010 President Barack Obama signed the Patient Protection and Affordability Act of 2010 (HR 3590) and its companion legislation the Health Care and Education Reconciliation Act of 2010, ushering in the most sweeping regulatory changes in health care payment policy since the Medicare Act of 1965, which established the Medicare program. The full effects of this legislation will not be fully implemented until 2016. The regulatory implications of this new law will be promulgated over the coming years. The reader should be forewarned that keeping current with major changes in health care policy is essential in providing proper advice and counsel to patients requiring long-term and intensive therapies to maximize their abilities to function. This legislation will allow many to access services

who have been excluded by payer enrollment policies, inability to purchase health care coverage, or both. This new coverage burden will be shared largely by employers and by new state and federal programs financed through new taxes and efforts to curtail fraud and abuse in health care. Although the details of providing funding for this significant expansion in services are to be worked out, there will likely be significant downward pressure on payment for services as well as an increase in efforts to compensate health care providers on the quality of their clinical and financial outcomes. Implementation of evidence-based practice and keeping current in "best practices" will be essential for every therapist as compensation systems evolve to meet the needs of patients and clients and the rising costs of health care.

SUMMARY

Payment for rehabilitation services is a complex topic that involves many legal, regulatory, and contractual details. To completely explain the complexities involved in documentation of patient care, medical billing, and claims adjudication would fill a volume similar to the size of this text. We have attempted to provide the treating therapist with a basic understanding of the payment systems involved in inpatient and outpatient services and the importance of documentation to the billing and payment process, provided basic steps for inclusion of diagnosis and intervention coding, and provided an overview of payment policy for outpatient services. Therapists must keep in mind that the regulatory and legislative world of health care is in a continual state of flux and that there are a number of critical areas that affect payment for services that were not touched on in this chapter. These would include the areas of Medicare and corporate compliance, the HIPAA privacy and security rules, currently evolving issues related to the Medicare caps on therapy services, and individual state practice acts for various health care providers. The reader would be well served to get specific questions and concerns addressed by knowledgeable individuals or to consult source documents on these important areas. The increasing reliance on electronic data interchange will necessitate improvements in the ICD-9 coding system to ICD-10, requiring the reader to seek appropriate training. Emerging health care reform initiatives will create new opportunities for coverage of individuals with chronic conditions but will place additional financial strain on the system and our economy, with possible consequences on health care provider compensation and payment policies.

Acknowledgment

With sincere appreciation for editorial contributions by Bob Niklewicz, PT, DHSc.

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 27 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

Rehabilitation Management of Clients with Neurological System Pathology

CHAPTER 11 Neonates and Parents: Neurodevelopmental Perspectives in the Neonatal Intensive Care Unit and Follow-Up

JANE K. SWEENEY, PT, PhD, PCS, C/NDT, FAPTA, TERESA GUTIERREZ, PT, MS, PCS, C/NDT, and JOANNA C. BEACHY, MD, PhD, FAAP

KEY TERMS

high-risk clinical signs
medical complications of prematurity
neonatal intensive care unit environment
neuromotor assessment
neuromotor intervention
parent instruction
physiological and musculoskeletal risks
subspecialty training

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Discuss three theoretical frameworks guiding neonatal therapy services in the neonatal intensive care unit.
2. Identify the physiological and structural vulnerabilities of preterm infants that predispose them to stress during neonatal therapy procedures.
3. Outline supervised clinical practicum components and pediatric clinical experiences to prepare for entry into neonatal intensive care unit practice.
4. Describe how the grief process may affect behavior and caregiving performance of parents of low-birth-weight neonates.
5. Differentiate the developmental course and neuromotor risk signs in infants with emerging neuromotor impairment from the clinical characteristics of infants with transient movement dysfunction.
6. Identify instruments for neuromotor examination of high-risk infants in neonatal intensive care units and in follow-up clinics and compare psychometric features of the tests.
7. Describe program plans and follow-up for low-birth-weight infants in neonatal intensive care unit and home settings.

Premature birth is associated with an increased prevalence of major and minor neurodevelopmental disability. Advancements in newborn resuscitation and neonatal intensive care have contributed to greatly improved survival of infants with low birth weight (LBW), but risk of neurodevelopmental sequelae remains high.^{1,2}

Although brain injury can be documented by ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) in infants, prediction of subsequent neurodevelopmental outcome is still relatively unreliable.³⁻⁶ Serial clinical examinations and careful monitoring of neurodevelopmental status are therefore critical during the neonatal period and discharge from the neonatal intensive care unit (NICU) through the outpatient phase of care. Pediatric therapists with mentored, subspecialty training in neonatology

and infant therapy approaches can serve these increasing numbers of surviving neonates at neurodevelopmental risk by (1) providing valuable diagnostic data through neurological and developmental examination, (2) participating in developmental and environmental interventions adapted to each infant's physiological, motor, and behavioral needs, (3) facilitating and coordinating interdisciplinary case management for infants and parents, and (4) reinforcing preventive aspects of health care through early intervention and long-term developmental monitoring.

Clinical management of neonates at developmental risk and their parents during the NICU and outpatient follow-up phases is the focus of this chapter. A theoretical framework for neonatal practice is presented, and an overview of neonatal complications associated with adverse outcomes is

provided. In-depth discussion in the neonatal section includes indications for referral based on risk, neurodevelopmental examination instruments, high-risk profiles in the neonatal period, treatment planning, and therapy strategies in the NICU. The section on outpatient follow-up focuses on critical time periods for neuromotor and musculoskeletal reexamination, assessment tools, and clinical cases.

THEORETICAL FRAMEWORK

Concepts of dynamic systems, neonatal behavioral organization, and parental hope and empowerment provide a theoretical framework for neonatal therapy practice. In this section are three models that provide a theoretical structure for practitioners designing and implementing neuromotor and neurobehavioral programs for neonates and their parents.

Dynamic Systems

Dynamic systems theory applied to infants in the NICU refers first to the presence of multiple interacting structural and physiological systems within the infant to produce functional behaviors and second to the dynamic interactions between the infant and the environment. In [Figure 11-1](#), neonatal movement and postural control are targeted as a core focus in neonatal therapy, with overlapping and interacting influences from the cardiopulmonary,⁷ behavioral, neuromuscular, musculoskeletal, and integumentary systems. A change or intervention affecting one system may diminish or enhance stability in the other dynamic systems within the infant. Similarly, a change in the infant's environment may impair or improve the infant's functional performance.

This theory guides the neonatal practitioner to consider the many potential physiological and anatomical influences (dynamic systems within the infant) that make preterm infants vulnerable to stress during caregiving procedures, including

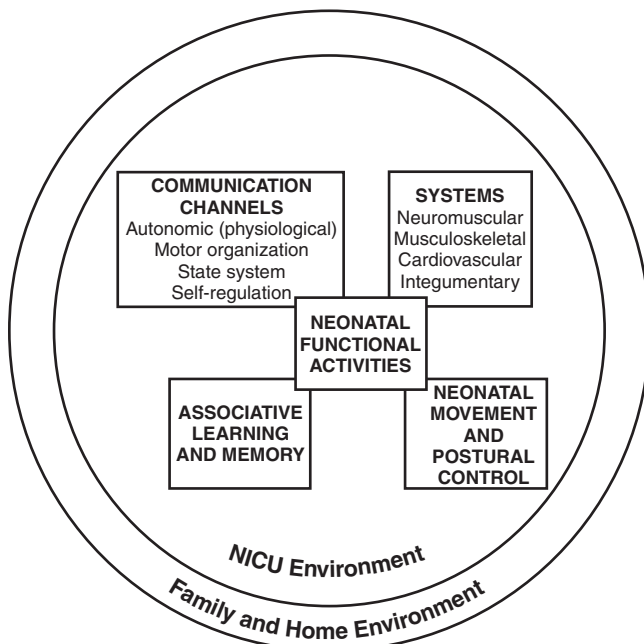

Figure 11-1 ■ Dynamic systems within neonates and interacting external influences on functional performance. (From Sweeney JK, Heriza CB, Blanchard Y, Dusing SC: Neonatal physical therapy. Part II: practice frameworks and evidence-based practice guidelines. *Pediatr Phys Ther* 22:3, 2010.)

neonatal therapy. In dynamic systems theory, emphasis is placed on the contributions of the interacting environments of the NICU, home, and community in constraining or facilitating the functional performance of the infant.⁸

Synactive Model of Infant Behavior

The synactive model of infant behavioral organization is a specific neonatal dynamic systems model for establishing physiological stability as the foundation for organization of motor, behavioral state, and attention or interactive behaviors in infants. Als and colleagues⁹⁻¹¹ described a “synactive” process of four subsystems interacting as the neonate responds to the stresses of the extrauterine environment. They theorized that the basic subsystem of physiological organization must first be stabilized for the other subsystems to emerge and allow the infant to maintain behavioral state control and then interact positively with the environment ([Figure 11-2](#)).

To evaluate infant behavior within the subsystems of function addressed in the synactive model, Als and colleagues^{10,11} developed the Assessment of Preterm Infants' Behavior (APIB). With the development of this assessment instrument, a fifth subsystem of behavioral organization, self-regulation, was added to the synactive model. The self-regulation subsystem consists of physiological, motor, and behavioral state strategies used by the neonate to maintain balance within and between the subsystems. For example, many infants born preterm appear to regulate overstimulating environmental conditions with a behavioral state strategy of withdrawing into a drowsy or light sleep state, thereby shutting out sensory input. The withdrawal strategy is used more frequently than crying because it requires less energy and causes less physiological drain on immature, inefficient organ systems.

Fetters¹² placed the synactive model within a dynamic systems framework to demonstrate the effect of a therapeutic intervention on an infant's multiple subsystems ([Figure 11-3](#)). She explained that although a neonatal therapy intervention is offered to the infant at the level of the person, outcome is measured at the systems level, where many subsystems may be affected. For example, the motor outcome from neonatal therapy procedures is frequently influenced by “synaction,” or simultaneous effects, of an infant's physiological stability and behavioral state. Physiological state and behavioral state are therefore probable

Figure 11-2 ■ Pyramid of synactive theory of infant behavioral organization with physiological stability at the foundation.

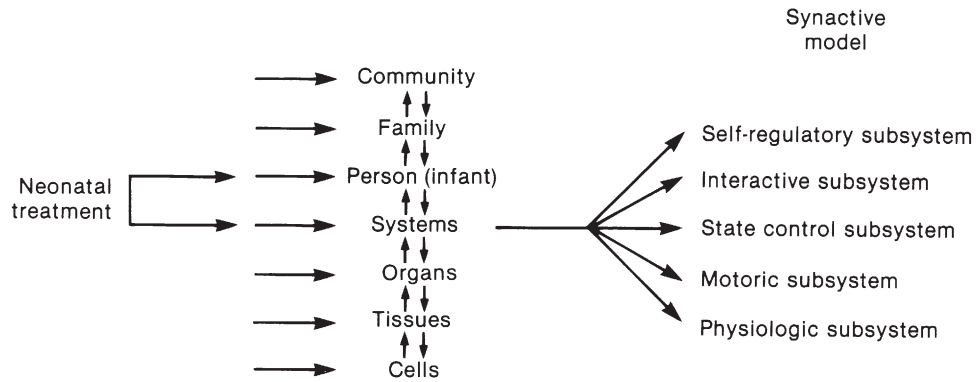

Figure 11-3 ■ Combined dynamic systems and synactive models. (Modified from Fetters L: Sensorimotor management of the high-risk neonate. *Phys Occup Ther Pediatr* 6:217, 1986.)

confounding variables during research on motor behavior in neonatal subjects. Neonatal therapists may find this combined dynamic systems and synactive framework helpful in conceptualizing and assessing changes in infants’ multiple subsystems during and after therapy procedures.

Hope-Empowerment Model

A major component of the intervention process in neonatal therapy is the interpersonal helping relationship with the family. A hope-empowerment framework (Figure 11-4) may guide neonatal practitioners in building the therapeutic partnership with parents; facilitating adaptive coping; and empowering them to participate in caregiving, problem solving, and advocacy. The birth of an infant at risk for a disability, or the diagnosis of such a disability, may create both developmental and situational crises for the parents and the family system. The developmental crisis involves adapting to changing roles in the transition to parenthood and in expanding the family system. Although not occurring unexpectedly, this developmental transition for the parents brings lifestyle changes that may be stressful and cause conflict.¹³ Because parents are experiencing (mourning) loss of the “wished for” baby they have been visualizing in the past 6 months, they often struggle with developing a bond with their “real” baby in the NICU.¹⁴

A situational crisis occurs from unexpected external events presenting a sudden, overwhelming threat or loss for which previous coping strategies either are not applicable or are immobilized.¹⁵ The unfamiliar, high-technology, often chaotic NICU environment creates many situational stresses that challenge parenting efforts and destabilize the family system.¹⁶ The language of the nursery is unfamiliar and intimidating. The sight of fragile, sick infants surrounded by medical equipment and the sound of monitor alarms are frightening. The high frequency of seemingly uncomfortable, but required, medical procedures for the infant are of financial and humanistic concern to parents. No previous experiences in everyday life have prepared parents for this unnatural, emergency-oriented environment. This emotional trauma of unexpected financial and ongoing psychological stresses during parenting and caregiving efforts in the NICU contributes to potential posttraumatic stress disorder in parents of infants requiring intensive care.^{17,18}

The quality and orientation of the helping relationship in neonatal therapy affect the coping style of parents as they try to adapt to developmental and situational crises (see Figure 11-4). Although parents and neonatal therapists enter the

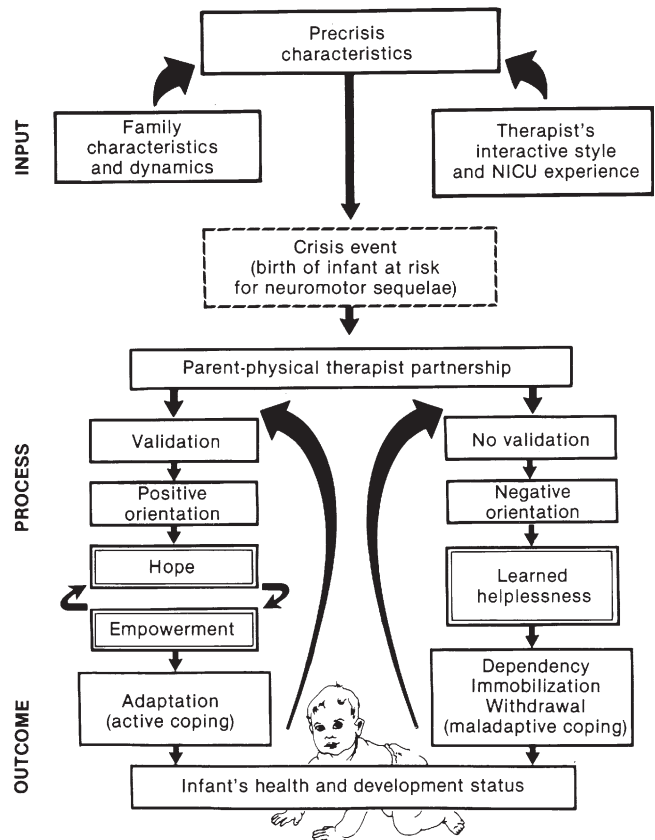

Figure 11-4 ■ Hope-empowerment (left) versus learned helplessness (right) processes of the therapeutic partnership between parents and the neonatal therapist.

partnership with established interactive styles and varying life and professional experiences, the initial contacts during assessment and program planning set the stage for either a positive or a negative orientation to the relationship.

Despite many uncertainties about the clinical course, prognosis, and quality of social support, a positive orientation is activated by validation or acknowledgment of parents’ feelings and experiences. Validation then becomes a catalyst to a hope-empowerment process in which many crisis events, negative feelings, and insecurities are acknowledged in a positive, supportive, nonjudgmental context in which decision-making power is shared.¹⁹ In contrast, a negative

orientation may be inadvertently facilitated by information overloading without exploration and validation of parents' feelings, experiences, and learning styles. This may lead to magnified uncertainty, fear, and powerlessness with the misperception of excessive complexity in the proposed neuromotor intervention activities.

In a hope-empowerment framework, parent participation in neuromotor intervention allows sharing of power and responsibility and promotes continuous, mutual setting and revision of goals with reality grounding. Adaptive power can be generated by helping parents stabilize and focus energy and plans and by encouraging active participation in intervention and advocacy activities.¹⁹ Exploring external power sources (e.g., Parent to Parent USA or other parent-to-parent support groups²⁰) early in the therapeutic relationship may help parents focus and mobilize.²⁰⁻²³

Hope and empowerment are interactive processes. They are influenced by existential philosophy: the hope to adapt to what is and the hope to later find peace of mind and meaning for the situation, regardless of the infant's outcome. In describing the effect of a prematurely born infant on the parenting process, Mercer²⁴ related that "hope seems to be a motivational, emotional component that gives parents energy to cope, to continue to work, and to strive for the best outcome for a child." She viewed the destruction of hope as contributing to the physical and emotional withdrawal frequently observed in parents who attempt to protect themselves from additional pain and disappointment and then have difficulty reattaching to the infant.

Hope contributes to the resilience parents need to get through the arduous 1- to 4-month NICU hospitalization period and then begin to face the future in their home and community with an infant at neurodevelopmental risk. Groopman²⁵ proposed that hope provides the courage to confront obstacles and the capacity to surmount them. He described the process of creating a *middle ground* where truth (of the circumstances) and hope reside together as one of the most important and complex aspects in the art of caregiving.

In a hope-empowerment context, parental teaching activities are carefully selected to contribute to pleasurable interaction between infant and parent. Gradual participation in infant care activities and therapeutic handling in the NICU provide experience and build confidence for continuation in the home environment.

Conversely, if the parents' learning styles, goals, priorities, values, time constraints, energy levels, and emotional availability are not considered in the design of the developmental program, the parents may experience failure, loss of self-esteem, powerlessness, immobilization, or dependency. The neonatal therapist may recognize signs of learned helplessness in parents when they show nonattendance, noncompliance, negative interactions with infant and staff, or a hopeless outlook during bedside teaching sessions.

New events in the infant's health or developmental status may create new crises and destabilize the coping processes. In long-term follow-up many opportunities occur within the partnership to validate new fears and chronic uncertainties within a hopeful, positively oriented, helping relationship. The alleviation of hopelessness is a critical helping task in health care. This model provides a conceptual framework for sharing the gifts of hope and power with parents and caregivers.

NEONATAL COMPLICATIONS ASSOCIATED WITH ADVERSE OUTCOMES

Improvements in neonatal intensive care over the last 30 years have led to the increased survival of preterm and term infants. Specific obstetric advances include establishment of specialized tertiary care centers, earlier identification of high-risk pregnancies, improvements in prenatal diagnosis, and medications used to stabilize maternal medical conditions and enhance fetal well-being. Respiratory compromise in preterm infants has significantly decreased as a result of (1) maternal betamethasone administration to promote fetal lung maturity; (2) availability of commercial surfactant to improve pulmonary function; and (3) advances in ventilator design and capability, enhancing management of respiratory distress with significantly diminished pulmonary dysfunction. In addition, improvements in continuous monitoring of vital signs, radiological imaging techniques, delivery of medications, and maintenance of thermal stability have aided earlier identification of neonatal problems and enhanced improvements in care. Increased survival is most evident in the extremely low-birth-weight (ELBW) infant, that is, birth weight less than 1000 g. For infants born at 23 weeks of gestation, survival has increased from approximately 0% to more than 50%, and for infants born at 26 weeks of gestation, survival has increased from 25% to 85%.²⁶ It is important to note that the incidence of severe neurological injury has decreased over time in these extremely preterm infants. However, a significant number of preterm infants will exhibit long-term neurological impairment owing to increased survival.

The long-term effect of a neurological insult on the developing brain depends on the timing of the injury, the gestational age of the infant, and the nature and duration of the insult.²⁷ During the first month of gestation, the neural tube is formed. Neurological insult at this time leads to abnormal neural tube development, specifically anencephaly, encephalocele, or myelomeningocele. Neuronal proliferation is nearly complete by 5 months of gestation. All neurons and glial cells originate in the ventricular and subventricular zone (germinal matrix). Disorders of proliferation result in microcephaly, with either decreased size or decreased number of proliferating neuronal units or macrocephaly. Neuronal migration occurs at 3 to 6 months of gestation, and neurons are guided by glial cells to form neuronal columns. Subplate neurons, essential for correct organization of the brain, are formed at this time. Insults during this period of development result in marked disturbance of neurological structure and function with aberrations noted in gyral formation (lissencephaly, schizencephaly, and polymicrogyria) and/or absence of the corpus callosum.

Organization, consisting of elaboration of subplate neurons, orientation of cortical neurons, development of dendrites and axons, synaptogenesis and apoptosis, occurs from 5 months of gestation through several years after birth. Subplate neurons are present from 22 to 35 weeks of gestation; they form connections between neurons and guide axons and dendritic projections to the appropriate targets. Subplate neurons are sensitive to hypoxia and result in abnormal brain development and impaired long-term neurological outcome. Synaptogenesis before birth is experience independent. However, synaptic formation and elimination via apoptosis (programmed cell death) are most active after birth and are thought to be experience dependent. This process confers plasticity to the brain and is the basis of individuality. The presence and importance of subplate neurons as well as synaptogenesis coincide with the time that

preterm infants are in the NICU and make the preterm brain especially vulnerable to perturbations such as hypoxia, medications, stress, and pain.

The final phase of brain organization is glial maturation to astrocytes and oligodendrocytes. Astrocytes help maintain the blood-brain barrier, provide nutrient support, regulate neurotransmitter and potassium concentration, and assist in neuronal repair after injury. Oligodendrocytes produce myelin, a protective fatty sheath that surrounds axons (white matter) and facilitates nerve transmission. Myelination starts in midgestation and continues through adulthood. Oligodendrocytes are especially sensitive to hypoxia and other insults. Disruption of normal myelination results in white matter hypoplasia and periventricular leukomalacia (PVL) (see later discussion) leading to impaired motor function.²⁷

The most common neonatal problems associated with impaired neurological functioning and long-term developmental delay are listed in Table 11-1. In addition to descriptions of neonatal neurological conditions, a discussion is provided on the impact on neonatal development of maternal medication, such as drugs of abuse and psychotropic medications. The importance of developmental follow-up for healthy “late” preterm infants born at 34 to 36 $\frac{1}{7}$ weeks of gestation is also discussed in this section.

Intraventricular Hemorrhage

Intraventricular hemorrhage (IVH) is the most common brain injury in preterm infants born under 32 weeks of gestation and is a significant risk factor for the development of neurodevelopmental deficits. The incidence of IVH varies inversely with gestational age. Approximately 15% of infants born at 1000 g or less will have severe IVH. Although the incidence of severe IVH has decreased over time, an increased number of these infants survive owing to improvements in clinical care and technology, leading to an increase in the number of surviving preterm infants who are significantly affected by IVH.

IVH originates in the microcirculation or capillary network of the germinal matrix.²⁸ The germinal matrix is located adjacent to the ventricle and is a well vascularized area owing to the high metabolic demand from the rapidly proliferating neuronal stem cells. Vessels in the germinal matrix are thin walled and fragile, which predisposes them to rupture. In addition, preterm infants have impaired autoregulation—that is, the inability to maintain cerebral blood flow across a large range of blood pressures. Thus during labor, delivery, and the immediate postpartum transition period, changes in blood pressure can lead to cerebral hypoperfusion and ischemia as well as to hyperperfusion and vessel rupture. Alterations in CO₂ lead to either reduced cerebral blood flow from hypocarbia or increased flow from hypercarbia. Other risk factors

for IVH include asphyxia, fluid bolus infusion (especially of hypertonic solutions), anemia, and pain.²⁹ Platelet and coagulation disturbances have been implicated as risk factors for the development of IVH. IVH is rarely seen in infants with gestational age greater than 32 weeks owing to the developmental involution of vessels in the germinal matrix.

Diagnosed by cranial ultrasound, IVH is graded in severity from 1 to 4,²⁸ with grade 1 IVH being the most mild because the hemorrhage is confined to the germinal matrix. In grade 2 IVH, the hemorrhage extends into the ventricle (Figure 11-5). Grade 3 IVH occurs when the hemorrhage fills more than 50% of the ventricle and causes ventricular distention. Grade 4 IVH, or periventricular hemorrhagic infarct (PVHI), is a complication of IVH caused by venous congestion of the terminal veins that border the lateral ventricles leading to white matter necrosis (see later).³⁰ It is important to note that IVH may not be apparent on cranial ultrasound in the first few days after birth. However, 90% of IVHs can be detected by day 4. In addition, the full extent of the hemorrhage may not be appreciated for several days after the initial diagnosis of IVH is made.²⁸ The evolution of grades 3 and 4 IVH over 10 days is shown in Figure 11-6, A and B.

Many researchers have investigated the relationship of IVH grades with severity of neurodevelopment delay. In general, grades 1 and 2 IVH are not associated with a significant increase in developmental abnormalities but do not ensure normalcy. Infants with severe IVH (grade 3 and/or 4) have increased mortality and are at markedly increased risk for developmental disabilities, specifically spastic hemiplegia or diplegia affecting the lower extremities. As can be seen in Figure 11-7, motor tracts innervating the lower extremities are in close proximity to the area of the germinal matrix and the site of the origin of IVH leading to lower-extremity spastic cerebral palsy (CP). However, abnormalities visible on cranial ultrasound are not able to absolutely predict long-term outcome because the amount of cortex damaged and the neuronal tracts affected by IVH cannot be identified by ultrasound. In addition, ultrasound may not be sensitive enough to identify PVL (see later).

TABLE 11-1 ■ NEONATAL COMPLICATIONS AFFECTING BRAIN DEVELOPMENT

AGE	SPECIFIC INSULT
Preterm	Intraventricular hemorrhage (IVH) Periventricular hemorrhagic infarct (PVHI) Posthemorrhagic ventricular dilatation (PHVD) Periventricular leukomalacia (PVL) Necrotizing enterocolitis (NEC)
Term	Hypoxic-ischemic encephalopathy (HIE)

Figure 11-5 ■ Grade 2 intraventricular hemorrhage is illustrated by the *arrow* indicating the area of the germinal matrix bleed. The *arrowhead* points to blood layering in the posterior aspect of the lateral ventricle.

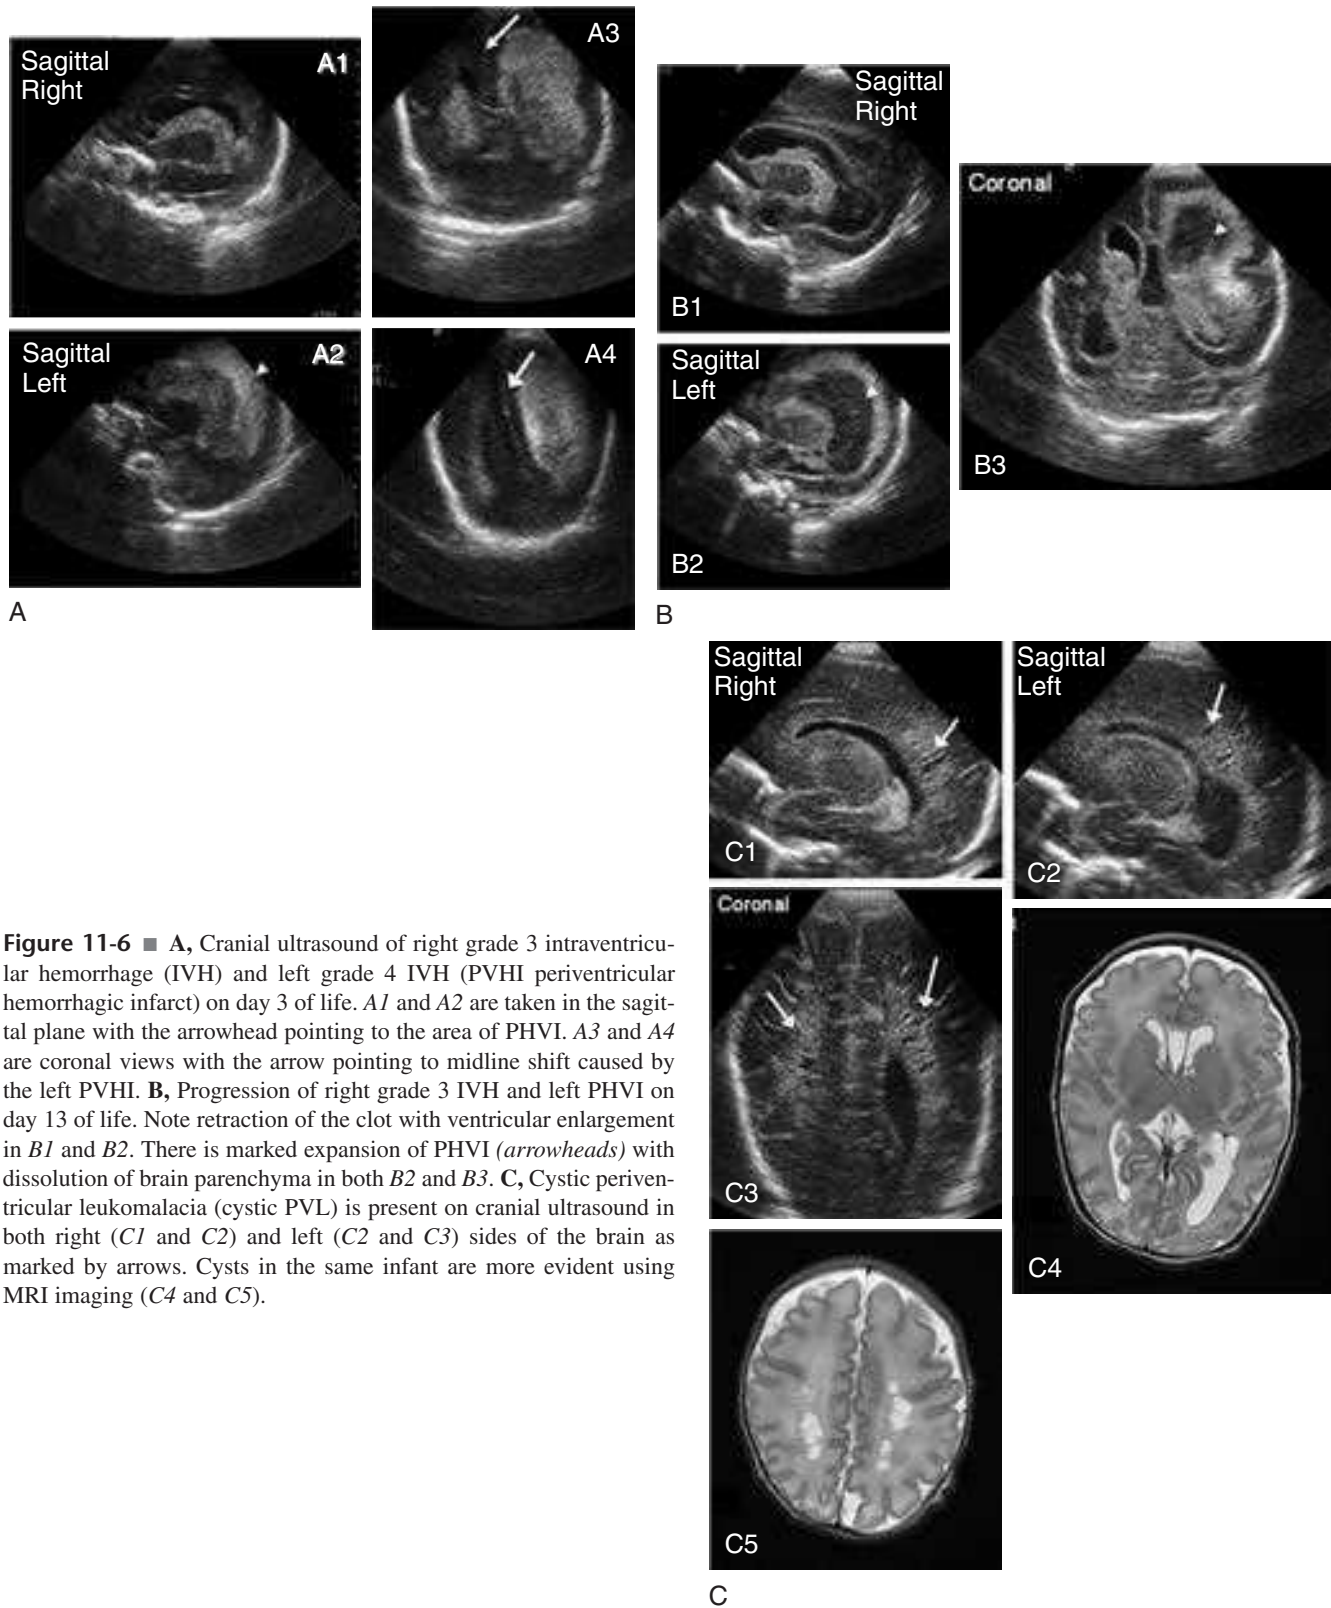

Figure 11-6 ■ A, Cranial ultrasound of right grade 3 intraventricular hemorrhage (IVH) and left grade 4 IVH (PVHI periventricular hemorrhagic infarct) on day 3 of life. *A1* and *A2* are taken in the sagittal plane with the arrowhead pointing to the area of PVHI. *A3* and *A4* are coronal views with the arrow pointing to midline shift caused by the left PVHI. **B,** Progression of right grade 3 IVH and left PVHI on day 13 of life. Note retraction of the clot with ventricular enlargement in *B1* and *B2*. There is marked expansion of PVHI (*arrowheads*) with dissolution of brain parenchyma in both *B2* and *B3*. **C,** Cystic periventricular leukomalacia (cystic PVL) is present on cranial ultrasound in both right (*C1* and *C2*) and left (*C2* and *C3*) sides of the brain as marked by arrows. Cysts in the same infant are more evident using MRI imaging (*C4* and *C5*).

Periventricular Hemorrhagic Infarct

Grade 4 IVH was originally thought to be an extension of IVH into the parenchyma but is actually a known complication of IVH.³⁰ PVHI is caused by venous compression of the terminal veins that border the lateral ventricles leading to impaired venous drainage and congestion and eventually hemorrhagic

infarction. The usual initial distribution of PVHI seen on cranial ultrasound is fan-shaped echodensities in the periventricular location (see [Figure 11-6, A2-4](#)). Over time there is destruction of preoligodendrocytes and motor axons leading to white matter necrosis and the development of porencephalic cyst. PVHI is usually unilateral (approximately 70%),

Figure 11-7 ■ Schematic diagram of corticospinal tract fibers that extend from the motor cortex through the periventricular region into the pyramid of the medulla. The lower motor neurons affected by intraventricular hemorrhage and periventricular hemorrhagic infarct are located in close proximity to the ventricle. Bulbar and upper motor neuron tracts are affected in term infants with hypoxic-ischemic encephalopathy and are parasylvian in location. (From Volpe JJ: *Hypoxic ischemic encephalopathy: neuropathology and pathogenesis*. In Volpe JJ: *Neurology of the neonate*, Philadelphia, 1995, WB Saunders.)

and approximately three quarters of cases are associated with severe IVH [grade 3 and 4]. Infants with small, unilateral PVHI have no increased risk of developmental delays compared with infants with grade 3 IVH. However, if the PVHI is bilateral or if multiple porencephalic cysts are present, the risk of severe motor impairment and CP is significantly increased. In addition, approximately 50% of infants with PVHI have visual field defects, probably secondary to damage to the axons of nerves carrying information to the visual cortex.³⁰

Posthemorrhagic Ventricular Dilatation

Approximately 50% of infants with severe IVH will develop posthemorrhagic ventricular dilatation (PHVD) from either blockage of the normal flow of cerebrospinal fluid (CSF) or decreased absorption of CSF. Approximately 50% to 75% of these infants will develop *progressive* PHVD, resulting in need for treatment. The severity of ventricular dilatation can be measured via serial cranial ultrasound examinations.^{31,32} Severe ventricular dilatation is usually evident by 2 to 3 weeks after birth. Rapid increase in head circumference does not occur until approximately 4 weeks after birth.³³ Posthemorrhagic ventricular dilatation is treated by serial removal of CSF by spinal tap, subgaleal shunt, or placement of an Ommaya reservoir. Removal of CSF has been shown to decrease intracranial pressure and improve cerebral perfusion³⁴ and also to increase cortical gray and white matter.³⁵ In addition, there is indirect evidence that ventricular distention itself may cause secondary brain injury through stretching and disruption of axons, gliosis, and loss of oligodendrocytes.

No consensus has been reached on the optimal management of PHVD. Ventriculoperitoneal (VP) shunt placement

is necessary in infants with PHVD that does not resolve with serial removal of CSF. Significant complications of VP shunt include sepsis, specifically ventriculitis, or shunt malfunction such as blockage or failure. These complications necessitate shunt revisions, which further compromise these fragile infants. Researchers from a consortium of 17 tertiary NICUs recently published results on the neurodevelopmental outcome at 2 years of age of ELBW infants with grade 3 and 4 IVH who were born from 1993 to 2002.³⁶ Infants who required VP shunt placement had significantly worse outcomes than infants with grade 3 or 4 IVH alone (Table 11-2). Moreover, the number of infants who were untestable (MDI or PDI = 49) because of severe neurodevelopmental handicap was significantly increased in the group of infants who received a VP shunt. In addition, CP was significantly more prevalent in infants who had a VP shunt placed than in infants with only grade 3 or 4 IVH.

Recent retrospective studies from the Netherlands indicated that earlier intervention when the ventricles are moderately dilated significantly decreased the need for VP shunt from 62% to 16% and trended to improve long-term developmental outcome with a decreased incidence of moderate to severe handicap.^{32,37} Thus, halting the progression of PHVD and decreasing the need for VP shunt is likely to improve long-term outcome in these infants. However, because PHVD can spontaneously resolve without intervention, identification of factors that can accurately predict which infant will develop persistent PHVD and consequently require VP shunt placement is needed.

Periventricular Leukomalacia

PVL is nonhemorrhagic cellular necrosis of periventricular white matter in the arterial watershed area and is present in less than 10% of preterm infants. Like IVH, PVL is inversely related to gestational age. PVL is the most common ischemic injury to the preterm infant and results from lack of cerebral autoregulation leading to decreased blood flow in the vulnerable watershed arterial vessels. Subplate neurons, critical for normal neuronal organization and interaction, are destroyed in PVL, leading to decreased white matter. In addition, preoligodendrocytes are exquisitely sensitive to oxygen and glucose deprivation leading to markedly abnormal myelination.

TABLE 11-2 ■ OUTCOME OF EXTREMELY LOW-BIRTH-WEIGHT INFANTS WITH GRADE 3 OR 4 INTRAVENTRICULAR HEMORRHAGE WITH OR WITHOUT VENTRICULOPERITONEAL (VP) SHUNT

	NO VP SHUNT	VP SHUNT	P
MDI <70	326/719 (45.3%)	146/214 (68.2%)	<.0001
MDI = 49	130/719 (18.1%)	87/214 (40.7%)	<.0001
PDI <70	263/711 (37.0%)	163/214 (76.2%)	<.0001
PDI = 49	149/711 (21.0%)	113/214 (52.8%)	<.0001
CP	217/767 (28.3%)	158/227 (69.6%)	<.0001

CP, Cerebral palsy; MDI, Mental Developmental Index; PDI, Psychomotor Development Index.

PVL can be either cystic (see [Figure 11-6, C](#)) or global and may be difficult to identify on radiological images. Cystic PVL results from the focal dissolution of cellular tissue approximately 3 weeks after the insult and can be identified on ultrasound if greater than 0.5 cm in diameter.²⁷ However, cysts visualized by cranial ultrasound may disappear over time owing to fibrosis and gliosis. Thus the incidence of cystic PVL is felt to be underestimated by cranial ultrasound examination. Global PVL results from diffuse white matter injury and myelin loss. This finding can be subtle with moderate ventricular dilatation and/or a mild increase in extraaxial fluid on cranial imaging. Infants with severe PVL have marked ventricular dilatation, increased extraaxial fluid, and decreased head growth.

MRI obtained at term is more sensitive in identifying white matter injury than cranial ultrasound and is predictive of subsequent neurosensory impairment and cognitive delay present in up to 50% of extremely preterm infants.³⁸ Newer techniques, such as diffusion tensor imaging (DTI), functional connectivity MRI (fcMRI), and morphometry for analysis of cortical folding are being investigated as early markers of impaired neurodevelopmental outcome. Diffusion tensor imaging measures the restriction of water diffusion in the myelin sheath surrounding axons and yields information at the microstructure level about axon caliber changes and aberrations in myelination. In addition, DTI allows for visualization of brain fiber tracks and neuronal connectivity. In research, fMRI is used to investigate interaction between areas of the brain at rest and during tasks by analyzing changes in blood flow. Morphometric analysis of sequential MRI scans has been used to create maps of cortical folding with quantification of surface area and degree of gyral formation. White matter injury results in delayed myelination and altered cortical folding.³⁸ Both fMRI and morphometric analysis of cortical folding are currently available only in research studies, not in clinical management.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is the most common neonatal intestinal disease, with an incidence of 10% in extremely preterm infants. The hallmark of NEC is pneumatosis intestinalis. NEC is initially treated medically with antibiotic therapy and cessation of enteral feedings. Surgery for NEC refractory to medical treatment or for intestinal perforation occurs in up to 50% of cases and has increased mortality of 20% to 40% compared with infants who are able to be treated medically. The cause of NEC is not established, but risk factors include prematurity, umbilical artery catheterization, asphyxia, congenital heart disease, blood transfusion, and enteral feedings. Several viruses (adenovirus, enterovirus, and rotavirus) and bacteria have been implicated as causative agents for NEC. However, bacteremia may be a secondary finding because infants with NEC are frequently in a septic condition either at the time of presentation of NEC or after intestinal perforation.

Complications of NEC include sepsis, wound infection, and stricture formation (10% to 35%) requiring repeated surgery. Growth of infants with NEC can be impaired due to feeding intolerance, prolonged total parenteral nutrition (TPN), removal of significant amounts of intestine, and repeated surgeries and infections. Persistence of weight at less than 10% for age is correlated with poor neuromotor and neurodevelopmental outcome.³⁹ Failure to achieve normalization of head

growth is associated with abnormal performance at 1 year and probably reflects significant white matter injury. Infants with surgically managed NEC have been shown to have significantly increased incidence of CP (24% versus 15%), deafness (4.1% versus 1.5%), and blindness (4.1% versus 1%).³⁹ Meta-analysis of seven studies investigating the impact of NEC on neurodevelopmental outcome showed that infants with surgically treated NEC have a statistically significant increase in cognitive, psychomotor, and neurodevelopmental impairment compared with age-matched preterm infants without NEC.⁴⁰ Impaired neurodevelopmental outcome in infants with NEC is further exacerbated by associated sepsis and the release of inflammatory cytokines and mediators in addition to hypoxia, all of which contribute to further insult to preoligodendrocytes, leading to white matter injury.

Cerebellar Injury

The cerebellum is essential for gross and fine motor control, coordination, and motor sequencing and plays an important role in attention and language.³⁶ The clinical hallmark of damage to the cerebellum is ataxia. However, recent advances in functional MRI (fMRI) have demonstrated that there are interactions between the cerebellum and nonmotor areas of the brain involved in language, attention, and mental imagery. Cerebellar injury can also be noted early in neonatal development from cranial ultrasound of the posterior fossa (mastoid view). The incidence of cerebellar injury may be as high as 20% in ELBW infants.⁴¹ Although the mechanism for damage is unknown, IVH is present in more than 75% of infants with cerebellar injury, implying similar risk factors for both IVH and cerebellar hemorrhage or the possibility that IVH leads to cerebellar hemorrhage. The majority of cerebellar lesions (70%) are unilateral.

Preterm infants with isolated cerebellar hemorrhage exhibit significant neurological impairments: hypotonia (100%), abnormal gait (40%), ophthalmological abnormalities (approximately 40%), and microcephaly (17%).⁴² Overall, preterm infants with cerebellar hemorrhage performed significantly lower on tests of gross and fine motor skills and have deficits in vision and expressive and receptive language. Infants with both cerebellar injury and IVH have greater motor impairment than infants with isolated cerebellar hemorrhage. Socially, infants with isolated cerebellar hemorrhage exhibit delayed communication skills, decreased social skills with more withdrawn behavior, and impaired ability to attend to tasks. Thus, cerebellar injury increases the risk for poor neurodevelopmental outcome in cognition, learning, and behavior in preterm infants.⁴² For long-term effects of cerebellar damage, refer to Chapter 21.

Hypoxic-Ischemic Encephalopathy

Perinatal asphyxia, the result of a hypoxic-ischemic (HI) insult, affects three to five per 1000 live births and leads to hypoxic-ischemic encephalopathy (HIE) in 0.5 to one per 1000 live births. Impaired oxygen delivery to the fetus can result from maternal hypotension, placental abruption, placental insufficiency, cord prolapse, prolonged labor, and/or traumatic delivery. Approximately 15% to 20% of infants with HIE will die, and 25% of the surviving infants will exhibit permanent neurological sequelae. Clinical findings will vary depending on the timing and duration of the HI insult, preconditioning and fetal adaptive mechanisms, comorbidities, and resuscitative efforts. Infants who are

intrauterine growth restricted are at increased risk of an HI insult due to decreased nutrient reserves.⁴³
