KEY TERMS

Basal ganglia
 Dystonia
 Huntington disease
 Parkinson disease

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe the circuitry of the basal ganglia.
2. Relate the anatomy and physiology of the basal ganglia to its roles in sensorimotor and cognitive processes.
3. Use the information on anatomy, physiology, and pharmacology to explain the signs and symptoms seen in classic disease states—for example, Parkinson disease, Huntington disease, and dystonia.
4. Develop an evaluation plan for patients with diseases of the basal ganglia.
5. Develop an intervention plan for patients, with the rationale for treatment methods.
6. Determine treatment effectiveness, especially in the case of degenerative disease.
7. Integrate the information in this chapter with the information provided in Section I of this book to develop treatment plans for patients with metabolic or toxic disorders.

This chapter considers the degenerative, metabolic, hereditary, and genetic disorders that typically have their onset in adulthood, including Parkinson disease, parkinsonian syndromes, Huntington chorea, Wilson disease, dystonias, heavy metal poisoning, and drug intoxication. Because of the wide variety of diseases with their wide variety of causes, the concentration is on understanding the clinical problems and commonalities that exist within this grouping. In general, the practice parameter of the diseases discussed in this chapter is the physical therapy diagnostic parameter 5E: Impaired motor and sensory integrity associated with progressive disorders of the central nervous system, from the *Guide to Physical Therapist Practice*.¹ Although the occupational therapy guide does not classify practice parameters in that manner, the concepts and clinical reasoning process can be used by both professionals. The predominant area of the brain affected by these disorders is the basal ganglia: this group of central nervous system (CNS) structures is therefore discussed in some detail.

THE BASAL GANGLIA

The most commonly seen disorders affecting the basal ganglia include Parkinson disease, Huntington chorea, and dystonias, including drug-induced dyskinesias. All of these medical diagnoses involve impairments in muscle tone, movement coordination and motor control, and postural stability and the presence of extraneous movement. Taken together, these disorders now affect approximately 1 million people in the United States.²⁻⁴

To understand how this area of the brain can account for such a wide variety of symptoms, the anatomy, physiology, and neurochemistry of the basal ganglia structures must be considered.

Anatomy

The dorsal or sensorimotor basal ganglia are composed of three nuclei located at the base of the cerebral cortex—hence their name. These nuclei are the caudate nucleus, the putamen, and the globus pallidus. Two brain stem nuclei, the substantia nigra and the subthalamic nucleus, are included as part of the basal ganglia because they have a close functional relation to the forebrain nuclei. In addition, connections between the basal ganglia and the pedunculopontine nucleus (PPN) are important in regulating underlying tone. Other parts of the basal ganglia, the ventral basal ganglia, are intimately related to the limbic system and are discussed in Chapter 5. The anatomical location of the various parts of the basal ganglia is shown in Figure 20-1.

The caudate nucleus and the putamen are similar structures embryologically, anatomically, and functionally and are often referred to together as the neostriatum—a term derived from the word *striate* and used to denote pathways from and to the caudate and putamen. An older term, *corpus striatum*, refers to the caudate, putamen, and globus pallidus. The various connections and interconnections of this system are discussed on the basis of these definitions.

Afferent Pathways

Functionally, the basal ganglia can be divided into an afferent portion and an efferent portion (Figure 20-2). The afferent structures are the caudate and putamen. They receive input from the entire cerebral cortex, the intralaminar thalamic nuclei, and the centromedian-parafascicular complex of the thalamus as well as from the substantia nigra and the dorsal raphe nucleus, both located within the brain stem. The projections from the cortex are systematically arranged so that the frontal cortex projects to the head of the caudate and putamen and the visual cortex projects to the tail. In addition,

Figure 20-1 ■ A coronal section of the anatomical location of various parts of the basal ganglia. (Reprinted from Nolte J: *The human brain: an introduction to its anatomy*, St Louis, 1981, CV Mosby.)

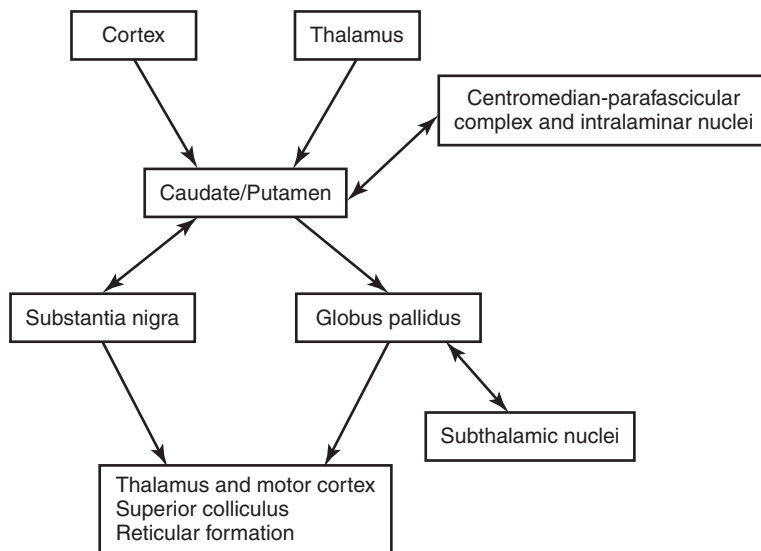

Figure 20-2 ■ Afferent and efferent portions of the basal ganglia.

the prefrontal cortex projects mainly to the caudate, whereas the sensorimotor cortex projects mainly to the putamen.⁵⁻⁸ Projections from the cortical regions that represent the proximal musculature, and those from the premotor regions may be bilateral.^{6,9-11} These close and profuse connections between the cortex and the basal ganglia suggest a close interfunctional relationship. The projections from the thalamus to the caudate-putamen are also somatotopically arranged. The heaviest projections are from the centromedian nucleus, and these nuclei also receive massive input from the motor cortex.⁷⁻¹⁰

The somatotopic arrangement of the cortico-striatal-thalamic-cortical pathways is maintained throughout the loop. This finding has led to an important functional hypothesis that the basal ganglia form parallel pathways subserving specific sensorimotor and associative functions.⁵ The putamen is linked to the sensorimotor functions and the caudate to the associative, including cognitive functions.^{9,12}

As knowledge of the circuitry of the basal ganglia has advanced, so has the knowledge regarding the microscopic structure. The caudate-putamen looks somewhat homogeneous because of the predominance of one cell type. Careful analysis using precise staining methods has demonstrated the appearance of patches within these nuclei. It is hypothesized that this organization is important for the ability of the basal ganglia to modulate ongoing sensory input and choose the appropriate motor response.¹² The intrinsic structure of the caudate-putamen also suggests that at least nigral input occurs in a way that could immediately modulate the input coming from the cortex.^{13,14}

Efferent Pathways

The input that has been processed in the caudate-putamen is sent to the globus pallidus (pallidum) and substantia nigra (nigra), which constitute the efferent portion of the basal ganglia. The globus pallidus and substantia nigra are each divided into two regions. The globus pallidus has an external and an internal region; the substantia nigra consists of the dorsal pars compacta and the ventral pars reticulata. Embryologically and microscopically, the internal segment of the globus pallidus and the pars reticulata of the substantia nigra are similar. These two regions are the primary efferent structures for the basal ganglia. The projections from the caudate and putamen to the pallidum and nigra maintain a somatotopic arrangement.^{10,15,16} From these structures the information is transmitted to the thalamus and then to the cortex, still maintaining somatotopy. The superior colliculus, the PPN, and other, less defined brain stem structures (perhaps the reticular formation) also receive pallidal and nigral output. All output of the basal ganglia has then been processed through the globus pallidus and/or the substantia nigra before proceeding to other areas of the brain (see Figure 20-2).

Pathways to the Motor System

Information processed in the basal ganglia can influence the motor system in several ways, but no direct pathway to the alpha or gamma motor neurons of the spinal cord exists. The first route is the projection to the ventroanterior and ventrolateral nuclei of the thalamus, which then project predominantly to the premotor cortex. Another pathway is

through the superior colliculus and then to the tectospinal tract. Pathways exist from the globus pallidus and substantia nigra that terminate in areas of the reticular formation (e.g., the PPN) and thus may influence the motor system through the reticulospinal pathways. Anatomically the basal ganglia are therefore in good position to affect the motor system at many levels. Many of these connections are also areas that receive cerebellar input, and thus these two regions of the brain have ample opportunity to further integrate movement responses.¹⁷

The basic circuitry of the basal ganglia comprises two loops.⁷ The loops for the sensorimotor system are shown in Figure 20-3. The direct loop is the loop that begins in the motor regions of the cortex and projects to the putamen and then directly to the globus pallidus, the internal segment, and on to the thalamus. The indirect pathway adds the subthalamic nucleus between the globus pallidus, external segment, and internal segment before sending the signal on to the thalamus. The subthalamic nucleus also receives direct

(Reprinted from Alexander GE, Crutcher MD: Functional architecture of basal ganglia circuits: neural substrates of parallel processing, *Trends Neurosci* 13:266-271, 1990.)

input from the premotor and motor cortex as well as from the pallidum.^{18,19} The darkened neurons represent inhibitory connections, and the open neurons represent excitatory connections. In general, the direct pathway, by disinhibition, activates the thalamocortical pathway; the indirect pathway inhibits the thalamocortical system. The role of these loops in normal and diseased states is clarified in the discussion of the physiology and pharmacology of the basal ganglia.

In summary, input from the motor cortex, all other areas of the cortex, parts of the thalamus, and the substantia nigra enter the basal ganglia through the caudate and putamen. Here they are processed and sent on to the globus pallidus and substantia nigra. The appropriate “gain” of the system is adjusted, for example, how large a movement is necessary or how much postural stability is needed. The information is sent to the muscles by way of the thalamus and motor cortex, the superior colliculus, and/or the reticular formation.

Physiology

The caudate and putamen are composed of neurons that fire slowly; the globus pallidus neurons fire tonically at high rates. The low firing rates of the caudate-putamen are partially a result of the nature of thalamic inputs. Input from the cortex seems to have priority over input from the thalamus and substantia nigra. These data indicate that the cortex is instrumental in regulating the responsiveness of caudate and putamen neurons.²⁰ In turn, basal ganglia stimulation may prepare the cortex for subsequent inputs; this might be especially important when a response must be withheld until an appropriate stimulus occurs, such as keeping the foot on the brake until the light turns green.²⁰⁻²³ Mink hypothesized that basal ganglia inputs to the cortex activate only the most necessary pathways and inhibit all unnecessary pathways (Figure 20-4).²⁴

The pattern of neuronal firing in the direct and indirect pathways also suggests that the basal ganglia modify input to the cortex. The neurons of the efferent portion of the basal ganglia respond with either phasic increases or phasic decreases in activity, which in turn will affect the activity in the thalamus and hence the cortex. A decrease in activity of the internal segment of the globus pallidus removes inhibition to the thalamus and thus enables cortical activation. Whether the two pathways are activated concurrently or whether different activities activate the two pathways separately is not yet known; either way, the basal ganglia would have a role in cortical activation and modulation. One of the current views in relationship to disease processes is that an underactive direct pathway and/or an overactive indirect pathway would lead to decreased activation of the cortex and hence bradykinesia and akinesia, whereas an overactive direct pathway and/or underactive indirect pathway would lead to the presence of extraneous movements (see Figure 20-3).^{6,25}

How do these pathways relate to everyday function? Rigidity could be explained by too much muscle activity (through the pathways from the basal ganglia to the PPN and on to the spinal cord). Akinesia and bradykinesia typical of individuals with Parkinson disease are caused by insufficient excitation or too many conflicting patterns of movement. Increased extraneous movements are characteristic of basal ganglia diseases and can be attributed to the dysfunctions within these pathways. If the amount of muscle activity and the sequence and timing of activation are inappropriate, the

individual will have difficulty in selecting the environmentally appropriate behavior.²⁴⁻²⁷ Aldridge and colleagues found that the basal ganglia were modulated dependent on the purpose of the impending movement.²⁷

Relationship of the Basal Ganglia to Movement and Posture

Lesion experiments; single and multiple unit recordings in awake, behaving animals; careful observations of the sequelae of human disease processes; and the results of functional magnetic stimulation studies in humans have provided some answers regarding the precise role of the basal ganglia in movement and posture.

Automatic Movement

The earliest view of the basal ganglia came from Willis in 1664. He hypothesized that the corpus striatum received “the notion of spontaneous localized movements in ascending tracts.... Conversely, from here tendencies are dispatched to enact notions without reflection [automatic movements] over descending pathways” (p. 7).²⁸ Willis possessed great insights in the discussion of the signs and symptoms of basal ganglia disease. Magendie in 1841 demonstrated that removal of the striatum bilaterally produced compulsive movements, whereas removal of only one striatum produced no visible effect.²⁹ Studies by Nothnagel³⁰ demonstrated that lesions of the nigra tended to produce immobility. With the advent of the use of electrical stimulation

in the late nineteenth century, further information on the function of the basal ganglia was gathered. Stimulation of the caudate nucleus did not (and does not) produce movement of muscles or limbs as occurs with stimulation of the motor cortex. However, at higher levels of current, total body patterns and postures were usually evoked. The earliest stimulation of the caudate nucleus produced an increase of flexion of the head, trunk, and limbs and tonic contraction of the facial muscles.³¹ These early studies are mentioned because of the insights they provide for the symptoms of the disorders of today.

Motor Problems in Animals

Contemporary experiments using lesion paradigms show a wide variety of motor problems in a variety of animals. Hypokinesia, a decrease or poverty of movements, a decreased amount of exploration of novel environments, and a tendency to assume a fixed posture are the most common problems after a lesion in the basal ganglia. These motoric dysfunctions are seen regardless of the method by which the lesion is made: pharmacologic, surgical, or by stimulation. In essence, movements are altered in scale (related to the gain), take longer for completion, and take place under altered conditions of antagonistic muscle interactions (e.g., contraction).³²⁻⁴⁰

Movement Initiation and Preparation

The hypothesis that the basal ganglia are involved in movement initiation and preparation is an area of some research disagreement. A “readiness potential,” recorded from the scalp of human beings before movement and thought to reflect basal ganglia activity, is more apparent in complex than in simple movements, for example, before dorsiflexion with gait but not before dorsiflexion when sitting.⁴¹⁻⁴⁴

Neuronal recordings from awake, behaving animals found that units in the basal ganglia alter their activity before changes in the electromyographic activity of the prime movers of the task.⁴⁵⁻⁵¹ Studies recording from multiple units in animals moving freely in their home environment suggest that neurons in the caudate-putamen and in the substantia nigra are activated in sequential, purposeful movements.²⁷

Postural Adjustments

The basal ganglia have been implicated in the process of posture and postural adjustments. People with diseases of the basal ganglia assume flexed or other fixed postures as the disease progresses (Figure 20-5). In addition, these individuals have decreased postural stability and are therefore at risk for falls. Animal experiments indicate that a deficit exists in determining response based on one’s own body position, or “egocentric localization.”⁵²⁻⁵⁴ This deficit decreases the ability of a person with basal ganglia disease to modify a postural response to the precise environmental demands.

Martin,⁵⁵ in his extensive studies of individuals with Parkinson disease, was the first to describe severe disturbances in posture, especially when vision was occluded. Melnick and colleagues⁵⁶ showed that a decrease in static postural adjustments in persons with Parkinson disease could be seen early in the disease process.⁵⁷ Bloem and colleagues⁵⁸⁻⁶⁰ and Visser and colleagues^{61,62} meticulously studied the reflexes involved in postural adjustments and

Figure 20-5 ■ Typical posture of a patient with Parkinson disease from the front and from the side. Note the flexed spine, mild flexion at the hips and knees, and excessive dorsiflexion with weight predominantly on the heels. Patient was at Hoehn and Yahr stage 2.5.

described deficits in the longer loop reflexes but not in the short latency reflex associated with the stretch reflex.

Others have investigated the interactions of the sensory systems involved in balance in those with Parkinson disease.⁶²⁻⁶⁶ Bloem and colleagues⁶⁰ and Visser and colleagues⁶² concluded that postural instability was caused by a decrease in proprioception. In a recent review of proprioception and postural stability and motor control, Nicola and colleagues also describe the kinesthetic and proprioceptive deficits in people with Parkinson disease. Nicola and colleagues concluded that there was a “failure” in the body map similar to the failure in egocentric localization described previously.⁵⁴ A decrease in the ability to use proprioceptive and kinesthetic information to properly scale the input and response also contributes to a loss of balance reactions.

Perceptual and Cognitive Functions

The basal ganglia are not solely motor systems. The previous paragraphs demonstrate the role of the basal ganglia in sensory integration. The basal ganglia are also involved in cognitive functions and responses associated with reward.^{36,37,48,50,67-70} Researchers have found that learned

movements are more affected by basal ganglia lesions than reflexes, that neurons in the basal ganglia are responsive to some sensory input, especially proprioceptive input, and that neurons in other parts of the basal ganglia are responsive to reward and anticipation of the reward.^{26,71,72} Klockgether and Dichgans⁷³ as well as Jobst and colleagues⁷⁴ found that patients with Parkinson disease likewise had impairments in kinesthesia and that as a person moved a limb further from the body's center, kinesthetic sense decreased. Schneider and colleagues⁷⁵ found that animals that developed parkinsonian symptoms from a neurotoxin had deficits in operantly conditioned behavior. They suggested that the decrease in performance resulted from a "defect in the linkage" between a stimulus and the motor output centers. These sensory difficulties may be important factors in evaluation and treatment of basal ganglia diseases, especially those associated with dystonia.

The basal ganglia appear to be involved in the process of withholding a response until it is appropriate.⁷⁶ A deficit in alternation of response may be the result of a tendency toward perseveration of a previously reinforced cue.⁷⁷ Additional deficits exist in remembering or relearning tasks requiring a temporal sequence.⁷⁸ Graybiel²⁶ integrated the behavioral findings with information from her anatomical and chemical studies to suggest that the basal ganglia are important in providing behavioral flexibility. She hypothesizes that the basal ganglia are involved in procedural learning that leads to the development of habits. These habits become routine and are easily performed without conscious effort. Because these activities can proceed without thought, we are free to react to new events in our environment and to think. She and colleagues have performed electrophysiological experiments that explain this learning process, and these studies demonstrate great plasticity in basal ganglia networks.⁷⁹ This enables the individual to select the proper movements in the proper environmental context. An elegant study by Brown and colleagues⁸⁰ demonstrates a model of the basal ganglia that can reflect these cognitive and learning activities. Their model seems to integrate many of the functions of the basal ganglia with the physiology and pharmacology of the entire system. These cognitive dimensions are important to remember when developing a plan of care for a patient with basal ganglia dysfunction.

Humans with basal ganglia disease also show problems in perceptual abilities, including deficits in tasks that involve perception of interpersonal and intrapersonal space.⁸¹ In pursuit-tracking tests individuals with Parkinson disease had particular difficulties in correcting errors⁷⁷; if the motor system is inflexibly set, corrections can be made only by a complete reprogramming.

The ability to perform cognitive activities involves integrating sensory information and, on the basis of this information, making an appropriate response. The basal ganglia seem to have a sensory integrative function as evidenced by experiments that show a multisensory and heterotopic convergence of somatic, visual, auditory, and vestibular stimuli.^{26,71,72} Segundo and Machne⁸² hypothesized that the function of the basal ganglia was not subjective recognition of the stimuli but rather in the regulation of posture and movements of the body in space and in the production of complex motor acts. Nicola and colleagues had similar conclusions.⁵⁴

For movements to be properly controlled and properly sequenced, the two sides of the body need to be well integrated. There is anatomical evidence that suggests some means of bilateral control for the basal ganglia. A lesion of one caudate nucleus or nigrostriatal pathway produces a change in the unit activity of the remaining caudate.^{78,83} Studies of the dopaminergic pathway also indicate interactions between the two sides of the body.⁸³ For this reason one may find deficits in function even on the "uninvolved" side of an individual with disease of the basal ganglia. It is also possible that diseases of the basal ganglia may go unnoticed until damage is found bilaterally.

This summary of experimental results on the function of the basal ganglia illustrates several points. At least in some general way the basal ganglia are involved in the processes of movement related to preparing the organism for future motion and future reward. This may include preparing the cortex for approximate time activation, setting the postural reflexes or the gamma motor neuron system, organizing sensory input to produce a motor response in an appropriate environmental context, and inhibiting all unnecessary motor activity. Because of the multilevel involvement of the basal ganglia in movement, it is crucial that clinicians carefully observe all aspects of movement (simple and complex) with and without interference of sensory cues or performance of dual tasks as well as postural tone during examination and treatment and the responses to treatment (see Chapter 9).

Neurotransmitters

Before a detailed analysis of the diseases of the basal ganglia can be considered, a brief description of the neurotransmitters of this region is necessary. The most prevalent diseases discussed in this chapter indicate a deficit in specific neurotransmitters. The pharmacological treatment of Parkinson disease and, in the future, perhaps other "basal ganglia plus" diseases, is based on these neurochemical deficits. The basal ganglia possess high concentrations of many of the suspected neurotransmitters: dopamine (DA), acetylcholine (ACh), γ -aminobutyric acid (GABA), substance P, and the enkephalins and endorphins. This discussion, however, includes only the first three neurotransmitters. A diagram of the basal ganglia pathways, which includes the neurotransmitters, is shown in [Figure 20-6](#).

DA is the major neurotransmitter of the nigrostriatal pathway. It is produced in the pars compacta of the substantia nigra. The axon terminals of these dopaminergic neurons are located in the caudate nucleus and putamen. DA appears to be excitatory to the neurons in the direct pathway (GABA and substance P neurons) and inhibitory to the neurons in the indirect pathway (GABA and enkephalin neurons).² This dual effect means that a loss of DA will lead to a loss of excitation in the direct pathway and an excess of excitation of the indirect pathway, leading to a powerful decrease in activation of the thalamocortical pathway.

Several DA receptors exist; however, their chemical interactions permit the continued use of D1 and D2 receptor classes.⁷ The role of DA may modulate the effects of other neurotransmitters such as glutamate. Many new drugs (called the *dopamine agonists*) influence only one of these receptors. Recent experiments have been trying to determine which behaviors are mediated by which DA receptor in the

hope that this research may lead to more effective drug treatment with fewer side effects.

Because various drugs and chemicals can act as agonists (similar to) and antagonists (blocking the action of) of DA, they are used in treating disease involving the basal ganglia. Agonists include amantadine, apomorphine, and a class of drugs called the *ergot alkaloids* (e.g., bromocriptine). Amphetamine, which prevents the reuptake of DA, can enhance the effect of any DA present in the system. Antagonists include haloperidol, clozapine, and antipsychotic drugs of the phenothiazine class. With time these drugs may deplete the basal ganglia of DA and thus cause Parkinson disease or tardive dyskinesia. Similar effects on the DA system are observed in a single dose of methamphetamine (see Chapter 36).⁸⁴

ACh is believed to be the neurotransmitter of the small interneurons of the caudate and putamen. It is presumed to inhibit the action of DA in this region and classically must be “in balance” with DA (and GABA). Dopaminergic axon terminals are found on cholinergic neurons. Substances that increase dopaminergic activity decrease release of ACh and vice versa.⁸⁵ The antagonists of ACh, such as belladonna

alkaloids and atropine-like drugs, were one of the first class of drugs used in the treatment of Parkinson disease. ACh antagonists are still used as adjuncts to treatment for patients with Parkinson disease. As some of the drugs to treat dementia are ACh agonists, care must be used when these are prescribed for the person with basal ganglia dysfunction, especially Parkinson disease.

GABA is an inhibitory neurotransmitter that is found throughout the brain. In the basal ganglia it is synthesized in the caudate nucleus and putamen and transmitted to the globus pallidus and substantia nigra.⁸⁶ GABA in the basal ganglia may permit movement to occur by allowing a distribution of neuronal firing. It also may provide a means of feedback inhibition in the efferent parts of the basal ganglia so that the program of activity is not repeated unless needed.⁸⁶ Individuals with Huntington disease have a deficiency of this chemical. Although agonists of GABA exist (e.g., muscimol and imidazole acetic acid), a successful drug for the treatment of Huntington disease has not yet been found. This may be a result of either the ubiquitous nature of GABA or the very complex circuitry and interrelationships that exist among GABA, ACh, and DA.

In addition to the transmitters discussed, co-transmitters may be found in the basal ganglia. Two such co-transmitters are cholecystinin and neurotensin. The interactions of these co-transmitters may alter the sensitivity of DA receptors. Fuxe and colleagues⁸⁷ suggest that the interactions of co-transmitters may alter the “set point” of transmission in synapses. They may therefore be important in one of the side effects of DA therapy, supersensitivity.

Lastly, the neurotransmitter from the cortex to the caudate nucleus and putamen is glutamate. Studies are ongoing to investigate glutamate antagonists as a treatment for Parkinson disease. Glutamate receptors use calcium, and in the future, drugs affecting calcium channels may also have a therapeutic effect.

SPECIFIC CLINICAL PROBLEMS ARISING FROM BASAL GANGLIA DYSFUNCTION

Parkinson Disease

Parkinson disease, first described by Parkinson in 1807, is a disease characterized by rigidity, bradykinesia (slow movement), micrographia, masked face, postural abnormalities, and a resting tremor. As might be suspected from the review of functional physiology of the basal ganglia, the postural abnormalities include an assumption of a flexed posture, a lack of equilibrium reactions, especially of the labyrinthine equilibrium reactions, and a decrease in trunk rotation. Parkinson disease is among the most prevalent of all CNS degenerative diseases. Presently there are an estimated 1 million people in the United States with this disease, with approximately 60,000 new cases each year; the incidence is 4.5 to 20.5 and the prevalence is 31 to 347 per 100,000. (Refer to the list of websites at the end of this chapter.) Incidence increases with advancing age, and it is estimated that one in three adults over the age of 85 will have this disease.² The personal and societal burden of Parkinson disease is great and includes the costs of actual treatment, the burden of caregiving, and the costs of lost earnings in patients under the age of 65.⁸⁸

The pathology of Parkinson disease consists of a decrease in the DA stores of the substantia nigra with a consequent depigmentation of this structure and the presence of Lewy bodies (intracellular inclusions). It is DA that gives the substantia nigra its coloration (and hence its name); therefore the lighter the nigra, the greater the DA loss.

The cause of Parkinson disease remains unknown, and the consensus is that it is multifactorial.^{89,90} A slow viral process or long-term effects of early infection were implicated in postencephalitic parkinsonism. Some evidence indicates involvement of environmental factors and that interaction of environment and aging lead to a critical decrease in DA. Several investigators have found a link between growing up in a rural area and Parkinson disease; the important factors include pesticide use, insecticide use, and elements in well water.⁹¹⁻⁹⁷ Accumulation of free radicals, cell death to excitatory neurons from toxins, and dysfunction of nigral mitochondria have all been implicated in the pathological process. The genetics of Parkinson disease is still debated. Although twin studies indicate that there may not be a single gene involved in Parkinson disease, as in Huntington disease, a family history may be an important risk factor.^{93,98-101} Very recently a large-scale study found two genetic loci to be associated with Parkinson disease.¹⁰² So the debate continues, with most neurologists agreeing that the multifactorial approach will yield the best opportunity to develop a cure.

In view of possible treatment effects for Parkinson disease, it is interesting that a study by Sasco and others¹⁰³ found an inverse relationship, albeit small, between participation in exercise or sports and later development of Parkinson disease. The loss of DA from the substantia nigra leads to alterations in both the direct and indirect pathways of the basal ganglia, resulting in a decrease in excitatory thalamic input to the cortex and perhaps a decrease in inhibitory surround that leads to the symptoms of Parkinson disease.

Symptoms

Bradykinesia and Akinesia. Bradykinesia (a decrease in motion) and akinesia (a lack of motion) are characterized by an inability to initiate and perform purposeful movements. They are also associated with a tendency to assume and maintain fixed postures. All aspects of movement are affected, including initiation, alteration in direction, and the ability to stop a movement once it is begun. Spontaneous or associated movements, such as swinging of the arms in gait or smiling at a funny story, are also affected. Bradykinesia is hypothesized to be the result of a decrease in activation of the supplementary motor cortex, premotor cortex, and motor cortex.¹⁰⁴ The resting level of activity in these areas of the cortex may be decreased so that a greater amount of excitatory input from other areas of the brain would be necessary before movement patterns could be activated. In the individual with Parkinson disease, an increase in cortically initiated movement even for such “subcortical” activities as walking supports this hypothesis. Automatic activities are cortically controlled, and each individual aspect seems to be separately programmed. Associated movements in the trunk and other extremities are not automatic. This means that great energy must be expended whenever movement is begun.¹⁰⁵

Bradykinesia and akinesia affect performance of all types of movements; however, complex movements are more

involved than simple movements, such as dorsiflexing the foot at toe-off in walking as opposed to dorsiflexing the foot in a seated position.^{71,106-109} In addition, patients with parkinsonism have increased difficulty performing simultaneous or sequential tasks, over and above that seen with simple tasks. Parkinsonian patients must complete one movement before they can begin to perform the next, whereas control subjects are able to integrate two movements more smoothly in sequence. This deficit has been shown in a variety of tasks from performing an elbow movement and grip to tracing a moving line on a video screen. The patient with Parkinson disease behaves as if one motor program must be completely played out before the next one begins, and there is no advance planning for the next movement while the current movement is in progress.^{106-108,110,111} Morris and colleagues demonstrated a similar phenomenon in walking. Patients with parkinsonism were unable to perform walking while carrying a tray with a glass of water and had even more difficulty when walking and reciting a numerical sequence.^{112,113}

Sequential movements become more impaired as more movements are strung together; for example, a square is disproportionately slower to draw than a triangle; a pentagon, more difficult than a square.^{5,106} These results indicate that patients with Parkinson disease have difficulty with transitions between movements. Transitional difficulties are more impaired in tasks requiring a series of different movements than tasks requiring a series of repetitive movements. For example, an individual will have less difficulty continually riding a stationary bike than movement requiring transitions such as coming from a chair to standing, walking, and turning a corner. Therefore treatment must include complex movements with directional changes to ensure that the patient is safe outside the treatment setting.

Bradykinesia is not caused by rigidity or an inability to relax. This was demonstrated in an electromyographic analysis of voluntary movements of persons with Parkinson disease.¹¹⁴ Although the pattern of electromyographic agonist-antagonists burst is correct, these bursts are not large enough, resulting in an inability to generate muscle force rapidly enough. Even in slow, smooth movements, however, these individuals demonstrated alternating bursts in the flexor and extensor muscle groups. This type of pattern, expected in rapid movements that require the immediate activation of the antagonist to halt the motion, interferes with slow, smooth, continuous motion. Other researchers have found an alteration in the recruitment order of single motor units.^{115,116} These alterations included a delay in recruitment, pauses in the motor unit once it was recruited, and an inability to increase firing rates. These persons therefore would have a delay in activation of muscles and an inability to properly sustain muscle contraction for movement, and a decreased ability to dissipate force rapidly.^{24,115,117} Such changes may account for perceived decreases in strength that are seen in persons with Parkinson disease. They are also important to remember in both treatment planning and the efficacy of treatment efficiency.

Rigidity. The rigidity (increased resistance to passive movement) of Parkinson disease may be characterized as either “lead pipe” or “cogwheel.” The cogwheel type of rigidity is a combination of lead-pipe rigidity with tremor. In rigidity there is an increased resistance to movement throughout the entire range in both directions without the

classic clasp-knife reflex so characteristic of spasticity. Procaine injections can decrease the rigidity without affecting the decrease of spontaneous movements, confirming that rigidity is not the same phenomenon as bradykinesia.^{118,119}

Rigidity is not caused by an increase in gamma motor neuron activity, a decrease in recurrent inhibition, or a generalized excitability in the motor system.¹²⁰ Long- and middle-latency reflexes are enhanced in parkinsonism, and the increase in long-latency reflexes approximates the observable increase in muscle tone. Short-latency reflexes (i.e., deep tendon reflexes), on the other hand, may be normal in persons with Parkinson disease.

Tatton and others¹²¹ found differences in certain cortical long-loop reflexes in normal and drug-induced parkinsonian monkeys, which led them to speculate that the “reflex gain” of the CNS may lose its ability to adjust to changing environmental situations. For example, in normal persons the background level of motor neuron excitability is different for the task of writing than for the task of lifting a heavy object; in individuals with Parkinson disease motor neuron excitability would be set at the same level. Similarly, in the normal individual there would be a difference in excitability if the environmental demands were for excitation or inhibition of a muscle; for the individual with Parkinson disease, there would be similar motor neuron excitability regardless of task demands. Furthermore, this lack of modulation may mean that the person with parkinsonism perceives himself or herself to be moving farther than he or she is actually moving. It is also consistent with a decrease in system flexibility and an inability to adjust to equilibrium perturbations.^{58,59,65}

An important aspect of rigidity is that it might increase energy expenditure.¹²² This would increase the patient’s perception of effort on movement and may be related to feelings of fatigue, especially postexercise fatigue.¹²³

Tremor. The tremor observed in Parkinson disease is present at rest, usually disappears or decreases with movement, and has a regular rhythm of about 4 to 7 beats per second. Some people with Parkinson disease may have a postural tremor. The electromyographic tracing of a person with such a tremor shows rhythmical, alternating bursting of antagonistic muscles. Tremor can be produced as an isolated finding in experimental animals that have lesions in various parts of the brain stem or that have been treated with drugs, especially DA antagonists. DA depletion, however, is not the sole cause of tremor. It appears that efferent pathways, especially from the basal ganglia to the thalamus, must be intact because lesions of these fibers decrease or abolish the tremor.¹²⁴ Poirier and colleagues¹²⁴ proposed that tremor results from a combined lesion of the basal ganglia and cerebellar–red nucleus pathways. Because both the basal ganglia and the cerebellum project to the thalamus, a lesion of the thalamus can abolish the tremor regardless of the specific pathway(s). Although tremor may be cosmetically disabling, the tremor rarely interferes with activities of daily living (ADLs).

Postural Instability. Postural instability is a serious problem in parkinsonism that leads to increased episodes of falling and the sequelae of falls. More than two thirds of all patients with parkinsonism fall, and more than 10% fall more than once a week.¹²⁵ People with Parkinson disease have a ninefold risk of recurrent falls compared with age-matched control subjects.^{60,126-130} Patients have an increased

likelihood of falling as the duration of the disease increases. Drug treatment is not usually effective in reducing the incidence of falls. Deep brain stimulation and exercise, on the other hand, have been shown to be effective in increasing functional skills and/or motor performance; these improvements may decrease the number of falls.¹³¹⁻¹³⁴ Large randomized clinical trials have been performed to determine the efficacy of exercise.¹³⁵

Although the causes of balance difficulties are not known, several hypotheses exist. One explanation for postural instability is ineffective sensory processing. Several investigators have found deficits in proprioceptive and kinesthetic processing.^{55,74,117,136} For example, Martin⁵⁵ found that labyrinthine equilibrium reactions were delayed in patients with Parkinson disease. Studies of the vestibular system itself, however, have shown that this system functions normally. Pastor and colleagues¹³⁷ studied central vestibular processing in patients with Parkinson disease and found that the vestibular system responds normally and that patients can integrate vestibular input with the input from other sensory systems. This group hypothesized that the parkinsonian patients had an inability to adequately compensate for baseline instability. This theory is in partial agreement with studies by Beckley, Boehm, and others^{58,59,65} demonstrating that patients with Parkinson disease were unable to adjust the size of long- and middle-latency reflex responses to the degree of perturbation. These patients are therefore unable to activate muscle force proportional to displacement. Melnick and colleagues⁵⁶ found that subjects with Parkinson disease were unable to maintain balance on a sway-referenced force plate. Glatt¹³⁸ found that patients with Parkinson disease did not demonstrate anticipatory postural reactions and, in fact, behaved exactly as a rigid body with joints. Horak and colleagues,^{139,140} in a variety of studies, reported similar findings and found defects in strategy selection as well; patients with Parkinson disease chose neither a pure hip strategy nor a pure ankle strategy but mixed the two in an inappropriate and maladaptive response. Investigators have found that antiparkinsonian medications could improve background postural tone but did not improve automatic postural responses to external displacements.^{58,59,65,139-141} Other studies have demonstrated deficits in proprioceptive perception—what has been termed an “impaired proprioceptive body map.” Patients with Parkinson disease did not alter anticipatory postural adjustments in response to step width changes, unlike control subjects.¹⁴² Increased step width requires increased lateral reactive forces to unload the stance leg. The lack of ability to prepare for these extra forces may indicate that narrow stance width, start hesitation, and freezing of gait are compensatory mechanisms to proprioceptive loss.¹³⁶ Likewise, when patients could not see their limbs, they had difficulty moving the foot to a predetermined location in response to perturbation. Control subjects had no difficulty.^{143,144} Taken together, it appears that postural instability results from inflexibility in response repertoire; an inability to inhibit unwanted programs; the interaction of akinesia, bradykinesia, and rigidity; and some disturbance in central sensory processing.

Gait. The typical parkinsonian gait is characterized by decreased velocity and stride length.^{145,146} As a consequence, foot clearance is decreased, which again places the individual at greater fall risk.¹⁴⁷ In many patients, especially

as the disease progresses, speed and shortening of stride progressively worsen as if the individual is trying to catch up with his or her center of gravity; this is termed *festination*. Forward festination is called *propulsion*; backward festination is known as *retropulsion*. One hypothesis is that festinating gait is caused by the decreased equilibrium responses. If walking is a series of controlled falls and if normal responses to falling are delayed or not strong enough, then the individual will either fall completely or continue to take short, running-like steps. The abnormal motor unit firing seen with bradykinesia may also be the cause of ever-shortening steps. If the motor unit cannot build up a high enough frequency or if it pauses in the middle of the movement, then the full range of the movement would decrease; in walking this would lead to shorter steps. Festination may also be the result of other changes in the kinematics of gait.

The changes in gait kinematics include changes in excursion of the hip and ankle joints (Figure 20-7). Instead of a heel-toe, the patient may have a flat-footed or, with disease progression, a toe-heel sequence. The patient with Parkinson disease appears to have lost the adult gait pattern and is using a more primitive pattern. The flat-footed gait decreases the ability to step over obstacles or to walk on carpeted surfaces. The use of three-dimensional gait analysis has shown that there is a decrease in plantarflexion at terminal stance. Changes are also seen in hip flexion, which may alter ankle excursion. However, qualitative aspects of the timing of joint excursion appear intact. Figure 20-7 illustrates the joint angles in a 55-year-old patient with Parkinson disease compared with adults without basal ganglia dysfunction.¹⁴⁸

Gait and postural difficulties are the two impairments that cause the greatest handicap to persons with parkinsonism. They have been found to be the major elements of disability at home and work for these patients.

Perception, Attention, and Cognitive Deficits. Especially in recent years, researchers have tried to address the cognitive and perceptual impairments of people with Parkinson disease.^{136,149-152} Whereas the movement deficits are hypothesized to be caused by a decrease in putaminal excitation of the cortex, the learning and perceptual deficits are hypothesized to be caused by a decrease in cortical excitation from the caudate nucleus.¹¹¹ The deficits are of frontal lobe function and include an inability to shift attention, an inability to quickly access “working memory,” and difficulty with visuospatial perception and discrimination. Research attention has focused on the specific deficits of parkinsonian patients compared with patients with Alzheimer disease, patients with frontal lobe damage, and those with temporal lobe damage.^{149,152,153} The perceptual deficits of all groups appear to increase with progression of the disease process. In general, patients have difficulty in shifting attention to a previously irrelevant stimulus,¹⁵⁴ learning under conditions requiring selective attention,¹⁵⁴ or selecting the correct motor response on the basis of sensory stimuli.¹⁵⁵⁻¹⁵⁷ There is also evidence that DA is involved in selection of responses that will be rewarding.⁵⁴ These impairments will affect treatment strategies.

Learning deficits also have been found in patients with parkinsonism; procedural learning has been particularly implicated, as would be indicated based on the physiology of the system. Procedural learning is learning that occurs

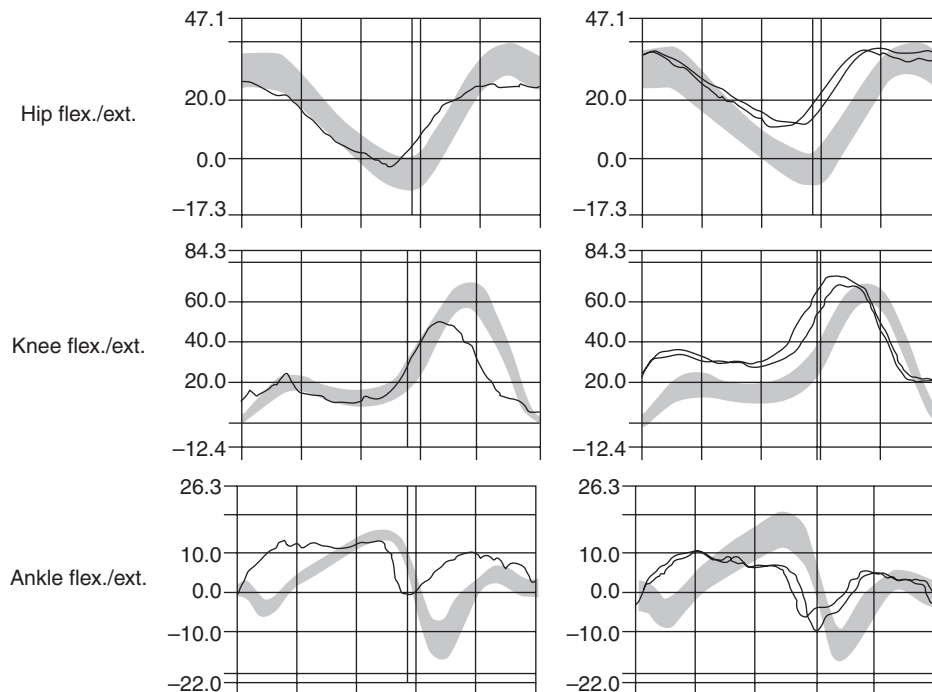

Figure 20-7 ■ Angles of excursion during gait in a patient with Parkinson disease. Shaded areas are mean \pm standard deviations for adults without Parkinson disease; black lines represent a patient with Parkinson disease. Movement shown for right and left lower extremities. Note decreases, especially in left lower extremity for extension and bilateral decreased plantarflexion.

with practice or, as defined by Saint-Cyr and colleagues,¹⁵⁸ “the ability gradually to acquire a motor skill or even a cognitive routine through repeated exposure to a specific activity constrained by invariant rules.” In their tests, patients with Parkinson disease did very poorly on tests of procedural learning, but their declarative learning was within normal limits. Pascual-Leone and colleagues¹¹¹ studied procedural learning in more detail. They found that patients with Parkinson disease could acquire procedural learning but needed more practice than control subjects did. They also found that the ability to translate procedural knowledge to declarative knowledge was more efficient if it occurred with visual input alone rather than the combination of visual input with motor task. This may be a rationale for more therapy, not less.

Nonmotor Symptoms. Nonmotor symptoms are consistently seen in patients with Parkinson disease and may be attributable to dopaminergic pathways outside the basal ganglia. Braak¹⁵⁹ hypothesized that Parkinson disease actually begins with DA deterioration in the medulla and progresses rostrally. Often the first signs are loss of sense of smell, constipation, vivid dreams (rapid-eye movement [REM] behavior disorder), and orthostatic hypotension.^{160,161} Orthostatic hypotension may cause some dizziness and requires coordination of medications for other medical problems. L-Dopa and DA agonists may lower blood pressure; blood pressure medication may need to be altered once antiparkinsonian drugs have been prescribed. Although not all people with these problems have Parkinson disease, when they are combined they may indicate risk for this disorder. Because physical therapy may be most effective when started early, researchers are trying to learn more about these early symptoms.

Other nonmotor symptoms that decrease quality of life include incontinence in men and women, sexual dysfunction, excess saliva, weight changes, and skin problems. Nonmotor symptoms that can interfere with and complicate physical and occupational treatment include fatigue, fear, anxiety, and depression. Urinary incontinence is important because it increases the risk of hospitalization and mortality.¹⁶²

Sleep disorders are widespread in Parkinson disease and include more than just REM sleep disorder.¹⁶³ The patient may experience daytime drowsiness and decreased sleep at night. There appears to be a lack of consolidation of sleep with decreased total sleep time as well as the presence of restless leg syndrome.¹⁶⁴ Daytime drowsiness may be a side effect of medication; however, it can also be exacerbated after therapeutic exercise, so a cool-down period is necessary before the patient sits down and relaxes.

Another side effect of medication is presence of hallucinations. Many patients report seeing very ugly creatures or monsters, and when such hallucinations occur in the therapeutic session they can be most uncomfortable for the therapist and the patient. These hallucinations also make it difficult for the patient to use adjunct treatments such as computer games and virtual reality activities.

Nonmotor symptoms often predominate as the disease progresses.¹⁶⁰ They contribute to severe disability, impaired quality of life, and shortened life expectancy. As the disease progresses, cognitive problems also become more frequent. Braak¹⁵⁹ hypothesized that this was an indication

of rostral progression of dopaminergic involvement. Cognitive involvement can include memory loss, confused thinking, and dementia. Parkinson disease medications may worsen these cognitive impairments. The nonmotor symptoms of Parkinson disease have been addressed in a practice parameter recommendation by the American Academy of Neurology.¹⁶¹

Stages of Parkinson Disease

Parkinson disease is a progressive disorder.¹⁶⁵ The initial motor symptom is often a resting tremor or unilateral micrographia (bradykinesia of the upper extremity). With time, rigidity and bradykinesia are seen bilaterally, and postural alterations and axial symptoms then begin to occur. This commonly starts with an increase in neck, trunk, and hip flexion that, accompanied by a decrease in righting and balance responses, leads to a decreased ability to maintain the center of gravity over the base of support.

While these postural changes are occurring, so does an increase in rigidity, which is most apparent in the trunk and proximal and axial musculature. Trunk rotation becomes severely decreased; there is no arm swing during gait and no spontaneous facial expression; and movement becomes more and more difficult to initiate. Movement is usually produced with great concentration and is perhaps cortically generated, therefore bypassing the damaged basal ganglia pathways. This great concentration then makes movement tiring, which heightens the debilitating effects of the disease.

Eventually the individual becomes wheelchair bound and dependent. In the late and severe stages of the disease, especially without therapeutic attention for movement dysfunctions, the client may become bedridden and may demonstrate a fixed trunk-flexion contracture regardless of the position in which the person is placed. This posture has been called the “phantom pillow” syndrome because, even when lying supine, the person’s head is flexed as if on a pillow.

Throughout this progressive deterioration of movement, there is also a decrease in higher-level sensory processing. In addition, the patient can perform only one task at a time. Reports of dementia range from 30% to 93% in patients with Parkinson disease.¹⁶⁶ The presence of dementia in this population may indicate involvement of the ACh or noradrenergic mesolimbic system. In this case, treatment with anticholinergic drugs may increase a tendency toward dementia, especially in older patients. Sometimes cognitive deficits are inferred because of slowed responses, spatial problems, sensory processing problems, and a masked face (see Chapter 36).

The most serious complication of Parkinson disease is bronchopneumonia. Decreased activity in general and decreased chest expansion may be contributing factors. The mortality rate is greater than in the general population, and death is usually from pneumonia.

Staging of Parkinson disease uses the Hoehn and Yahr scale (Table 20-1).¹⁶⁵ Originally developed as a 5-point scale, in recent years 0, 1.5, and 2.5 measurements have been added. The 1.5 and 2.5 ratings have not been validated, but because their use is so common, the latest recommendation is to continue using them while the validity is studied.¹⁶⁷

TABLE 20-1 ■ HOEHN AND YAHR STAGING SCALE FOR PARKINSON DISEASE

STAGE	PROGRESSION OF SYMPTOMS
0	No signs of disease.
1	Unilateral symptoms only.
1.5	Unilateral and axial involvement.
2	Bilateral symptoms. No impairment of balance.
2.5	Mild bilateral disease with recovery on pull test.
3	Balance impairment. Mild to moderate disease. Physically independent.
4	Severe disability, but still able to walk or stand unassisted.
5	Needing a wheelchair or bedridden unless assisted.

The Hoehn and Yahr scale is commonly used to describe how the symptoms of Parkinson disease progress. The original scale included stages 1 through 5.¹⁶⁵ Stage 0 has since been added, and stages 1.5 and 2.5 have been proposed to best indicate the relative level of disability in this population.¹⁶⁷

Pharmacological Considerations and Medical Management

The knowledge that the symptoms of Parkinson disease are caused by a decrease in DA led to the pharmacological management of this disease. Because DA itself does not cross the blood-brain barrier, levo-dihydroxyphenylalanine (L-dopa), a precursor of DA that does, has been used to treat Parkinson disease since the late 1960s.¹⁶⁸⁻¹⁷⁰ An inhibitor of aromatic amino acid decarboxylation (carbidopa) is usually given with L-dopa to prevent the conversion to DA before entering the brain. The decarboxylase inhibitor allows a reduction in dosage of L-dopa itself, which helps decrease the cardiac and gastrointestinal side effects of DA.

Amantadine is another drug that has been effective in the treatment of patients with Parkinson disease. Although the mechanism of action of this antiviral medication is unknown, it is thought to include a facilitation of release of catecholamines (of which DA is one) from stores in the neuron that are readily releasable. It is often administered in combination with L-dopa.

Treatment of Parkinson disease with L-dopa in these various combinations is extremely helpful in reducing bradykinesia and rigidity. It is less effective in reducing tremor and the postural instability. Because Parkinson disease involves the nigral neurons, the receptors and the neurons in the striatum (which are postsynaptic to dopaminergic neurons) remain intact and initially are somewhat responsive to DA.^{171,172} With time, however, the receptors appear to lose their sensitivity, and the prolonged effectiveness (10 years or more) of L-dopa therapy is questionable.¹⁷³⁻¹⁷⁵ A further complication of L-dopa therapy is the development of involuntary movements (dyskinesias) and the “on-off” phenomenon—a short-duration response resulting in sudden improvement of symptoms followed by a rapid decline in symptomatic relief and perhaps the appearance of dyskinesias and/or dystonias.^{176,177} With time the “on” effect becomes of shorter and shorter duration.^{173,176,178,179} Controlled-release or slow-release L-dopa may decrease these side effects. The effectiveness of

L-dopa does not appear to be closely correlated with the stage of the disease.

The use of L-dopa alone or in combination with carbidopa has not provided a cure or even prevented the degeneration of Parkinson disease.^{178,179} As more has become known about the DA receptor, specific agonists have been developed. Ropinirole, pramipexole, pergolide, and bromocriptine are examples of DA receptor D2 agonists that are used alone or with L-dopa. The agonists are thought to decrease the wearing-off effects as well as decrease the dyskinesias that occur with long-term L-dopa use, but L-dopa remains the most effective medication. It is quite likely that newer D2 and/or D2-D1 (DA receptor D1) agonists will be developed. Pharmacological interventions also include drugs that prevent the breakdown of DA (e.g., catechol-*O*-methyltransferase [COMT] inhibitors) and/or its reuptake. Entacapone is an example of a COMT inhibitor.¹⁸⁰

Another approach to pharmacological treatment of individuals with Parkinson disease was developed from research on a designer drug that contained the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). It was found that the conversion of MPTP to the active neurotoxin MPP+ could be prevented by monoamine oxidase inhibitors such as deprenyl and pargyline.^{73,179} Deprenyl, rasagiline, and selegiline are now used before the initiation of, or in conjunction with, L-dopa and carbidopa.

Another treatment alternative is surgery performed in precise areas of the basal ganglia, known as *stereotaxic surgery*. Stereotaxic surgery is an old technique that has made a comeback based on the new knowledge of basal ganglia connectivity and improvements in the procedural instrumentation.* Initially, one of the structures of the basal ganglia was lesioned with freezing or high-frequency stimulation. Today the globus pallidus internal segment or the subthalamic nucleus is stimulated with implanted electrodes. This technique is known as *deep-brain stimulation (DBS)*. DBS has now been approved by the U.S. Food and Drug Administration (FDA). An advantage of deep brain stimulation over permanent lesions is that DBS is reversible and is safer for bilateral surgeries. Stimulation of the globus pallidus internal segment or subthalamic nucleus has been shown to decrease all symptoms; subthalamic nucleus stimulation is also effective in reducing dyskinesias and may lessen the amount of medication taken.¹⁸³⁻¹⁸⁵ Effects of stimulation are greater for symptoms manifested in the “off” state. Deep brain stimulation has been demonstrated to improve rigidity, bradykinesia, and akinesia, as well as gait^{57,184,186-189} and balance.^{56,190} It has also been demonstrated to improve movement velocity and speed of muscle recruitment for activity.^{190,191} The proposed mechanism of action is interference with the abnormal neuronal firing.^{192,193} In a randomized, controlled, clinical trial, DBS was more effective in reducing symptoms and increasing quality of life than medication.^{194,195} This group also found that although some side effects were worse (e.g., brain hemorrhage), the total number of adverse reactions was greater in the medication group. Whether stimulation of the subthalamic nucleus is neuroprotective, that is, prevents further degeneration, is presently under investigation. Thalamic stimulation is used

*References 6, 7, 76, 173, 181, 182.

for decreasing tremor. Therapists may find that intense treatment immediately after these surgeries may be able to take advantage of neural plasticity.

Fetal transplantation of the substantia nigra to the caudate nucleus remains under investigation. A double-blind, placebo-controlled trial was completed with mixed results.^{192,196-198} Studies continue, including those of dose, cell type, and placement of cells. Recently, however, there was a report of Lewy-body inclusions in grafted cells 14 years after the transplant.¹⁹⁹ The authors concluded that Parkinson disease was an ongoing process and that what caused the disease initially, also affected the grafted cells.

Examination of the Client with Parkinson Disease

The previous sections introduced the symptoms of Parkinson disease and hypothesized pathophysiological explanations for these symptoms. Examination of the client with Parkinson disease should include the degree of rigidity, bradykinesia, balance impairments, and gait abnormalities and how much these symptoms interfere with ADLs—that is, how the symptoms are influencing the client's participation in life. The outcome measures used in the examination of patients with Parkinson disease should be as objective as possible.

The Hoehn and Yahr Scale (see [Table 20-1](#)) is frequently used to describe the general severity of disease.¹⁶⁵ The Unified Parkinson's Disease Rating Scale (UPDRS) is the most widely used assessment tool to describe all facets of impairment: cognitive and emotional status, ADL ability, motor function, and side effects of medication.²⁰⁰⁻²⁰² The UPDRS is also frequently used to measure the efficacy of treatments. Another clinical scale is the Core Assessment Program for Intracerebral Transplantation (CAPIT), which includes timed tests.²⁰³ This scale was designed to standardize assessments of patients with Parkinson disease who undergo surgical intervention. It is comprehensive and more time-consuming and therefore tends to be used more in research than in the clinic. Knowledge of these scales will help the physical therapist in communication and interactions with other health care professionals even though the scales may not be ideal for planning physical and occupational therapeutic interventions.

Assessment of functional activities will be most beneficial for treatment planning and reevaluation. In addition to assessing how the patient performs the activity, the time it takes to complete an activity must be measured. For example, gait is assessed by general pattern, speed, and distance, as well as the effects of interfering stimuli including walking while performing cognitive tasks. It is advantageous to evaluate forward and backward walking as well as braiding and the ability to alter gait speed in each of these conditions.^{145,146} Available objective tests of gait and functional mobility include the Timed Up-and-Go Test, 10-meter walk test, the 5 or 10 Times Sit-to-Stand Test, the Dynamic Gait Index, or any of the objective standardized tests presented in Chapter 8. Careful observation of how the person performs a task would be useful for treatment planning. For example, when rising from a chair, does the patient move forward in the chair, place the feet underneath the knees, and lean forward before rising?

A careful analysis of balance is imperative for the patient with Parkinson disease. This must include assessment with

and without vision and the differences between the two conditions (see the section on balance in Chapter 22). Assessing challenges to balance such as tandem walking or standing on a compliant surface is important, especially in the early stages of the disease. This may be the first sign of balance impairment. Posturography is the most sensitive measure of postural instability, especially in the early stages of the disease (Hoehn and Yahr stages 1 and 2).⁵⁸ A clinically useful tool to assess dynamic balance is the functional reach test, which has been shown to be an effective, predictive tool in people with Parkinson disease as it is in the elderly.²⁰⁴ The Balance Evaluation Systems Test (BESTest) is also an appropriate comprehensive measure for those with Parkinson disease. Obtaining a falls history continues to be a reliable predictor of future falls and is easy to measure. (Refer to Chapters 8 and 22 for specifics on these tests.)

An assessment of chest expansion and vital capacity should also be included. This is important because of their contribution to the complication of pneumonia. For this reason, when rigidity is assessed, the muscles of respiration should be included, along with extremity and trunk assessment. Active and passive range of movement, general strength, chest expansion, and vital capacity should also be measured on regular intervals. At present a complete and easy-to-use form for evaluation does not exist for Parkinson disease.

General Prognosis, Treatment Goals, and Rationale

As with all treatment, the prognosis (functional goals and established time parameters) is based on the general goals related to the findings from the examination of each client and the client's expectations and functional requirements. Parkinson disease must be understood as a degenerative disease when establishing the prognosis and treatment plan. Nonpharmacological and surgical interventions, especially physical therapy treatment, are especially important in the beginning of the disease.²⁰⁵ In general, goals include increasing movement and range of motion (ROM) in the entire trunk as well as the extremities, maintaining or improving chest expansion, improving balance reactions, and maintaining or restoring functional abilities. Increased movement may in fact modify the progression of the disease.^{206,207} It may further help to retard dementia. Although L-dopa decreases the bradykinesia, it alone will not be effective in increasing movement or improving balance; therefore, aggressive intervention in the early stages is necessary. Increasing trunk rotation goes hand in hand with increasing range of movement and motion in general. The longer clients are kept mobile, the less likely they are to develop pneumonia and the longer they can maintain independence in ADLs. Ideally, rehabilitation interventions should begin at the first sign of the disease, but this is not always possible. Treatment initiated while the disease is still unilateral (Hoehn and Yahr stage 1) is more advantageous.^{208,209}

Treatment Procedures

Overall, physical rehabilitation is effective in the treatment of people with Parkinson disease. The results are greater when treatment is started early in the disease process, but it has been shown to be effective in Hoehn and Yahr stages 1 to 3. The American Academy of Neurology recommends

physical therapy in its practice parameters.²¹⁰ The bottom line is that treatment by movement specialists that incorporates complex, sequential movements with multiple sensory inputs creates demands for responses that are environmentally appropriate, challenges balance, uses large-amplitude movements, and is fun and effective. Many treatment regimens have been used, and almost all have been successful. Animal research indicates that exercise and forced functional movements may protect the dopaminergic neurons.²¹¹ The following paragraphs will provide more precise information and more precise details.

Basic principles for treatment of the person with Parkinson disease will, of course, depend on the areas of impairment and handicap revealed in the evaluation. Certain principles, however, are true for all stages of the disease. First, the activities selected must engage the patient: the patient must find the activities interesting enough to do them regularly. Variety is important to facilitate shifts in movement as well as in thought. And movements must be *big!* (In fact, one treatment technique even uses that word in its name.) Activities that are designed to improve balance are valuable even in the early stages of the disease. To date, many rehabilitative techniques and exercises have demonstrated improvement in function for people with Parkinson disease, and there have now been a few randomized clinical trials with small numbers of patients to test efficacy of the varied techniques. Programs that emphasize sensory-motor integration, agility, and motor learning demonstrate decreased progression of disease and improved motor function.²¹²⁻²²⁷ Programs that involve the coordination of dual motor-cognitive tasks and complex sequences of movements and that force the participant to quickly change movements dependent on environmental conditions have resulted in improved performance on the Timed Up-and-Go Test, the UPDRS, the 10-meter walk test, and a variety of balance tests. Some of these programs include the Lee Silverman Voice Treatment (LSVT BIG) program, sensory attention focused exercise (PD SAFEx), ballroom dance, Zumba, tai chi, karate, computer game playing, and alpine hiking.

Most of the studies referenced previously have included people at Hoehn and Yahr stages 1 to 3. As the person progresses, practice of precise ADLs is advisable. These include rising from a chair, getting out of bed, turning in bed, adjusting covers, and being aware of posture. At the later stages of the disease, breathing exercises will need to be a more prominent aspect of treatment. Big movements still need to be stressed. At these later stages of the disease, use of assistive equipment may also need to be taught. What follows are ideas for treatment of more specific aspects of the disease. These are ideas and are not exhaustive. The words *big*, *fun*, and *novel* are good words to remember when planning treatment.

Decreasing Rigidity. Movement throughout a full ROM is crucial, especially early in the disease process, to prevent changes in the properties of muscle itself. In Parkinson disease the contractile elements of flexors become shortened and those of the extensor surface become lengthened, enhancing the development of the flexed posture that is traditionally present.²²⁸ For most patients, treatment proceeds better if rigidity is decreased early in the treatment session. In fact, movement therapy interventions appear to have more lasting effects when the treatment is performed during the “on” phase of a medication cycle.

Many relaxation techniques appear to be effective in reducing rigidity, including gentle, slow rocking, rotation of the extremities and trunk, and the use of yoga (see Chapters 9 and 39). In the client with Parkinson disease, success in relaxation may be better achieved in the sitting or standing positions because rigidity may increase in the supine position.⁹¹ Furthermore, because the proximal muscles are often more involved than the distal muscles, relaxation may be easier to achieve by following a distal-to-proximal progression. The inverted position may be used with care. Initially this position facilitates some relaxation (increase in parasympathetic tone) and then increases trunk extension, which is important for the parkinsonian client. Relaxation may also be effective in reducing the tremor of Parkinson disease. Once a decrease in rigidity has been achieved, movement must be initiated in order to use the newfound range in a functional way.

Therapeutic Programs. Exercise itself is important for the person with Parkinson disease. There is a relationship between longevity and physical activity.²²⁹ Those who exercise have lower mortality rates.²²⁹ Some evidence also indicates that exercise may alter the magnitude of free radicals and other compounds linked to aging and parkinsonism. Immunological function may also be improved with exercise. Sascio and colleagues¹⁰³ demonstrated a link between a lack of exercise and development of parkinsonism. Finally, the role of aerobic fitness itself may be a factor in reducing dysfunction.¹⁰³ Animal data indicate that functional exercise decreased DA loss after a variety of lesion models.^{129,208,209,211,230} Some of the animal activities were similar to the complex, sensory-motor and agility programs now used in patient programs.^{213,218,221,222} Aerobic exercise may improve pulmonary function in patients with Parkinson disease because these functions appear to suffer from deficiencies in rapid force generation of the respiratory muscles, similar to limb musculature.²³¹ Exercise is most beneficial when it is begun early in the disease process as is recommended in all books, pamphlets, and websites for the patient.²³² (Refer to the list of websites at the end of this chapter.) All research on the effects of exercise programs in parkinsonism indicates this point. When the use of forced functional activities is delayed too long, few beneficial effects of exercise on the DA system have been shown in animal studies.^{208,209} Hurwitz²³³ found that patients who were still independently mobile at home and in the community benefited the most from a home program. Schenkman and Butler²²⁸ also indicate that patients in the earlier stages of the disease had the best potential for improvement. If patients practice regular physical exercise in conjunction with disease-specific exercises, the ill effects of inactivity will not potentiate the effects of the disease process itself. Although most patients with Parkinson disease can achieve an adequate exercise level, many clients have fitness levels that are poor or very poor before the medical diagnosis.¹²² Exercise, even once a week, can be effective in improving gait and balance in clients with Parkinson disease when practiced over several months.^{212,234}

So far almost all studies have found that exercise under the guidance of a therapist is effective.²¹³⁻²²⁷ Palmer and colleagues²³⁵ used precise, quantitative measures to assess motor signs, grip strength, coordination, and speed as well as measurements of the long-latency stretch reflex after two exercise programs in patients with Parkinson disease. These two programs were the United Parkinson Foundation

program and karate training. Their results indicated improvement over 12 weeks in gait, grip strength, and coordination of fine motor control tasks and no change in a decline in movements requiring speed. The patients all felt an increase in general well-being. A study by Comella and colleagues²³⁶ as well as one by Patti and colleagues²³⁷ also found decreases in parkinsonian symptoms with physical and occupational therapy. However, these studies found no long-term carryover once therapy had been discontinued. The authors never explain the exercise program precisely nor the instructions provided for a home program.

Rhythmical exercise has been shown to decrease rigidity and bradykinesia and improve gait over time.^{212,238-254} Ballroom dancing is a form of rhythmical therapy for patients with Parkinson disease that incorporates rhythmical movement, rotation, balance, and coordination.²¹² A program of tango versus waltz and foxtrot indicated that although both groups improved on the UPDRS motor scale, Berg Balance Scale, 6-minute walk distance, and backward stride length, the tango group had greater improvements.^{214,217,225} The waltz and foxtrot, which are easier dances, may be beneficial for those at more advanced stages of the disease. The use of dance also facilitates changing direction. Our program using Latin dance (predominantly mambo and cha-cha) and other weight-bearing exercise demonstrated similar improvements in balance and especially initiation of gait.^{212,234,247,255} Similar effects were seen in tai chi, which demands attention to movement and increases challenges to balance and control of movement. Tai chi has been shown to be effective in improving gait and balance parameters.²²⁰

Studies using a program emphasizing sensory awareness of the size of movement have shown improvement in both speed of movement and gait parameters.^{224,226,227} PD SAFEx,²²⁶ a program that focuses attention on sensory awareness, was shown to improve gait and function on the UPDRS in a randomized controlled study. A group that engaged in aerobic exercise alone improved gait but not symptoms. A group that continued usual activities did not demonstrate improvements on any outcome measure. These authors concluded that programs emphasizing increased sensory feedback and awareness were superior in reducing the symptoms and improving the function of patients with Parkinson disease.

Treadmill training has been used in Parkinson disease exercise programs. Use of the treadmill with body-weight support increases safety and allows the therapist to control speed of movement as well as perturbations. Some studies have used cued treadmill training with good results and carryover to the home.²⁵⁶ Cognitive tasks and other dual tasks have also been added during treadmill training with good results.²⁵⁷ These studies found collectively improved measures of balance and gait, as well as reduced fear of falling and number of falls.^{213,221}

Physical activity and movement appear to increase quality of life by decreasing depression and improving mood and initiative.^{248,258} Group classes can serve as an extra support system for patients with Parkinson disease and their spouses.* A carefully structured low-impact aerobics program appears to be beneficial to patients even with long-standing disease.²³⁴

One program designed for those at Hoehn and Yahr stage 2.5 or 3 begins with seated activities for upper extremities (Figure 20-8, A) and combination movements for warmup (Figure 20-8, B). The participants then progress to standing and marching activities that incorporate coordinated movements of arms and legs as well as balance and trunk rotation (Figure 20-9). All movements are performed to music similar to that used in aerobics classes in any gym or health club (Figure 20-10). (The rationale for the use of external cues and the role of rhythm in gait training are discussed in subsequent paragraphs.) A cool-down period allows participants to practice fine motor coordination activities of the hands (Figure 20-11). Many Parkinson disease associations also have audiotapes for exercises (e.g., United Parkinson Foundation).

The use of computer games to improve symptoms is currently under investigation. These games force the participant to move in precise ways or to shift weight to score points. Many “off-the-shelf” games exist and have been used with older adults (the predominant patient population of those with Parkinson disease) to increase activity levels. For some with Parkinson disease, even in the early stages, these games

Figure 20-8 ■ Seated aerobics or warmup exercises. **A**, Clients are using bilateral upper-extremity patterns to facilitate trunk rotation. Instruction was to let the head follow the hands. **B**, This exercise encourages trunk rotation, large movements, and coordination of the upper and lower extremities. Clients are to reach with the arms and touch the opposite foot. This coordination is difficult for those with Parkinson disease, and many clients initially could not move the arms and legs at the same time.

*References 210, 226, 227, 238, 249, 258.

Figure 20-9 ■ Initial warmup in standing. Clients are to walk with the head up, with the back as straight as possible, and to take large steps. When the group began, walking was the major aerobic activity and was used to increase endurance and encourage movement. Nonambulatory patients march in place while seated.

Figure 20-10 ■ Walking in a “waltz rhythm” (slow, quick, quick) emphasizes a big step for the slow step. Note lack of automatic arm swing. Also note flexed posture of seated patient during rest period.

Figure 20-11 ■ Cool-down period allows time to work on fine finger movements. Thumb abduction with rounded fingers and various rhythms are used to increase coordination. Note “masked face” appearance.

are too fast or too confusing. A feasibility study showed that disease-specific games could be used, and enjoyed by those with Parkinson disease.²⁵⁹

The most successful exercise programs appear to be those that incorporate context-dependent responses and a varied environment. All of the previously listed examples of these activities are presented in [Box 20-1](#). Aerobic exercises that are not as effective in requiring context-dependent responses are presented in [Box 20-2](#). Research has shown the importance of adjusting the response to the specific task and has also demonstrated the importance of practice for the parkinsonian patient.^{157,260} The principles of motor learning are of paramount importance in the treatment program of these patients. Random practice may enable the patient to learn the correct schema by which to regulate the extent, speed, and direction of the movement. Random practice also may be important in facilitating the ability of the patient to shift attention and to learn to access “working memory.” The parkinsonian patient may benefit from visual instruction and mental rehearsal before performing the movement.^{137,157} In addition, the instructions used need to be pertinent to the task at hand.

BOX 20-1 ■ EXERCISES THAT PROMOTE CONTEXT-DEPENDENT RESPONSES

The following exercises promote context-dependent responses and are recommended for people with movement disorders:

1. Walking outdoors
2. Karate and other martial arts
3. Dancing (all forms)
4. Ball sports (various types)
5. Cross-country and downhill skiing
6. Well-structured, low-impact aerobics classes
7. Treadmill training with guidance of a movement specialist

This list is a sample of activities; it should not be considered all inclusive.

BOX 20-2 ■ EXERCISES THAT PROMOTE FITNESS AND INCREASE RANGE OF MOTION BUT NOT CONTEXT-DEPENDENT RESPONSES

The following exercises promote fitness and increase range of motion but not context-dependent responses and are recommended for people with movement disorders.

1. Treadmill walking without guidance or supervision
2. Stationary bicycle riding
3. Using strengthening machines and free weights (with low weights or low resistance)
4. Using step exercises and stair climbers
5. Using rowing machines
6. Swimming laps

This list is a sample of activities; it should not be considered all inclusive.

Strengthening. Strengthening exercises have been promoted for the patient with Parkinson disease. With disuse comes decreased strength. Weakness occurs with initial contraction and also with prolonged contraction. Manual muscle testing may not reveal losses in strength; however, most of the successful exercise programs previously mentioned did include functional strength training as part of the program. High-resistance eccentric resistance can produce muscle hypertrophy and may effect improvements in mobility.²⁶¹ Another study used “sports activities” in a twice-per-week program.¹⁵⁸ The program included exercises on land designed to improve gait and balance and exercises in the water to increase strength. These investigators reported significant improvements in UPDRS scores, cognitive function, and mood in addition to ADL and motor scores during the 14-week program. Interestingly, they also found decreases in dyskinesia. The greatest changes in exercise appeared early and were maintained up to 6 weeks after cessation of the exercise program. According to the literature, functional strength training seems to be more effective than weightlifting if the goal is improvement in ADLs.¹⁵⁸ An important part of any strengthening program is the trunk musculature. Spinal extensors need to be exercised, and spinal flexibility likewise encouraged.²⁶²

Use of Cues for Improving Gait. As the disease progresses, intensive exercise programs may need to be revised or altered. By stage 2.5, gait disorders are the most common diagnosis for which the person with Parkinson disease will see a therapist. Many aspects of gait are amenable to treatment. The problems that cause the biggest ambulation limitation are freezing and small steps. Both auditory and visual stimuli have been used in treatment of parkinsonian gait disorders. Thaut and colleagues²⁶³ demonstrated that use of a metronome or carefully synthesized music improves stride length and speed and that these improvements remain up to 5 weeks after the cessation of the auditory stimulus.²³⁴ Melnick and colleagues²³⁴ also demonstrated both immediate and longer-lasting improvements in gait with a rhythmic exercise program once a week in patients needing assistance to walk. A study by Nieuwboer and colleagues²⁵⁶ used auditory, visual, or somatosensory cues in the patient’s home. The patient chose the cue that was best for him or her. The cues were provided in a variety of tasks including walking with dual tasks and walking sideways and backward. Cues were effective in decreasing freezing, but there was only a small effect when the cues were stopped. There may be a difference in the use of cueing for those who freeze during gait and those who do not. The use of cues may be more effective for those who do not have frequent freezing episodes.²⁶⁴

People with Parkinson disease find climbing stairs easier than walking on a flat surface because of the visual stimulation provided by the stairs. Visual stimuli have been effective in freezing episodes. These include the use of lines on the floor and stair climbing. Martin⁵⁵ found that parallel lines were more facilitating than other lines and that the space between lines was also important; the lines cannot be too close together. The use of visual stimuli has scant evidence of carryover. One client used visual stimuli in special glasses that provided constant lines for the client to step over. At present these glasses are not commercially available. Dunne and colleagues²⁶⁵ described a cane that could

present a visual cue for the patient who has freezing episodes. Canes can be especially useful for patients who fall because of freezing. If a specialized cane is not available, the client can turn his or her own cane upside down. Other visual cues have been used to help initiate movement after freezing. For example, one patient tosses pennies ahead of him and steps over them. (He cautions that one should not bend to pick them up as this will again lead to freezing.) Another watches the movement of a person walking beside him; the movement of that person’s feet encourages his feet to move. The U walker has a laser line that can be added to provide lines on the ground. Morris and colleagues¹⁴⁷ have tried to increase carryover of visual stimuli by incorporating them with a program of visualization. Their clients practiced walking with lines until the steps were near normal in size; the clients were then to visualize the lines on the floor as they walked. Their visualization program met with initial success. Increasing the magnitude of the step or the amplitude of the movement appears to be the most important component for improvement in gait and a decrease in freezing.¹⁴⁷ Tactile cueing has also been demonstrated to improve gait ability.²⁶⁶

Gait rehabilitation must include walking in crowds, through doorways, and on different surfaces. Practicing walking slowly and quickly is important, as is walking with differing stride lengths, because in the real world step length and speed must change with environmental demands. The principles of motor learning presented in Chapter 4 appear to be very helpful for facilitating carryover of the therapeutic effects in our preliminary studies. One word of caution, however; as previously mentioned, the person with Parkinson disease has difficulty performing two tasks at once, such as walking and performing math problems or walking with a glass of water on a tray.^{113,130,155} The patient may have to concentrate only on walking as the disease progresses, to increase patient safety.

Balance. Another problem for which therapy is indicated is impaired balance, especially because drug and surgical treatments are ineffective in remediating this problem. This problem will eventually affect all persons with Parkinson disease.²⁶⁷ If at all possible, the client should be instructed to practice balance exercises at the early stages of the disease. Equilibrium reactions in all planes of movement and under different controls should be encouraged. Techniques to increase dynamic balance control should be included, especially turning the body and turning the head. All three balance strategies need to be addressed and then practiced in a variety of environmental conditions. The newer computerized games that target balance have provided a fun and therapeutic method for keeping interest in balance exercises.^{130,135,136,142,143} (See Chapter 22 for other procedures to improve balance.)

Dual Task Performance. Rarely will the client with Parkinson disease state that he or she has difficulty performing two tasks at once. Nonetheless, this is quite apparent in very simple activities, such as requiring the patient to count backward and walk at the same time.^{146,268} One solution is to instruct the client to attend to only one task at a time. Another is to have the client practice doing two things at the same time and constantly alter activities in a random practice mode during treatment. The efficacy of these two approaches has yet to be studied.

Activities of Daily Living. Transitional movements pose great problems for the client, especially by Hoehn and Yahr stage 3. This is most likely because normal postural adjustments are no longer automatic and they become a sequential task. Practice with frequent review is helpful. Some researchers report improvement in moving from a seated to a standing position after practicing techniques designed to increase forward weight shift (e.g., leaning on a chair while standing up).^{269,270} Visualization of this task has demonstrated carryover. If getting up from a chair becomes too difficult, chairs with seats that lift up have been used effectively.

Bed mobility is another important consideration for patients with Parkinson disease. Rolling in bed and rising from the supine position become difficult and need to be practiced, with increased emphasis on trunk rotation. A firm bed may make getting in and out of bed easier. Rolling and getting out of bed is a task that may be easy for the patient on the hard mat tables in the clinic but difficult on the softer bed at the client's home. Tempur-Pedic beds may make movement even more difficult than traditional beds by Hoehn and Yahr stage 3. Most patients report that satin sheets with silk or satin pajamas make moving in bed far easier. This is true in both the early and later stages of the disease. Teaching the client to roll onto the side and lower the legs off the bed facilitates getting out of bed; the client may not be using this method and so learning or relearning this movement is important. Beds with a head that can be raised electrically may be helpful as the disease progresses, but while sleeping the patient should lower the head as close to horizontal as possible.

Breathing exercises are crucial for the patient with Parkinson disease. As stated previously, the most common cause of death is pneumonia. Chest expansion may be included in upper-extremity activities such as swinging the arm. The clinician may also have the client shout—especially with some kind of rhythmical chant, even a simple “left, right” while walking. With disease progression, specific breathing exercises need to be incorporated. This is crucial for the patient who is no longer able to walk.

In addition to treatment in the therapy department, the parkinsonian client also should be given a home program. The home program should encourage moderate, consistent exercise as part of the normal day. Periodic checks may enhance compliance. Fatigue should be avoided and the exercise graded to the individual's capability. The therapist should keep in mind that learned skills such as various sports are sometimes less affected than automatic movements, perhaps because these skills may rely on cortical involvement.¹⁶

Fatigue is a frequent complaint of people with Parkinson disease. Although it has been correlated with disease progression, depression, and sleep disturbances, it also exists in up to 44% of those without depression or sleep difficulty.²⁷¹ This type of fatigue is over and above what is associated with the exertion of an exercise program and may be one reason people with Parkinson disease no longer exercise. The client with Parkinson disease frequently experiences postexercise fatigue. If a person is so tired after exercise that he or she cannot perform normal ADLs, exercise will not become a part of the client's daily routine. Postexercise fatigue is easily alleviated by a gradual and extended cool-down period.

Patients frequently ask about the timing of medication and exercise. For any form of exercise in parkinsonism to be effective, movement must be possible, especially movement through the full arc of the joint. It seems plausible, therefore, that exercise should be performed during the “on” period of the medication cycle. On the other hand, perhaps a more long-lasting effect would result if the patient with Parkinson disease tried to exercise without medication. The question of the effects of exercise on DA agonist absorption was investigated by Carter and colleagues.²⁷² These authors concluded that the effect was variable from patient to patient, but the response of each patient was consistent. However, none of the patients exercised vigorously, which may have skewed the results. Reuter and colleagues²⁷³ interpreted a decrease in dyskinesia seen after an exercise program as indicative of more efficient DA absorption. Nevertheless, this study supports the concept that the patient needs to be “in tune” with his or her own response and adjust medications and exercise to a schedule accordingly. The therapist is also involved in the prescription of assistive devices. The use of ambulatory aids for patients with Parkinson disease is an area with no clear-cut guidelines. Because coordination of upper and lower extremities is often difficult, the ability to use a cane or walker is often limited. The patient may drag the cane or carry the walker. Walkers with wheels sometimes increase the festinating gait, and the patient may simply fall over the walker. Nonetheless, four-wheel walkers with pushdown brakes appear to work best for many clients. A walker that is in the brake condition at the start and requires the patient to push on handles to walk may also be safer. For patients with a tendency to fall backward, an assistive device may simply be something to carry backward with them. Therefore the reason for using the assistive device must be carefully assessed. Walkers, walking sticks, or canes can be helpful for the person who is able to walk with a heel-toe gait pattern but lacks postural stability. The height of walker or cane should be adjusted carefully to promote trunk extension and avoid an increase in trunk flexion. A walking stick, or the use of two sticks as in hiking, is less likely to promote flexion than a cane. A survey by Mutch and colleagues²⁵⁰ in Ireland found that nearly half of the patients responding used some type of assistive device. These devices included devices for walking, reaching, rising from bed, and performing ADLs. Patients with Parkinson disease may also benefit from assistive devices for eating or writing.

As Parkinson disease progresses the patient may experience difficulty in swallowing and even chewing. Therapy for oral-motor control should be initiated, and a dietician consultation may be necessary to ensure adequate nutrition. A dietician may also be beneficial in guiding the patient's protein intake. A diet high in protein may reduce the responsiveness of the patient to DA replacement therapy.¹⁴⁶ Regulating the amount and timing of protein ingestion can improve the efficacy of drug treatment in some patients. Use of vitamins is a subject that appears on many websites for patients with Parkinson disease, and the patient should be reminded to consult with his or her physician when changing vitamins.

The resurgence of surgery as a treatment alternative in Parkinson disease, including stimulation of deep brain sites that may alter neuroplasticity, means that the therapist will

face new and exciting challenges in treatment.²⁷⁴ Intense physical therapy, especially incorporating complex motor skills, has been demonstrated to be effective in improving function after a subthalamic nucleus lesion in animal studies.²⁷⁵ Therefore, intense physical therapy after surgery may be necessary to maximize benefits from all surgeries in Parkinson disease (as well as in Huntington disease and the dystonias).

Finally, therapeutic rehabilitation and exercise may modify but cannot halt or reverse the progression of this degenerative disease. The therapist can assist the client and family in coping with the constraints of this disease, enhancing the patient's quality of life throughout its course. As stated in one study of Parkinson disease, the total cost of treatment must also include the cost to the spouse or other family members.²

Differences between Parkinson Disease and Parkinson Plus Syndromes: Theoretical and Practical Considerations

Several other neurodegenerative diseases are grouped together as "Parkinson plus" syndromes. Clients with these syndromes usually do not respond to L-dopa intervention. The most common of these is progressive supranuclear palsy (PSP). Symptoms of this disease include bradykinesia, gait instability with frequent falls, rigidity, and a vertical gaze palsy. These clients can be evaluated and treated in a manner similar to clients with Parkinson disease. However, PSP usually involves more cognitive impairment and the progression is more rapid; within a decade the patient is typically immobile.

Multiple system atrophy (MSA) is a degenerative disease that affects various areas of the CNS, causing problems with movement, balance, and autonomic functions. The disease is characterized by bradykinesia and rigidity and a tendency to walk with a wide base of support. A person with MSA often has frontal lobe dysfunction as well. Unfortunately, L-dopa is not effective in treating this disorder.

Because these syndromes are more rare than Parkinson disease and far more variable, no studies have been undertaken regarding rehabilitation intervention efficacy. Because accurate differential diagnosis is important in patient planning, a thorough evaluation by a neurologist is highly recommended.

Huntington Disease

Huntington disease (formerly *Huntington's chorea*) is another degenerative disease of the basal ganglia.²⁷⁶ It is the classic disorder representing hyperactivity in the basal ganglia circuitry.²⁷⁷ This disease gets its name from the family of physicians who described its patterns of inheritance. Huntington disease is inherited as an autosomal dominant trait and affects approximately 6.5 per 100,000 people.³ The defect is on the short arm of chromosome 4.²⁷⁸ The defect alters DNA so that there is an increase in the cytosine-adenine-guanine (CAG) sequence; in normal individuals there are 10 to 28 CAG triple repeats, but in the individual with Huntington disease there are 36 to 120 repeats.⁶⁴ The longer the length of the CAG triple repeats, the earlier the onset of the disease. The CAG repeat is related to glutamine. The target protein affected by the polyglutamine expansion has been named *huntingtin*. Huntingtin combines

with ubiquitin and induces intranuclear inclusions and interference with mitochondrial function. The defect is characterized by severe loss of the medium spiny neurons and preservation of the ACh spiny neurons. There are decreases in choline acetyltransferase (CAT), ACh, the number of muscarinic ACh receptors, glutamic acid decarboxylase, and substance P. There is generally no decrease in DA, norepinephrine, or serotonin (5HT), although more recent studies with single-photon emission computed tomography (SPECT) indicate that DA does diminish significantly in the later stages of the disease.²⁷⁹

Huntington disease is usually manifested after the age of 30 years, although childhood forms appear rarely. Those younger than 20 years with the disease account for approximately 10% of all people with Huntington disease. Death from this disease occurs about 15 to 25 years after the onset of symptoms, although as in Parkinson disease the earliest symptom is not known.

A marker for the Huntington gene has been detected.²⁷⁸ If the family pedigree is known and the chromosomes of the parents can be obtained, detection of which offspring have the faulty chromosome is possible presymptomatically. Of course, early detection of this disease involves ethical and practical issues. At present, although testing is available, it is not widely used. Furthermore, testing for Huntington disease is typically available only to those older than 18 years. Despite these problems, localization of the gene and the repeat is promising and offers hope for improved means of treatment.

Huntington disease affects neurons in the basal ganglia as well as the frontal cortex. The movement disorders are presumed to be related to degeneration of the striatal neurons, specifically the enkephalinergic neurons.¹⁶ The cognitive and emotional symptoms are associated with cortical destruction.

Symptoms

Some of the signs and symptoms of Huntington disease are similar to those of Parkinson disease: abnormalities in postural reactions, trunk rotation, distribution of tone, and extraneous movements. Individuals with Huntington disease, however, are at the other end of the spectrum; rather than a paucity of movement, they exhibit too much movement, which is evident in the trunk and face in addition to the extremities. The gait takes on an ataxic, dancing appearance (in fact, *chorea* means to dance in Greek), and fine movements become clumsy and slowed.²⁸⁰ As with the person with parkinsonism, there is a decrease in associated movements (e.g., arm swing). The extraneous movements are of the choreoathetoid type, that is, involuntary, irregular isolated movements that may be jerky and arrhythmic as in chorea, to rhythmical and wormlike as in athetosis. Usually, however, these occur in successive movements so that the entire picture is one of complex movement patterns. The "movement generator" aspects of the basal ganglia seem to be continuously active, as would fit the hypothesis of a disruption in the indirect pathway. As the disease progresses, the choreiform movements may give way to akinesia and rigidity.

Gait patterns of the person with Huntington disease are in some ways similar to those of Parkinson disease. Gait velocity and stride length are decreased. The decrease in velocity

is correlated with disease progression. Unlike the person with Parkinson disease, however, the person with Huntington disease has a decreased cadence as well.²⁸¹ The base of support is increased (again unlike the pattern seen in Parkinson disease). In addition, lateral sway is increased along with great variability in distal movements.

Disruptions in movement for the person with Huntington disease reflect the role of the basal ganglia in movement. For example, the person with Huntington disease, like the person with Parkinson disease, has difficulty responding to internal cues; he or she also has difficulty with internal rhythms. Kinematic analysis of upper-extremity complex tasks demonstrates that the person with Huntington disease must rely on visual guidance in the termination of a movement. This has been interpreted to indicate impairment in the development and fine-tuning of an internal representation of the task.²⁸² These clients have increasing difficulty with more complex movements in the absence of advanced cues.^{283,284} The lack of internal cuing in the person with Huntington disease has been linked to the increased variability of response seen in these clients.²⁸⁵

The face is also affected in Huntington disease. Speech, breathing, and swallowing lack normal control and coordination. Speech lacks rhythm, as might be expected with decreased internal timing, and is often soft. Swallowing and therefore eating may also be difficult, are common problems, and often are accompanied by weight loss. In fact, some suggest that a person with decreased body weight and a parental history of the disease is at greater risk.^{286,287} Impaired voluntary eye movement is often the first sign of Huntington disease. The person with Huntington disease has difficulty with initiation and control of saccadic eye movements.

The exact mechanisms for the production of choreoathetoid movements are unknown. Because these extraneous movements are part of a person's normal repertoire of movement patterns, they may be "released" at inappropriate times and without any modulation. A postmortem examination showed a decrease in GABA that was greater in the globus pallidus external segment than the internal segment. This agrees with the previously described current model.⁶ Recent use of positron emission tomography (PET) scans demonstrates loss of ACh and GABA neurons.²⁸⁸ A pattern therefore may be executed before it is necessary, and inappropriate portions of a movement pattern cannot be inhibited. Petajan²⁸⁹ found motor unit activity indicative of bradykinesia. Recordings of single motor units in the muscles indicates that persons with Huntington disease have a loss of control evidenced by an inability to recruit single motor units.²⁸⁹ As the efforts at control increased, these individuals demonstrated an overflow of motor unit activity that resulted in full choreiform movements. Those in the earlier stages of the disease demonstrated what the experimenters termed "microchorea," or small ballistic activations of motor units.²⁸⁹ As in Parkinson disease, difficulty occurs in modulating motor neuron excitability. Another finding in this experiment revealed motor unit activity indicative of bradykinesia. Yanagasawa²⁹⁰ used surface EMG recordings to classify involuntary muscle contractions in Huntington disease patients with varying movement disorders from chorea to rigidity. He found brief, reciprocal, irregular contractions in those patients with classic chorea, and tonic nonreciprocal

contractions in those patients with rigidity. Presence of athetosis or dystonia was associated with slow, reciprocal contractions. During sustained contractions, EMG activity demonstrated brief, irregular cessation of activity in the choreic patients. Thus patients with Huntington disease have interruption of normal motor function at rest and during sustained activity (e.g., stabilizing contractions).

The abnormal postural reactions of the person with Huntington disease may occur from a misinterpretation of sensory input, especially vestibular and proprioceptive (similar to the parkinsonian syndrome). However, the dementia of Huntington disease precludes further testing.

In addition to the involvement of the motor systems, the individual with Huntington disease also shows signs of dementia and emotional disorders that become worse as the disease progresses. Neuropsychological tests are therefore part of the Unified Huntington's Disease Rating Scale (UHDRS). The client may show lack of judgment and loss of memory, deterioration in speech and writing (i.e., severe decrease in ability to communicate), depression, hostility, and feelings of incompetence. IQ decreases, with performance measures decreasing more rapidly than verbal levels. Evidence of ideomotor apraxia is also present, especially as the disease progresses.²⁹¹ Suicide is fairly common.

Stages of Huntington Disease

Huntington disease is a progressive disorder. The initial symptoms are most often incoordination, clumsiness, or jerkiness. A classic test for eliciting choreiform movements in this early stage is a simple grip test. The client grips the examiner's hand and maintains that grip for a few seconds. The person with Huntington disease displays what is descriptively called the "milkmaid's sign"; alternate increases and decreases in the grip that are perhaps the equivalent of the electromyographic abnormalities seen during sustained contractions. Facial grimacing or the inability to perform complex facial movements also may be present very early.

In many cases the dementia and psychological symptoms of Huntington disease occur after the onset of the neurological signs. In cases in which very subtle personality changes occur first, the diagnosis may be more difficult. Such persons may appear forgetful or unable to manage appointments and financial affairs. They may be thought to have early senility, or they may show signs of severe depression or schizophrenia. Early diagnosis may be important, and SPECT is showing promise for early detection of the disease.²⁹²

With time, the combination of the psychological and neurological problems causes the individual to lose all ability to work and perform ADLs. This person eventually can be cared for only in an extended care facility. By this time the choreiform movements have given way to rigidity, and the patient is bedridden. Death is usually caused by infection, but suicide is also common. [Figure 20-12](#) shows the stages of Huntington disease according to Shoulson and Fahn.²⁹³

Pharmacological Considerations and Medical Management

Advances in the pharmacological management of Parkinson disease have led to a great deal of research in an effort to find appropriate drugs for the management of Huntington

	Engagement in occupation		Capacity to handle financial affairs		Capacity to manage domestic responsibility		Capacity to perform activities of daily living		Care can be provided at

disease.²⁹⁴⁻²⁹⁹ At present, however, no fully effective medication is available for this disease. Each symptom is treated with its own medication.

The symptoms of Huntington disease indicate an increase in dopaminergic effect. At autopsy a decreased number of intrinsic neurons of the striatum that contain the neurotransmitter GABA or ACh are found. Biochemical studies reveal a definite decrease in GABA concentration in addition to a decrease in ACh concentration in the basal ganglia. Therefore drug therapy depends on drugs that are cholinergic or GABA-containing agonists and those that act as DA antagonists. To date, the DA antagonists have been more effective in ameliorating neurological symptoms; however, these drugs have severe side effects including parkinsonism—for example, bradykinesia and rigidity—and tardive dyskinesia.²⁹⁴ There is no evidence that improvement of the choreiform movements leads to improved function.

In general, pharmacological treatment is not started until the choreiform movements interfere with function because these drugs have side effects that may be worse than the chorea.³⁰⁰ Perphenazine, haloperidol (Haldol), and reserpine are still the most commonly used medications. The first two block the DA receptors themselves; reserpine depletes DA stores in the brain. Side effects include depression, drowsiness, a parkinsonian type of syndrome, and sometimes dyskinesia. Drugs such as choline, which would increase ACh concentrations, have produced only transient improvement.¹⁸⁸ Many efforts have been undertaken to find a GABA agonist that would reduce the symptoms of Huntington disease, but these have been unsuccessful so far.^{300,301} The problem with finding a medication to increase GABA is that such a drug will probably cause inhibition throughout the brain, not just in the basal ganglia. Thus the individual's level of alertness and ability to function might be reduced—something the person with Huntington disease can ill afford.³⁰¹ Riluzole, a drug that blocks glutaminergic neurotransmission, has been tried with initial success.³⁰² A 2009 Cochrane review concluded that no pharmacological intervention demonstrated disease-modifying or disease-progression effects.³⁰³

The dementia and personality problems interfere more with life tasks than do the presence of movement disorders. Medications are usually prescribed as combinations of drugs to treat the specific emotional and psychological symptoms. Cortical degeneration is most certainly involved, but disruption of the heavy corticostriate projections also may be a factor in the progression of this disease. Although alterations in DA have been implicated in psychotic problems such as schizophrenia, the role of the basal ganglia in thought processes is, at best, little understood. In the words of Woody Guthrie, “There’s just not no hope. Nor not no treatment known to cure me of my dizzy called Chorea.”³⁰⁴

At present the best hope for the person with Huntington disease lies in a better understanding of the genetic mechanisms causing destruction of the GABA-containing cells in the striatum and cortical destruction. In the meantime, correct and early diagnosis is important in providing the proper early intervention, which must include counseling.³⁰⁵ In an effort to facilitate research into the causes as well as the treatment of the disease, the Commission for the Control of Huntington's Disease has set up several research centers, including a brain and tissue bank. Research has also begun on the use of tissue transplantation. As with Parkinson disease, the tissue does survive, but the results are even more preliminary than for parkinsonism.

Examination of the Client with Huntington Disease

The standard medical evaluation is the UHDRS.³⁰⁶ This comprehensive evaluation examines cognitive function as well as motor function. The physical or occupational therapy evaluation of a person with Huntington disease must include an assessment of the degree of functional ability and how the chorea interferes with function. Which extremities, including the face, are involved? Does the client have any cortical control of the chorea or any means (i.e., tricks) of allaying these extraneous movements? What exacerbates the symptoms? What lessens them? A simple rating scale is the capacity to perform ADLs (see Figure 20-12). A standardized ADL assessment with space to write in how the client

performs these activities or why she or he cannot perform them would be helpful.

Gait analysis can include a timed walk test and cadence assessment; stride length can then be calculated. A subjective assessment of variability and incoordination should also be made. In addition, posture and equilibrium reactions should be tested. What associated reactions, if any, are present? In assessing posture, care should be taken to observe the posture of the extremities in addition to the trunk, head, and neck. Dystonic posturing should be carefully noted, especially if the client is taking medication. Any changes should be reported to the physician.

A gross assessment of strength should be made, with particular attention paid to the ability to stabilize the trunk and proximal joints. To reduce the effects of rigidity, ROM measurements become important as the disease progresses.

In the assessment of the client with Huntington disease, the stage of psychological involvement and mental state must be reliably assessed during both evaluation and treatment. SPECT and other computer tomography scans may give some clues to the amount of cortical and basal ganglia degeneration, which can assist in determining possible cortical functioning. There does not seem to be a consensus in research or clinical practice for which measurements are most sensitive to change or best reflect function for the patient with Huntington disease.

General Treatment Goals and Rationale

Maintenance of the optimal quality of life is the most important goal for treatment of persons with Huntington disease and their families, including maintenance of functional skills and advice to the family on adaptive equipment. Techniques that reduce tone may also reduce choreiform movements. Increasing stability about the shoulders, trunk, neck, and hips helps maintain function. Respiratory function should be kept as high as possible. Again, the evaluation results dictate treatment procedures.

Treatment Procedures

The Commission for the Control of Huntington's Disease³⁰⁷ stated that these individuals are underserved by physical and occupational therapy. Peacock³⁰⁸ surveyed physical therapists in one state. Of the 585 therapists who responded, only 15.5% had worked with at least one patient with Huntington disease, and 6.2% had worked with more than one patient; this confirmed the underutilization of physical and occupational therapy today. Hayden³⁰⁴ and Peacock³⁰⁸ suggest that therapy can improve quality of life for this population. A 2008 article by Busse and colleagues³⁰⁹ demonstrated that there is still underutilization of therapy services. They also found that there no routine outcome measurements for the stages of the disease, and they suggested that management of falls and decreased mobility dysfunction could be a treatment goal of physical therapy interventions. Although animal models of Huntington disease exist, there have been few studies investigating possible movement interventions. In one animal study even a little environmental enrichment improved the ability of Huntington mice on a rotarod test and slowed the progression of the disease.³¹⁰ The mice getting even more enrichment showed improvement on more behavioral tests as well as changes in the striatum. Recently a few articles have been published examining physical and

occupational therapy treatment techniques for holistic therapy and for treating specific problems.³¹¹⁻³¹³ See Chapter 9 for other specific therapeutic interventions.

A study by Zinzi and colleagues³¹¹ was a nonrandom pilot study that incorporated gait, balance, and transfer training. Strengthening of the extremities, trunk, and muscles of respiration as well as coordination and postural stability activities were included. The program was undertaken with occupational therapy to include cognitive, rehabilitation, and ADL training. Participants were engaged in the intensive inpatient program for 3 weeks for 8 hours per day, 5 days a week, 3 times a year. The data indicate that there was significant improvement in motor function and in ADL performance and that these subjects did not show deterioration over the 3 years of the study—a positive outcome for a degenerative disease.

Treatment of the person with Huntington disease has some parallels with the treatment of cerebral palsy athetosis. These techniques, however, must be adapted to the adult. Of critical importance are the techniques for improving coactivation and trunk stability. The use of the pivot-prone and withdrawal patterns of Rood are helpful, and their benefit may be increased with the use of Thera-Band. Neck co-contraction and trunk stability may improve, or at least oral functions may be maintained. In addition, the techniques of rhythmical stabilization in all positions as well as heavy work patterns of Rood should be helpful.³¹⁴ Yet movements practiced out of context may not carry over into functional activities; thus practicing coactivation in functional patterns during treatment if at all possible is recommended. Whereas in Parkinson disease the emphasis is on large-amplitude movements, movements for the person with Huntington disease need to be of smaller amplitude and controlled.

The gait disorder of Huntington disease has been shown to respond to rhythmical auditory stimuli in one study.³¹⁵ The ability to respond decreases in those most severely involved, indicating that treatment in the later stages of the disease may not be amenable to rhythmical stimuli. Another finding of this study was that cadence was a larger problem than stride length, especially at normal and fast speeds (compare this with the findings in Parkinson disease). Interestingly, people with Huntington disease were able to modulate gait to a metronome but had more difficulty with musical cues even when the tempos were identical. Subjects with Huntington disease demonstrated short-term carryover of metronome auditory stimuli to gait without auditory stimuli. Although the long-term carryover was not studied, using a metronome in gait training may be helpful in clients with Huntington disease. A more recent study using a metronome to cue gait during single and dual task gait activities found that participants with Huntington disease had difficulty synchronizing steps to a metronome in all conditions.³¹³

Relaxation aids the reduction of extraneous movements. In the early stages of the disease methods that require active participation of the client, such as biofeedback and traditional relaxation exercises, may be included. As dementia becomes more apparent, more passive techniques such as slow rocking and neutral warmth must be used. These techniques are also helpful in reducing the choreiform movements of the mouth and tongue, which may prove useful for the dentist and those responsible for proper nutrition of the client. In most cases of Huntington disease, the individual is

quite thin (almost emaciated) and begins to age rapidly as the disease progresses. The extraneous movements, especially as they become more severe, increase metabolic demands, and nutrition therefore becomes increasingly important. Attention therefore must be paid to head, neck, and oral-motor control. Increased pressure on the lips may aid in lip closure and facilitate swallowing. Special straws with a mouthpiece similar to a pacifier may be useful. A dietician should be consulted for assistance in teaching the family how to prepare balanced and appetizing meals and snacks that are still easy to swallow.

The degree of dementia influences treatment options. Conscious efforts to control extraneous movements will be more difficult as cognitive function decreases. New memories and new patterns of movements are more difficult to establish. The therapist therefore must use techniques that require subcortical control and must keep in mind that the client can sometimes remember old, normal patterns of movement. An encouraging treatment method may be the use of imagery. Yáguez and colleagues³¹² found that patients with Huntington disease could use imagery to compensate for impairments in a graphomotor design task.

Peacock's study³⁰⁸ suggests that group programs including strength, flexibility, balance, coordination, and breathing exercises may be very successful, especially in the early stages of the disease. This was confirmed in the study by Zinzi.³¹¹ No amount of physical or occupational therapy, however, can prevent neuronal cell loss. Because Huntington disease is a progressive, degenerative disease, the client's condition will get worse, although the Zinzi study suggested that the progression might be slowed with integrated therapy.³¹¹ Eventually, goals must be aimed at preventing total immobility and assisting caretakers in transfer techniques and advising them in the use of adaptive equipment. One aspect of treatment that cannot be measured but is important in my view is the degree of hope offered just by the fact that a health professional is providing ongoing care. This may lessen the client's degree of despair and depression and may help maintain quality of life.

Wilson Disease

Wilson disease, or hepatolenticular degeneration, is a disease caused by faulty copper metabolism. The toxic effects of copper lead to degeneration of the liver and the basal ganglia. Wilson disease, inherited as an autosomal recessive trait, affects a very small percentage of the population. If the disease is recognized and properly treated, the patient can expect function without restriction and a normal life span.

Wilson disease is characterized by an increase in the amount of copper absorbed from the intestinal tract, a subsequent elevation in the amount of copper in the blood serum, and an increase in the amount of copper deposited in tissue.³¹⁶ Ceruloplasmin is concomitantly reduced. The increase in tissue copper may interfere with various enzyme systems of particular cells. The connection of copper with DA metabolism may account for the basal ganglia involvement.

Neuronal degeneration is present in the globus pallidus and putamen and to a lesser extent in the caudate nucleus. Atrophy may be present in the gray matter of the cortex and the dentate nucleus of the cerebellum.

Symptoms

The deposition of the excess copper in the cornea results in the classic diagnostic sign of Wilson disease, the Kayser-Fleischer ring: a brownish-green or brownish-red ring found in the sclerocorneal junction.

Several forms of Wilson disease have been classified on the basis of the signs and symptoms. One type entails only liver involvement and no neurological signs. A dystonic form is most common in those with an onset of the disease after age 20 years. The individual shows the same abnormal positioning of the limbs and trunk that characterizes the dystonia, rigidity, and bradykinesia seen in Parkinson disease. Associated reactions and facial expressions are absent. Festinating gait and flexed posture are present. Tremor of the hand, head, and body may be present.

If the onset of the disease occurs before age 20, the appearance of choreoathetoid movements of the face and upper extremities is usually present. The gait resembles that of the individual with Huntington disease. This early-onset form is accompanied by a rapid deterioration.³¹⁷

Common to all forms of Wilson disease that involve brain structures are difficulty in speaking and swallowing, incoordination, and personality changes. The personality changes are the first signs of the disease, especially emotional lability and impaired judgment. If the disease progresses, dementia and cirrhosis of the liver increase and motor function progressively decreases.

The postures and movement patterns seen in people with Wilson disease include dystonic movements involving twisting and rotation of limbs, with sustained contraction at the end of the movement.¹⁶ As Wilson disease progresses, the classic abnormal posture of increased flexion occurs, along with rigidity that can progress to the inability to move if severe enough. Dystonia, like bradykinesia and choreoathetosis, belongs on a continuum of the extraneous movements present with basal ganglia involvement. Dysfunction of the cerebellum and intralaminar nuclei of the thalamus may also contribute to these impairments of posture and movement.³¹⁸ A peculiar aspect of dystonia is that it can be decreased with proprioceptive or tactile inputs.¹⁶ As with other diseases of the basal ganglia, an imbalance or abnormal response in the neurotransmitters occurs in Wilson disease; however, the precise imbalance is not yet known.

Stages of the Disease

The first symptom of Wilson disease is usually a change in the individual's personality. Either when this becomes severe enough or when the movement disorder appears, a diagnosis can be made by the presence of the Kayser-Fleischer ring in the eye or by an analysis of copper metabolism. Because Wilson disease is now treatable by chemical means, the full progression of this disease is usually not seen. If left untreated, the dystonia becomes worse and the person becomes more rigid. In addition, muscle weakness can occur and progress, seizures may develop, and the dementia and personality disorder also become worse.

Medical Management

Wilson disease is usually one of the first diseases to be ruled out when a patient manifests movement disorders and behavioral problems, especially in the younger patient. Because the signs and symptoms of Wilson disease are caused

by an increased absorption of copper, treatment consists of drugs that will inhibit this absorption. Concomitantly, copper intake in the diet is restricted; no nuts, chocolate, liver, shellfish, dried fruit, or mushrooms. Zinc salt, which blocks the absorption of copper in the stomach and has no side effects, is now the treatment of choice. Penicillamine and trientine increase urinary excretion of copper, but there are serious side effects to these drugs. If the copper imbalance is treated, the neurological signs do not progress.

Examination and Treatment Intervention

Because Wilson disease is fully managed medically and can be diagnosed early, it may not be of concern to the therapist. If the client is referred for therapy, treatment techniques should be wholly based on symptoms. Examination is similar to that of the person with Parkinson or Huntington disease. It consists of describing the type of extraneous movement present, when it is present, and factors that influence the degree of dystonia. Ease of movement should also be assessed and may be timed as for the patient with Parkinson disease. In addition, range of movement and strength should be evaluated, especially if the disease is progressing.

Treatment is then designed to alleviate the problems. Extraneous movements may be reduced by any technique that will reduce tone. Positioning is important. If bradykinesia is the major sign, then treatment would be similar to that used for people with Parkinson disease; if trunk stability is poor, the therapist proceeds as in Huntington disease. The client with Wilson disease has knowledge of what normal movement feels like and usually has good cognitive abilities at the time treatment is started. Because of the emotional lability, which is one of the first symptoms in this disease, the treatment session should be well planned and quite structured.

Tardive Dyskinesia

Tardive dyskinesia is usually a drug-induced disorder and thus will be used to indicate the problems that can arise from drug intoxication. In particular this section concentrates on the problems associated with drugs that affect DA metabolism and/or reuptake, including amphetamine, methamphetamine, haloperidol, and classes of drugs used in treatment of psychotic disorders: the phenothiazines, butyrophenones, and thioxanthenes. As the use and misuse of drugs becomes more common, these types of disorders may become more frequent. (Refer to Chapter 36 for additional information.)

The use of phenothiazines (one of the neuroleptics) has become a very effective and common treatment for schizophrenia. This treatment protocol has enabled many schizophrenics to leave the mental institution. These drugs are DA antagonists and thus decrease the amount of DA in the brain. The exact site of the brain involved in schizophrenia itself is not within the scope of this chapter, but the neurological signs that occur will be discussed. As might be expected, they involve structures within the basal ganglia. Tardive dyskinesia is a gradual disease that occurs after long-term drug treatment. The most typical involvement is of the mouth, tongue, and muscles of mastication; therefore tardive dyskinesia may be called *orofacial* or *buccolingual-masticatory* (BLM) dyskinesia.

Symptoms

Dyskinesia is defined as an inability to perform voluntary movement.³⁰⁵ In practical terms, however, dyskinesia is usually a series of rhythmical extraneous movements. In tardive dyskinesia this typically begins with, or may be confined to, the region of the face. These extraneous movements may include choreoathetoid or dystonic movements. Because of abnormality in basal ganglia function, abnormalities in postural tone and postural adjustments are also present. Instead of the typical flexed posture of Parkinson disease, clients with tardive dyskinesia show extension of the trunk with increased lordosis and neck flexion.³¹⁹ This description of the disease is rather broad, but the problems of drug-induced movement disorders are varied. They may take the form of drug-induced Parkinson disease or dystonia. In tardive dyskinesia, akinesia and rigidity similar to that seen in parkinsonism may exist simultaneously with the choreoathetoid-like movements. The key factor in tardive dyskinesia is its slow onset after the ingestion of neuroleptic medications.

Etiology

Although many people take neuroleptic medication, only a small percentage acquires tardive dyskinesia. Many factors may predispose an individual to movement disorders. One of these is age.³²⁰ This might be expected because of the influence of aging processes on the concentration of DA. Gender may also be a factor. Women, and older women in particular, are more at risk for tardive dyskinesia, perhaps because of decreased estrogen.³¹⁹ The absolute amount of neuroleptic ingested may also be a factor, but to date definitive studies have not been completed. So far the length of time the individual takes medication does not appear to be a strong predisposing factor. As the biological abnormalities of schizophrenia become better understood, further understanding of the causes of tardive dyskinesia also may be elucidated. The development of tardive dyskinesia is hypothesized to be caused by supersensitivity.^{305,321} With the use of drugs that deplete the brain of DA, the brain becomes more sensitive to it. And, in fact, in humans the withdrawal of neuroleptics tends to heighten the disease; essentially, withdrawal of the DA antagonist means that far more DA is able to act on these already sensitive terminals.^{305,321,322}

Because of the effectiveness of long-term treatment for schizophrenia provided by neuroleptics, research into the underlying cause and therefore treatment of the major side effect, the motor disorders, has greatly increased.³²³ But as with Parkinson disease and Huntington disease, animal models are difficult to produce. However, experimental evidence indicates that the basal ganglia are involved in movements about the face, especially the mouth, and buccolingual dyskinesia is the most frequently encountered symptom in tardive dyskinesia.^{69,70} The response of basal ganglia neurons to sensory input shows increasing localization of response with age; the region about the mouth becomes increasingly sensitive.⁷⁰ Further research along these lines, both in normal animals and in those with lesions, may answer the question of what is happening at a neuronal level. This would facilitate pharmacological and therapeutic interventions.

Pharmacological and Medical Management

The most important treatment for tardive dyskinesia is prevention. Today, DA receptor agonists are prescribed only when other, newer medications are not effective. Tardive dyskinesia is often irreversible. The withdrawal of medication, in fact, may increase the movement disorders. Or recovery may take even more time than that required for the onset of the disease. Strangely, sometimes the drug that caused the disease may be the drug that reduces the symptoms; that is, increasing the dose may lessen the movement disorder. This might be expected if supersensitivity to DA is involved. But again, with time the increased dose will also cause a reappearance of the symptoms. The Movement Disorder Society and WE MOVE recommend that the physician evaluate the schizophrenic patient at 3-month intervals to prevent the disease. (Refer to the list of websites at the end of this chapter.)

The use of other drugs in conjunction with the neuroleptics has been tried in various animal models of the disease. As might be expected, anticholinergic drugs (which would worsen an imbalance between DA and ACh) worsen the dyskinesia. Lithium has been successful in one animal model of dyskinesia.³⁰⁵ Some neuroleptic drugs seem to have less effect on movement than others; however, the side effects of one such drug, chlorpromazine, are life-threatening. Reducing the buildup of phenylalanine is also indicated as a way to decrease occurrence of tardive dyskinesia. A medical food comprising branched-chain amino acids seems to reduce concentration of phenylalanine and was effective in reducing the movement disorder in one clinical trial. More research is needed into both the mechanisms of schizophrenia and the mechanisms for the production of the abnormal movements.

Evaluation and Treatment Interventions for Dyskinesia

The effectiveness of rehabilitation therapy intervention in drug-induced dyskinesia is, as yet, not completely known. However, because the neuroleptics do provide an effective long-term treatment of schizophrenia, and because amphetamines and methamphetamine are being abused, therapists need to become aware of the problem and offer some assistance. Early drug holidays (time without use of drugs) may be of value in treatment of tardive dyskinesia, and therefore early awareness of incipient changes in motor function may be of value. Assessment of patients receiving drug therapy could perhaps begin before treatment and then at prescribed intervals. The knowledge that postural adjustments are abnormal in most basal ganglia diseases means that analysis of posture statically and in motion might provide early clues of development of movement disorders. The same would be true for balance reactions and changes in tone with changes in position. Once movement disorders appear, an assessment of when and where the extraneous movements occur is important. (See Chapter 8 for general examination tools and Chapter 22 specifically for tests of balance.)

General treatment is similar to that used in Huntington disease; oral treatment corresponds to that for the athetotic child with cerebral palsy. If a hyperreactivity to sensory stimulus exists, then oral desensitization may be of value.

Ameliorating the oral grimacing, of course, would be helpful for the schizophrenic person who is trying to return to society. The effectiveness of physical and occupational therapy treatment cannot be assessed until therapists become involved with these clients and record the effectiveness of their interventions. In cases in which the parkinsonian-like symptoms are stronger than the dyskinetic movements, treatment would follow the plan for the individual with Parkinson disease. As yet, physical therapy for drug-induced dyskinesias is not mentioned on websites to the physician or the patient.

Other Considerations

Other drugs besides neuroleptics may also produce movement disorders. Amphetamine, for example, has been shown to cause long-term changes in brain function even with very small doses.³²⁴⁻³²⁶ Adults who were hyperactive as children sometimes show a decrease in the readiness potential.³²⁷ Further longitudinal research and research using PET scans and functional magnetic resonance imaging (fMRI) are underway to determine the role that medications used in treating hyperactive children, such as methylphenidate (Ritalin), might play in changing the architecture of the basal ganglia and causing movement disorders.⁸⁴ The problem of drug-induced movement disorders may become an ever-increasing one for the therapist.

In 1982 several young people were treated for rigidity and “catatonia” after the use of what they thought was heroin. Careful examination of these patients revealed that they had parkinsonian-like symptoms.^{38,105} The chemical responsible for the symptomatology was MPTP, a meperidine analog that was an impurity in the designer heroin. This discovery has enabled research in animals and clinical studies in humans and may enable better understanding of the pathogenesis and, in turn, of the treatment of the disease. One hypothesized cause of Parkinson disease implicated environmental toxins (because some herbicides such as paraquat resemble the chemical structure of MPTP) and the involvement of superoxide free radicals.^{92,328,329} More complete epidemiological studies are now underway to investigate Parkinson disease to determine the relationship to specific herbicides and pesticides.

Methamphetamine use also induces movement disorders. The MRI of even infrequent users shows damage to the basal ganglia.^{330,331} A child born to a mother using methamphetamine may also have movement disorders and delayed achievement of developmental milestones. Another recreational drug, cocaine has long been known to produce parkinsonian movement disorders.³³²

Dystonia

General Information

Dystonia is a movement disorder characterized by sustained muscle contraction in the extreme end range of a movement, frequently with a rotational component. There are inherited dystonias that usually involve the entire body. These dystonias are most prevalent in those of European Jewish descent. Focal dystonias involve just one joint or a few neighboring joints, such as spasmodic torticollis or writing cramps. Full-body dystonia is a disease of the basal ganglia, and the

current view is that focal dystonia also involves lesions of precise areas of the basal ganglia.

Generalized and focal dystonias manifest differently and have different pathophysiologies and therefore different treatments. They will therefore be separated in this part of the chapter. However, in all cases of dystonia, excessive coactivation of agonists and antagonists occurs that interferes with the timing, execution, and loss of independent joint motions. Rarely are any abnormalities of muscle tone present, *per se*—that is, no increase in deep tendon reflexes or rigidity occurs. Muscle strength and ROM are usually within normal limits unless disuse leads to weakness.

Generalized Dystonia

Symptoms. The person with generalized dystonia will begin a movement (such as walking) and then will experience a torsional contraction of the trunk; of the upper extremity, especially at the shoulder; and in the ankle, foot, and toes. These contractions may be so strong that further movement is impossible. Many patients experience pain as the muscles remain contracted for long periods of time.³³³

Etiology. The cause of generalized dystonia is predominantly genetic, involving the *DYT* gene.³³⁴

Pharmacological and Medical Management. There are few treatments for generalized dystonia. DA agonists and L-dopa are sometimes effective.

Evaluation and Treatment Intervention. Evaluation of the person with generalized dystonia will be similar to the evaluation of the person with tardive dyskinesia or Huntington disease. Several ADLs should be examined. And the way that dystonia interferes with these ADLs is of most importance for treatment. In addition to the full extent of the motoric abnormality, it is also important to test sensation, especially higher level sensory processing such as precise localization of touch, graphesthesia, and kinesthesia.

Movement therapy interventions are only now being developed for generalized dystonia. Overall, treatment similar to that in Huntington disease that emphasizes treating the symptoms may be beneficial. One successful program uses sensory integration and relearning techniques performed with attention.³³⁵ Practice is a crucial element of treatment, and the client must be willing to practice the sensory tasks many, many times throughout the day for benefit.

Other Considerations. As with other extraneous movements associated with basal ganglia disorders, relaxation can reduce the muscle contraction. However, I have found that the time to incorporate the relaxation is before the full-blown development of the muscle contraction—a difficult task. Therefore clients should practice relaxation on a regular basis. There is frequently a psychological aspect to the focal dystonias that may necessitate intervention from a psychiatrist or psychologist.

Focal Dystonias

Spasmodic torticollis is the most common focal dystonia. The person with this disorder will have involuntary contractions of neck muscles that result in head turning and head extension and flexion movements that are often sustained for long periods of time. Other common sites of focal involvement are the vocal cords; the tongue and swallowing muscles; the facial muscles, especially about the eye; the hand; and the toes. Writer's cramp is a task-specific dystonia,

unlike other focal dystonias. An interesting phenomenon of dystonia is the fact that many patients will develop a sensory or motor “trick” that will decrease the severity of the muscle contraction(s) and may even stop these movements.^{333,336}

Symptoms. Symptoms of focal dystonia will depend on the site of involvement. For example, in the case of spasmodic torticollis, the symptom is pain and an inability to control a movement of the head to the side.

The signs and symptoms of focal hand dystonia are variable. The problem may initially manifest as an abnormality in the quality of sound produced by a musical instrument (e.g., a deterioration of vibration in a violinist),³³⁷ increasing errors in task performance, unusual fatigue or sense of weakness, or involuntary or excessive movement of a single digit or multiple digits. Initially the symptoms are subtle and virtually indistinguishable from the normal variations that may be seen in the execution experienced by all musicians studying technically demanding music or software engineers who spend excessive hours at the computer. Frequently, a person engaged in a profession with high repetition of tasks who has minimal pain but vague motor control problems or somatosensory dysfunction is manifesting early signs of focal dystonia.³³⁸ Although a co-contraction of flexors and extensors can be observed while an individual with hand dystonia performs the target task, at rest and during the performance of nontarget tasks the hand appears to function normally. Some patients demonstrate a variety of subtle abnormalities such as a reduced arm swing; loss of smooth, controlled grasping; a physiological tremor; hypermobility of the interphalangeal joints; decreased ROM in some upper limb joints (e.g., shoulder abduction, external rotation, finger abduction, forearm pronation); neurovascular entrapment; compression neuropathy; or poor posture.³³⁹⁻³⁴⁴

Etiology. The cause of focal dystonias is unknown and multifactorial. Frucht³⁴⁴ observed that task-specific hand dystonia seemed to begin after motor skills had been acquired rather than during skill acquisition. Thus, focal hand dystonia in a musician is probably not a disorder of motor learning but a disruption of acquired, complex, motor programs. The data also suggested that peripheral environmental influences seem to play an important role in molding the dystonic phenotype. For example, the hand performing the more complex musical tasks (e.g., right hand in pianists and guitarists, left hand in violinists), seemed to be more predisposed to the development of dystonia. In addition, the dystonia usually began in one finger and spread to adjacent fingers, rarely skipping a finger. Furthermore, the ulnar side of the hand (fingers 4 and 5) was disproportionately affected, potentially because of the challenging ergonomics and technical stresses of the musical instrument required for this part of the hand in terms of gripping and activation of individual finger movements.³⁴⁵

Pharmacological and Medical Management. The most common medical treatment for the focal dystonias is botulinum toxin. This toxin binds with the ACh receptors on the muscle and prevents the muscle from contracting. The injections are made under electromyographic guidance so that only those motor units involved in the production of the extraneous movements are paralyzed. However, the treatment does not cause permanent change, so the patient must repeat these injections every 3 to 4 months. Some people

develop antibodies to the toxin, rendering it then ineffective.^{346,347} Therefore, medical management prevents the abnormal movement but is not a cure.

Evaluation and Treatment. Overall, treatment of focal dystonia will depend on the joint or joint involved. The duration of the dystonia, the trigger, and the person's trick, if any, to relieve the dystonia must be noted. Tricks are sensory in nature and help relieve the pain often associated with the extreme movement. The Toronto Western Spasmodic Torticollis Rating Scale (TWSTRS) is one evaluation for the person with spasmodic torticollis.³⁴⁸

Several ADLs should be examined. For example, in hand dystonia, the person should be evaluated using the instrument producing the dystonia (i.e., the pen in writer's cramp) as well as other tools (e.g., a fork). In addition, there seems to be position dependence, so writing while prone may not evoke the dystonia despite severe inability to hold the pen at a desk.³⁴⁹

In addition to the full extent of the motoric abnormality, sensation, especially higher-level sensations such as precise localization of touch, graphesthesia, and kinesthesia must be assessed. Byl and colleagues found changes in the sensory cortex after development of focal hand dystonia.^{335,349-352} Recent evidence suggests that balance, particularly dynamic balance, should also be assessed in patients with torticollis.³⁵³ These balance difficulties have not been relieved with botulinum toxin.

Movement therapy interventions are now being developed. One successful program uses sensory integration and relearning techniques performed with attention.³⁵⁴ Practice is a crucial element of treatment and the client must be willing to practice the sensory tasks many times throughout the

day for benefit. The client practices cognitively demanding sensory discrimination tasks throughout the day and tries to use only tension-free movements.³⁴⁹

Treatment for the person with torticollis must include a relearning of midline before the person can begin to practice normal movement away from midline. The client may find this relearning process easier after botulinum injection. See Chapter 9 for further treatment interventions appropriate for patients with focal dystonias.

Other Considerations. As with other extraneous movements associated with basal ganglia disorders, relaxation can reduce the muscle contraction. However, the time to incorporate relaxation is before the full-blown development of the muscle contraction—a difficult task. This task requires a shift in paradigm to a health and wellness model and prevention (see Chapter 2). Therefore clients should practice relaxation on a regular basis. A psychological aspect to the focal dystonias frequently necessitates intervention from a psychiatrist or psychologist.

METABOLIC DISEASES AFFECTING OTHER REGIONS OF THE BRAIN

All alterations of metabolism, if allowed to continue, will affect nervous system function. This includes alterations in sodium, water, sugar, and hormonal balance. Table 20-2 lists metabolic diseases that often have neurological sequelae. Proper treatment is usually medical management of the imbalance. Physical therapeutic intervention, if necessary, should address specific neurological symptoms.

Ingestion of or exposure to heavy metals may also lead to CNS disease. Table 20-3 describes the sequelae of these problems.

TABLE 20-2 ■ NEUROLOGICAL COMPLICATIONS OF METABOLIC DISORDERS

METABOLIC PROBLEM	TREATMENT	NEUROLOGICAL COMPLICATION
Decreased sodium (too much water)	Restriction of water intake	Muscle twitching, seizures, coma
Increased sodium	Slow rehydration	Cerebral edema, muscle rigidity, decerebrate rigidity
Decreased potassium (hypokalemia), often caused by aldosteronism	Restoration of potassium levels after assessing primary cause	Changes in resting potential of neuron; hyperpolarization; muscle weakness and fatigue with eventual total paralysis
Magnesium imbalance	Improved diet, intravenous magnesium	Mental confusion, muscle twitching, myoclonus, tachycardia, hyperreflexia, extraneous movements, seizures
Diabetes mellitus	Proper control of diabetes	Peripheral neuropathy, pseudotabes, possible seizures and coma
Hypoglycemia	Treatment of primary cause; diet adjustment	Anoxia of the brain, seizures, mental confusion
Hyperthyroidism	Thyroid-blocking agents; intravenous fluids, hydrocortisone, and propranolol if patient is in thyroid crisis	Hyperkinesia, irritability, nervousness, emotional lability, symmetrical peripheral neuropathy
Hypothyroidism	Thyroid supplement	Sluggishness, mental and motor retardation, muscle weakness, sometimes muscle pain
Hypercalcemia	Treatment of primary cause, which is often hyperparathyroidism, vitamin D malignancy (therefore surgical removal)	Headache, weakness, fatigue, proximal neuropathy, rigidity, tremor, disorientation
Hypocalcemia	Intravenous administration of calcium (possible medical emergency)	Hyperexcitability of the peripheral and central nervous systems, which can lead to tetany and convulsions

TABLE 20-3 ■ NEUROLOGICAL COMPLICATIONS OF HEAVY METAL POISONING

TYPE OF METAL	TREATMENT	NEUROLOGICAL COMPLICATION
LEAD Source: lead paint, industrial (fumes of molten lead)	Elimination of source, reduction of fluids, intravenous urea or mannitol, use of chelating agents	Interstitial edema and hemorrhage (especially in cerebellum) in acute poisoning; all levels of central nervous system affected in chronic long-term poisoning In children: seizures, mental retardation, behavior problems, hyperactivity In adults: spasticity, rigidity, dementia, personality changes Peripheral neuropathy may occur in adults and children
ARSENIC Source: paint and insecticides	Removal of source, gastric lavage, intravenous fluids, maintenance of electrolyte balance; penicillamine used in acute poisoning	Demyelination of peripheral nerves in all extremities
MANGANESE Source: industrial if manganese dust is not removed; symptoms appear 2-25 yr after exposure	Levodopa	Neuronal loss in basal ganglia, substantia nigra, and cerebellum Initially psychiatric disturbances, including nervousness, irritability, and a tendency toward compulsive acts Later, muscular weakness and parkinsonian symptoms
MERCURY Rare, but may affect farmers and dental office workers	Penicillamine; function returns only with physical, occupational, and speech therapy	Loss of neurons, especially in cerebellum; also in cortex near calcarine fissure Alternating periods of confusion, drowsiness, and stupor with restlessness and excitability Ataxia, dysarthria, visual deterioration

SUMMARY

This chapter has focused on the pathophysiology, evaluation, and treatment of genetic, hereditary, and metabolic diseases affecting adults. In all of these diseases the therapist or movement specialist is an important (though sometimes underused) part of the rehabilitation team. Knowledge of the possible mechanisms involved in the production of the varying movement disorders may make the appropriate evaluation and subsequent treatment more meaningful. Even with degenerative, progressive disorders the therapist plays an important role in maintaining quality of life and assists the client and family in coping with the disease. The importance of documentation (see Chapter 10) and publication of cases and larger controlled studies cannot be overstressed. Both will assist in the development of improved therapeutic techniques and may help researchers in planning and interpreting appropriate experimental studies. Establishment of efficacy will be the first step toward evidence-based practice and a critical link in the evolution of professionals who have been identified as movement specialists.

With the advent of the Internet, many websites have been created to focus on diseases and conditions mentioned in this chapter. In addition, the organization WE MOVE (Worldwide Education and Awareness for Movement Disorders) has a website for both patients and care providers (www.wemove.org). These sites answer many questions for

patients and provide information on making day-to-day life easier. Local and national support groups and foundations also provide information and support for the patient and caregiver. Most also have separate sections for health care providers.

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 354 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

CASE STUDY 20-1 ■ PATIENT WITH PARKINSON DISEASE, HOEHN AND YAHR STAGE 1

Ms. T. is a 55-year-old woman who was diagnosed with Parkinson disease 1 year ago. The disease began in her left arm and leg when she noticed increasing stiffness and difficulty moving. She complains of some instability in walking and recently has developed a slight resting tremor in the left hand. On initial evaluation she had full active and passive ROM in all extremities, neck, and trunk. There is a mild resting tremor present in the left hand. There is mild cogwheel rigidity in the left upper and lower extremities; there is some intermittent resistance to passive movement in the right upper extremity as well. Strength is grossly within normal limits throughout. Sensation is intact throughout. Equilibrium reactions are delayed, but the patient demonstrates an ankle strategy on a flat surface and a hip strategy when standing on the balance beam; there is no mixing of the synergies, and her balance responses are appropriate to the degree of displacement.

The patient is able to stand in the sharpened Romberg position for 30 seconds with the eyes open and 20 seconds with eyes closed. She can stand on the right leg for 30 seconds with eyes open and 15 seconds with eyes closed; she can stand on the left leg for 15 seconds with eyes open and 10 seconds with eyes closed. When walking, she has a heel-toe sequence, shortened stride length, and normal stride width. There is no arm swing on the left and a diminished arm swing on the right. There is no trunk rotation and very slight trunk flexion throughout the gait cycle. Speed is within normal limits for a 25-foot walk. The patient is able to turn freely. She has recently begun to experience a foot dystonia, which is worse with fatigue. It has interfered with her daily walking program and

her tennis, an activity she enjoys with her husband twice a week. Her only medication is deprenyl.

This patient is in Hoehn and Yahr stage 1, with some beginning of bilateral symptoms and progression to stage 2. She is young, is employed full-time, and has been involved in regular exercise for the past 10 years. Her complaints are of stiffness, slowed movements, and foot dystonia. Because her symptoms are mild at present and she has good balance in standing and walking, this patient should be encouraged to continue exercising regularly. She should try to maintain her tennis, as this requires complex, sequential, context-dependent movements. Although tennis involves motor responses to external cues, it does necessitate rapid force generation and anticipatory movements. This should encourage continued motor learning. In addition, she should be encouraged to continue walking out of doors and practice alternating speed of walking. The dystonia is more difficult to resolve. It may be tied to medication, and differing medication schemes are now being tried. She is also on a program of stretching and strengthening of the ankle as well as a sensory stimulation program for the feet. Foam between the toes has helped to decrease dystonia early in the day.

Ms. T. has also been informed about the importance of maintaining chest expansion and monitoring her breathing. This will be important as the disease progresses. She attends a support group for young parkinsonian patients to increase her awareness of the disease, new treatments, and support. As the disease progresses, she will need a home program appropriate for her symptoms. The home program will be reassessed every 3 to 6 months.

CASE STUDY 20-2 ■ PATIENT WITH A SEVEN-YEAR HISTORY OF PARKINSON DISEASE, HOEHN AND YAHR STAGE 3

Mr. R. is a 68-year-old man with a 7-year history of Parkinson disease. He is currently in Hoehn and Yahr stage 3 of the disease progression. He falls two or three times a day, has difficulty eating, and has noticed weakness in his right hand. He would like to return to full activity including golf twice a week, swimming, and skiing. On evaluation he has moderate rigidity in all extremities; the right side is worse than the left. It is most marked in the right wrist, forearm, and hand. Shoulder flexion and abduction lack 15 degrees bilaterally. He has a 15-degree knee flexion contracture on the right; all other joints

in the lower extremity have range within functional limits. Strength is grossly 4 to 4+/5 on manual muscle testing throughout including grip strength. Sensation is within normal limits throughout. Sitting balance is good during static and dynamic activities.

The patient sits with a posterior pelvic tilt, rounded shoulders, and flexed neck. On rising to a standing position, he does move forward in the chair, which positions his feet under his knees. He does not lean forward as he stands and momentarily loses his balance on rising from a chair. Static standing balance

Continued

CASE STUDY 20-2 ■ PATIENT WITH A SEVEN-YEAR HISTORY OF PARKINSON DISEASE, HOEHN AND YAHR STAGE 3—cont'd

is fair, and dynamic balance is fair. When pushed on the sternum, he takes one or two steps backward, even to a gentle push. When pushed from behind he takes several steps forward. He lost his balance and required assistance when trying to catch a large ball thrown to the side. His gait pattern is typical of a parkinsonian patient. There is a shortened step and a flat-footed foot contact. He complains of festination and of freezing, but neither are observed during the evaluation. He turns “en bloc,” exhibiting no arm swing and no trunk rotation. He walks slowly and is unable to increase his speed measurably in a 25-foot walk. He is taking L-dopa-carbidopa and deprenyl. He tried taking another D2 agonist but experienced hallucinations. He was able to ski until last winter. At that time he found that he could not stand up once he fell down, and sometimes he fell without realizing that he was falling. He stated that he “did not think it was safe to ski.” He also no longer swims because he has difficulty breathing in the pool and coordinating his

breathing with the strokes. He does not play golf because it takes him so long.

This patient was encouraged to continue both to exercise and to socialize while exercising. He was encouraged to resume golf at times when his course is less crowded. In addition, he was given a home program consisting of activities to be performed in seated and standing positions that encourage trunk rotation and large movements and are coordinated with good breathing practices. He was given some balance exercises that challenge his equilibrium in a safe environment. His home program was monitored every 3 months because of the distance he must travel to come to the clinic. His wife was instructed to exercise with her husband and to exercise to music with him. He was referred to the speech pathologist for a swallowing evaluation and was given a therapeutic program for his speech and breathing. He is now able to play golf once a week; however he is not yet ready to resume swimming or skiing.

OVERVIEW

The cerebellum is a highly unique brain structure, easily recognizable by its location on the dorsal surface of the brain stem and the distinct, dense folia, or foldings, of its cortex. For centuries the cerebellum has been the object of intense investigation by scientists, in particular because of the extreme uniformity in the arrangement of neurons in the cerebellar cortex and the presence of very large Purkinje cells, which have an extensive fanlike dendritic arbor. The human cerebellum contains more neurons than any other brain region, suggesting that whatever its role in behavior, it requires the integration of vast amounts of information and may perform rather complex computations. Researchers agree that the cerebellum plays a critical role in coordinating and adapting movements, although how it does so is still not fully understood. It is now also clear that the cerebellum is connected to nonmotor regions of the brain, such as the prefrontal cortex, and therefore likely plays a role in cognitive and other nonmotor functions. Yet the most striking and debilitating effect of damage to the cerebellum is *ataxia*, which comes from the Greek and translates literally to “without order.” We will focus on this hallmark feature of cerebellar damage, which is incoordination of movements without overt muscle weakness.

In this chapter we will review critical features of cerebellar anatomy and physiology that help reveal the role of the cerebellum in motor control, and we will describe the major movement deficits associated with damage to the human cerebellum. We will highlight the most valuable and unique components of the physical therapy examination for clients with suspected cerebellar dysfunction and review the evidence for and against specific rehabilitation interventions targeting recovery of body functions, activities, and participation. Emphasis is placed on the importance of the physical therapist’s judgment in determining whether a recovery or a compensation approach should be implemented.

Types of Cerebellar Damage

Cerebellar ataxia can result from damage to the cerebellum itself or the pathways to or from it. Damage can occur from a number of different causes, such as stroke, tumor, degenerative disease, trauma, or malformation. The cause of cerebellar dysfunction is often an important consideration when determining a prognosis and developing a treatment plan. Other factors to consider include whether the cerebellar lesion is static versus progressive, whether it involves only the cerebellum or multiple neural structures, and whether it was present at birth or acquired.

Cerebellar strokes are rarer than cerebral strokes, but not entirely uncommon. They account for less than 5% of all

strokes.¹ These strokes can involve any of the three arteries that supply the cerebellum: the superior cerebellar artery, anterior inferior cerebellar artery, and posterior inferior cerebellar artery. Depending on the territory supplied by the damaged vessel (Table 21-1), there are stereotyped patterns of cerebellar and extracerebellar motor dysfunction that result. However, there is certainly some variation in distribution from person to person. Stroke involving the superior cerebellar artery often leads to dysmetria of ipsilateral arm movements, unsteadiness in walking, dysarthric speech, and nystagmus.¹ Stroke involving the anterior inferior cerebellar artery often causes both cerebellar and extracerebellar signs (owing to involvement of the pons) including dysmetria, vestibular signs, and facial sensory loss.¹ Finally, stroke involving the posterior inferior cerebellar artery is usually, in the long run, the most benign, though initially it often manifests with vertigo, unsteadiness, walking ataxia, and nystagmus.¹ The best predictor of recovery from cerebellar stroke is whether the deep cerebellar nuclei are involved: recovery is best when they are not damaged.²

Tumors in the posterior fossa (i.e., in or near the cerebellum) do occur, though they are more common in children than adults. Depending on the type and location, tumors may be treatable with surgical resection, chemotherapy, radiation therapy, or some combination of these. Children with cerebellar tumors often have a good prognosis for recovery because many of the types of tumors most common in this population are benign and can be removed. Children also typically recover very well after cerebellar damage from tumor resection and show little signs of cerebellar ataxia. Tumors in adulthood often are caused by a more aggressive form of cancer and therefore may carry a poorer prognosis. Second to tumor type, damage of the deep cerebellar nuclei is an important factor that predicts recovery, even more so than age.²

Several neurodegenerative diseases can damage the cerebellum (Table 21-2). One of the more common types of degenerative diseases is a group of hereditary, autosomal dominant diseases referred to as the spinocerebellar ataxias (SCAs). Currently there are 30 known distinct SCAs, which are named by numbers (e.g., SCA1, SCA2). Depending on the genetic abnormality, they can cause either purely cerebellar damage or combined cerebellar and extracerebellar damage.^{3,4} Most of the SCAs have onset in midlife and are slowly progressive, which means that children of an affected parent will likely not know if they are affected until adulthood. There are genetic tests for a subset of these diseases. Because onset of symptoms is delayed and there are no effective pharmacological treatments, genetic counseling is a must before families decide whether or not to have children undergo genetic testing. A related set of diseases

TABLE 21-1 ■ TERRITORIES OF THE CEREBELLAR ARTERIES

ARTERY	CEREBELLAR TERRITORY SUPPLIED
SCA	Superior or upper half (approximately) of the dorsal and upper third (approximately) of the ventral surface of the cerebellum except for the extreme lateral wing of the hemisphere Portions of the vermis and nodulus Substantial upper portions of the intermediate and lateral hemispheres Portions of the deep cerebellar nuclei Superior cerebellar peduncle
AICA	Middle 10%-30% of the ventral cerebellum, sometimes wrapping laterally to encompass a small portion of the most lateral aspects of the dorsal cerebellum Flocculus Small portions of the lateral hemisphere Middle and inferior cerebellar peduncles
PICA	Inferior or lower half (approximately) of the dorsal cerebellum and the inferior fourth to third of the ventral cerebellum Portions of the nodulus, vermis, intermediate and lateral hemispheres Portions of the deep cerebellar nuclei

Data from Amarenco P: The spectrum of cerebellar infarctions. *Neurology* 41:973–979, 1991; and Tatu L, Moulin T, Bogousslavsky J, Duvernoy H: Arterial territories of human brain: brainstem and cerebellum. *Neurology* 47:1125–1135, 1996.

AICA, Anterior inferior cerebellar artery; PICA, posterior inferior cerebellar artery; SCA, superior cerebellar artery.

Note: The cerebellar arteries also supply extracerebellar regions (i.e., portions of brain stem) not listed here.

TABLE 21-2 ■ SELECTED FORMS OF CEREBELLAR DAMAGE¹⁰²

ACQUIRED	DEGENERATIVE NONHEREDITARY
1. Stroke (infarct, hemorrhage)	1. Multiple system atrophy (MSA)
2. Tumor (primary brain tumor, metastatic disease)	2. Idiopathic late-onset cerebellar ataxia (ILOCA)
3. Structural (Chiari malformation, agenesis, hypoplasia, etc.)	
4. Toxicity (alcohol, heavy metals, drugs, solvents, etc.)	HEREDITARY
5. Immune-mediated (multiple sclerosis, gluten ataxia, etc.)	1. Autosomal dominant disorders (episodic ataxias, spinocerebellar ataxias)
6. Trauma	2. Autosomal recessive disorders (Friedreich ataxia, early onset cerebellar ataxia, etc.)
7. Infection (cerebellitis, etc.)	3. X-linked disorders (mitochondrial disease, fragile X-associated tremor, etc)
8. Endocrine (hypothyroidism)	

Data from Manto M, Marmolino D: Cerebellar ataxias. *Curr Opin Neurol* 22:419–429, 2009.

is the hereditary episodic ataxias,⁵ which are rare autosomal dominant diseases. As the name implies, clients with episodic ataxia will have periods of ataxia lasting minutes to hours, brought on by exercise, stress, or excitement. Some of the episodic ataxias respond well to medications.⁶

Cerebellar damage can occur from other sources as well. In traumatic brain injury, damage of the cerebellum is almost always found in the presence of widespread brain damage and is seen as a predictor of poorer outcome.⁷ The cerebellum is also particularly sensitive to toxins, including certain heavy metals and alcohol. Chronic alcoholism causes cerebellar atrophy preferentially involving the anterior superior vermis.^{8,9} The inflammatory disorder multiple sclerosis also frequently produces lesions in the cerebellum. Finally, congenital brain abnormalities such as Chiari malformation

damage the cerebellum by increased pressure and mechanical deformation. Recovery from cerebellar malformation is not understood; often these children have substantial damage to the brain stem or other neural structures, which may make therapy more challenging. A more comprehensive list of the variety of types of cerebellar damage is provided in [Table 21-2](#).

Given the wide range of cerebellar disorders, it is useful for the clinician to categorize the damage as progressive or nonprogressive. Clients with progressive disorders, such as the SCAs, are likely to experience worsening ataxia and decreased mobility over time, and will need periodic therapy over the life span for optimal function. In contrast, the condition of patients with nonprogressive disorders would not be expected to worsen, and some may have the potential for

substantial recovery. Note that when additional brain areas are involved, rehabilitation may be more challenging, theoretically because other, compensatory brain mechanisms may be impaired. This type of information is vital for making an appropriate prognosis and developing a long-term plan of care for clients with cerebellar dysfunction.

CEREBELLAR ANATOMY AND PHYSIOLOGY

A brief review of specific anatomical and physiological features is critical to understanding the mechanisms by which the cerebellum helps coordinate and adapt movement. Recall that most pathways between the cerebellum and spinal cord are uncrossed or double crossed, whereas pathways between the cerebellum and cerebrum are crossed. Hence a lesion to one side of the cerebellum produces ataxia and related cerebellar deficits involving the same side of the body as the lesion. Also note that the cerebellum has relatively few direct projections to the spinal cord. Instead, it exerts a strong influence on movement through its projections to cerebral and brain stem motor structures, as described later.

Anatomical Divisions

The cerebellum is part of the hindbrain and is positioned on the dorsal surface of the brain stem at approximately the level of the pons (Figure 21-1). It is connected to the brain stem by the superior, middle, and inferior cerebellar peduncles. The cerebellar peduncles contain all of the axons that transmit information to and from the cerebellum. The cerebellum can be anatomically divided into three lobes: the anterior, posterior, and flocculonodular lobes. The primary fissure divides the anterior and posterior lobes, and the posterolateral fissure divides the posterior and flocculonodular lobes (Figure 21-2).

Figure 21-1 ■ The cerebellum, bisected through the midsagittal plane. (Redrawn from Kandel ER, Schwartz JH, Jessell TM: *Principles of neural science*, ed 4, New York, 2000, McGraw-Hill Medical.)

Looking at a sagittal slice through the cerebellum, distinct cellular regions can be visualized. The most superficial region is the cerebellar cortex, which, unlike the cerebral cortex, contains only three layers. The arrangement of cells within the cortex is strikingly uniform across all cerebellar lobes and plays a vital role in determining cerebellar function, which will be described later. Deep to the cerebellar cortex is the white matter layer, which contains the axons of Purkinje cells projecting out from the cerebellar cortex and the axons of mossy and climbing fibers entering the cortex from other brain and spinal regions (see Figure 21-1). The cerebellar nuclei are the output structures of the cerebellum, and they make up the deepest region. Groups of neuronal cell bodies receive information coming into the cerebellum from a variety of brain and spinal cord regions and also from the cerebellar cortex, via Purkinje cell axons. The deep nuclei are arranged in pairs, with one nucleus of each pair on each side of the cerebellum. Most medially are the fastigial nuclei, followed by the globose and emboliform nuclei and most laterally the broad dentate nuclei (see Figure 21-2). The medial and lateral vestibular nuclei also receive input directly from the cerebellar flocculonodular lobe and are therefore considered to play a role as an additional set of cerebellar output structures.

Functional Divisions and Their Afferent and Efferent Projections

Probably the most useful way of thinking about the anatomy of the cerebellum is to divide it into distinct functional longitudinal “zones.”¹⁰ Each cerebellar zone consists of a region of cerebellar cortex and its own pair of deep cerebellar nuclei. Each zone also has projections to and from distinct areas of the brain and spinal cord. Thus, despite the regular arrangement of cells over the entire cerebellum, each functional longitudinal zone is uniquely positioned to control certain types of movement but not others.¹⁰⁻¹² See Table 21-3 for a summary.

The medial zone consists of the midline structure, the vermis, and the fastigial nuclei. This region of the cerebellum predominantly receives afferent information from the brain stem vestibular and reticular nuclei and the dorsal and ventral spinocerebellar pathways,¹³⁻¹⁸ which convey important information regarding the current sensorimotor state of the trunk and limbs.¹⁹⁻²¹ In turn, its outputs, through the fastigial nuclei, are largely to reticular and vestibular nuclei that will form part of the medial descending system (reticulospinal and vestibulospinal tracts), with some additional projections to the cerebral cortex via the thalamus.²²⁻²⁴ The medial cerebellar zone is involved in the control of posture and muscle tone, upright stance, locomotion, and in gaze and other eye movements.

The intermediate zone is made up of the intermediate hemispheres and the globose and emboliform nuclei. This region also receives inputs from the dorsal and ventral spinocerebellar pathways and brain stem reticular nuclei, as well as some projections from the cerebral cortex that arrive via the cerebropontocerebellar pathway.^{11,13,14,25,26} Major projections from this cerebellar zone are to the cerebral cortex via the thalamus and to the red nucleus.^{23,24,27} The intermediate zone is considered to be important in controlling coordination of agonist-antagonist muscle pairs during a variety of activities including walking and voluntary limb

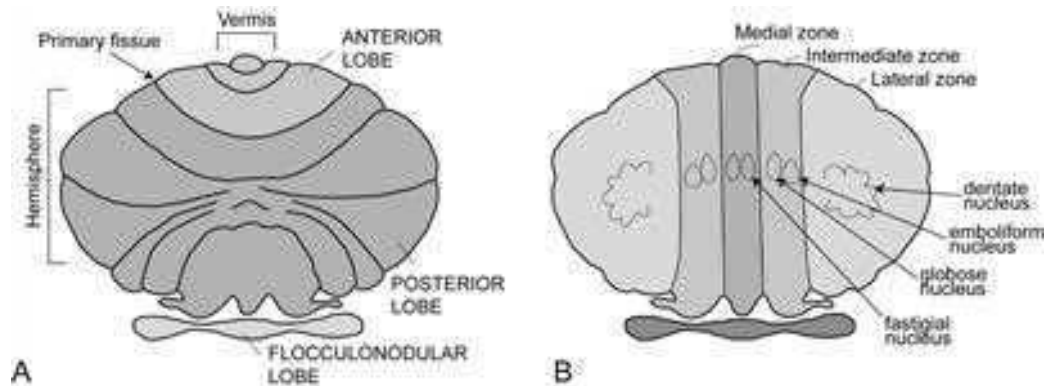

Figure 21-2 ■ The cerebellum, flattened, showing key structures. **A**, Different shading distinguishes the three lobes of the cerebellum. The cerebellar vermis and hemispheres are also identified. **B**, Functional longitudinal cerebellar zones, distinguished by different shading, and the locations of the deep cerebellar nuclei within each zone. (Redrawn from Kandel ER, Schwartz JH, Jessell TM: *Principles of neural science*, ed 4, New York, 2000, McGraw-Hill Medical.)

movements. The medial and intermediate zones of the cerebellum are collectively referred to as the *spinocerebellum*, because these are the only cerebellar regions that receive afferents from the spinal cord.

The largest region of the cerebellum is the lateral zone, which contains the two broad lateral hemispheres and their output structures, the dentate nuclei. Afferents to the lateral zone predominantly come from the cerebrum, from a wide variety of cortical areas including motor, premotor, and prefrontal cortices, parietal somatosensory and sensory association areas, and primary visual and auditory cortices.^{25,26} Outputs from the dentate travel mostly back to large areas of the cerebrum (through the thalamus), to many of the same areas from which afferents arrived in the cerebellum. Again, these include vast regions of sensorimotor cortices.²⁷⁻³³ Other efferent fibers project to the red nucleus in the brain stem. The lateral cerebellar zone plays a major role in control of complex, multijoint voluntary limb movements, particularly those involving visual guidance, and in the planning of complex movements and the assessment of movement errors. Because this region of the cerebellum interacts predominantly with the cerebrum, it is also commonly called the *cerebrocerebellum*. It is also sometimes referred to as the *neocerebellum* because it is considered to have arisen fairly recently in the phylogenetic tree, being much more expansive in primates than in lower animals.³⁴

The flocculonodular lobe can be considered a fourth zone of the cerebellum. It receives afferent projections directly from the vestibular primary afferents (semicircular canals and otoliths) as well as from vestibular nuclei and visual brain regions.^{11,13,14,16,18} Outputs from the flocculonodular lobe project directly to the medial and lateral vestibular nuclei of the brain stem, without a synapse in a deep cerebellar nucleus.^{12,22,35} For this reason, these vestibular nuclei are sometimes considered an additional set of deep cerebellar nuclei. This cerebellar zone helps control eye movements and balance. The well known vestibuloocular reflex (VOR), which provides gaze stabilization during head turning or walking, relies on the cerebellum for proper functioning.^{36,37} Because of its critical ties to the vestibular system, the flocculonodular lobe is also known as the *vestibulocerebellum* (see Figure 21-2).

Physiology of Cerebellar Neuronal Circuits

Within a longitudinal zone, thousands of microzones may exist,¹¹ each consisting of a highly organized group of connected cerebellar cortical neurons. A *microcomplex* is the name given to a neural circuit made up of a single microzone plus the other connected neurons with which it communicates directly. The following section provides a very brief overview of the circuits important for cerebellar function and reviews the flow of neuronal signals into and out of cerebellar microzones (Figure 21-3).

Most afferent information enters the cerebellum through one of two pathways: the mossy fiber pathway or the climbing fiber pathway. Both have important actions on cerebellar Purkinje cells. The mossy fiber pathway affects “beams” or rows of Purkinje cells oriented along the cerebellar folia. Dense mossy fiber inputs arise from a wide variety of regions, including the cerebral cortex, several subcortical areas, the brain stem, and the spinal cord. Mossy fibers enter the cerebellar cortex and synapse onto granule cells, whose axons ascend and branch into parallel fibers. Each parallel fiber extends long distances longitudinally and synapses onto many Purkinje cells, all located along the same beam.³⁸ Each parallel fiber has a relatively weak effect on single Purkinje cells, but the mass effect of many thousands of parallel fiber contacts with Purkinje cells drives the Purkinje cells to fire at high rates.³⁹ In contrast, each climbing fiber arises exclusively from the inferior olive, located in the brain stem, and contacts only a few (approximately 1 to 10) Purkinje cells.^{12,40,41} Each Purkinje cell receives information from only one climbing fiber, yet the climbing fiber’s effect on the Purkinje cell is powerful, causing large complex spikes.

The Purkinje cell provides the output for the cerebellar cortex; each Purkinje cell axon projects to one of the deep cerebellar nuclei. The mossy fiber and climbing fiber pathways affect Purkinje cells differently and are thought to transmit different types of information. Mossy fibers are active at very high rates (generating action potentials at approximately 100 Hz) and are highly modulated by various sensory stimuli and motor activity. They have been speculated to relay information related to the direction, velocity, duration, or magnitude of movements or sensory

TABLE 21-3 ■ FUNCTIONAL LONGITUDINAL CEREBELLAR ZONES

FUNCTIONAL ZONE	ALTERNATE NAME	MAJOR AFFERENTS	MAJOR EFFERENTS	ROLE IN MOVEMENT	CLINICAL SIGNS IF DAMAGED
Flocculonodular lobe Flocculo-nodular lobe; med & lat vestib nuclei	Vestibulocerebellum	■ Vestib primary afferents	■ Med & lat vestib nuclei	■ VOR	■ Nystagmus
		■ Vestib nuclei		■ Gaze and eye movements	■ Impaired VOR
		■ Visual areas		■ Posture and balance	■ Imbalance
Medial zone Vermis; fastigial nuclei	Spinocerebellum	■ Vestib & retic nuclei	■ Vestib & retic nuclei	■ Gaze and eye movements	■ Oculomotor deficits
		■ DSCT & VSCT	■ Cerebrum	■ Postural tone	■ Hypotonia
				■ Balance	■ Imbalance
			■ Locomotion	■ Falls	
				■ Gait ataxia

stimuli.⁴²⁻⁴⁵ Climbing fibers, however, are active at very low rates (approximately 1 to 4 Hz) and do not appear to be as strongly modulated by sensory stimuli or motor activity.^{40,46,47} There is still some disagreement regarding what sort of information is encoded in the climbing fiber signals, but the frequency of discharge appears to be too low to transmit information pertaining to specific parameters of sensory or motor events. The role of the climbing fiber is clearly important, however, because its firing produces large complex spikes in the Purkinje cells and can also powerfully affect subsequent Purkinje cell firing.^{41,48}

CEREBELLAR FUNCTION IN ADAPTING AND CONTROLLING MOVEMENT

The cytoarchitecture of the microzones is extremely stereotyped throughout the cerebellum, suggesting that it performs the same overall function regardless of whether it is acting on circuits controlling standing balance, eye movements, reaching and grasping, and so on. So what is the function of this cerebellar circuit? What aspect of motor control does it uniquely provide? Despite centuries of study, these questions have still not been answered completely. Although numerous theories of cerebellar function exist, here we limit the discussion to just a few that we view as particularly relevant.

Figure 21-3 ■ Schematic of the major cell types and their connections within the cerebellum. Excitatory synapses are indicated with a triangle; inhibitory synapses with a bar. *DCN*, Deep cerebellar nucleus; *IO*, inferior olive. (Redrawn from Ito M: Cerebellar circuitry as a neuronal machine. *Prog Neurobiol* 78:272–303, 2006.)

Theories of Cerebellar Function

One general theory states that a primary function of the cerebellum is in coordinating multiple limb segments to generate smooth and fluid multijoint movements.⁴⁹⁻⁵² This “motor coordinator” theory has support from behavioral studies demonstrating that multijoint movements appear to be particularly impaired in clients with cerebellar lesions.⁵⁰ Multijoint movements are inherently more complex than single joint movements because they require control of mechanical interaction torques; those occurring at one segment but caused by movement of other linked segments.⁵³ This model suggests that the cerebellum predicts the mechanical interactions between segments based on a stored internal knowledge of limb dynamics, and helps generate the correct motor commands for appropriate multijoint movements.

A second popular theory is the timer hypothesis. This idea proposes that the cerebellum is the main site for the temporal representation of movements.^{54,55} Supporters of this theory suggest that cerebellar output ultimately encodes the precise temporal sequence of muscle activation with such precision that a cerebellar lesion produces obvious deficits in the spatial domain (e.g., movement direction and magnitude) as well as the temporal domain.⁵⁶ Other studies have shown that individuals with cerebellar damage also have impairments in perceiving time intervals, suggesting that this could be a more general cerebellar function.^{57,58}

A third idea is that the cerebellum acts as an internal model to allow predictive control of movement. Sensory feedback is inadequate for movements that need to be both fast and accurate: it is too slow, and as a result, motor

corrections would be issued too late. Instead, the brain generates motor commands based on an internal prediction of how the command would move the body. This “feed-forward” control requires stored knowledge of the body’s dynamics, the environment, and the object to be manipulated, and it is learned from previous exposure. The neural representation of this knowledge is referred to as an *internal model*,⁵⁹⁻⁶² as it provides the ability to reproduce the effects of motor actions in the brain. The internal model theory for cerebellar function states that the cerebellum serves as the site of an internal model for movement. Accordingly, the incoordination of movement associated with cerebellar damage is a consequence of an inaccurate internal model, which disrupts nearly all aspects of feed-forward motor control.⁶³ This idea is appealing, as it could help explain the wide variety of motor behaviors (e.g., reaching, standing balance, eye movements) and movement parameters (e.g., force, direction) that can be impaired after cerebellar damage. Likewise, human behavioral studies have recently pointed out that cerebellar damage is frequently associated with impaired feed-forward control but relatively intact feedback mechanisms.^{64,65}

A related theory originates from the seminal works of Marr,⁶⁶ Albus,⁶⁷ and Ito,⁶⁸ in which the cerebellum was theorized to be a sort of “learning machine.” This theory was based on careful examination of the anatomy and physiology within cerebellar microcircuits, and today it continues to provide the basis for many of the current theories of cerebellar function (i.e., those described earlier). Central to the idea of cerebellar involvement in learning was the discovery

that Purkinje cell output can be radically altered by climbing fiber induction of long-term depression (LTD) of the parallel fiber–Purkinje cell synapse.⁴⁸ Hence, climbing fiber inputs onto Purkinje cells can be viewed as providing a unique type of teaching or error signal to the cerebellum. More recently, LTD, long-term potentiation (LTP), and nonsynaptic plasticity have all been shown to exist at numerous sites within the cerebellum, both in the cortex and in the deep cerebellar nuclei.⁶⁹⁻⁷² Thus there are multiple avenues for activity-dependent plasticity to occur within the cerebellum over relatively short time scales. It is presumed that the plastic changes in cerebellar output are responsible for changing motor behavior during the process of learning new skills.

To summarize, although the precise mechanisms are still under debate, a majority of researchers can agree on a few central themes of cerebellar function. First, the cerebellum is an integral structure for the coordination of movements. Second, precisely timed interactions between neurons produce activity-dependent plasticity at a number of different sites within the cerebellum. Presumably this plasticity plays a fundamental role in motor learning. Convergence of these two themes would seem to indicate that a major cerebellar function is to maintain optimal motor control through constant adaptive learning processes, so that movements are appropriately adjusted for varying environmental demands.

CLINICAL MANIFESTATIONS OF CEREBELLAR LESIONS

Ataxia is the primary sign of damage to the cerebellum or its input structures. *Ataxia* refers generally to uncoordinated or disordered movement, which, though most often associated with gait (*gait ataxia*), can also be used to describe uncoordinated arm or leg movements (*limb ataxia*). Ataxia is exacerbated by moving multiple joints together and by moving quickly. Because *ataxia* is a nonspecific term, it is important in both clinical and research settings to use more precise terminology to describe the specific aspects of motor performance that are impaired. Around the beginning of the twentieth century, Joseph Babinski and Gordon Holmes were two of the earliest investigators to describe many of these specific features we now discuss here.⁷³⁻⁷⁵

Dysmetria

Dysmetria specifically refers to an impaired ability to properly scale movement distance. Movements are described as either hypermetric or hypometric, referring to overshooting or undershooting of targets, respectively. Many clients with cerebellar lesions will show both forms of dysmetria even during successive movements (Figure 21-4).^{49,50} Dysmetria can be seen in both proximal and distal joints and occurs during both single-joint and multijoint movements, though multijoint movements worsen dysmetria (Figure 21-5).^{49,76-78} Slow movements tend to produce hypometria, whereas fast movements almost always bring about hypermetria.⁴⁹ For this reason, it has been speculated that hypometria represents more of a voluntary compensation for hypermetria than a primary impairment from cerebellar damage. Sometimes large end point errors can be reduced to some degree with visual feedback, but even the corrective movements themselves are still abnormal.⁷⁹

One proposed mechanism for dysmetria is an impaired ability to predict and account for the dynamics of the limbs.

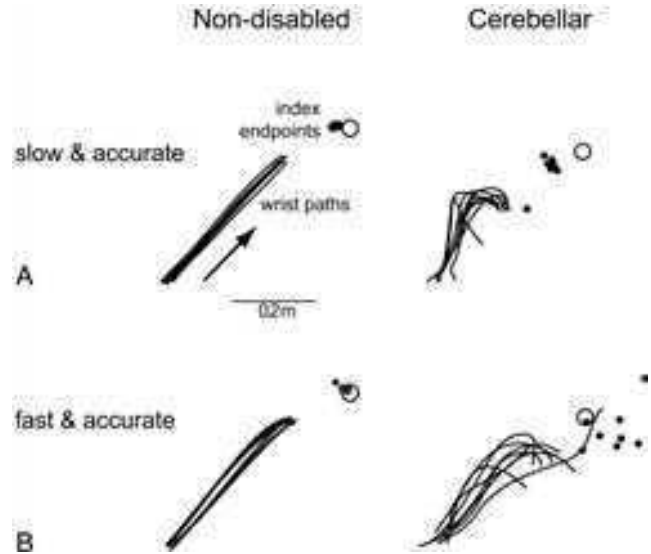

Figure 21-4 ■ Trajectories of the wrist (*solid lines*) and final end point positions of the tip of the index finger (*filled circles*) during (A) slow and accurate and (B) fast and accurate reaches from a typical nondisabled individual (*left*) and a subject with cerebellar damage (*right*). The subject with cerebellar damage shows dysmetria and an abnormally curved wrist path. Note also the tendency for hypometria during slow movements and hypermetria during fast movements (the same control and cerebellar subjects are shown in A and B). Several reaches are overlaid for each subject. *Arrow* indicates the reach direction. *Large open circles* indicate the target locations. (From Bastian AJ, Martin TA, Thach WT: Cerebellar ataxia: abnormal control of interaction torques across multiple joints. *J Neurophysiol* 76:492–509, 1996.)

In particular, clients with cerebellar lesions have been demonstrated to have a specific deficit in the ability to account for interaction torques,^{49,50} the rotational forces that act on a limb segment when another linked limb segment is in motion.⁶⁸ When the cerebellum is intact, the central nervous system is able to predict the effects of interaction torques and appropriately counter or exploit them so as to produce a smooth, straight, and accurate reach in a feed-forward manner. When the cerebellum is damaged, an incorrect or absent accounting for interaction torques leads to an incorrect feed-forward motor plan and subsequently an uncoordinated, overly curved and hypermetric or hypometric reach that requires feedback corrections to reach the target location.

Dyssynergia

Originally, Babinski⁸⁰ coined the term *asynergia* to mean a deficit in the coordination of movements of one body region or in one limb segment with movements of another. Today, *dyssynergia* is used to describe impairment of multijoint movements, wherein movements of specific segments are not properly sequenced or of the proper range or direction, resulting in uncoordinated multijoint movement. As indicated earlier, it is nearly universally true that clients with significant cerebellar damage show greater impairments during multijoint movements than single-joint movements. However, it is not fully understood whether the reason for that is because the deficits of single-joint movements are

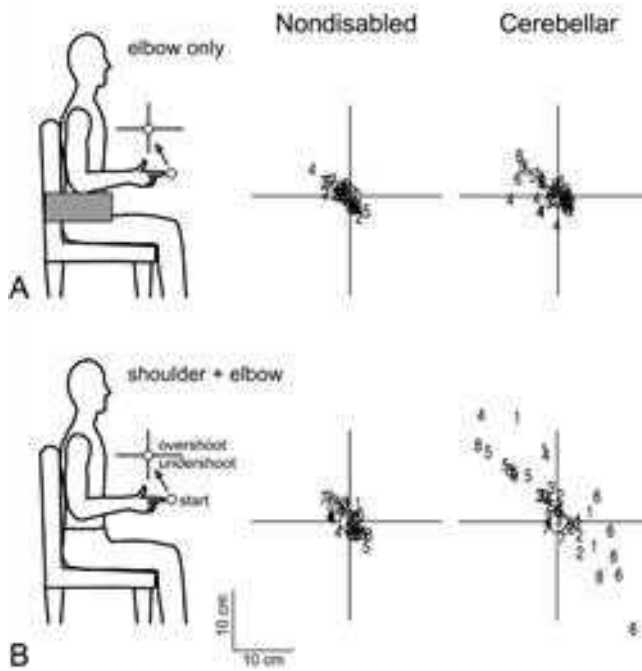

Figure 21-5 ■ Final end point positions of the tip of the index finger (numbers; each value corresponds to a different subject) during (A) single-joint (elbow only) and (B) multijoint (combined shoulder and elbow) reaches from nondisabled (*left*) and cerebellar (*right*) subjects. Cerebellar dysmetria (both hypometria and hypermetria) is greatly exacerbated during the multijoint reaching condition. Multiple reaches are shown for all subjects. *Arrow* indicates the reach direction. *Large open circles* indicate the target locations. (From Bastian AJ, Zackowski KM, Thach WT: Cerebellar ataxia: torque deficiency or torque mismatch between joints? *J Neurophysiol* 83:3019–3030, 2000.)

compounded during a multijoint movement or because the cerebellum plays a special and unique role in multijoint control. Dyssynergia appears to be related to dysmetria and therefore is probably also related to a deficit in predicting limb dynamics.⁴⁹

Dysdiadochokinesia

Dysdiadochokinesia specifically refers to a deficit in the coordination between agonist-antagonist muscle pairs elicited during voluntary rapid alternating movements.⁸⁰ Such coordination is typically tested during performance of simple, fast alternating movements such as forearm supination-pronation or hand or foot tapping. Characteristic deficits are excessive slowness along with inconsistency in the rate and range of the alternating movements, which worsen as the movement continues.⁷⁴ Dysdiadochokinesia appears to be caused by poor regulation of the timing of cessation of agonist muscle activity and the initiation of antagonist muscle activity,^{81,82} which could be related to a deficit in predicting limb dynamics. Indeed, rapid reversals in movement are dynamically difficult to control.

Decomposition

Movement decomposition refers to the breaking down of a movement sequence or a multijoint movement into a series of separate movements, each simpler than the combined

movement.⁷⁵ An example of this is the well known finding that clients with cerebellar damage, when asked to reach to a target in front of and above the resting arm, will often flex the shoulder first and then, while holding the shoulder fixed, extend the elbow.⁴⁹ This approach is generally slower and will produce a more curved trajectory of the finger to the target compared with nondisabled individuals, who would typically perform the shoulder flexion and elbow extension at the same time to produce a nearly straight-line finger trajectory. Most likely, decomposition reflects more of a compensatory strategy for dealing with impaired multi-joint movements than it does a primary sign of cerebellar damage.^{49,83}

Lack of Check

Lack of check, sometimes also referred to as excessive “rebound,” refers to the inability to rapidly and sufficiently halt movement of a body part after a strong isometric force, previously resisting movement of the body part, is suddenly released. Individuals without cerebellar damage can very quickly halt, or “check,” this unintended movement. Individuals with cerebellar damage, on the other hand, are known to have considerable movement in the direction opposite the previous resistance, to the point that the unchecked movement risks loss of upright balance or self-injury. This phenomenon is presumed to be caused by delayed cessation of agonist and/or delayed activation of antagonist muscles.

Cerebellar Tremor

Despite being a very common neurological sign, tremor is poorly defined and not well understood. There are several different forms of tremor, many with different causes, only some of which are related to cerebellar dysfunction, so it is important to distinguish among them. Tremor associated with damage to the cerebellum is typically called *action tremor*, reflecting the fact that it is absent at rest and elicited during muscle activation and distinguishing it from the resting tremor associated with Parkinson disease. Action tremor can be classified as postural or kinetic tremor.⁸⁴ Postural tremor occurs in muscles maintaining a static position against gravity (e.g., holding arms out in front of the body or standing in place), whereas kinetic tremor occurs in muscles producing an active voluntary movement. Therefore the movement oscillations are most visible in the same plane as the voluntary movement. Kinetic tremor typically occurs at relatively low frequencies (approximately 2 to 5 Hz) and can be observed during simple nontarget-directed movements such as forearm pronation and supination or foot tapping, or during targeted movements such as pointing during the finger-to-nose test. Intention tremor is a specific form of kinetic tremor that occurs during the terminal portions of visually guided movements toward a target. It may actually represent the multiple corrective movements, driven by visual feedback, to reach the target. As such, intention tremor can be tested by repeating the test movement with eyes closed; if the tremor decreases substantially or disappears, it is an intention tremor.⁷⁹

Classic cerebellar tremor is kinetic tremor with intention tremor at movement termination. In general, cerebellar tremor is thought to be caused by an insufficient ability to anticipate the effects of movement and excessive reliance on

sensory feedback loops.⁸⁵ Cerebellar tremor is highly influenced by sensory conditions and has a strong mechanical component; it is significantly reduced during isometric conditions or when vision is removed. It also can be decreased in some clients by adding an inertial load to the limb,⁸⁶ though that strategy may also increase dysmetria.⁸⁷ There may also be a significant central component to cerebellar tremor, possibly related to influences from the thalamus or the inferior olive.^{81,88}

Hypotonia

Hypotonia in clients with cerebellar damage was first described by Holmes.⁷⁵ It appears to arise from decreased excitatory drive to vestibulospinal and reticulospinal pathways, two major output pathways from the cerebellar vermis and flocculonodular lobe. The hypotonia usually manifests as a decrease in the extensor tone necessary for holding the body upright against gravity. In cats, lesions of either the vestibular or fastigial nuclei cause this sort of postural hypotonia.^{51,89-91} More recent observations in humans indicate that hypotonia is typically most problematic in cases of severe cerebellar hypoplasias affecting the vermis, such as Joubert syndrome,⁹² or in adults during the acute stage of cerebellar injury only. In cases of adult-onset acute injury, hypotonia usually resolves naturally over time and clients recover normal passive muscle tone and normal reflexes quickly. Thus hypotonia typically presents minimal to no problems for physical function.⁸¹

Imbalance

Another cardinal sign of cerebellar damage is postural instability in both static and dynamic conditions. Specifically, clients with cerebellar damage usually show increased postural sway; either excessive or diminished postural responses to perturbations; poor control of equilibrium during voluntary movements of the head, arms, or legs; and sometimes abnormal oscillations of the trunk, called *titubation*.

Classically, cerebellar imbalance during stance was considered to be of a similar magnitude whether or not the eyes are open; that is, little improvement noted with visual feedback^{73,75} and a negative Romberg test result. However, more recently, investigators using posturography measures have been able to distinguish several different categories of cerebellar imbalance during quiet standing, some of which do show improvement with visual stabilization.^{93,94} For instance, clients with cerebellar damage relatively isolated to the anterior lobe typically show increased postural sway, which is of a high velocity and low amplitude and occurs mainly in the anterior-posterior dimension. These individuals also tend to have associated postural tremor and increased intersegmental movements of the head, trunk, and legs and tend to improve when allowed visual information. On the other hand, localized damage to the vestibulo-cerebellum more often leads to increased postural sway that consists of low-frequency and high-amplitude movements without a preferred direction and without increased intersegmental movements. These individuals typically show no improvement with visual information. Clients with damage limited to the lateral cerebellum tend to have only slight or even no postural instability at all.⁹³⁻⁹⁵

Human cerebellar damage is also associated with hypermetric postural responses to surface displacements or during

step initiation; that is, dynamic instability.^{96,97} Specifically, clients tend to produce larger-than-normal surface-reactive torque responses and exaggerated and prolonged muscle activity, thereby overshooting the initial posture during the return phase of the recovery from a perturbation (Figure 21-6).

Gait Ataxia

Probably the greatest complaint and the most obvious sign of cerebellar damage is gait ataxia. This abnormal pattern of walking is often described as a “drunken” gait because clients often stagger and lose balance as if intoxicated. Early work of Holmes showed that patients with cerebellar lesions have severe difficulty maintaining balance during walking, which often leads to falls, typically directed backward and toward the side of the lesion. Holmes reported specifically that walking is slowed, with steps that are short, irregular in timing, and unequal in length. The legs sometimes lift overly high during the swing phase by excessive flexion at the hip and knee and then lower abruptly and with uncontrolled force. The trajectory of walking often veers erratically and patients have difficulty with stops or turns, especially if performed quickly.⁷⁵

Figure 21-6 ■ Postural responses from nondisabled control and cerebellar groups (average of 10 trials from 10 subjects in each group) after backward platform translations of 15 cm/s for 6 cm. Traces show (top to bottom) electromyographic recordings from various postural muscle groups, postural sway, shear force, surface torque, and platform displacement. Filled areas indicate the first 400 ms of activation in the electromyographic traces and the active surface-reactive forces in the shear force and torque traces. Postural responses of the cerebellar subjects are increased, with excessive and prolonged muscle activity (note especially the abnormal activation of flexor muscle groups), larger sway, and greater torque production. ABD, Rectus abdominis; fwd, forward; GAS, gastrocnemius; HAM, biceps femoris; PAR, paraspinals; pf, plantarflexion; QUA, rectus femoris; TIB, tibialis anterior. (Adapted with permission from the American Physiological Society. From Horak FB, Diener HC: Cerebellar control of postural scaling and central set in stance. *J Neurophysiol* 72:479–493, 1994.)

Those initial reports have now been confirmed numerous times; clients with cerebellar damage walk without the consistency in timing, length, and direction of steps typical of healthy adults.^{77,98} In some cases gait appears wide based. There is also increased variability in both the timing and movement excursion at the hip, knee, and ankle joints and irregularities in the resulting path of the foot during swing. Coordination between joints of one leg and between legs (intra-limb and interlimb coordination, respectively) is also abnormal.^{77,98,99} As an example, the timing of peak flexion at one joint with respect to other joints' positions may be altered or inconsistent. Often decomposition is also observed between hip and knee, knee and ankle, and/or hip and ankle joints.^{99,100}

A critical component of locomotor control is the requirement for stability and dynamic balance while maintaining forward propulsion. Thus imbalance, described previously, is also a major contributor to many features of gait ataxia. In fact, it has been shown that clients with cerebellar damage and significant balance deficits also typically demonstrate nearly all the classic features of gait ataxia (i.e., reduced stride lengths, increased stride widths, reduced joint excursions, abnormal swing foot trajectories, increased variability in foot placement, and joint-joint decomposition). In contrast, clients with cerebellar damage and significant leg coordination deficits but minimal or no balance deficits typically have very few walking abnormalities (Figure 21-7).^{101,102} Therefore during typical conditions of level walking, balance deficits contribute much more strongly to cerebellar gait ataxia than do leg coordination deficits.

Oculomotor Deficits

Eye movements are often dramatically impaired after cerebellar damage. Saccades are often slowed and dysmetric (can be hypermetric or hypometric).¹⁰³ Smooth pursuit may be “choppy,” referred to as *saccadic pursuit*, wherein the smooth tracking of a target is degraded into a series of shorter saccadic movements following behind the target.¹⁰⁴ The ability to cancel, or suppress, the VOR may be impaired or absent.¹⁰⁵ Finally, abnormal nystagmus may also be present. The nystagmus may occur during central gaze, or there may also be alternating nystagmus or rebound nystagmus. The most common form of nystagmus in cerebellar dysfunction is gaze-evoked nystagmus, indicating nystagmus elicited toward the end ranges of lateral and/or vertical gaze.^{106,107}

Clients with significant oculomotor abnormalities may be referred to vestibular specialists, but these deficits should never be ignored. Impaired eye movements may have a significant negative impact on physical function. For example, impaired saccades can prevent a client from reading, and saccadic pursuit can exacerbate already poor visually guided limb movements.¹⁰⁸ Perhaps most devastating, deficits related to impaired oculomotor control and vestibular reflexes often worsen dynamic balance and walking abilities.

Speech Impairments

Speech production may also be impaired when the cerebellum is damaged. Classically, the speech deficit associated with cerebellar damage is referred to as *scanning speech*, though it may be more generally referred to as *ataxic dysarthria*.

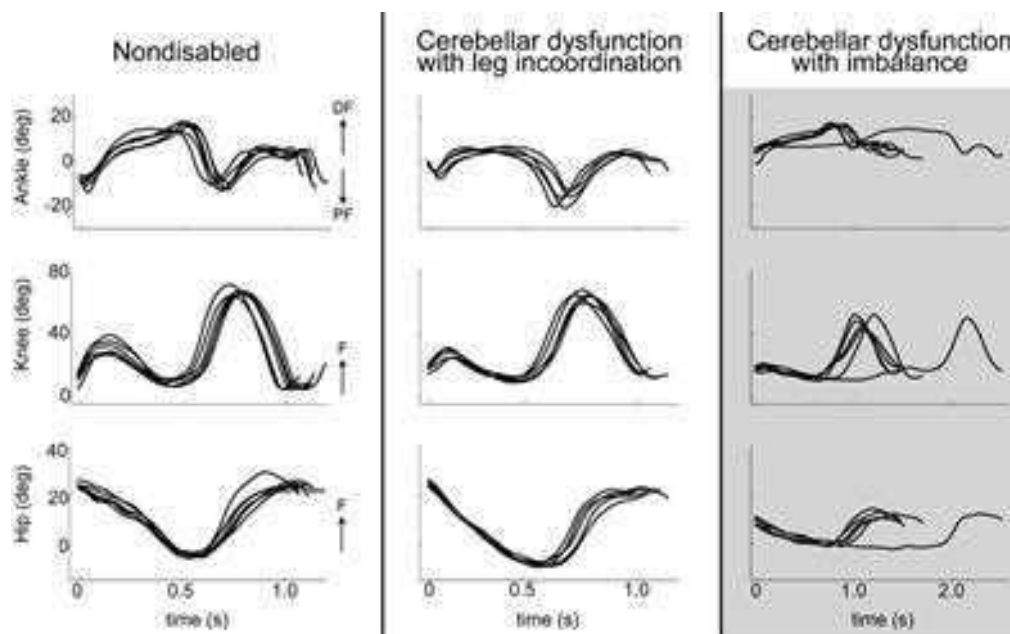

Figure 21-7 ■ Angular excursions at the ankle (*top row*), knee (*middle*), and hip (*bottom*) during fast walking from a typical nondisabled individual (*left column*), a subject with cerebellar dysfunction who has significant leg incoordination but minimal imbalance (*middle*), and a subject with cerebellar dysfunction who has significant imbalance but minimal leg incoordination (*right*). Several strides (from initial contact to next initial contact) are overlaid for each subject. The client with cerebellar imbalance (*shaded*) shows significant evidence of gait ataxia, including reduced joint excursions, excessive stride-to-stride variability, and abnormal timing between joints, whereas the client with cerebellar leg incoordination and no imbalance shows no evidence of gait ataxia. *DF*, Dorsiflexion; *F*, flexion; *PF*, plantarflexion. (Adapted with permission from the American Physiological Society. From Morton SM, Bastian AJ: Relative contributions of balance and voluntary leg-coordination deficits to cerebellar gait ataxia. *J Neurophysiol* 89:1844–1856, 2003.)

Similar to limb control deficits, the primary impairment of speech may be related to the planning and prediction of movements rather than the execution of speech components directly.¹⁰⁹ Also like limb movements, most speech impairments appear to be attributable to alterations in timing and coordination.^{143a} The most consistent characteristics of ataxic dysarthria are impaired articulation (the correct pronunciation of speech sounds) and impaired prosody (the pattern of stress and intonation of certain syllables or words). Other common findings include slowed speech and either a lack of or excessive loudness variability.¹⁰⁹ Traditionally, speech impairments are treated primarily by speech and language pathologists.

Impaired Motor Learning

A critical problem associated with cerebellar damage is impaired motor learning. In humans the cerebellum has been linked to learning of a wide variety of motor behaviors, including recovering balance after a perturbation,^{96,97} learning new walking patterns,^{64,100,111} adjusting voluntary limb movements,^{65,112,113} and making eye movements.^{114,115} The type of learning that appears most reliant on the cerebellum is associative and procedural. Specifically, the cerebellum appears to be essential for learning to adjust a motor behavior through repeated practice of, or exposure to, the behavior and using error information from one trial to improve performance on subsequent trials. It is important to note that cerebellum-dependent motor learning is driven by errors directly occurring during the movement rather than by other types of feedback, such as knowledge of results after the fact (e.g., hit or miss). Studies have suggested that the type of error that drives cerebellum-dependent learning is not the target error (i.e., “How far am I from the desired target?”), but instead what has been referred to as a *sensory prediction error* (i.e., “How far am I from where I predicted I would be?”).^{113,116}

In the laboratory setting, cerebellar learning is most easily tested via motor adaptation, a form of motor learning that requires a modification of an already well learned motor behavior for new environmental or physical demands (in contrast to learning of a completely novel skill). Adaptation is an error-driven learning process that is acquired on a time scale of minutes or hours, as opposed to days or weeks.^{117,118} It is an active process: movement adaptation takes trial-and-error practice of the task, in which errors during one trial change movement on the subsequent trial. Storage of the adapted movement is shown by the presence of aftereffects when the new demand is removed. Specifically, aftereffects are movement errors in the opposite direction to the original errors during adaptation and provide strong evidence that the central nervous system adjusts the predictive control for body movements with practice.^{62,119} Thus when the new demand is removed, a process of active “unlearning” or dead-adaptation must occur to return the movement to its original form. An example of a locomotor adaptation is shown in Figure 21-8. In this case, a walking adaptation is induced by having subjects walk on a split-belt treadmill, where one belt is moving at twice the speed of the other, forcing the two legs to walk at different speeds. Control subjects are able to rapidly restore appropriate step length symmetry after only a few minutes walking on the split-belt treadmill. They also appear to store the newly learned set of (predictive) motor

commands, demonstrated by large negative aftereffects (step length asymmetry in the reverse direction compared with early adaptation) when the treadmill belts are initially returned to a regular (nonsplit) pattern. In contrast, individuals with cerebellar damage typically show a slower rate of adaptation, a reduced magnitude of adaptation, or no adaptation at all, and small or no aftereffects (see Figure 21-8). All of these findings indicate a significant deficiency in the capability for motor adaptation in individuals with cerebellar damage. As indicated earlier, adaptation deficits have been demonstrated in this patient population with numerous behavioral tasks.*

Cerebellum-dependent adaptation is not the only form of motor learning, but it is an important one for rehabilitation for several reasons. First, adaptation is a highly automatic process to rapidly adjust movements for new, predictable demands (e.g., adjusting the walking pattern for snow or sand; adjusting eye movements for glasses). Individuals with impaired cerebellar adaptive learning must use other means to handle new task demands, such as conscious control strategies. This is obviously inefficient and difficult, as it means that the individuals must think much more about their movements and cannot tolerate distractions. Adaptation is also important because when it is repeated many times, it can result in more permanent storage of a movement pattern that can be called on immediately (i.e., no error-based period of adaptation required). A clear example of this is the use of new bifocal glasses. Initially, there is an adaptation process to adjust eye movements when switching between the top and bottom lenses because eye movements have to be bigger for magnified objects. Yet with repeated adaptation, the brain eventually stores two calibrations, one for making eye movements when viewing through the top lens and one for making eye movements when viewing through the bottom lens, that can be switched between instantly. Thus adaptation can lead to a more permanent, learned calibration that is used in specific situations. Clients with cerebellar damage will not be able to make these short-term adaptations normally, and theoretically one would expect that they will not be able to form the more permanent calibrations with repeated adaptation.

Other forms of motor learning may not depend on the cerebellum and thus may be particularly useful for rehabilitation for clients with cerebellar lesions, though this has never been formally tested. One example is use-dependent motor learning, in which a person strengthens a movement pattern with repeated practice of that same pattern.¹²⁰ It is not clear what mechanisms subserve this form of learning, though a Hebbian-like process in the cerebral cortex seems likely (i.e., repeated use strengthens the synapses in the brain that are engaged). Another form of motor learning is reward or reinforcement learning. This may involve basal ganglia circuits to strengthen movements that are rewarded.¹²¹ Whether individuals with cerebellar damage can use either of these other forms of learning has not been experimentally tested. Yet if they can, these learning mechanisms might provide important compensatory strategies for the loss of error-dependent adaptations.

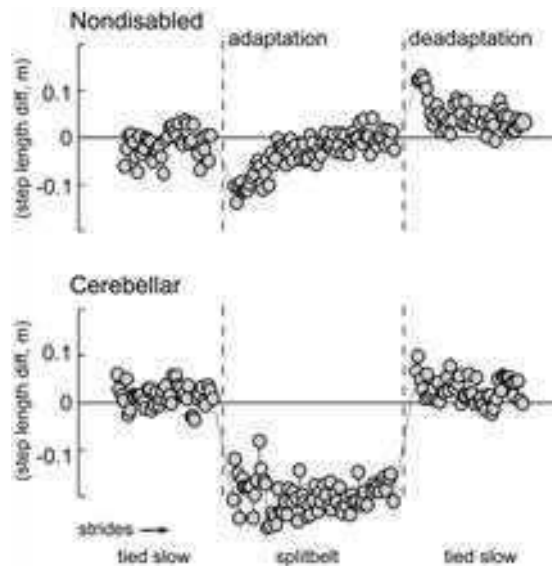

Figure 21-8 ■ Motor adaptation of step length symmetry during walking on a split-belt treadmill by a nondisabled individual (*top*) and a subject with cerebellar damage (*bottom*). Each data point represents the difference in step lengths between the legs (fast minus slow) for all strides during regular walking (belts tied, speed 0.5 m/s), split-belt adaptation walking (fast belt speed 1.0 m/s; slow belt speed 0.5 m/s), and deadaptation walking (belts tied, speed 0.5 m/s). Perfect symmetry between the legs is represented by a step length difference value of 0. Note that the split-belt condition perturbs step length symmetry initially in both subjects. The control subject rapidly adapts the walking pattern to restore appropriate step length symmetry while walking on split belts. The cerebellar subject does not adapt. Once the belts are returned to the tied condition, the control subject shows a large negative aftereffect; that is, perturbed step length symmetry in the reverse direction, which again is rapidly adjusted to restore near-symmetric step lengths. The cerebellar subject shows a reduced aftereffect and no deadaptation. (From Morton SM, Bastian AJ: Cerebellar contributions to locomotor adaptations during splitbelt treadmill walking. *J Neurosci* 26:9107–9116, 2006.)

Nonmotor Impairments

Within the last 25 years, researchers have exposed a possible role of the cerebellum in a number of nonmotor, cognitive behaviors. Much of the early evidence for cerebellar involvement in nonmotor tasks came from functional imaging studies showing increased activation within the cerebellum during performance of certain tasks with a predominant cognitive component, such as language processing.^{122,123} Speculation has since arisen that the cerebellum may be involved in not only language, but also working memory,¹²⁴ learning nonmotor associations between objects,¹²⁵ and higher-order executive functions.¹²⁶ Loss of control over emotional behaviors¹²⁷ and certain neurodevelopmental and neuropsychiatric disorders have also been said to be linked to cerebellar damage.^{128,129} However, interpretation of some investigations of the relationship between the cerebellum and cognition is limited in that it is sometimes difficult to separate the cognitive and motor components of a task, particularly in imaging studies in which subjects are instructed to perform some motor task to indicate a cognitive

choice.^{130,131} Nevertheless, anatomical studies have shown clearly that the cerebellum has connections to brain areas considered relatively purely cognitive in function, suggesting that a cognitive role for the cerebellum is likely.¹³²

Clinical Signs by Functional Division

Because of the organizational structure of the cerebellum into functional longitudinal divisions, discrete areas are associated with specific signs and symptoms. Thus, depending on the location and volume of cerebellar damage, clients may have just a few or nearly all of the clinical manifestations described earlier. Clients with damage to the flocculonodular lobe or midline zone typically demonstrate some (though usually transient) loss of postural tone, impaired upright posture and balance, gait ataxia, and oculomotor deficits.^{2,51} On the other hand, damage to the intermediate zone often results in action tremor, dysdiadochokinesia, and dysmetria of the limbs.^{2,51} Finally, damage to the lateral zone commonly produces dyssynergia, dysmetria, and difficulty planning complex limb movements, especially those that are visually guided (see Table 21-3).^{2,51}

Often, however, multiple longitudinal zones are affected at the same time. For instance, the arteries supplying the cerebellum each span more than one longitudinal zone, such that a stroke involving a single cerebellar artery would be likely to cause signs and symptoms associated with more than one zone (see Table 21-1). Degenerative disorders affecting the cerebellum also are typically pancerebellar, affecting large regions of the cerebellum. Hence these clients will also typically have a wide variety of signs and symptoms. A careful and thorough clinical examination is therefore a requirement before a diagnosis for physical therapy can be made in clients with cerebellar damage.

MEDICAL MANAGEMENT OF CEREBELLAR DAMAGE

The greatest limitation in caring for clients with cerebellar dysfunction is the lack of any curative treatment for most forms of cerebellar damage. Pharmacological agents have been used, but with limited success. Often, clients with ataxia and degenerative forms of cerebellar damage may be prescribed vitamin E, coenzyme Q10, and/or its synthetic analogs, but the effectiveness of these drugs in minimizing symptoms or otherwise slowing or halting the disease is largely unsubstantiated.^{133,134} Other drugs that may be used include acetazolamide, amantadine, 4-aminopyridine, and buspirone chlorhydrate,^{6,135-137} but these also have questionable effectiveness. Studies of the effectiveness of medications for cerebellar ataxia have been significantly limited by inadequate sample sizes, inappropriate outcome measures, and/or limited follow-up. Given the unsatisfactory results from pharmacological interventions thus far, most clients with cerebellar ataxias must rely primarily or solely on physical rehabilitation approaches to restore or reduce the symptoms of their disease.

PHYSICAL AND OCCUPATIONAL THERAPY MANAGEMENT OF CEREBELLAR MOVEMENT DYSFUNCTION

As is the case with all brain lesions, there is nearly always some level of natural, or spontaneous, recovery after damage to the cerebellum. The extent of recovery depends on

complex interactions among numerous factors including the source of damage; the severity, location, and volume of damage; the presence or absence of damage to other brain regions; the presence or absence of other coexisting medical conditions; age; and other factors. Several studies have now indicated that motor recovery from a first-ever ischemic cerebellar stroke is generally excellent, with minimal to no residual deficits in up to 83% of patients.¹³⁸⁻¹⁴⁰ On the other hand, individuals with degenerative cerebellar disorders tend to have progressively worsening clinical signs and symptoms.¹⁴¹ One study has shown that people with damage to the deep nuclei do not recover as well as those with damage to only the cerebellar cortex and white matter.² Another consideration is the degree to which other brain regions are lesioned. Individuals with cerebellar stroke or tumor may also have damage of the brain stem. Clients with multiple sclerosis or head injury often also have cerebral and spinal cord lesions. Moreover, the majority of the spinocerebellar ataxias (SCAs) affect other neural structures well beyond the cerebellum; these are often the corticospinal tract, cerebral cortex, basal ganglia, and sometimes the peripheral nervous system. Generally speaking, the presence of multiple lesion locations is associated with a poorer outcome, possibly because circuits that could otherwise serve a compensatory role are also damaged.¹⁴²

Physical/Occupational Therapy Evaluation

A majority of the components of the physical therapy examination for clients with cerebellar dysfunction are the same as would be performed with any client with a health condition that is primarily neurological in origin. Therefore we will discuss only the features that are unique or of critical importance for the client with cerebellar pathology. In the following sections we highlight just a few of these specific tests. [Box 21-1](#) contains a more complete list. One important note is that many of the tests for cerebellar movement dysfunction are sensitive but not specific to cerebellar pathologies. That is, although they often will reveal abnormalities in a client with cerebellar damage, their results are frequently also observed to be abnormal in clients with other, noncerebellar disorders of a neuromuscular origin. Therefore they should not be used in isolation to rule in or rule out cerebellar pathologies.

Tests of Impairments of Body Functions or Structures

At the level of body functions or structures, physical/occupational therapists use a variety of simple tests and measures to detect the typical movement impairments associated with cerebellar dysfunction. Many of these fall into the category of limb movement coordination tests. Particularly useful in the upper extremity are the finger-to-nose test, the alternating forearm supination-pronation test, and the hand or finger tapping test. The heel-to-knee test and foot or toe tapping test provide similar information for the lower extremity. Each of these tests informs the therapist about the presence and severity of many components of ataxia, including dysmetria, dyssynergia, dysdiadochokinesia, decomposition, and kinetic and/or intention tremor. Some general rules should be applied when performing and interpreting the findings from these clinical tests. First, it is important to perform the test on and compare both sides. Each test should

be repeated multiple times with the same limb, as subsequent movements may look strikingly different (e.g., hypometric on some trials, hypermetric on others). Comparing slow or preferred with “as fast as possible” speeds allows the clinician to determine the severity of the ataxia (generally worst with fastest movements) and how well the client is able to compensate when allowed full use of feedback mechanisms (the degree to which the movement is improved when performed slowly). It is also generally useful to compare the same movements with and without vision, to determine whether or not visual feedback improves movement quality. A final caution about the tests of voluntary movement coordination is that the examiner must carefully dissociate limb incoordination from deficits of balance and/or vision. For example, if the client has difficulty maintaining quiet unsupported sitting, he or she will most likely demonstrate several abnormal movement patterns that resemble classic limb ataxia when asked to move the limbs (e.g., dyssynergia, dysmetria) if tested in this unsupported position. In this situation the examiner cannot distinguish whether the deficits observed are caused by a true incoordination of voluntary limb movements or because of an inability to maintain the trunk in a stable and upright position that provides the limb a stable base from which to generate movement. Thus, to test coordination, the examiner must give the client the necessary head and trunk support required for the limb movement task (e.g., test sitting in a high-backed chair with manual support at the shoulders or perform in supine position) if the client is unable to provide this support by himself or herself. Similar confusion may arise if the client has significant visual or other oculomotor impairments such as diplopia. Here, the client would be likely to show apparent dysmetria during visually targeted movements, but it would not be possible to determine whether it was caused by real limb ataxia or a visual impairment preventing the client from accurately identifying the target location in space. This is not to say that it would not be beneficial to test limb coordination in positions or situations that also challenge balance and/or vision; only that during the initial examination of the client, one should be careful to ensure an accurate determination of the source of the movement impairment.

A major component of almost all physical therapy examinations of clients with cerebellar dysfunction is the posture and balance examination. Posture and balance should always be observed in both static and dynamic conditions and in both sitting and standing positions, as the client's capabilities allow. The examination is performed in the same manner as for clients with other neurological disorders and so is not described in detail here (see [Box 21-1](#) for suggested components to emphasize with clients with cerebellar dysfunction). Important considerations specific for clients with cerebellar dysfunction include careful monitoring for symptoms of nausea or vertigo (common in acute cerebellar stroke, may resolve quickly), observation for postural tremor or titubation, and observation of the recovery from perturbations and the presence of lack of check. Although physical therapists most often deal with posture and balance, occupational therapists also need to identify and examine these components in order to analyze movement activity problems that are based upon a functional trunk such as dressing, feeding, and other daily living activities.

BOX 21-1 ■ TYPICAL CLINICAL TESTS AND MEASURES FOR THE PHYSICAL THERAPY EVALUATION OF CEREBELLAR DYSFUNCTION

TESTS OF IMPAIRMENTS OF BODY FUNCTION OR STRUCTURE

1. Muscle tone

Hypotonia: Particularly involving postural extensor muscle groups. Can be assessed in supine, sitting, and/or standing position.

2. Voluntary movement coordination

For all coordination tests, the following guidelines are recommended, when appropriate: (1) compare both sides; (2) repeat each test multiple times; (3) compare slow or preferred versus “as fast as possible” speeds; (4) compare with and without vision.

Finger-to-nose test: Vary the target (fingertip) locations. Require near-full excursion at elbow and shoulder. Observe for speed, dysmetria, dyssynergia, decomposition, kinetic tremor, intention tremor.

Alternating forearm supination-pronation: Do not allow bracing of upper arm against trunk. Require elbow flexion and extension along with forearm movements. Observe for speed, dysmetria, dyssynergia, decomposition, dysdiadochokinesia, kinetic tremor.

Hand or finger tapping: Observe for speed, dysmetria, dysdiadochokinesia, kinetic tremor.

Drawing or handwriting sample: Compare with and without permitting bracing upper arm against trunk and/or forearm on writing surface. Observe for speed, dysmetria, dyssynergia, decomposition, kinetic tremor, intention tremor.

Holding static position, arms outstretched: Client holds position for several seconds. Observe for drift, postural tremor.

Resisted movements: Compare different levels of resistance. Observe for lack of check (rebound). Note: Ensure client safety; rebound may be extreme, destabilizing, and/or injurious in severe cases.

Heel-to-knee test: Client performs with shoes removed and in supine position to test full excursion at hip and to prevent bracing of thigh or hip on support surface. Client performs (1) repeated taps on knee with heel and (2) sliding the heel up and down the lower leg. Observe for speed, dysmetria, dyssynergia, decomposition, dysdiadochokinesia, kinetic tremor, intention tremor.

Foot or toe tapping: Observe for speed, dysmetria, dysdiadochokinesia, kinetic tremor.

3. Static and dynamic balance

Sitting balance: Client performs with and without upper and lower extremity support or with and without trunk support (as skill level permits), with and without vision. Test for recovery from self-imposed perturbations (upper extremity or head movements) or external perturbations (gentle pushes by examiner). Observe resting preferred posture, tremor, sway, ability and effort required to maintain position, recovery from perturbations or other loss of balance. Inquire about vertigo, nausea, and subjective perception of stability.

Standing balance: Client performs with and without upper and lower extremity support, with and without vision, and with feet apart and together. Test for recovery from self-imposed perturbations (upper extremity or head movements) or external perturbations (gentle pushes by examiner). Advanced testing: assume and maintain tandem stance and single limb stance. Observe resting preferred posture, natural foot position (base of support), tremor, sway, ability and effort required to maintain position, recovery from perturbations or other loss of balance. Inquire about vertigo, nausea, and subjective perception of stability.

4. Oculomotor performance

Smooth pursuit: Sitting, keeping the head still, client follows pen tip or similar small object with eyes. Test in all movement planes and directions and through full range of motion. Vary speed. Observe for saccadic (choppy) pursuit.

Saccades: Sitting, keeping the head still and when verbally prompted, client alternately fixes gaze on one of two pen tips, or a pen tip and the examiner’s nose, or other small objects. Vary the target (pen tip) locations, testing a variety of end point locations, directions of movement, and distances traveled, including full range of motion. Observe for dysmetria, particularly on initial trials.

Gaze-evoked nystagmus: Sitting, keeping the head still, client maintains gaze in a variety of locations, including near end ranges of lateral gaze. Observe for nystagmus, particularly toward the direction of gaze.

TESTS OF ACTIVITY LIMITATIONS

1. Bed mobility

2. Transfers

3. Gait

As skill level permits, client performs natural, narrow, and tandem gait. Compare preferred versus fastest speed and with and without vision. Test for recovery from self-imposed perturbations (upper extremity or head movements) or external perturbations (gentle pushes by examiner). Observe on inclines and declines, uneven surfaces, negotiating introduced obstacles. Observe walking while distracted (dual-task situation) and while holding an object with the upper extremity (e.g., hold a Styrofoam cup half-filled with water). Test turns and control through narrow areas such as a doorway. Observe for speed, irregularity of step height and distance, veering walking path, loss of balance, seeking out of upper extremity support surfaces or guarding, leg dyssynergia, decomposition (e.g., stiff knees, reduced ankle motion), widened base of support, truncal sway, kinetic tremor. Note distance tolerated and need for assistive devices and/or orthotics.

4. Stair climbing

5. Activities of daily living (ADLs): dressing, grooming, feeding, bathing, and so on

As described previously, because other areas of the nervous system are also frequently damaged along with the cerebellum, it may be appropriate to test for impairments of body functions or structures associated with pathology involving extracerebellar regions of the neuromuscular system. Most commonly this involves testing of muscle strength, somatosensation (including cutaneous sensation and proprioception), reflexes, passive muscle tone, and observation for signs of other motor abnormalities such as spasticity, dystonia, abnormal synergies, chorea, bradykinesia, or resting tremor.

It is also important to examine the client's initial level of endurance (fatigability), both in the cardiovascular and muscular systems. For the cardiovascular system, this can be approximated by recording the response to sustained aerobic exercise on one or more measurement scales (e.g., perceived exertion, heart rate, blood pressure, respiratory rate). See chapter 30 for additional information. For the muscular system, this can be approximated by recording the maximal number of repetitions of a specific set of muscle contractions or limb movements that can be tolerated before force output or range of motion is reduced. These types of measures can provide a gross gauge of the overall level of cardiovascular and musculoskeletal fitness of the client. Because cerebellar dysfunction often leads to movements being much more effortful and often exaggerated, it is extremely important that the client with cerebellar dysfunction obtain adequate endurance for safe participation in daily activities.

Tests of Activity Limitations

Tests of activity limitations should typically proceed similarly to the standard neurological examination. The observation of gait should be given particular attention, as gait ataxia is considered one of the most sensitive signs of cerebellar damage and the inability to walk safely is a major participation limitation for most clients with motor disorders.¹⁴³ Box 21-1 provides suggested components of the gait analysis for clients with cerebellar dysfunction. In addition, it may be necessary to evaluate the activity limitations related to speech, visual, and/or oculomotor deficits common to cerebellar dysfunction. With careful interviewing, the client may relay information about limitations in conversation and communication, reading, and so on that should be addressed in rehabilitation. The physical or occupational therapist may be the first health care professional to note these types of activity limitations and should refer the client to the proper professional for additional services.

Documentation of the body function or structure impairments and activity limitations should include not only the level of assistance, if any, required to perform the skill (or for the voluntary limb coordination tests, the degree of impairment, e.g., none, mild, moderate, or severe), but also a detailed description of the deficits observed during the attempted movement; that is, the movement quality. Specifically, the severity and frequency of the specific features of ataxia (e.g., decomposition, lack of check) should be reported when they accompany a given movement. Also useful is documentation of the time taken to perform certain tasks. For example, one might document performance of a functional reach and place task by a client with cerebellar dysfunction in the following way: "The client was able to

perform five repetitions of a block-stacking task with the right upper extremity in 9.4 seconds without significant drops or placement errors. Decomposition was observed between shoulder and elbow joints and obvious intention tremor was present during terminal block placement. When asked to repeat at a faster pace, the client performed the same task in 6.0 seconds with one block dropped and two misplaced on the stack (dysmetria). Notable dyssynergia was also present."

Standardized Clinical Scales

There are two common standardized rating scales that quantify the severity of cerebellar ataxia. The more well known is the International Cooperative Ataxia Rating Scale (ICARS).^{143a} This scale was first published in 1997 by the Ataxia Neuropharmacology Committee of the World Federation of Neurology in response to an established need for a universal scale to quantify ataxia in randomized clinical trials of pharmacological interventions for treating ataxia. The ICARS measures a client's ability to perform 19 specific activities or movements using an ordinal scale. The activities are grouped into categories based on whether they relate to cerebellar dysfunction affecting (1) posture and gait, (2) limb movements, (3) speech, or (4) oculomotor performance. A subscore is tallied for each category and a total score is obtained, ranging from 0 (no ataxia) to 100 (most severe ataxia). The ICARS has been found to be reliable in clients with cerebellar dysfunction and has established criterion-related and external validity.¹⁴⁴⁻¹⁴⁷ More recently, it was shown that the ICARS is sensitive to increases in ataxia severity over one year in persons with chronic cerebellar degeneration.¹⁴¹ The Scale for the Assessment and Rating of Ataxia (SARA) is a newer tool that was devised, at least in part, out of concern over the construct validity of the ICARS subscale structure.¹⁴⁸ The SARA is similar to the ICARS in that it quantifies performance of specific movements or activities on an ordinal scale (many of the test activities are the same or similar to those in the ICARS), but it does not categorize individual test items by body part. The SARA has fewer test items (only eight) and can therefore be administered faster in the clinical setting. The SARA has been shown to be reliable and valid for clients with SCAs.¹⁴⁸ Either the ICARS or SARA scale may be useful for longitudinal tracking of disease progression in cerebellar degeneration or for quantifying improvement of ataxia in clinical trials. The scales are detailed in [Appendixes 21-A and 21-B](#).

Diagnosis, Prognosis, and Plan of Care

Clients with cerebellar dysfunction should be given a diagnosis by physical and occupational therapy that identifies the primary movement dysfunction and helps direct treatment interventions to return the client to his or her desired level of activity and participation, if possible. Typically, determination of a movement diagnosis is based largely on both the results of the therapist's examination and evaluation, as well as on knowledge of the cause of the disorder and the extent of the lesion. The prognosis for recovery likewise depends highly on the cause and extent of the lesion. It is important to make a determination whether the impairments in body function or structure and activity limitations are expected to improve or expected not to improve or potentially to worsen over time (e.g., with disease

progression). For impairments and activity limitations that are expected to improve, emphasis should be placed on recovery of those skills; for those expected not to improve or to worsen, emphasis should be placed on instruction and practice of compensatory strategies and general conditioning to minimize degradation due to fatigue.

Physical/Occupational Therapy Interventions for Clients with Cerebellar Dysfunction

The literature on the effectiveness of rehabilitation interventions for individuals with primary cerebellar damage is extremely limited: there have been no randomized controlled trials published. Of the few studies on the effects of rehabilitation interventions in this patient population, all have been nonrandomized, noncontrolled small group^{101,149,150} or case study¹⁵¹⁻¹⁵⁵ designs. The fact that there are so few studies available, each featuring different client populations (e.g., post-stroke versus post-surgical tumor resection versus cerebellar degeneration) and different outcome measures, makes determining the most effective interventions difficult. Therefore we provide here only a description of the major themes that have arisen from these studies to date.

Gait and Balance Interventions

Many of the intervention studies for cerebellar ataxia emphasize stability and balance, especially during gait.^{101,149,153,155} This likely is a reflection of the tight link between gait and balance¹⁰² and the fact that gait ataxia is one of the most common and debilitating signs of cerebellar damage.¹⁰⁰ Common interventions include combinations of exercises targeting gaze, static stance, dynamic stance, gait, and complex gait activities.^{101,153} Some examples of exercises in each of these categories are detailed in **Box 21-2**. Dynamic balance activities performed while sitting, kneeling, and quadruped have also been advocated.¹⁰¹ Other interventions specific to the client's individual impairments of body structure or function should be implemented as necessary, for example, stretching of short or tight ankle plantarflexors and exercises for the VOR.^{101,153} Locomotor training over ground and on treadmills and with and without body weight support has also been used with some success in single case examples.^{151,156} It is not clear how imbalance is corrected in the body weight support environment, however. With all gait and balance activities, it is critical that the exercise be sufficiently and increasingly challenging, so as to facilitate plasticity in the nervous system.^{157,158} In a recent study in mice, it was suggested that trial-and-error practice is a requirement for regaining full motor recovery during cerebellar remyelination.¹⁵⁹

Aerobic Exercise and Resistance Training

Integration of aerobic exercise and resistance training into the treatment plan is recommended for a majority of clients with cerebellar dysfunction, particularly if it is expected the client will not regain premorbid status. If full recovery is not attained, nearly all types of movements will be generally more effortful, requiring increased energy expenditure and demanding greater concentration. It is well known that repetitive fatiguing activity worsens postural control^{160,161} and therefore may contribute to trips, falls, or other injuries.¹⁶² Because imbalance is such a common outcome for clients

with cerebellar dysfunction, incorporating both aerobic exercise to improve cardiovascular endurance and submaximal resistive exercise to improve muscle fatigue resistance appears appropriate. Aerobic exercise activities might include walking, dance, recumbent or stationary cycling, rowing, arm ergometry, swimming and aquatic exercise, as well as many other possibilities.

Consider More Intensive, Longer Duration Interventions

Because the cerebellum is thought to be a primary site of motor learning and individuals with cerebellar damage often have motor learning deficits, it is reasonable to consider whether these clients are capable of benefiting from any intervention that relies on trial-and-error motor practice.¹⁰¹ It has been suggested that rehabilitation for clients with significant cerebellar dysfunction may take longer (more trials, more sessions) and might not ever be complete. The question remains unanswered thus far. Of course, cerebellum-dependent motor adaptation is only one of many motor learning mechanisms, so it is possible that other processes can be engaged during rehabilitation. In support of this idea, it now appears that at least partial "re-learning" of more normal movement patterns is possible with selected cerebellar patient populations.^{101,150} Notably, in the literature, gains were reported under conditions of very frequent (10 hours/week) or very long (6 months) training schedules. This could be a necessity for clients with health conditions in which motor learning is impaired. **Figure 21-9** shows improvements in SARA scores and self-selected walking speeds in a group of individuals with significant progressive ataxia, in response to an intensive rehabilitation program targeting balance and dynamic intersegmental control. Much more research is needed to determine the full range of improvements possible, the minimal dosage of intervention required, and whether the benefits can be retained over the long term in this difficult patient population.

Compensatory Strategies

Compensation is a common component of the plan of care for clients with cerebellar dysfunction. Many clients begin using compensations subconsciously, whereas others need to be taught these strategies and when to use them. If the client is not expected to recover premorbid movement patterns, compensation can enable the individual to regain a certain prior level of activity or societal participation despite an abnormal movement pattern. Instruction in compensation can also be valuable in situations when full recovery is expected but the client would benefit from the use of compensatory strategies for the short term, such as for safety purposes. One compensatory strategy that works well for clients with cerebellar dysfunction is the instruction to simply slow down movements. Recall that slower movements are less dyssynergic and less hypermetric.⁴⁹ Voluntarily reducing the number of segments moving at the same time (i.e., decomposition) also helps reduce dyssynergia and dysmetria.^{49,83} In some cases, reminding clients to use visual cues can also be helpful, for instance, to use vertical markings of a doorway to maintain upright stability, although for certain types of cerebellar damage this is not effective.^{93,94} For gait, deliberately widening stance can be helpful, both for maintaining balance and for preventing tripping over a

BOX 21-2 ■ COMMON GAIT AND BALANCE INTERVENTIONS FOR CLIENTS WITH CEREBELLAR DYSFUNCTION

1. Gaze and eye movements
 - a. VOR: (i) visually fixate on stationary target, slow head movements; (ii) visually fixate on target moving in opposite direction, slow head movements; (iii) VOR cancellation, visually fixate on target moving in same direction, slow head movements. Progression: increase and vary speed, perform eyes closed, add complexity to background.
 - b. Saccades: active eyes alone and combined eye and head movements between two stationary targets. Progression: increase and vary speed.
2. Static stance
 - a. Feet together, arms across chest, eyes open and closed, with and without slow head movements. Progression: increase time with eyes closed, increase and vary speed of head movements.
 - b. Stand on foam, feet apart, arms across chest, eyes closed briefly and intermittently. Progression: narrow base of support, increase time with eyes closed.
 - c. Semitandem stance, arms across chest, eyes closed briefly and intermittently. Progression: narrow base to full tandem stance, increase time with eyes closed, perform semitandem stance on foam.
 - d. Unilateral stance, arms across chest, eyes open. Progression: perform with intermittent then longer periods with eyes closed, perform on foam.
3. Dynamic stance
 - a. March in place, arms across chest, eyes open and closed. Progression: increase time with eyes closed, add and incrementally increase pause time in unilateral stance, add head movements.
 - b. Standing toe taps, forward, backward, to the side, alternating legs, arms across chest, eyes open and closed. Progression: increase step distance, increase time with eyes closed, add head movements.
 - c. March in place on foam, arms across chest, eyes closed briefly and intermittently. Progression: increase time with eyes closed, add and incrementally increase pause time in unilateral stance.
 - d. Standing 360-degree turn, rightward, leftward, arms across chest, eyes open and closed. Progression: tighten turns, increase speed.
 - e. Standing reaches, feet apart and together, eyes open and closed. Progression: increase time with eyes closed, increase reach distance, vary directions, narrow base of support to feet together position.
 - f. Standing bends and squats, feet apart and together, eyes open and closed. Progression: increase time with eyes closed, narrow base of support to feet together, reach to touch the floor.
 - g. Transitions: standing to supine on floor and back up. Progression: transition into and out of all possible positions, with and without upper-extremity support, eyes open and closed, including kneel, half-kneel, quadruped, side sit, squat, and so on.
4. Gait
 - a. Narrow base of support, arms at sides. Progression: increase gait speed.
 - b. Normal base of support, arms at sides with periodic head movements. Progression: narrow base of support, increase and vary speed and frequency of head movements.
 - c. Gait with wide turns, arms at sides. Progression: sharpen angle of the turn, increase gait speed, add head movements.
 - d. Gait with eyes closed, arms at sides. Progression: add turns, add head movements, increase gait speed.
 - e. Gait with perturbations: (i) self-imposed (e.g., large arm movements); (ii) external (e.g., pushes by therapist). Progression: increase speed and amplitude of perturbations, make external perturbations unexpected.
5. Complex gait
 - a. Sideways and backward gait, eyes open, arms at sides. Progression: narrow base of support, add head movements, perform with eyes closed, increase gait speed.
 - b. Incline and decline gait, eyes open, arms at sides. Progression: narrow base of support, add head movements.
 - c. Gait on foam, padded or other compliant surface, eyes open, arms at sides. Progression: narrow base of support, add turns, add head movements, perform with eyes closed.
 - d. Semitandem gait, eyes open, arms at sides. Progression: narrow base to tandem gait, add head movements, perform with eyes closed.
 - e. Gait while negotiating obstacles, eyes open, arms at sides, avoid, step onto, step over. Progression: increase obstacle number and size, vary obstacle placement.
 - f. Gait while distracted, eyes open, arms at sides. Add cognitive task as a distracter; start with responding to simple yes-no questions, progress to difficult tasks (e.g., counting, performing two- or three-digit addition, subtraction).

VOR, Vestibuloocular reflex.

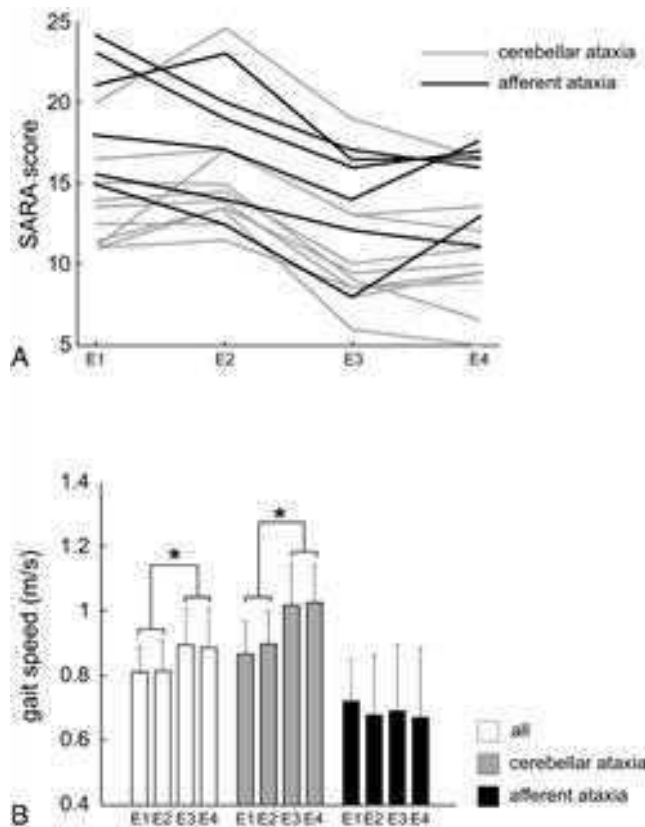

Figure 21-9 ■ Changes in (A) SARA scores and (B) self-selected walking speeds for 16 individuals with progressive ataxia who completed 4 weeks of intensive (1 hr/day, 3 days/wk supervised training plus 1 hr/day, 7 days/wk independent home exercise) rehabilitation emphasizing balance. Measures were recorded at four time periods (E1 to E4), corresponding to 8 weeks preintervention (E1), immediately preintervention (E2), immediately postintervention (E3), and 8 weeks postintervention (E4). Subjects were categorized as having either a predominant cerebellar ataxia (e.g., SCA2, SCA6, idiopathic cerebellar ataxia, or another autosomal dominant cerebellar ataxia) or a predominant afferent ataxia (e.g., Friedreich ataxia or other significant somatosensory neuropathy). The group overall showed significant improvements in both measures (reduced SARA scores and increased walking speeds) after the 4 weeks of exercise and retained these improvements over a further 8 weeks. When broken down by ataxia category, subjects with a predominant cerebellar ataxia, but not the subjects with a predominant sensory ataxia, showed a significant improvement in walking speed. (Asterisks [*] denote significant improvements immediately following the intervention, while no significant changes occurred during pre and post intervention periods.) SARA, Scale for the Assessment and Rating of Ataxia. (Adapted with permission from the American Academy of Neurology. From Ilg W, Synofzik M, Brötz D, et al: Intensive coordinative training improves motor performance in degenerative cerebellar disease. *Neurology* 73:1823–1830, 2009.)

foot. The use of assistive devices for gait should be considered on a case-by-case basis. For some clients, facilitating upper-extremity support and increasing the base of support improve balance during gait. However, for others, the level of skill required to coordinate controlling the device with the movements of arms and legs is too difficult, and using the device actually worsens the instability. Generally speaking,

clients with significant imbalance and limb ataxia but who are ambulatory will often not be safe with any type of cane and instead require a wheeled walker and/or the physical assistance of a caretaker to walk. A final strategy is to remove or minimize distractions during effortful activities. Distraction, for example, dividing attention between a motor and a cognitive task, can worsen ataxia.¹⁶³

The Controversy of Weighting

Rehabilitation textbooks have traditionally supported the use of weights for adults and particularly children with cerebellar dysfunction and ataxia. Either the trunk may be weighted by having the client wear a vest or pack that is weighted, increasing the load on the body axially,¹⁶⁴ or the limbs may be weighted individually^{165,166} with simple wrist or ankle weights. Presumably this trend was based on the common finding, first noted by Holmes,⁷⁴ that clients with cerebellar dysfunction appear improved (move more smoothly and with reduced tremor) if they are asked to hold a heavy weight in the hand while moving the arm. Today it is known that cerebellar tremor is at least in part mechanical in nature, such that anything that adds inertia to the moving segment would reduce the amplitude of the tremor.⁸⁶ This most likely explains the improvement that has been reported. However, this apparent benefit would certainly not continue once the weight is removed, and a reduction in tremor does not indicate a normalization of any other parameters of movement. In fact, weighting of the extremities would seem a questionable choice, given the known difficulty of clients with cerebellar dysfunction to predict and account for limb dynamics or to account for interaction torques.^{49,50} Addition of weights, particularly to the distal segments, would seem only to make this task more difficult. Evidence for this has been demonstrated in a study of patients with cerebellar ataxia in which it was shown that weighting the extremities worsens the amount of hypermetria during a simple single-joint wrist movement task.⁸⁷

One unintended consequence of weighting is that it tends to slow movements down. As described earlier, slower movements are less hypermetric and less dyssynergic than preferred-speed or fast movements. In early studies of weighting, speed was not monitored or controlled for, so a simple reduction in movement speed could account for the immediate apparent improvement described in some reports.^{165,166} Therefore weighting may indeed provide a benefit to some clients with ataxia but it is most likely an indirect one, related more to decreased movement speed. Accordingly, the significant potential for negative consequences of weighting (i.e., worsened hypermetria, increased interaction torques, and the annoyance and physical awkwardness of weights) makes this intervention option seem inferior to the simpler strategy of instructing the client in voluntarily moving more slowly.¹⁶⁷

SUMMARY

The cerebellum is highly unique, in terms of its anatomy, its physiology, and the movement-related impairments individuals experience if it becomes damaged. Ataxia, or movement incoordination, is the major sign of cerebellar damage and can affect limb movements, eye movements, speech, balance, and walking. Depending on which cerebellar functional longitudinal zone is lesioned, one or more of

these specific categories of movements will be impaired. Although the precise mechanisms are not yet fully understood, it is widely acknowledged that the cerebellum is integral to (1) coordination of movements, particularly fast, multijoint movements and (2) adaptation of movements to changes in body conditions or the environment and learning new movement patterns based on trial-and-error practice (motor learning). Unfortunately, evidence for the effectiveness of rehabilitation interventions for individuals with primary cerebellar damage is extremely limited and incomplete. One critical factor in the evaluative process is the determination of whether the body function or structure impairments and activity limitations are expected to improve or expected not to improve or even worsen, as is the case in progressive diseases. If expected to improve, emphasis should be placed on trial-and-error practice of increasingly challenging motor activities. Balance and gait skills may be highlighted. On the other hand, if recovery is not expected, instruction and practice of compensatory

strategies and general conditioning may be effective in at least partially restoring prior participation levels.

APPENDIX 21-A ■ International Cooperative Ataxia Rating Scale (ICARS)

I. POSTURE AND GAIT DISTURBANCES

1. Walking capacities (Observe walking 10 m, near a wall, including half-turn.)

- 0 = Normal
- 1 = Almost normal naturally but unable to walk with feet in tandem position
- 2 = Walking without support but clearly abnormally and irregularly
- 3 = Walking without support but with considerable staggering; difficulties in half-turn
- 4 = Walking with autonomous support not possible; uses the episodic support of the wall
- 5 = Walking possible only with one stick
- 6 = Walking possible only with two special sticks or with a stroller
- 7 = Walking only with accompanying person
- 8 = Walking impossible, even with accompanying person (wheelchair)

Score: _____

2. Gait speed (Observe only if subject scores <4 on preceding test; otherwise automatically score this test as 4.)

- 0 = Normal
- 1 = Slightly reduced
- 2 = Markedly reduced
- 3 = Extremely slow
- 4 = Walking with autonomous support no longer possible

Score: _____

3. Standing capacities, eyes open (Ask subject to stand on one foot; if impossible, ask to stand with feet in tandem; if impossible, ask to stand with feet together. For the natural position, ask subject to find a comfortable standing position.)

- 0 = Normal; able to stand on one foot >10 s
- 1 = Able to stand with feet together but no longer able to stand on one foot >10 s
- 2 = Able to stand with feet together but no longer able to stand with feet in tandem position
- 3 = No longer able to stand with feet together but able to stand in natural position without support, with no or moderate sway
- 4 = Standing in natural position without support, with considerable sway and considerable corrections
- 5 = Unable to stand in natural position without strong support of one arm
- 6 = Unable to stand at all, even with strong support of two arms

Score: _____

4. Spread of feet in natural position without support, eyes open (Ask subject to find a comfortable position, then measure the distance between medial malleoli.)

- 0 = Normal (<10 cm)
- 1 = Slightly enlarged (>10 cm)
- 2 = Clearly enlarged (25-35 cm)
- 3 = Severely enlarged (>35 cm)
- 4 = Standing in natural position impossible

Score: _____

5. Body sway with feet together, eyes open

- 0 = Normal
- 1 = Slight oscillations
- 2 = Moderate oscillations (<10 cm at the level of head)
- 3 = Severe oscillations (>10 cm at the level of head), threatening the upright position

4 = Immediate falling

Score: _____

6. Body sway with feet together, eyes closed

- 0 = Normal
- 1 = Slight oscillations
- 2 = Moderate oscillations (<10 cm at the level of head)
- 3 = Severe oscillations (>10 cm at the level of head), threatening the upright position
- 4 = Immediate falling

Score: _____

7. Quality of sitting position (on flat, hard surface, thighs together, arms folded)

- 0 = Normal
- 1 = With slight oscillations of the trunk
- 2 = With moderate oscillations of the trunk and legs
- 3 = With severe disequilibrium
- 4 = Impossible

Score: _____

Posture and Gait Subscore: _____/34

II. KINETIC FUNCTIONS

8. Knee-tibia test: decomposition of movement and intention tremor (Subject is supine with head tilted to allow visual control. Ask subject to raise one leg in the air (to a height of approximately 40 cm) and place heel on opposite knee and then slide the heel down the anterior tibial surface of the resting leg toward the ankle. On reaching the ankle joint, the leg is again raised, and the action repeated. Repeat for at least three trials on each side.)

- 0 = Normal
- 1 = Heel lowering in continuous axis, but movement is decomposed in several phases (without real jerks) or abnormally slow
- 2 = Heel lowering jerkily in the axis
- 3 = Heel lowering jerkily with lateral movements
- 4 = Heel lowering jerkily with extremely strong lateral movements or test impossible

Score right: _____ Score left: _____

9. Action tremor in the heel-to-knee test (Same test as preceding one; visual control required. Observe action tremor of the heel when asked to hold the heel on the knee for a few seconds before sliding down the leg.)

- 0 = No trouble
- 1 = Tremor stops immediately when the heel reaches the knee
- 2 = Tremor stops in <10 s after reaching the knee
- 3 = Tremor continues >10 s after reaching the knee
- 4 = Uninterrupted tremor or test impossible

Score right: _____ Score left: _____

10. Finger-to-nose test: decomposition and dysmetria (Subject sitting; visual control required. Start trials with hands resting on knees. Repeat for at least three trials on each side.)

- 0 = No trouble
- 1 = Oscillating movement without decomposition of the movement
- 2 = Segmented movement in two phases and/or moderate dysmetria in reaching nose
- 3 = Segmented movement in more than two phases and/or considerable dysmetria in reaching nose
- 4 = Dysmetria preventing the subject from reaching nose

Score right: _____ Score left: _____

APPENDIX 21-A ■ International Cooperative Ataxia Rating Scale (ICARS)—cont'd

11. Finger-to-nose test: kinetic tremor of the finger (Same test as preceding one; visual control required. Observe movement tremor occurring during the ballistic phase of the movement.)

- 0 = No trouble
- 1 = Simple swerve of the movement
- 2 = Mild tremor, estimated amplitude <10 cm
- 3 = Moderate tremor, estimated amplitude 10 to 40 cm
- 4 = Severe tremor, estimated amplitude >40 cm

Score right: _____ Score left: _____

12. Finger-finger test: action tremor and/or instability (Subject sitting. Ask subject to flex, abduct and internally rotate shoulders and then flex elbows so as to have both index fingers pointing at each other at midline. Subject is to maintain index finger positions for approximately 10 s, at distance of approximately 1 cm apart (not touching) and hands at the level of the thorax.)

- 0 = Normal
- 1 = Mild instability
- 2 = Moderate oscillations of finger, estimated amplitude <10 cm
- 3 = Considerable oscillations of finger, estimated amplitude 10 to 40 cm
- 4 = Jerky movements, amplitude >40 cm

Score right: _____ Score left: _____

13. Pronation-supination alternating movements (Subject sitting. Ask subject to raise the forearm vertically and alternate supinating and pronating the forearm on the lap, combining elbow flexion and extension with forearm supination and pronation.)

- 0 = Normal
- 1 = Slightly irregular and slowed
- 2 = Clearly irregular and slowed, but without sway of the elbow
- 3 = Extremely irregular and slowed movement, with sway of the elbow
- 4 = Movement completely disorganized or impossible

Score right: _____ Score left: _____

14. Drawing of the Archimedes' spiral on a predrawn pattern (Subject sitting at a table with a sheet of paper fixed in place. Ask subject to trace the spiral with a pen using the dominant hand; no timing requirements.)

- 0 = Normal
- 1 = Impairment and decomposition, the line quitting the pattern slightly, but without hypermetric swerve
- 2 = Line completely out of the pattern, with recrossings and/or hypermetric swerves
- 3 = Major disturbance caused by hypermetria and decomposition
- 4 = Drawing completely disorganized or impossible

Score: _____

Limb Kinetics Subscore: _____/52

III. SPEECH DISORDERS

15. Dysarthria: fluency of speech (Ask subject to repeat a standard phrase several times; for instance, "A mischievous spectacle in Czechoslovakia".)

- 0 = Normal
- 1 = Mild modification of fluency
- 2 = Moderate modification of fluency
- 3 = Considerably slow and dysarthric speech
- 4 = No speech

Score: _____

16. Dysarthria: clarity of speech

- 0 = Normal
- 1 = Suggestion of slurring
- 2 = Definite slurring, most words understandable
- 3 = Severe slurring, speech not understandable
- 4 = No speech

Score: _____

Dysarthria Subscore: _____/8

IV. OCULOMOTOR DISORDERS

17. Gaze-evoked nystagmus (Ask subject to look laterally at examiner's finger. Observe for nystagmus, mainly horizontal, but could be oblique, rotary, or vertical.)

- 0 = Normal
- 1 = Transient
- 2 = Persistent but moderate
- 3 = Persistent and severe

Score: _____

18. Abnormalities of ocular pursuit (Ask subject to follow the slow lateral movement of the examiner's finger.)

- 0 = Normal
- 1 = Slightly saccadic
- 2 = Clearly saccadic

Score: _____

19. Dysmetria of the saccade (Examiner's two fingers are placed, one in each temporal visual field of the subject, whose eyes are in the primary position. Ask subject to shift eyes to look laterally at the finger, first on the right and then on the left. Average overshoot or undershoot of the two sides is then estimated.)

- 0 = Absent
- 1 = Bilateral clear overshoot or undershoot of the saccade

Score: _____

Oculomotor Subscore: _____/6

**TOTAL ATAXIA SCORE (SUM OF FOUR SUBSCORES):
_____/100**

Modified with permission from Trouillas P, Takayanagi T, Hallett M, et al: International Cooperative Ataxia Rating Scale for pharmacological assessment of the cerebellar syndrome. The Ataxia Neuropharmacology Committee of the World Federation of Neurology. *Neurol Sci* 145:205–211, 1997.

APPENDIX 21-B ■ Scale for the Assessment and Rating of Ataxia (SARA)

- 1. Gait** (Subject (a) walks at a safe distance parallel to a wall including a half-turn (turn around to face the opposite direction of gait) and (b) walks in tandem (heels to toes) without support.)

0 = Normal, no difficulties in walking, turning, or walking tandem (up to one misstep allowed)
 1 = Slight difficulties but visible only when walking 10 consecutive steps in tandem
 2 = Clearly abnormal, tandem walking >10 steps not possible
 3 = Considerable staggering, difficulties in half-turn, but walks without support
 4 = Marked staggering, intermittent support of the wall required
 5 = Severe staggering, permanent support of one stick or light support by one arm required
 6 = Walking >10 m only with strong support (two special sticks or stroller or accompanying person)
 7 = Walking <10 m only with strong support (two special sticks or stroller or accompanying person)
 8 = Unable to walk, even supported

Score: _____

- 2. Stance** (Subject stands (a) in natural position, (b) with feet together in parallel (big toes touching each other), and (c) in tandem (both feet on one line, no space between heel and toe). Subject does not wear shoes, eyes are open. For each condition, three trials are allowed. Best trial is rated.)

0 = Normal, able to stand in tandem for >10 s
 1 = Able to stand with feet together without sway but not in tandem for >10 s
 2 = Able to stand with feet together for >10 s but only with sway
 3 = Able to stand for >10 s without support in natural position but not with feet together
 4 = Able to stand for >10 s in natural position only with intermittent support
 5 = Able to stand >10 s in natural position only with constant support of one arm
 6 = Unable to stand for >10 s even with constant support of one arm

Score: _____

- 3. Sitting** (Subject sits on an examination table without support of feet, eyes open and arms outstretched to the front.)

0 = Normal, no difficulties sitting >10 s
 1 = Slight difficulties, intermittent sway
 2 = Constant sway but able to sit >10 s without support
 3 = Able to sit for >10 s only with intermittent support
 4 = Unable to sit for >10 s without continuous support

Score: _____

- 4. Speech disturbance** (Speech is assessed during normal conversation.)

0 = Normal
 1 = Suggestion of speech disturbance
 2 = Impaired speech but easy to understand
 3 = Occasional words difficult to understand
 4 = Many words difficult to understand
 5 = Only single words understandable
 6 = Speech unintelligible, anarthria

Score: _____

- 5. Finger chase** (Subject seated comfortably, feet and trunk supported if needed. Examiner sits in front of subject and performs five consecutive sudden and fast pointing movements in

unpredictable directions in a frontal plane, at about 50% of subject's reach distance. Movements are approximately 30 cm in distance and occur at a rate of approximately one reach every 2 s. Ask subject to follow the movements, pointing with his or her index finger as fast and precisely as possible. Average performance of last three movements is rated. Rate separately for each side.)

0 = No dysmetria
 1 = Dysmetria, undershooting or overshooting target <5 cm
 2 = Dysmetria, undershooting or overshooting target <15 cm
 3 = Dysmetria, undershooting or overshooting target >15 cm
 4 = Unable to perform five pointing movements

Score right: _____ Score left: _____ Mean score
 ((R + L)/2): _____

- 6. Nose-finger test** (Subject seated comfortably, feet and trunk supported if needed. Ask subject to point repeatedly with the index finger from his or her nose to examiner's finger, which is in front at about 90% of subject's reach distance. Movements are performed at moderate speed. Average performance of movements is rated according to the amplitude of the kinetic tremor. Rate separately for each side.)

0 = No tremor
 1 = Tremor with an amplitude <2 cm
 2 = Tremor with an amplitude <5 cm
 3 = Tremor with an amplitude >5 cm
 4 = Unable to perform five pointing movements

Score right: _____ Score left: _____ Mean score
 ((R + L)/2): _____

- 7. Fast alternating hand movements** (Subject seated comfortably, feet and trunk supported if needed. Ask subject to perform 10 cycles of repetitive alternation of pronation and supination of the forearm on his or her thigh as fast and as precisely as possible. Demonstrate the movement at a speed of approximately 10 cycles in 7 s. Record times for movement execution. Rate separately for each side.)

0 = Normal, no irregularities, performs in <10 s
 1 = Slightly irregular but performs in <10 s
 2 = Clearly irregular, single movements difficult to distinguish or relevant interruptions, but performs in <10 s
 3 = Very irregular, single movements difficult to distinguish or relevant interruptions, performs in >10 s
 4 = Unable to complete 10 cycles

Score right: _____ Score left: _____ Mean score
 ((R + L)/2): _____

- 8. Heel-shin slide** (Subject supine on examination bed without sight of his legs. Ask subject to lift one leg, point with the heel to the opposite knee, slide down along the shin to the ankle, and lay the leg back on the examination bed. The task is performed three times. The slide component of the movement should be performed within 1 s. If subject slides down without contact to shin in all three trials, rate as 4. Rate separately for each side.)

0 = Normal
 1 = Slightly abnormal, contact to shin maintained
 2 = Clearly abnormal, goes off shin ≤3 times during 3 cycles
 3 = Severely abnormal, goes off shin ≥4 times during 3 cycles
 4 = Unable to perform the task

Score right: _____ Score left: _____ Mean score
 ((R + L)/2): _____

Total Ataxia Score (Sum of Eight Test Scores): _____/40

CHAPTER 22 Balance and Vestibular Dysfunction

LESLIE K. ALLISON, PT, PhD, and KENDA FULLER, PT, NCS

KEY TERMS

activity limitation
anticipatory postural adjustments
automatic postural responses
balance
base of support
body system problems
center of gravity
impairment
limit of stability
motor learning stages
participation
sensory conflict
sensory environment
strategies
systems model or systems approach
volitional postural movements

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe both central and peripheral sensory and motor components of the postural control system.
2. List common postural control impairments found in clients with neurological problems.
3. List commonly used balance tests, and distinguish which are appropriate for clients at low, moderate, and high levels of function.
4. Differentiate how test results are used to identify body system impairments and activity limitations that limit participation.
5. Analyze the interaction of individual, task, and environmental factors that affect balance.
6. Describe how to plan and progress balance exercise programs to increase the use of, or compensation with, available sensory inputs.
7. Describe how to plan and progress balance exercise programs to facilitate anticipatory postural adjustments to prevent balance loss and provoke automatic postural responses to regain balance after unexpected disturbances.
8. Describe how to plan and progress balance exercise programs to increase the control of center of gravity in upright postures and during gait.
9. Describe how to increase the difficulty level of balance exercise programs in order to promote the automaticity of postural control during functional activities.
10. Identify and analyze the function of the vestibular system.
11. Describe how to facilitate adaptation and central nervous system reorganization to regain control of balance and decrease dizziness.
12. Identify patterns of recovery that influence choices of intervention.

Balance Function and Disorders

Leslie Allison, PT, PhD

No matter what the neurological diagnosis, a disease or injury that affects the nervous system is likely to compromise one or more of the postural control mechanisms. For example, clients with such diverse diagnoses as stroke, head trauma, spinal cord injury, peripheral neuropathy, multiple sclerosis (MS), Parkinson disease, cerebellar dysfunction, cerebral palsy, and Guillian-Barré syndrome all experience disequilibrium problems. One common thread among all these different medical diagnoses is the presence of balance impairments. Clients with different medical diagnoses may have the same balance impairments, and clients with the same medical diagnosis may have different balance impairments depending on which portions of the postural control system are involved.¹ To optimally understand and manage balance problems, a test of each balance component and the interactive nature of the components is important. The traditional medical “diagnostic” model does not provide this information and is not the most beneficial model for planning balance rehabilitation interventions. The medical diagnosis is relevant: knowing whether

deficits are permanent or temporary, and whether recovery or progressive decline is expected, is critical. This medical prognostic information will assist physical and occupational therapists in goal setting and intervention planning.

The International Classification of Functioning, Disability and Health (ICF) model described in Chapter 1 and illustrated in Figure 1-1 describes the interactions of body function and structure problems (impairments) and activity limitations as seen in clients with balance disorders, and how these functional activity limitations restrict an individual’s ability to participate in life situations, thus decreasing quality of life. Balance impairments negatively affect function, often reducing the individual’s ability to participate fully in life.² These impairments often restrict activity levels, produce abnormal compensatory motor behavior, and may require devices for support or assistance from another person. Falls can result when imbalance is severe, leading to secondary injuries. To avoid these consequences and advance the functional status of clients, therapists should understand both the demands that various environments and functional tasks place on postural control systems and the impairments that may diminish the ability of those systems to respond adequately.

BALANCE

Definitions of Balance

Balance is a complex process involving the reception and integration of sensory inputs and the planning and execution of movement to achieve a goal requiring upright posture. It is the ability to control the center of gravity (COG) over the base of support in a given sensory environment.^{3,4} The COG is an imaginary point in space, calculated biomechanically from measured forces and moments, where the sum total of all the forces equals zero. In a person standing quietly the COG is located just forward of the spine at approximately the S2 level. With movement of the body and its segments, the location of the COG in space constantly changes. The base of support is the body surface that experiences pressure as a result of body weight and gravity; in standing it is the feet, and in sitting it includes the thighs and buttocks. The size of the base of support will affect the difficulty level of the balancing task. A broad base of support makes the task easier; a narrow base makes it more challenging. The COG can travel farther while still remaining over the base if the base is large. The “shape” of the base of support will alter the distance that the COG can move in certain directions.

Any given base of support places a limit on the distance a body can move without either falling (as the COG exceeds the base of support) or establishing a new base of support by reaching or stepping (to relocate the base of support under the COG). This perimeter is frequently referred to as the *limit of stability* or *stability limit*.^{3,5} It is the farthest distance in any direction a person can lean (away from midline) without altering the original base of support by stepping, reaching, or falling.

Environmental Context

This biomechanical task of keeping the COG over the base of support is always accomplished within an environmental context, which is detected by the sensory systems. The sensory environment is the set of conditions that exist, or are perceived to exist, in the external world that may affect balance. Peripheral sensory receptors gather information about the environment, body position and motion in relation to the environment, and body segment positions and motions in relation to the self. Central sensory structures process this information to perceive body orientation, position, and motion and to determine the opportunities and limitations present in the environment. Gravity is one environmental condition that must be dealt with to remain stable. It is a constant condition for everyone except astronauts in space. Surface and visual conditions, however, may vary significantly and may be stable or unstable. Unstable surface conditions might include the subway, a sandy beach, a gravel driveway, or an icy parking lot. Common unstable visual conditions are experienced on mass transit, in crowds, or on a boat. Rapid head movements may render even a stable visual environment unusable for postural cues, and darkness may preclude the use of vision. The more stable the environment, the lower the demand on the individual for balance control. Unstable environments place greater demands on the postural control systems.

Balance is also affected by an individual’s intentions to achieve certain goals and the purposeful tasks that are undertaken. Volitional balance disturbances are self-initiated

almost constantly, such as shifting from foot to foot, reaching for the telephone, or catching an object that is falling from a high shelf. Even reactions to involuntary balance disturbances, such as a slip or trip, are modified on the basis of the immediate task. A man carrying a bag of groceries who slips may drop the bag to reach with both hands and catch himself. If he is instead carrying his infant child, he may reach with only one hand or even take the fall if by doing so he can protect the infant from harm. Often in real life we perform several tasks at once, such as carrying a laundry basket while walking, or talking on a cellular phone while climbing a flight of stairs. When tasks are undertaken concurrently, attention must be divided between them, which may also affect balance abilities.

All these variables—the location of the COG, the base of support, the limit of stability, the surface conditions, the visual environment, the intentions and task choices—are inconstant, producing changing demands on the systems that control balance. The integrity and interaction of postural control mechanisms allow a wide range of movements and functions to be achieved without loss of balance.

HUMAN CONTROL OF BALANCE

Early studies of postural control mechanisms using selectively lesioned cats and primates focused on reflexive and reactive equilibrium responses that are relatively “hard-wired.”⁶ These valuable studies brought to light certain stereotypical motor responses to specific sensory stimuli, such as the crossed extension reflex or tonic neck reflexes. There is no doubt that these reflexive and reactive responses—for example, the vestibuloocular reflex (VOR) and the protective extension reactions—are foundational to normal postural control. However, the postural control system encompasses much more than these subcortically driven components. Balance abilities are heavily influenced by higher-level neural circuitry and other systems (e.g., cognitive, musculoskeletal), as well.⁵ In addition, the nervous system is influenced by and responsive to the demands placed on it by the tasks being accomplished and the environments in which those tasks are performed.⁷⁻⁹ All of these facets are included in a systems approach to dynamic equilibrium.¹⁰⁻¹² Examination and intervention methods based on this systems model have consequently evolved.^{11,13}

The Systems Approach

The dynamic systems model for dynamic equilibrium recognizes that balance is a result of interactions among the individual, the task(s) the individual is performing, and the environment in which the task(s) must be performed. These interactions are represented in [Figure 22-1](#). Within the individual, both sensory inputs and processing systems (left side of figure) and motor planning and execution systems (right side of figure) are critical. Both peripheral components (lower part of figure) and central components (upper part of figure) of the systems are involved in the cycle. The cycle is driven both by purposeful choices of the individual (tasks) and by demands placed on the individual by the environment. Successful function of the sensory systems allows recognition of body position and motion in relation to self and the world. The desired outcome from the motor systems is the generation of movement sufficient to maintain balance and perform the chosen, goal-directed task(s).

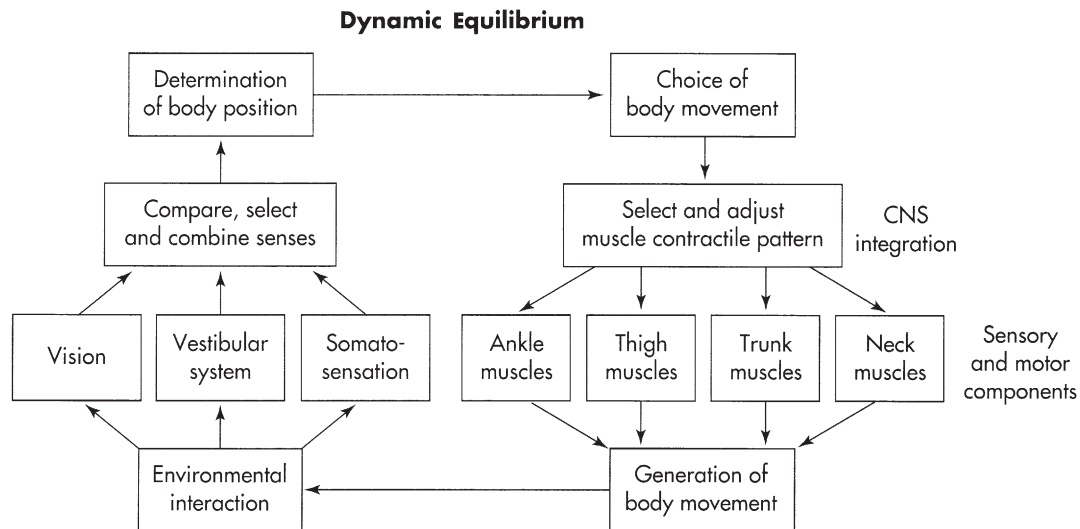

Figure 22-1 ■ The systems model of postural control illustrates the constant cycle that occurs simultaneously at many levels. (Reprinted with permission from NeuroCom International, Clackamas, Ore.)

Peripheral Sensory Reception

The three primary peripheral sensory inputs contributing to postural control are the bilateral receptors of the somatosensory, visual, and vestibular systems.^{4,10} Somatosensory receptors located in the joints, ligaments, muscles, and skin provide information about muscle length, stretch, tension, and contraction; pain, temperature, and pressure; and joint position. The feet, ankles, knees, hips, back, neck, and eye muscles all furnish useful information for balance maintenance. Somatosensation is the dominant sense for upright postural control and is responsible for triggering automatic postural responses (APRs). Somatosensory loss significantly impairs balance. Loss of peripheral somatosensation occurs in clients with loss or disease of or injury to the peripheral sensory receptors or afferent sensory nerves. Examples include clients with diabetic neuropathy, peripheral vascular disease, spinal cord injury, and amputation.

Visual receptors in the eyes perform dual tasks. Central (or foveal) vision allows environmental orientation, contributing to the perception of verticality and object motion, as well as identification of the hazards and opportunities presented by the environment.¹⁰ For example, a kayaker may see rocks in a stream as a hazard to be avoided, whereas a hiker who wants to cross the stream may see the same rocks as a welcome opportunity. Peripheral (or ambient) vision detects the motion of the self in relation to the environment, including head movements and postural sway. Peripheral vision is largely subconscious, whereas central visual inputs tend to receive more conscious recognition.¹⁰ Both are normally used for postural control. Vision is critical for feed-forward, or anticipatory, postural control in changing environments. This includes planning for functional movements such as reaching and grasping, and especially for successful navigation during gait. Vision loss also impairs balance. Loss of peripheral visual inputs occurs in clients with disease of or injury to the eyes or afferent cranial nerves. Examples include clients with cataracts, macular degeneration, glaucoma, or diabetic retinopathy.

The vestibular system provides the central nervous system (CNS) with information about the position and motion

of the head. The position of the head in relation to gravity is detected through the otolith system. Horizontal and vertical accelerations, as in riding in a car or an elevator, are also detected by the otoliths.¹⁴ Movements of the head are detected through the semicircular canals. Head movement stimulates both sets of semicircular canals, so that the vestibular nerve on one side becomes inhibited while the other becomes excited. The vestibular system provides sensory redundancy in the information obtained from each separate vestibular apparatus. If the peripheral vestibular system is damaged on one side, the information can be captured by the intact canals on the opposite side. The vestibular system is critical for balance because it uniquely identifies self-motion as different from motion in the environment. **Box 22-1** describes the sensory components of the vestibular system. Vestibular loss also impairs balance. Loss of peripheral vestibular inputs occurs in clients with disease of or injury to the peripheral sensory receptors or afferent cranial nerves. Examples include clients with head injury involving temporal bone damage, acoustic neuroma, benign positional vertigo (BPV), or Meniere disease. For a comprehensive review of the vestibular system and vestibular disorders, please see the vestibular section of this chapter beginning on [page 689](#).

Orientation to the wider environment, primarily from vision, allows feed-forward, or anticipatory, postural adjustments. Prior experience and high attentional capacity improve anticipatory postural adjustments significantly. Detection of head movement by the vestibular and cervical somatosensory systems and of body sway by somatosensory and peripheral visual systems provides feedback for APRs. Note that the better anticipatory abilities become, the fewer balance errors occur. Fewer balance errors mean fewer losses of balance and a reduced need to produce APRs.

Disease of or damage to any of the peripheral sensory receptors or afferent pathways impairs or removes the detection capabilities of the system, rendering sensory information unavailable for use in postural control. Many patients with neurological diagnoses have peripheral sensory impairments.

BOX 22-1 ■ SENSORY COMPONENTS OF THE VESTIBULAR SYSTEM LABYRINTHS

SEMICIRCULAR CANALS

- Semicircular canals are ring-shaped, fluid-filled structures containing hair cells that respond to fluid movement when the head moves.
- The canals are arranged so that when the head moves, the direction and velocity in each canal are compared with a mutually perpendicular canal on the opposite side of the head.
- The brain uses the relative change in firing from each side to identify the direction of rotation. This provides for sensory redundancy; the brain interprets motion by comparing information from each side to calculate the velocity and direction of head turns.
- The orientation of the three semicircular canals on each side corresponds to the directions of neck motion, flexion and extension, right and left rotation, and right and left side-bending. This relation supports the integration of vestibular inputs with somatosensory information from the cervical spine.

OTOLITHS

- Located in the vestibule or central component of the labyrinth, the otoliths respond to gravity and linear acceleration through hair cell deflection.
- These compartments contain multiple hair cells attached to the walls and connected to the vestibular nerve. These hair cells are embedded in a gel-like substance called the *macula*.
- Sitting on top of the macula are crystals of calcium carbonate, known as *otoconia*. The purpose of the otoconia is to establish mass so that the hair cells can measure the effects of gravity as well as movement.
- The otoliths respond to movement of the head by the shearing effect of the otoconia pressing on the macula and displacing the hair cell in the opposite direction of the movement. These signals from the otoliths are used to compare this motion with the resting tone established by gravity.

Central Sensory Perception

The brain processes all the environmentally available sensory information gathered by the peripheral receptors in varying degrees. This processing is usually referred to as *multisensory integration* or *sensory organization*.^{4,10} Central sensory structures function first to compare available inputs between two sides and among three sensory systems. The somatosensory system alone is unable to distinguish surface tilts from body tilts. Also, the visual system by itself cannot discriminate movement of the environment from movement of the body.¹⁴ The vestibular system by itself cannot tell if head movement through space is produced by neck motion or trunk and hip motion. Therefore the brain needs information from all three senses to correctly distinguish self-motion from motion in the environment.

How are sensory inputs from separate senses combined to form perceptions of position and motion? For example, consider the movement of turning your head to one side to look over your shoulder. When the head turns to one side, firing

will increase in one vestibular organ and decrease proportionately in the other. This is known as *push-pull function*, and the information from each side is considered to “match.” With the same example, if the eyes are open while the head moves, the rate of the visual flow will be equal and the direction of the visual flow will be opposite to the rate and direction of information from the vestibular inputs. The muscles on one side of the neck will shorten and on the other side will stretch. The inputs from these three systems are congruent. If both sides and all three systems provide compatible inputs, the process of sensory organization is simplified.

When changes in the environment occur, the relative availability, accuracy, and usefulness of information from the three sensory systems may also change. Sensory organization also includes an adaptive process, called *multisensory reweighting*, that permits the CNS to prioritize the sources of sensory information when environmental conditions change.^{15,16} Available, accurate, and useful information is “upweighted,” whereas unavailable, inaccurate, or less-useful information is “downweighted.” For example, in dark environments, vision would be downweighted and somatosensory and vestibular information would be upweighted. This adaptive process is imperfect, however, and balance is not as well controlled when any sense must be downweighted as it is when all three senses are available and accurate. Individuals with peripheral sensory loss or central sensory processing deficits may have difficulty reweighting quickly and fully. This impairs their ability to adapt to, and remain stable in, changing environments.¹⁷

Sensory conflict can arise when information between sides or between systems is not synchronous. Sensory organization processing then becomes more complex because the brain must then recognize any discrepancies and select the correct inputs on which to base motor responses. The vestibular system may be used as an internal reference to determine accuracy of the other two senses when they conflict. For example, a driver stopped at a red light suddenly hits the brake when an adjacent vehicle begins to roll. Movement of the other car detected by the peripheral visual system is momentarily misperceived as self-motion. In this situation, the vestibular and somatosensory systems do not detect motion, but the forward visual flow is interpreted as backward motion. Because the brain failed to suppress the (mismatched) visual inputs, the braking response was generated.

When the brain recognizes that the information coming from one sensory input is inaccurate or unavailable, as is the case when somatosensory information is diminished post-stroke, it must depend more on the remaining senses (in this case, vision and vestibular system) to determine position and motion in space. The brain then compares and uses information from senses it considers accurate for balance. An individual with the problem just described may compensate for the loss of somatosensory function by becoming visually dependent for balance during movement. If vision subsequently also becomes disrupted as this client ages, his ability to orient in space will be further compromised. This will impair balance and increase risk of falls.

Activities or environments that create sensory conflict or demand sensory resolution become more difficult to manage when the vestibular system is deficient or underused. These situations, such as going down stairs, riding escalators or elevators, walking on uneven ground, and making quick

turns, are often avoided. When sensory conflicts cannot be resolved rapidly, dizziness or motion sickness occurs.

Intrinsic central sensory processing impairments also can produce sensory conflict. An adult hemiplegic patient with pusher syndrome illustrates an inability to integrate visual, vestibular, and somatosensory inputs for midline orientation. Within a single system, discrepancies between the sides are also problematic. Unequal firing from opposite sides of the vestibular system, as in unilateral vestibular hypofunction, produces a mismatch that is subsequently interpreted as head rotation when head movement does not occur. This spinning sensation is known as *vertigo*.¹⁴ Vertigo is resolved if the brain is able to adapt to the mismatch. For further information on vertigo, refer to the section on the vestibular system.

Finally, the central processing mechanisms combine any available and accurate inputs to answer the questions “Where am I?” and “How am I moving?” This includes both an internal relation of the body segments to one another (e.g., head in relation to trunk, trunk in relation to feet) and an external relation of the body to the outside world (e.g., feet in relation to surface, arm in relation to handrail). CNS disease or trauma involving the parietal lobe may impair these processing mechanisms so that even available, accurate sensory inputs are not recognized or incorporated into determinations of position and movement.^{18,19} Impairments of central sensory processing may occur after stroke, head trauma, tumors, or aneurysms; with disease processes such as MS; and with aging.

Central Motor Planning and Control

Whereas sensory processing allows the interaction of the individual and the environment, motor planning underlies the interaction of the individual and the task. Aside from reflexive activity such as breathing and blinking, most motor actions are voluntary and occur because some goal is to be achieved. That is not to say that reflexes occur separately from volitional movements; for example, the vestibuloocular reflex is active concurrently with visual tracking activity, but most actions occur because of some purposeful intent.¹⁴ These task intentions precede motor actions.^{10,20} Wrist and hand movements vary depending on what is to be grasped (a cup versus a doorknob); foot placement and trunk position vary depending on what is to be lifted (a heavy suitcase versus a laundry basket). The initiation of volitional motor actions depends on intention, attention, and motivation.^{10,21}

Once an objective (“Where do I want to be?” “What do I want to do?”) has been chosen, the next step in motor planning is to determine how to best accomplish the goal given the many options that are potentially available. For example, when the task demands fine skills or accuracy, the dominant hand is preferred; when the task involves lifting a large or heavy object, both hands are preferred. In addition to which limbs, joints, and muscles will be used, motor planning also adjusts the timing, sequencing, and force modulation. This can be demonstrated in various reaching tasks. Reaching to remove a hot item from the oven will occur slowly, whereas reaching to put an arm through a sleeve will occur more quickly. Optimal motor plans are developed with knowledge of self (abilities and limitations), knowledge of task (characteristics of successful performance), and knowledge of the environment (risks and opportunities).²¹

The motor plan must be transmitted to the peripheral motor system to be enacted. A copy of the intended movement plan is sent to the cerebellum during the transmission. When the movement begins, incoming sensory inputs (feedback) about the actual movements and performance outcome are compared with the intended movements and performance outcome. Movement errors (the difference between the intended and the actual movement) and performance errors (desired goal not achieved) are detected, and plans for correction are then formed and transmitted. This process of error detection and error correction is the foundation of motor learning.

Clients with CNS disorders often have central motor planning and control system problems. After a stroke, clients may have hypertonus and poor reciprocal inhibition; clients with head trauma may have difficulty initiating or ceasing movements; clients with Parkinson disease exhibit bradykinesia; and those with cerebellar ataxia display modulation problems.²²

Peripheral Motor Execution

Movement is accomplished through the bilateral joints and muscles. Normal range of motion (ROM), strength, and endurance of the feet, ankles, knees, hips, back, neck, and eyes must be present for the execution of the full range of normal balance movements. Decreased ankle dorsiflexion ROM, for example, restricts the forward limits of stability. Strength deficits are a primary cause of movement abnormalities in both central and peripheral nervous system disorders. In addition, weakness may be the result of force modulation deficits or disuse.¹¹ Balance is directly affected by loss of strength. For example, weakness of the hip extensors and abductors will impede successful use of a hip strategy for upright trunk control. Initially adequate toe clearance may diminish with fatigue. Many clients with neurological issues also have stiffness and contractures as a result of persistent weakness or hypertonus. Restrictions in ROM also limit balance abilities.

The ability to achieve static postural alignment, although necessary for normal balance, is not sufficient to allow volitional functions. Adequate strength (to control body weight and any additional loads) through normal postural sway ranges is needed to permit dynamic balance activities such as reaching, leaning, and lifting. Postural control demands are increased during gait because the forces of momentum and the interaction between recruitment, timing, and velocity also must be regulated.²³ Traditionally considered orthopedic problems, deficits in strength, ROM, posture, and endurance have a great impact on balance abilities. Attention must be given to these musculoskeletal system problems in examination of and intervention for clients with neurological diagnoses.

Influence of Other Systems

Balance abilities are also influenced by other systems. Attention, cognition and judgment, and memory are critical for optimal balance function and are often impaired in hemiplegic and head-injured clients as well as those who have progressive neurological disorders. Attentional deficits reduce awareness of environmental hazards and opportunities, interfering with anticipatory postural control.¹² When balance is threatened, an inability to allocate attention to the necessary task of balance

versus a secondary, less necessary task increases the risk of falls. Cognitive problems such as distractibility, poor judgment, and slowed processing also increase the risk of falls. Memory loss may preclude recall of safety measures. Depression, emotional lability, agitation, or denial of impairments also can increase the risks for loss of balance. In addition to having a direct impact on balance abilities themselves, these cognitive and behavioral problems impede motor learning processes, which are crucial for the relearning of balance skills.

Constant Cyclic Nature

The systems model of postural control previously presented illustrates the constant cycle that simultaneously occurs at many levels. Attention and intention allow feed-forward processing for active sensory search of the environment and motor planning, both of which are needed for anticipatory postural control. Movements are initiated and executed with resultant sensory experiences and error detection, or feedback. Successful movements are repeated and refined; unsuccessful ones are modified. The nature of this cycle presents the clinician with opportunities for intervention after the appropriate examination of sensory, motor, and cognitive functions. Through feedback and practice, balance abilities can improve.²⁴

Motor Components of Balance

Reflexes

Many levels of neuromuscular control must be functioning to produce normal postural movements. At the most basic level, reflexes and righting reactions support postural orientation. The VOR and the vestibulospinal reflex (VSR) contribute to orientation of the eyes, head, and body to self and environment.¹⁰

When motion of the head is identified by the semicircular canals, it triggers a response within the oculomotor system called the *vestibuloocular reflex*. This causes the eyes to move in the opposite direction of the head but at the same speed. Stimulation of the otoliths drives the eyes to respond to linear head movement. Quick movements of the head will trigger the VOR.²⁵

The VOR allows the coordination of eye and head movements. When the eyes are fixed on an object while the head is moving, the VOR supports gaze stabilization. Visuo-ocular responses often work concurrently with the VOR. They permit “smooth pursuit” when the head is fixed while the eyes move and visual tracking when both the eyes and the head move simultaneously.¹⁰

The VSR helps control movement and stabilize the body. Both the semicircular canals and the otoliths activate and modulate muscles of the neck, trunk, and extremities after head movement to maintain balance. The VSR permits stability of the body when the head moves and is important for the coordination of the trunk over the extremities in upright postures. Righting reactions support the orientation of the head in relation to the trunk and the head position relative to gravity and include labyrinthine head righting, optical head righting, and body-on-head righting.¹⁰

Automatic Postural Responses

At the next level, automatic postural responses operate to keep the COG over the base of support. They are a set of functionally organized, long-loop responses that act to keep

the body in a state of equilibrium.^{3,4} *Functionally organized* means that the responses, although stereotypical, are matched to the perturbing stimulus in direction and amplitude. If the stimulus is a push to the right, the response is a shift to the left, toward midline. The larger the stimulus, the greater the response. Automatic postural responses always occur in response to an unexpected stimulus and are typically triggered by somatosensory inputs. Because they occur rapidly, in less than 250 ms, they are not under immediate volitional control.

Four automatic postural responses have been described. Ankle strategy describes postural sway control from the ankles and feet. The head and hips travel in the same direction at the same time, with the body moving as a unit over the feet (Figure 22-2, A). Muscle contractile patterns are from distal to proximal (i.e., gastrocnemius, hamstrings, paraspinals). This strategy is used when sway is small, slow, and near midline. It occurs when the surface is broad and stable enough to allow pressure against it to produce forces that can counteract sway to stabilize the body. Ankle strategy is typically used to control anterior-posterior sway, because most of the degrees of freedom at the ankle are in this direction.

Hip strategy involves postural sway control from the pelvis and trunk. The head and hips travel in opposite directions, with body segment movements counteracting one another (Figure 22-2, B). Muscle contractile patterns are from proximal to distal (i.e., abdominals, quadriceps, tibialis anterior). This strategy is observed when sway is large, fast, and nearing the limit of stability or if the surface is too narrow or unstable to permit effective counterpressure of the feet against the surface. Hip strategy is used to control both anterior-posterior and medial-lateral sway. Hip strategy in the medial-lateral direction involves weight shifts from foot to foot; any client with difficulty weight-shifting quickly and accurately will have difficulty with medial-lateral hip strategy.

Suspensory strategy involves a lowering of the COG toward the base of support by bilateral lower-extremity flexion or a slight squatting motion (Figure 22-2, C). By shortening the distance between the COG and the base of support, the task of controlling the COG is made easier. This strategy is often used when a combination of stability and mobility is required, as in windsurfing.

Stepping and reaching strategies involve steps with the feet or reaches with the arms in an attempt to reestablish a new base of support with the active limb(s) when the COG

Figure 22-2 ■ Automatic postural responses. **A**, Ankle strategy. **B**, Hip strategy. **C**, Suspensory strategy. **D**, Stepping strategy. (From Hasson S: *Clinical exercise physiology*, St Louis, 1994, Mosby.)

has exceeded the original base of support (Figure 22-2, D). A successful stepping strategy is the best way to avoid a fall after a slip or trip.

Misconceptions about these APR strategies are common. First, these strategies do not function in daily life as separately as they are described in the early research literature. In quiet standing, for example, frequency analysis of unperturbed postural sway in healthy adults reveals that both ankle and hip strategies occur in combination, simultaneously.²⁶ In perturbation studies, mixed use of strategies is often seen unless the perturbation is clearly below or above certain-sized thresholds. Second, these strategies occur in response to disturbances from all directions, not just in pure anterior-posterior or medial-lateral directions.²⁷ Third, although these strategies are stereotypical in humans, great individual variation in strategy selection and performance comes from other influential factors. For example, many people use stepping strategy for most perturbations unless specifically instructed not to step or unless the conditions do not permit a step. An anxious person may reach or step much sooner than a relaxed person with similar physical deficits. Last, all these strategies do *not* occur in sequence with every balance disturbance.^{28,29} In other words, individuals normally do not try ankle strategy and wait until it fails before trying hip strategy, then wait until it fails before trying stepping strategy (although early learning may involve such exploration). Because these responses must occur extremely rapidly to prevent balance loss, such a sequential approach would be inefficient and ineffective. Instead, the normal response is the emergence of the single strategy best suited to the particular perturbation, the limitations of the individual, and the conditions in the environment.

Abnormal use of automatic postural responses is often observed in individuals with neurological disorders. Clients with vestibular deficits typically rely on ankle strategy, which permits the head to remain aligned with the body and sustains congruence between vestibular and somatosensory inputs. Use of hip strategy may be modified or limited because when the head is moving in the opposite direction as the COG, vestibular and somatosensory inputs are not congruent. Activities that require use of hip strategy, such as standing in tandem or on one leg, can be a problem for clients with bilateral vestibular loss or an uncompensated vestibular lesion. However, some cases involve excessive use of hip strategy on a level surface (when an ankle strategy would suffice).³⁰ This may reflect abnormal integration of the somatosensory and vestibular information. If peripheral somatosensation is impaired, as in diabetic neuropathy, or central sensory weighting of somatosensory inputs is inadequate, hip strategy may dominate.

Clients with somatosensory loss, distal lower extremity weakness or hypotonus, restricted ankle ROM, and/or reduced limits of stability typically rely on hip strategy. This occurs because the client cannot feel the surface or the feet well enough to modulate foot pressure against the surface, because the person cannot generate sufficient force against the surface with the ankle muscles, or because restricted ankle ROM prevents COG sway. The use of hip strategy is normal when the COG is at or near the limits of stability and a step is either not possible or not desired.

When the hip or ankle strategy is not efficient enough to control the movement of the center of pressure, or if conditions

and instructions permit a stepping response, stepping strategy may be preferred. Individuals who are fearful of falling often perceive even slight body sway as threatening instability. They may use stepping and reaching strategies exclusively whether or not these “rescue” strategies are actually necessary.

Anticipatory Postural Adjustments

Anticipatory postural adjustments are similar to automatic postural responses, but they occur before the actual disturbance.²⁰ If a balance disturbance is predicted, the body will respond in advance by developing a “postural set” to counteract the coming forces. For example, if an individual lifts an empty suitcase thinking it is full and heavy, the anticipatory forces generated before the lift (to counter the anticipated weight) will cause excessive movement and brief instability. Failure to produce these anticipatory adjustments increases the risk of sudden balance loss, creating the need to use rapid, reactive automatic postural responses to prevent a fall. For clients with deficits in reaction time or automatic postural responses, superior use of anticipatory postural control can help the client avoid the unexpected perturbations that make automatic postural responses necessary.

In balance laboratories, anticipatory postural adjustments are studied using electromyography so that muscle activity before observable movement can be measured. In the clinic, problems with anticipatory adjustments may be observed when the client fails to counteract a predicted disturbance, such as “don’t let me push you backward,” or fails to integrate postural control tasks during other activities, such as the inability to step smoothly over an anticipated obstacle during gait or inability to maintain sitting balance when both arms are intentionally lifted overhead.

Volitional Postural Movements

Volitional postural movements are under conscious control. Weight shifts to allow an individual to reach the telephone or put the dishes in the dishwasher, for example, are self-initiated disturbances of the COG to accomplish a goal. Volitional postural movements can range from simple weight shifts to complex balance skills of skaters and gymnasts. They can occur after a stimulus or be self-initiated. Volitional postural movements can occur quickly or slowly, depending on the goal at hand. The more complex or unfamiliar the task, the slower the response time. Use of a variety of movements that might successfully achieve a goal is possible. Volitional postural movements are strongly modified by prior experience and instruction. Automatic and anticipatory postural responses allow the continuous unconscious control of balance, whereas volitional postural movements permit conscious activity. This level of postural motor control is the most frequently tested and treated in clinical practice, but it is by no means sufficient by itself to produce normal balance.

CLINICAL ASSESSMENT OF BALANCE

Objectives of Testing

When present, activity limitations need to be identified and measured. Functional scales are typically used to determine the presence and severity of these limitations, not necessarily why those limitations exist. From these functional tests, decisions can be made about whether to treat and, if so, what

tasks need to be practiced. If treatment is indicated, clinicians must make judgments about what to treat. Further testing to identify and measure impairments is then necessary to know what systems are involved. A comprehensive evaluation of balance includes both functional and impairment tests.¹²

No single quick-and-easy test of balance can adequately cover the many multidimensional aspects of balance, although many such tests have great value as screening tools. However, a comprehensive test battery, called the Balance Evaluation Systems Test (BESTest), based on the systems model has been developed that provides clinicians with a thorough examination at the impairment level (Figure 22-3).³¹ The BESTest takes more time to administer than, for example, a single-leg stance test, but results from the BESTest give the clinician a far more complete and accurate picture of the client's balance impairments than any single-item test or screening test can. Armed with these results, the clinician can develop interventions specifically targeted to the impaired systems. For clients whose primary problems include imbalance, the clinician's investment of time to perform this comprehensive test battery yields a valuable outcome. A shorter version of this test, the mini-BESTest, has subsequently been published.³² It takes less time to administer but likewise provides a less complete picture of the client's balance systems. Specifically, it does not include any items from the biomechanical constraints or stabilities limits categories. Even so, it is superior to single-item tests or screening tests that are not based on the systems model and do not identify balance system impairments that should be addressed in the intervention plan.

No single, simple test for balance is possible because balance is such a complex sensorimotor process.³³ Many relatively simple balance tests exist, but not all tests are appropriate for all clients. Different tests may be needed to answer specific questions. For example, several good tests have been developed to determine the risk of falls in elderly people. These would be insufficient to discern whether an injured dancer can resume practice or an injured roofer is ready to return to work. Clinicians should understand the advantages and limitations of different balance tests to be able to select appropriate evaluative tools.

In general, a balance test will not be useful unless it sufficiently challenges the postural control system being tested. Tests for stability ("static balance") are appropriate for clients who are having difficulty simply finding midline or holding still in sitting or standing. They are of much less value for clients with higher-level abilities. Conversely, single-leg stance tests or sensory tests with a foam surface may be far too difficult for clients with lower-level abilities to perform.

A word of caution about interpreting test results is indicated. Most clinical tests rely on observations of motor behavior to arrive at some conclusion about what systems have problems and how they affect movement. Abnormal motor behavior has many causes, and clinicians should be careful before concluding that an observed behavior is caused by problems in a certain system. For example, the Romberg test is commonly assumed to test the use of vestibular inputs. Yet during the test, both somatosensory and vestibular inputs are (normally) used for balance control. If balance control is deficient, is the vestibular system necessarily the culprit? Could somatosensory system deficits also result in a poor

test result? Or, alternatively, because the Romberg test is performed with feet together, what effect would hip weakness have on the ability to stand with a narrowed base of support? When using a test whose results may be altered by problems in more than one system, any relevant system should be evaluated. If multiple system deficits exist, and they often do in clients with neurological conditions, then use caution in making "commonly assumed" conclusions on the basis of clinical test results.

Because so many balance tests are available, several questions must be asked to determine whether a test is appropriate for use.³³ For what purpose and population was the test designed? Can that test be used legitimately for a different purpose or with a different population? Is it valid? Is it repeatable by different examiners or by the same examiner multiple times? Are results reliable? In what populations are they reliable? What is the threshold for this test—that is, how large must performance changes be before this test can detect them? Are normative data available for comparison? These questions are being investigated but have not yet been answered for many of the clinical balance tests commonly used by therapists with the many different neurological populations they treat. Some of the evidence already reported may be frustrating to clinicians. For example, the Timed Up-and-Go test (TUG) predicts falls in community-dwelling older adults but not in acute-care hospital populations.^{34,35} For several balance tests such as the Functional Reach Test, the Berg Balance Scale, and others, the cutoff scores used for accurate prediction of falls in clients with Parkinson disease are different from the cutoff scores used in older adults without Parkinson disease.³⁶ These examples make it clear that clinicians must understand their clients and the characteristics of the various balance tests in order to select the most appropriate tests and interpret test results for each client.

Types of Balance Tests

Balance tests can be grouped or classified by type. Different types of tests measure different facets of postural control (Table 22-1). Quiet standing (static) refers to tests in which the client is standing and the movement goal is to hold still. Disturbances to balance, called *perturbations*, may or may not be applied. Active standing (dynamic) tests also position the patient standing, but the movement goal involves voluntary weight shifting. Sensory manipulation tests use altered surface and visual conditions to determine how well the CNS is using and reweighting sensory inputs for postural control. Functional balance, mobility, and gait scales involve the performance of whole-body movement tasks, such as sitting to standing, walking, and stepping over objects. A few test batteries offer a combination of the preceding tests. The BESTest is the most comprehensive test battery to date. Dual-task tests have been developed to examine the effect of concurrent activities and divided attention on balance and mobility performance. A commonly accepted test for sitting balance in adults is not yet available, although clients with neurological problems often need sitting balance retraining in early stages. Clinicians typically modify standing tests or pediatric sitting tests to assess sitting balance in adult clients with neurological conditions. For example, the Functional Reach Test has been used to measure excursion in seated individuals with spinal cord injuries.³⁷

I. Biomechanical Constraints	1. Base of support	2. CoM alignment	3. Ankle strength and ROM	4. Hip/trunk lateral strength	5. Sit on floor and stand up

	Multiple Tasks Test

Quiet Standing

The classic Romberg test was originally developed to “examine the effect of posterior column disease upon upright stance.”³⁸ The client stands with feet parallel and together and then closes the eyes for 20 to 30 seconds. The examiner subjectively judges the amount of sway. Quantification of sway can be accomplished with a videotape, forceplate, or, more recently, accelerometer.^{39,40} Excessive sway, loss of balance, or stepping during this test is abnormal. The sharpened Romberg,³⁸ also known as the *tandem Romberg*, requires the client to stand with feet in a heel-to-toe position and arms folded across the chest, eyes closed for 60 seconds. Often four trials of this test are timed with a stopwatch, for a maximum score of 240 seconds.

One-legged stance tests (OLSTs) are commonly used.^{38,41} Both legs must be alternately tested, and differences between sides are noted. The client stands on both feet and

places hands on the hips or crosses the arms over the chest, then picks up one leg and holds it with the hip in neutral and the knee flexed to 90 degrees. The lifted leg may *not* be pressed into the stance leg. This test is scored with a stopwatch. Five 30-second trials are performed for each leg (alternating legs), with a maximum possible score of 150 seconds per leg. Normal young subjects are able to stand for 30 seconds, but this may not be a reasonable expectation for frail older clients.³⁸

In both the Romberg test and the OLST, problems in sensory organization processes can be observed. To determine how much of the stability is achieved through visual stabilization, each test can be repeated with eyes closed. The client with visual dependency for balance will often have an immediate loss of balance when the eyes are closed. (Remember, visual dependency may be a sign of somatosensory or vestibular loss, or both.) As noted earlier, the client with somatosensory or vestibular loss may have difficulty producing the hip strategy necessary to perform these tasks.

A battery of timed stance tests has been developed by Bohannon and Leary.⁴² This set of tests varies the foot position (apart, together, tandem, and single leg) and the availability of visual information (eyes open and closed) to produce eight different combinations. Maintenance of balance in each condition is timed for a maximum of 30 seconds; the assigned score is the total number of seconds that balance could be maintained. The best possible score on this test is 240 seconds. This test is reliable, valid, and sensitive to change over time.⁴²

A related test is the Balance Error Scoring System, or BESS test, which was developed for use with athletes to screen for concussion effects.^{43,44} The original BESS test involved three stance positions (double-leg stance with feet together, single-leg stance, tandem stance) on two surfaces (firm and foam), thus providing six conditions. The eyes are closed in all conditions. Each trial is 20 seconds in duration. The examiner observes and counts the number of balance errors that are made in each condition. The six observed errors include hands lifted off waist; opening eyes; step, stumble, or balance loss; moving a hip past 30 degrees of abduction; lifting the forefoot or heel; and remaining out of the test position for more than 5 seconds. If more than one error occurs at the same time, for example, opening eyes and hands off waist, only one error is counted. When measured in high-level young adults, the reliability of this test improved with the removal of the double-leg stance condition, which produced few to no errors in this high-functioning population, and the addition of three trials in each of the remaining four conditions. The modified BESS test thus includes only four conditions.⁴⁵ This test has not been investigated for use in traditional neurological rehabilitation populations.

Objective postural sway measures can be obtained by computerized force plates (Figure 22-4) or wearable accelerometers (Figure 22-5).^{40,46-48} The client is asked to adopt a standardized foot placement if possible (this varies by manufacturer) and to stand quietly with arms at the sides or hands on hips for 20 or 30 seconds. Sway with both eyes open and eyes closed is commonly measured. Graphic and numerical quantification is provided. Normative data may be provided. These more technical measures are able to detect more subtle problems and are more sensitive to change in performance after treatment than are rating scales or timed measures.

Figure 22-4 ■ Graphic and numerical postural sway measures using a computerized force plate system. *Top left*, Normal subject, eyes open. *Top right*, Healthy subject, eyes closed. *Bottom left*, Client with Parkinson disease, eyes open. *Bottom right*, Client with Parkinson disease, eyes closed. Automatic postural responses are assessed by the client's response to perturbations. It is imperative that clinicians include APR testing in their balance assessment because APRs are the motor responses necessary to prevent loss of balance and falls. The push-and-release test is a clinically useful method with a five-point ordinal rating scale.^{31,49,50} Testing for ankle and hip strategies ("in-place" strategies) requires that the clinician (1) place his or her hands on the front or back of the patient's shoulders, (2) ask the patient to remain still and centered by resisting the pressure applied by the hands (producing isometric muscle activity), (3) watch for the toes or heels to begin to raise slightly (the clinician increases pressure until this occurs), then (4) suddenly release the push. Both forward and backward directions are tested; the clinician always stands where he or she can support the client in case of balance loss. Testing for stepping strategy follows the same concept but is performed differently. Instead of keeping the client's COG at midline, the client leans his or her weight into the clinician's hands, shifting the COG away from midline toward the outer limit of stability before the release. The correct client response is to step to reestablish a new base of support underneath the new position of the COG. Forward, backward, and both lateral directions are tested. When nudge or push tests are performed predictably (i.e., "don't let me push you backward"), this is assessment of anticipatory postural control. When the release happens unpredictably (no cues, unpredictable timing), automatic postural responses can be assessed. Perturbations of different strengths from multiple different directions should be given.

Figure 22-5 ■ **A**, A wearable accelerometer for motion detection that can be used to measure postural sway and other physical motions. **B**, The accelerometer worn in a belt at the L5-S1 level. **C**, Postural sway data recorded by the accelerometer. (Photographs courtesy McRoberts B, The Hague, The Netherlands.)

Figure 22-6 ■ Surface perturbations during (A) the adaptation test and (B) the motor control test using computerized dynamic posturography. Force plate measures include latency and amount of response and adaptation of the response to repeated perturbations. (From Hasson S: *Clinical exercise physiology*, St Louis, 1994, Mosby.)

The Motor Control Test (MCT) is a computerized test of automatic postural responses that perturbs the client through surface displacement (Figure 22-6, B).³ The client stands on a dynamic (movable) forceplate with feet parallel and arms at sides. The support surface rapidly translates (slides) forward or backward. This surface displacement results in a rapid shift in the relation between the COG and the base of support. The expected responses are directionally specific (to the direction of the stimulus) forces generated against the surface to bring the COG back to the center. Response latencies, strength, and symmetry are measured. Normative data are available. This test can be used to look for abnormal stepping strategies when failure to select hip strategy occurs. The MCT is the most standardized and reliable test of automatic postural responses, but it is not widely used because it requires computerized equipment.

Active Standing

Volitional control of the COG is evaluated by asking the client to make voluntary movements that require weight shifting. The Functional Reach Test was developed for use with older adults to determine risk of falls.⁵¹ The client stands near a wall with feet parallel. Attached to the wall at shoulder height is a yardstick. The client is asked to make a fist and raise the arm nearest the wall to 90 degrees of shoulder flexion. The examiner notes the position of the fist on the yardstick. The client is then asked to lean forward as far as possible, and the examiner notes the end position of the fist on the yardstick (Figure 22-7). Beginning position is subtracted from end position to obtain a change unit in inches. Three trials are performed. Normative data are available, and the test is reliable. However, the standard error of measurement for this test may be as high as 2 inches, meaning that a change in score of less than 2 inches cannot be attributed to clinical improvement because it may reflect only measurement error. Subsequent studies have not shown that this test is useful for fall prediction.⁵²⁻⁵⁴

One serious limitation of the Functional Reach Test is that it measures sway in only one direction (forward). An expansion of this test has been devised to measure sway in

Figure 22-7 ■ During the Functional Reach Test, the client is asked to reach forward as far as possible from a comfortable standing posture. The excursion of the arm from start to finish is measured by a yardstick affixed to the wall at shoulder height. **A**, Functional reach, starting position. **B**, Functional reach, ending position.

four directions.⁵⁵ The multidirectional reach test is conceptually equivalent but measures sway anteriorly, posteriorly, and laterally to both sides. This test should provide a more comprehensive picture of volitional COG control limitations. Validity and mean values have been established for community-dwelling older adults.⁵⁶

The limits of stability test uses a computerized forceplate to measure postural sway away from midline in eight directions.^{46,57} Clients assume a standardized foot position and control a cursor on the computer monitor by shifting their weight. They are asked to move the cursor from midline to eight targets on the screen (Figure 22-8). Measures include movement velocity, directional control (path sway), measures

Figure 22-8 ■ Graphic postural sway measures from the limits of stability test using a computerized force plate system (numerical measures not shown). of excursion (length of the trajectory of the COG), and reaction time. This test should be performed once for familiarization, then a second time for scoring purposes. Second and subsequent tests are reliable. Normative data are available.

A very challenging test used primarily in athletic populations is the Star Excursion Balance Test (SEBT) (Figure 22-9).^{58,59} The SEBT could be used, for example, in high-level traumatic brain injury (TBI) clients who require more demanding test conditions. However, although there is evidence for the validity and reliability of this test in orthopedic populations, as yet this test has not been investigated for use in neurological populations. The SEBT is in concept a lower-extremity functional reach test, requiring single-leg stance on one leg and a reach

with the other leg. The original SEBT included eight directions; currently the SEBT is typically performed in three directions: center-forward, right-rear, and left-rear.⁶⁰ Three tape measures are taped to the floor, radiating out from the same center point. The two rear tape measures are at a 45-degree angle from the center line. The client stands on one foot with the great toe on the center point, then reaches the maximum distance away from the center with the lifted foot. The distance is recorded by the examiner. This is done in all three directions, with the lifted leg having to cross behind the stance leg to reach to the opposite-side rear tape. Six practice trials in each direction are given before recording scores to eliminate a learning effect, although recent evidence suggests four practice trials may be sufficient.⁶¹ Three scored trials in each direction are performed. Both legs are tested.^{61a}

Bolded arrows in the anterior, posteromedial, and posterolateral directions indicate the three directions used in the modified SEBT. (From Brumitt J: *Assessing athletic balance with the Star Excursion Balance Test*. NSCA Perform Train J 7:6, 2008.)

Sensory Manipulation

Sensory inputs play a critical role in postural control, but few tests to measure their use to produce a balance performance outcome have been developed. The Sensory Organization Test (SOT) uses a computerized, movable forceplate and movable visual surround to alter the surface and visual environments systematically.^{3,4} The client stands on the forceplate with feet parallel and arms at the sides and is asked to stand quietly. Three 20-second trials under each of six sensory conditions are performed (Figure 22-10). In conditions one, two, and three the support surface (forceplate) is fixed. During conditions four, five, and six the support surface is sway referenced to the sway of the client. In other words, the movement of the surface is matched to the movement of the client in a 1:1 ratio. This responsive surface movement maintains a near-constant ankle joint angle despite body sway, rendering the somatosensory information from the feet and ankles inaccurate for use in balance maintenance. Visual inputs are undisturbed in conditions one and four. Vision is absent (eyes are closed) in conditions two and five. The movable visual surround is sway referenced in conditions three and six. This responsive visual surround movement maintains a near-constant distance between the eyes and the visual environment despite body sway, rendering visual inputs from

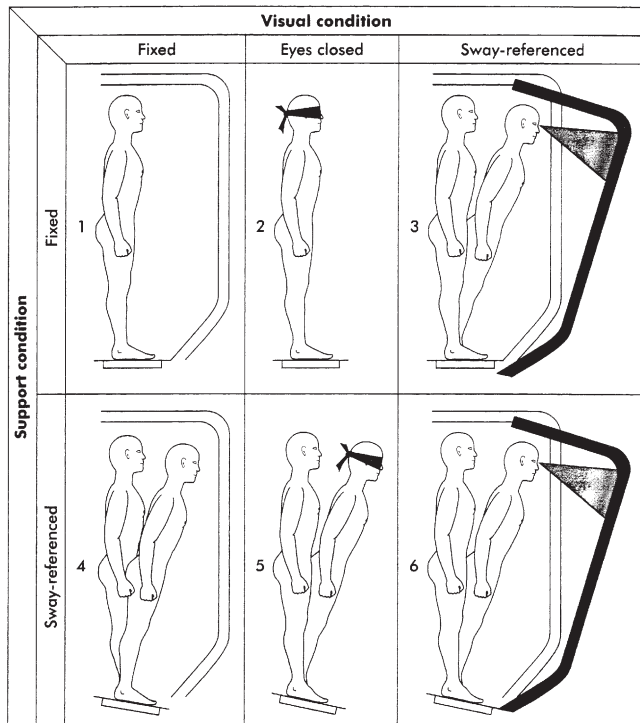

Figure 22-10 ■ The six Sensory Organization Test conditions. The Sensory Organization Test determines the relative reliance on visual, vestibular, and somatosensory inputs for postural control using computerized dynamic posturography. (From Hasson S: *Clinical exercise physiology*, St Louis, 1994, Mosby.)

the eyes inaccurate for balance maintenance in those two conditions.

Under condition one, all three senses (vision, vestibular sense, and somatosensory sense) are available and accurate. Body sway is measured by the forceplate; this initial measurement forms the baseline against which subsequent measures are compared (Figure 22-11). Under condition two the eyes are closed, so only somatosensory and vestibular cues remain. In an individual with normal movement function, the somatosensory inputs will dominate in this condition. By comparing sway during condition two with sway during condition one, detection of how well the client is using somatosensory inputs for balance control is possible. Clients with somatosensory loss from spinal cord injury, diabetes, or amputation have difficulty in condition two. Functional situations with inadequate lighting or unusable visual cues (e.g., busy carpeting) are similar to condition two.

Under condition four, the support surface is sway referenced (somatosensory cues are available but are inaccurate), so only visual and vestibular cues remain useful. In a normal client the visual inputs will dominate in this condition. Comparing sway during condition four with sway during condition one indicates how well the client is using visual inputs for balance control. Clients with visual loss caused by diabetes, cataracts, or field loss have difficulty in condition four. Functional situations that correlate with condition four include compliant surfaces (beach, soft ground, gravel driveway) and unstable surfaces (boat deck, slipping throw rug).

Under condition five, the eyes are closed (visual cues are absent) and the support surface is sway referenced (somatosensory cues are inaccurate), leaving the vestibular inputs as the only remaining sense that is both available and accurate. Comparison of sway during condition five with sway during condition one indicates how well the client is using vestibular inputs for balance control. Clients with vestibular loss caused by head injury, MS, or acoustic neuroma may have difficulty with condition five. Many elderly clients also may be unstable in this condition. Functional situations in which these clients may be at risk for falls would have both inadequate lighting and compliant or unsteady surfaces (e.g., walking on a gravel driveway or thick carpet in the dark).

Under both conditions three and six, the visual surround is sway referenced (visual cues are available but inaccurate). By comparing sway during these two conditions with sway in the absence of vision (conditions two and five, with eyes closed), determining how well the client can recognize and subsequently suppress inaccurate visual inputs when they conflict with somatosensory and vestibular cues is possible. Some clients with CNS lesions (e.g., head injury, stroke, tumor) may have difficulty with this condition. Clients who cannot recognize and ignore inaccurate visual cues cannot distinguish whether they are moving or the environment is moving. If they perceive that they are moving (away from midline) when they are not, they may often actively generate postural responses to “right” themselves. These responses, invoked to bring the COG to midline, then result in movement away from the midline. The inaccurate perception leads to a self-initiated loss of balance. Functional situations that correlate with this test condition include public transportation, grocery and library aisles, and moving walkways.

The SOT is valid and reliable in the absence of motoric problems, which increase sway for reasons unrelated to sensory reception and perception. Normative data are available.

The Clinical Test of Sensory Interaction on Balance (CTSIB) is a clinical version of the SOT that does not use computerized forceplate technology.⁶² The concept of the six conditions remains intact (Figure 22-12). Instead of sway measures, the examiner uses a stopwatch and visual observation. A thick foam pad substitutes for the moving forceplate during conditions four, five, and six. In normal individuals and clients with peripheral vestibular lesions, measures with foam correlate to moving forceplate measures.⁶³ Originally, a modified Japanese lantern substituted for the moving visual surround in conditions three and six. Studies have not shown that measures using the Japanese lantern correlate with the moving visual surround measures. Most clinicians now perform the modified CTSIB with just four conditions, eyes open and closed on a firm surface and eyes open and closed on the foam surface. The client is asked to stand with feet parallel and arms at sides or hands on hips. At least three and up to five 30-second trials of each condition are performed.¹⁸ The watch is stopped if the client steps, reaches, or falls during the 30 seconds. If the client is very steady for 30 seconds on the first trial of a condition, some clinicians choose not to test the remaining trials in that condition and will give the client a full score for that condition. A maximum score for five trials of each condition is 150 seconds. Individuals with normal movement abilities are able to stand without stepping, reaching, or exhibiting loss of balance for 30 seconds per trial per condition. It is

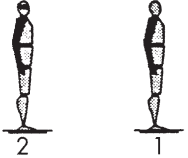

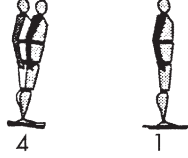

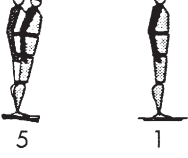

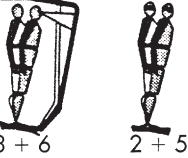

SENSORY ANALYSIS			
RATIO NAME	TEST CONDITIONS	RATIO PAIR	SIGNIFICANCE
SOM Somatosensory		$\frac{\text{Condition 1}}{\text{Condition 2}}$	Question: Does sway increase when visual cues are removed? Low scores: Patient makes poor use of somatosensory references.
VIS Visual		$\frac{\text{Condition 4}}{\text{Condition 1}}$	Question: Does sway increase when somatosensory cues are inaccurate? Low scores: Patient makes poor use of visual references.
VEST Vestibular		$\frac{\text{Condition 5}}{\text{Condition 1}}$	Question: Does sway increase when visual cues are removed and somatosensory cues are inaccurate? Low scores: Patient makes poor use of vestibular cues, or vestibular cues unavailable.
PREF Visual Preference		$\frac{\text{Condition 3} + 6}{\text{Condition 2} + 5}$	Question: Do inaccurate visual cues result in increased sway compared to no visual cues? Low scores: Patient relies on visual cues even when they are inaccurate.

Figure 22-11 ■ Postural sway measures from each of the six Sensory Organization Test conditions are compared, and the ratios are used to identify impairments in the use of sensory inputs for postural control. (From Jacobson GP, Newman CW, Kartush JM: *Handbook of balance function testing*, St Louis, 1993, Mosby.)

normal for sway to increase slightly as the conditions increase in difficulty. The CTSIB may not be a reliable measure in clients with hemiplegia or other conditions that involve motor deficits in, or abnormal response time through, the lower extremities and trunk.⁶⁴ The clinician can use the information regarding client response in a variety of environmental conditions to determine intervention management strategies.⁶⁵

Vestibular System Tests

Please refer to the vestibular section for a thorough presentation of vestibular disorders and their management.

Active Stepping

The ability to change the base of support without balance loss then to reestablish COG stability over the new base of support is a balance-dependent skill critical for functional activities. The four square step test is a timed stepping test in a standardized, structured format in forward, backward, and lateral directions (Figure 22-13).⁶⁶ A simple plus sign-shaped grid is laid out on the floor using four straight canes, dowel rods, or plastic piping. This creates four quadrants. The client begins standing in the rear-left quadrant, steps forward over the first bar to stand with both feet in the front-left quadrant, steps rightward over the second bar to stand with both feet in the right-front quadrant, steps backward over the third bar to

stand with both feet in the right-rear quadrant, steps leftward over the fourth bar to stand with both feet in the left-rear quadrant (starting location), then reverses direction, going back through each quadrant in the same way until standing again with both feet in the rear-left quadrant. The outcome measure is the time it takes the client to perform this task correctly, clearing each bar completely with each foot. This test has been used with older adults, individuals with vestibular disorders, and clients poststroke.^{67,68}

Functional Scales

A comprehensive balance evaluation must include both impairment-based tests of body systems and activity-based functional measures. Functional scales help address the activity limitations. By asking the client to perform functional tasks that demand balance skills, the clinician can determine the presence of activity limitations that will affect the individual's ability to participate in life, and identify the tasks that the client needs to practice. Three mobility scales and three gait scales focus on postural control; five of these were developed for the elderly population to determine risk of falls. Many clinicians are also using them to assess clients with neurological conditions, although their usefulness with neurological populations is less well-documented. Far fewer standardized tests for high-level balance skills have been developed; some clinicians adapt tests used by athletes, but

Figure 22-12 ■ The Clinical Test of Sensory Interactions on Balance uses foam and a Japanese lantern to replicate the six sensory conditions. A stopwatch is used to time trials.

Figure 22-13 ■ The floor grid for the timed Four Square Step Test (FSST). Arrows indicate the direction of the steps. (From Dite W, Temple VA: A clinical test of stepping and change of direction to identify multiple falling older adults. *Arch Phys Med Rehabil* 83:1568, 2002.)

these are often too difficult for many neurologically involved clients.

The Berg Balance Scale consists of 14 tasks that the client is asked to perform.⁶⁹ The examiner rates the client on each task by using an ordinal rating scale of 0 to 4, in which 0 is unable to perform and 4 is able to perform without difficulty. This test is highly reliable. It was originally designed for assessing risk of falls in older adults, and cutoff scores for fall risk vary depending on which of several studies is consulted.^{70,71} Use of higher cutoff scores may erroneously identify nonfallers as fallers; use of lower cutoff scores may erroneously identify fallers as nonfallers. The Berg Balance Scale has also been used with clients after stroke.⁷²⁻⁷⁵

The original Get-Up-and-Go Test is made up of seven items and subjectively scored on an ordinal rating scale of 1 to 5, in which 1 is normal and 5 is severely abnormal.⁷⁶ This test has been modified by making it a timed measure to increase its objectivity and reliability, which is now high. The TUG test eliminates the “standing steady” segment and uses a stopwatch to time the performance.⁷⁷ Clients are asked to rise from a chair with arms, walk 3 meters as fast as they safely can, turn, walk back to the chair, and sit down. This test may be performed with an assistive device; however, the use of a device will alter the speed at which the task can be accomplished, and any retesting must be done with the same device to produce comparable results. Originally designed

to assess frailty in older adults, the test is now more commonly used to assess fall risk in this population. Young adults typically perform this task in 5 to 7 seconds, healthy older adults in 7 to 9 seconds (low risk), moderate-risk older adults in 10 to 12 seconds, and high-risk older adults in 13 seconds or more.^{78,79} These cut-off scores are for older adults walking without assistive devices. Improvements in test performance that are not captured by the time score alone should also be documented, for example, if the client can now perform the test without the use of chair arms to stand up, or without an assistive device.

The Tinetti Performance-Oriented Mobility Assessment—Balance subscale (POMA-Balance) is a list of nine items scored on scales of either 0 to 1 or 0 to 2, with the higher numbers reflecting better (more normal) performance.⁸⁰ The score value is specific to the item. The best possible score is 16, with a score of 10 or lower indicating a high risk of falls.⁸¹

Most balance and mobility scales have been developed to assess risk of falls in older adults. Many share similar items. See Table 22-2 for a summary of scale items.

The Tinetti Performance-Oriented Mobility Assessment—Gait subscale (POMA-Gait) is a list of seven normal aspects of gait that are observed by the examiner as the client walks at a self-selected pace and then at a rapid but safe pace.⁸⁰ Scoring scales are again either 0 to 1 or 0 to 2, and higher numbers indicate better performance. Score values are specific to the item being observed (Table 22-3). The best possible score is a 12; scores of 8 or below indicate a high risk of

falls. When combined, the Tinetti POMA balance and gait scales offer a best possible score of 28, with scores of 19 or less indicating a high fall risk.

The original Gait Assessment Rating Scale (GARS) is a list of 16 abnormal aspects of gait observed by the examiner as the client walks at a self-selected pace (see Table 22-3).⁸² These abnormalities are commonly seen in older adults who fall, who are fearful of falling, or both. The items are scored on a scale of 0 to 3, with lower numbers reflecting better (less abnormal) performance. The best possible score is 0. This gait scale provides some relative numerical indication of the quality of gait. A shorter, modified version of this test, the Modified GARS, has been developed. The Modified GARS (GARS-M) includes nine of the original items plus a gait velocity measure. It provides equivalent sensitivity and takes less time to perform.⁸³ These two gait scales were developed to assess risk of falls in older adults.

The Dynamic Gait Index (DGI) is a gait test specifically designed to look at postural control during gait.¹² It includes eight items requiring changes in gait speed, walking with horizontal and vertical head turning, whole-body turns during gait, stepping over and around obstacles, and stair ascent and descent. Items on this test are scored on a 4-point ordinal scale of 0 to 3, with 3 being normal performance and 0 indicating severe impairment. The best possible score on this test is a 24, and scores of less than 19 points have been associated with impairment of gait and fall risk. The presence of head motion and whole-body turns in this test may help identify clients with potential vestibular dysfunction.

The reliability of this test is high.^{71,84,85} A modified and slightly more difficult version of this test, the Functional Gait Assessment (FGA), has been developed specifically for use with patients with vestibular disorders.⁸⁶ The best possible score on the FGA is 30 points, and a score of 22 points or below can be used to classify fall risk and predict unexplained falls in community-dwelling older adults.⁸⁷

The three gait tests listed previously are distinct from traditional gait tests because they focus on elements of postural control during gait. One very important traditional gait measure that should be included in the assessment of balance and gait in older adults and clients with neurological disorders is gait speed. This measure has been termed “the sixth vital sign” for older adults because of its strong association with level of dependence in activities of daily living (ADLs) and instrumental ADLs (IADLs), probability of hospitalization, risk of falls, eventual discharge location, and ambulation category.⁸⁸

Combination Test Batteries

Because no single test can give a complete picture of a client’s balance abilities, individual test items are often combined to form a test battery. Several of the tests described earlier, such as the Berg Balance Scale and the Tinetti POMA, include a combination of multiple items and could be categorized as combination test batteries. Different items on a test may challenge different components of the postural

control system to permit a more complete assessment of the client’s balance abilities.

The BESTest is an excellent comprehensive test battery based on the systems model of postural control (see Figure 22-3).³¹ It includes seven categories representing components of postural control: biomechanical constraints; stability limits; anticipatory postural adjustments; automatic postural responses; sensory orientation, and stability during gait. Within each category are individual test items and, in some cases, existing tests. For example, the sensory orientation category contains the individual item “Stand on incline with eyes closed” and the four-condition CTSIB discussed earlier. Although the BESTest takes approximately 30 minutes to administer, the information acquired helps to identify which underlying components of the postural control system are causing the observed balance problems. Armed with this critical information, the clinician can design a customized, individualized intervention program that targets the sources of imbalance in each client.

A shorter version of this test has been developed, the Mini-BESTest (see Figure 22-3).³² It includes 14 of the original 36 items, has a compressed rating scale, and takes approximately 15 minutes to administer. It does not include any items from the biomechanical constraints category or the stability limits category. This does not mean that these components need not be measured. Biomechanical constraints such as hip and ankle weakness, and constricted limits of stability, seriously negatively affect balance and should be tested in addition to administration of the Mini-BESTest. The compressed rating scale may reduce the ability of this test to reflect a client’s progress over time.

The Fregly-Graybiel Ataxia Test Battery is a more challenging test appropriate for clients with higher-level balance skills. It includes eight test items that the client must perform (Figure 22-14).³⁸ Standing trials in tandem stance both off and on a rail with eyes open and closed are timed. Timed single-leg stance trials also are performed for each leg. Walking 10 steps with eyes closed is included. Five trials of each task are given. Trials are stopped if the client uncrosses the arms, opens the eyes (during eyes-closed trials), steps (during standing trials), or falls. Trials are judged on a pass-fail basis. This test battery is valid for use with clients who have peripheral vestibular dysfunction. Normative data are available from a normative database composed primarily of findings in young men. As noted earlier, clients must be at a high level motorically to perform these tasks. This test is a good choice for clients with higher-level abilities because it does provide more demanding balance tasks. Interpretations regarding a client’s use of sensory inputs when motor involvement is also present cannot be made with certainty.

The Fugl-Meyer Sensorimotor Assessment of Balance Performance is a subset of the Fugl-Meyer Physical Performance Battery, which was designed for use with hemiplegic clients (Figure 22-15).¹⁸ Three sitting and four standing balance activities are listed. The items are scored on a 0 to 2 scale, with score values specific to each item. Higher scores indicate better performance; the maximum (best) score is 14. However, a client could achieve this score of 14 and still not have normal balance.

The Dizziness Handicap Inventory (DHI) was developed to identify specific functional, emotional, or physical problems associated with an individual’s reaction to imbalance or

FREGLY TEST

Condition	Trials				
	1	2	3	4	5
1. Sharpened Romberg, EC (60 sec; feet in tandem)					
2. Walk on Rail, EO (5 steps; best 3/5 trials)					
3. Stand on Rail, EO (3 trials; 60 sec/trial)					
4. Stand on Rail, EC (3 trials; 60 sec/trial)				x	x
5. Stand on Right Leg, on Floor, EC (5 trials; 30 sec/trial)				x	
6. Stand on Left Leg, on Floor, EC (5 trials; 30 sec/trial)					
7. Walk on Floor, EC (3 trials; 10 steps each)				x	x
8. Stand sideways on rail (characterize sway)*					

*Added by the author to observe the movement strategy used by the individual.
EO, eyes open; EC, eyes closed.

Figure 22-14 ■ A combination of tasks (Romberg test, one-legged stance test [OLST], walking) and environments (eyes open, eyes closed, rail) are included in the Fregly-Graybiel Ataxia Test Battery. (From Newton R: Review of tests of standing balance abilities. *Brain Inj* 3:335, 1989.)

FUGL-MEYER

Test	Scoring	Maximum Possible Score	Attained Score
1. Sit without support _____	0—Cannot maintain sitting without support 1—Can sit unsupported less than 5 minutes 2—Can sit longer than 5 minutes		
2. Parachute reaction, non-affected side _____	0—Does not abduct shoulder or extend elbow 1—Impaired reaction 2—Normal reaction		
3. Parachute reaction, affected side _____	Scoring is the same as for test 2		
4. Stand with support _____	0—Cannot stand 1—Stands with maximum support 2—Stands with minimum support for 1 minute		
5. Stand without support _____	0—Cannot stand without support 1—Stands less than 1 minute or sways 2—Stands with good balance more than 1 minute		
6. Stand on unaffected side _____	0—Cannot be maintained longer than 1–2 seconds 1—Stands balanced 4–9 seconds 2—Stands balanced more than 10 seconds		
7. Stand on affected side _____	Scoring is the same as for test 6		
		Maximum Balance Score	/14

Figure 22-15 ■ The Fugl-Meyer Sensorimotor Assessment of Balance Performance includes both low-level and high-level tasks. (From DiFabio RP, Badke MB: Relationship of sensory organization to balance function in patients with hemiplegia. *Phys Ther* 70:20, 1990.)

dizziness.^{89,90} The DHI assesses the client’s perception of the effects of the balance problem and the client’s level of emotional adjustment. It also looks at perceived physical limitations as a consequence of the disorder. Twenty-five items are divided into three subscales in this self-assessment inventory. Included are a nine-item functional scale, a nine-item emotional scale, and a seven-item physical scale. Each item is assigned a value of four points for a “yes,” two points for a “sometimes,” and zero points for a “no.” This inventory is reliable, is easy to administer, and can be used to evaluate treatment outcomes.⁹¹ Changes in scores on the functionally based DHI correlate highly with changes in scores on the impairment-based SOT.⁸⁹

The DHI can be given before the initial evaluation to help determine which physical tests should be performed. An astute clinician can see patterns of dysfunction within the reported symptom level. For example, visual motion sensitivity and visual dependency can be indicated from the answers about grocery stores, crowds, riding in a car, or difficulty at night. Imbalance usually is indicated when the client has difficulty walking down a sidewalk and using stairs. Patients with chronic mild head injury often will report many activities as most provoking because of their inability to integrate the sensory systems and poor motor control for balance.

Dual-Task Tests

In everyday life tasks, normal balance is largely unconscious and does not compete for attentional resources. In clients with balance disorders, however, the challenge of maintaining postural control during upright activities and gait is often sufficient to demand the use of attentional resources. The interaction of cognitive demands and postural control demands is examined in dual-task tests that add concurrent cognitive and motor tasks to gait tasks. At the simplest level are the walking while talking (WWT) and stops walking when talking (SWWT) tests.⁹²⁻⁹⁵ In these tests the client is asked to walk and, while the client is walking, the clinician asks the client one or more questions and observes if the client must stop walking to answer the question(s). If so, the test result is positive—that is, the client must stop attending to the postural control demands of walking to reallocate attention to the cognitive task. These are gross measures, apt to identify only those with more severe attentional balance problems or to misidentify clients who prefer to chat and rest rather than keep walking. A more formalized dual-task test is the Multiple Tasks Test (MTT), which includes eight items involving gait plus other verbal cognitive and motor tasks such as carrying a tray and avoiding obstacles.^{96,97} Two dual-task versions of the TUG have been developed. The TUG-Manual involves performing the TUG while carrying a cup nearly full of water. The TUG-Cognitive involves performing the TUG while subtracting backward from a randomly selected number or spelling words backward.⁹⁸ The Walking and Remembering Test (WART) requires the client to remember a set of numbers that the tester speaks aloud while the client walks as quickly as possible while trying not to step off of a narrow path.⁹⁹ Once the walk is completed, the client must repeat the numbers in sequence. For all dual-task tests, performance of each single task is measured separately first. Then the dual-task performance is recorded. The difference for each of the two scores (physical and cognitive performance) between undivided attention and divided attention conditions is calculated.

Balance Confidence Tests

Reduced participation in functional activities may occur not only because balance impairments impede participation, but also when clients are anxious about falling. Fear of falling may lead individuals to avoid activities that they remain quite capable of doing.¹⁰⁰ In turn, prolonged self-restriction of activity leads to the many negative consequences of being sedentary—decreased ROM, weakness, low endurance, and so on—and thus ironically further impairs balance and increases fall risk.^{101,102} As this worsening balance and increased risk is perceived by the client, further activity restriction occurs, creating a self-perpetuating downward spiral leading to social isolation, anxiety, and depression.^{103,104} It is just as important to address poor balance confidence as it is to address poor balance, for without sufficient balance confidence a client will not participate in activities even if balance abilities permit him or her to do so. The client will lose all the gains made in therapy if he or she does not remain active, and he or she will not be active if fearful of falling.

The two most commonly used measures of balance confidence are the Activities-specific Balance Confidence Scale (ABC Scale), and the Falls Efficacy Scale (FES).^{105,106} Both

are questionnaires that are easy to administer. The ABC Scale consists of 16 items that range in difficulty from “walk around the house” to “walk outside on icy sidewalks.” Several of the items inquire about activities in public places, for example, parking lots and escalators. Clients are asked how confident they are that they could do each of the activities without losing their balance or becoming unsteady. Responses are given on a scale from 0 to 100 in increments of 10, with higher numbers indicating higher confidence. More recently a short version, the ABC-6, has been developed. It has six of the original 16 items and takes less time to administer, yet retains good reliability and correlation with balance and fall risk measures.¹⁰⁷ The FES consists of 10 activity items that are less difficult than the items on the ABC Scale. Items on the FES include getting in and out of a chair and answering the door or a phone. All of the items refer to activities done in the home. Clients are asked how confident they are that they could do each of the activities without falling. Responses are given on a scale from 1 to 10, with lower numbers indicating higher confidence. The Modified FES (MFES) has 14 activity items and includes two activities done outside the home and three activities done in public spaces. It also takes into account whether or not an assistive device is used.¹⁰⁸ Scoring is identical to that of the original FES.

A third measure of fear of falling is the Survey of Activities and Fear of Falling in the Elderly (SAFFE).¹⁰⁹ This measurement instrument is more involved than the ABC Scale or MFES; however, it provides additional information specific to activity restriction that is valuable to the clinician. The SAFFE has 11 activity items that are similar in nature to the items on the other two scales, including community activities. This questionnaire asks if the client actually does the activity or not. If he or she does the activity, the questionnaire asks how worried the client is that he or she might fall during the activity, on a scale from 1 to 4. Lower numbers indicate increased worry. If the client does not do the activity, the client is asked whether the reason he or she does not do the activity is fear of falling, with degree of fear scored on the scale from 1 to 4, or whether the client does not do the activity for reasons other than fear, and what those other reasons are. For each item, clients also indicate whether the frequency of doing the activity has increased, decreased, or remained the same. The SAFFE takes longer to administer than the ABC Scale or MFES but provides explicit results about activity restriction not obtained from the other two scales.

The Fear of Falling Avoidance Behavior Questionnaire (FFABQ) is a recently developed instrument with a focus on activity avoidance versus fear.¹¹⁰ It lists 14 different activities, ranging in difficulty from walking and preparing meals to going up and down stairs to engaging in recreational activities such as sports or traveling. Clients rate whether or not they agree with a statement that they avoid a specified activity on a 5-point scale from 0 (completely disagree) to 4 (completely agree). This questionnaire is reliable, with scores that discriminate between previous fallers and non-fallers, and more versus less active individuals. The shift from an emphasis on fear or confidence as in the ABC and FES, to activity avoidance as in the SAFFE and FFABQ is an important and positive one for physical and occupational therapists. As the ICF health and disablement model describes, our goals are to increase activity and participation to achieve an improved quality of life for our clients.

Considerations in the Selection of Balance Tests

To determine the type and level of challenge of the tests to be used during the examination, a thorough subjective history is critical. In describing the symptoms and the situations that cause dizziness or imbalance, the client offers clues to possible deficits and thereby the measures that will help identify them.

Many of the functional scales previously reviewed were designed to determine whether balance is abnormal in elderly clients who have no medical diagnosis, in other words, as screening tools. Clinicians working with clearly diagnosed clients with neurological conditions often do not need such tools to establish that balance skills are abnormal because the deficits are patently obvious. These screening tools can be useful, however, to identify disabilities, establish a baseline, monitor progress, and document outcomes.

Many clinical facilities have their own therapy evaluation forms that include a section on balance. Items and scoring are usually defined by the facility. They are not standardized across sites, as are published scales, and are rarely tested for measurement qualities such as validity and reliability. As rehabilitation professions evolve toward evidence-based practice, nonstandardized tests with unknown measurement quality are no longer acceptable. Clinicians should use standardized, objective, quantifiable, valid tests with high reliability, sensitivity, and specificity whenever possible. Facilities insistent on using their own tests should conduct research to ensure that they are valid, reliable, and responsive to change over time. A functional balance rating scale is important in the evaluation of clients with neurological impairment. To be responsive enough to measure changes in clients who clearly are not (and may never be) clinically normal, scales should have at least five, and perhaps seven, possible relative scores.

In addition, additional tests are necessary to assess the systems that may affect postural control to help identify and measure impairments (e.g., ROM, strength, sensation and sensory organization, motor planning and control). These types of measures should be sensitive, objective, and quantifiable. Unfortunately, some body system components do not have objective, quantifiable clinical measures (e.g., motor planning, coordination). In these cases, clinicians must continue to use subjective rating scales.

Other factors to include when deciding what tests to use are the time required to perform the test, the number of staff members who must be present, and the space and equipment needed. Clinicians must weigh the potential benefits of technological tools (e.g., computerized forceplates, isokinetics, motion analysis, electromyography) against their cost and practicality (i.e., their cost-effectiveness). The test must be suitable for the client's level of functioning (physical and cognitive). Many head-injured clients, for example, cannot initially participate in traditional forms of testing because of cognitive limitations.

PROBLEM IDENTIFICATION, GOAL SETTING, AND TREATMENT PLANNING

Clinical Decision Making

Treatment of clients with neurological diagnoses is based on the particular set of impairments and activity limitations possessed by each individual. Remediation of balance deficits similarly must be specific to the involved body systems and functional activity losses in each client. Clinicians should generate an overall problem list for each client; if imbalance is a listed problem, then a sublist of balance problems also can be developed (Figure 22-16).

EXAMPLE OF BALANCE PROBLEM LIST

General Problem List	Balance Problem List
1. Decreased strength (L) side	
2. Decreased ROM (L) shoulder	
3. Decreased endurance	
4. Impaired sensation (L) side	
5. Decreased balance	<ul style="list-style-type: none"> a. Decreased weight bearing on left (L) LE b. Unable to maintain midline orientation c. Extraneous sway with eyes closed d. Unable to stand on (L) LE e. Decreased limits of stability to 40/100% f. Unable to shift to (L) side g. Unable to establish stable base of support h. Unable to stand on unstable surface i. Unable to perform hip strategy
6. Increased tone (L) side	
7. Synergistic movement (L) side	
8. Min. assist transfers	
9. Mod. assist ambulation	

Figure 22-16 ■ An example of a balance-specific problem list (as a subset of a general problem list), which should be developed to guide balance rehabilitation treatments.

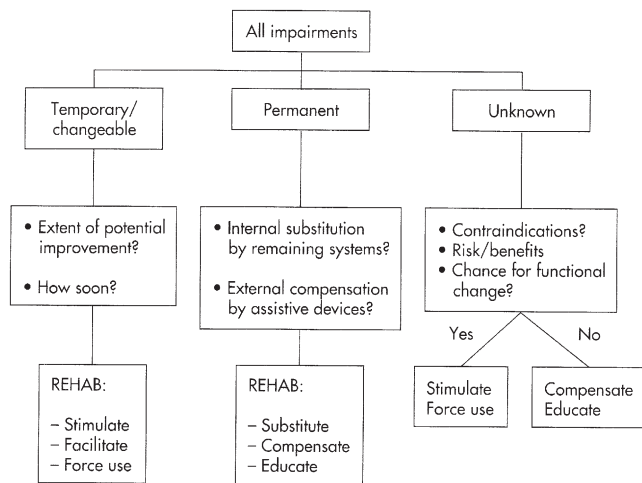

Figure 22-17 ■ A clinical decision-making tree to illustrate the treatment-planning process in balance rehabilitation.

To direct and establish priorities for treatment, clinicians must review the problem list and ask themselves the following questions (Figure 22-17): Which impairments are temporary and can be remediated? How much improvement can be expected? How soon will it occur? Which impairments are permanent or progressive and must be compensated for? What other body systems can be counted on to substitute? What external compensations may be needed?

For some clients with neurological impairments, knowing whether a problem is permanent or temporary is not possible, as in recovery from a stroke or head injury. In

others with progressive diseases such as Parkinson disease or MS, the rate of decline is unknown and abilities may fluctuate. In these cases the clinician should consider the following issues: Would a consultation provide the required information? If so, referral is appropriate. Do any contraindications to treatment exist? What are the risks and benefits of providing versus withholding treatment? Is some amount of functional improvement possible? If no contraindications are present, the benefits outweigh the risks, and functional improvement is expected, then a trial of treatment may be given, even if knowing for certain whether the problem(s) will respond to the treatment is not possible. In these cases especially, a baseline must be established against which to measure any change. Change for the worse or no change after a reasonable trial period indicates that treatment should be altered or discontinued.

Using the Systems Model to Identify Postural Control Impairments

The systems approach is useful to develop a balance problem list because it can be applied to different diagnoses equally well and allows deficits in multiple systems to be recognized. Table 22-4 illustrates several examples of ways this framework is used to identify balance deficits in clients with different neurological diagnoses.

For each client, problems affecting postural control should be described in objective, measurable terms whenever possible. For example, the term “impaired vision” is too vague; “four-line drop on eye chart” is more specific. “Poor use of visual inputs for balance control” is an interpretation; the objective result could be stated “Loss of balance after less than 15 seconds on 5/5 trials of standing on

TABLE 22-4 ■ EXAMPLES OF MEDICAL DIAGNOSES AND RELATED IMPAIRMENTS AFFECTING BALANCE

IMPAIRMENTS FROM SYSTEMS MODEL	CLIENT WITH DIABETIC STROKE	CLIENT WITH PARKINSON DISEASE	CLIENT WITH INCOMPLETE PARAPLEGIA
PERIPHERAL SENSORY			
Vision	Retinopathy	Cataracts	
Vestibular		Hair cell loss	
Somatosensory	Peripheral neuropathy	Slowed transmission time	Complete loss
CENTRAL SENSORY			
Vision	Hemianopia	Vision dominant	Needs superior use to compensate
Vestibular	Failure to use inputs		Needs superior use to compensate
Somatosensory	Failure to use inputs	Failure to use inputs	
Strategy selection	Step dominant	Ankle dominant	Hip dominant
Perception of position in space	Midline shift with left neglect	Restricted limits of stability	
CENTRAL MOTOR			
Timing	Increased reaction time	Bradykinesia	
Sequencing	Disordered	Co-contraction	
Force modulation	Spasticity	Rigidity	
Error correction	Use right side only		
PERIPHERAL MOTOR			
Range of motion	Knee hyperextension	Bilateral ankle plantar flexor contractures	Hip flexion contractures
Strength	Decreased left side	Decreased bilateral extremities and trunk	Severe weakness bilateral lower extremities and trunk
Endurance	Severely impaired	Moderately impaired	Mildly impaired

foam, eyes open.” Documenting problems in this manner makes goal writing (and subsequent treatment planning) much easier.

Writing Goals on the Basis of Body Structure and Function Impairments and Activity Limitations

Goals also should be stated in objective and measurable terms so that their achievement can be judged. “Improved balance” is open to any interpretation, whereas “able to stand on right leg for 30 seconds on 3/3 trials” and “walks tandem entire length of balance beam without misstep 7/10 times” are measurable goals. These types of goals may be helpful to the clinician who understands the link between impairments and function, but they may seem nonfunctional (and therefore unnecessary) to others who read them (e.g., case managers, third-party payers). From their standpoint, incorporating the functional task that will be positively affected by its achievement into the impairment goal is beneficial; for example, “able to stand on right leg for 10 seconds at a time so that stairs can be ascended and descended step-over-step without railing,” or “walks tandem on balance beam to demonstrate ability to avoid falls using hip strategy.” By describing the specific system problem (e.g., power, range, balance strategies) as it relates to function in the treatment objectives, clinicians force themselves to focus on functional outcomes and illustrate for others why these goals are meaningful. The need for and validity of the treatment are then more likely to be clearly perceived. At times, goal documentation requirements may specify that the goals be purely functional in nature. Writing goals without impairment components may meet the needs of the reviewer, but they will not help to direct clinical interventions to the specific components that need to be addressed in each individual client. Documentation must meet reviewer requirements, but for one’s own benefit, writing a separate set of goals with the dual impairment-function component will assist the clinician with planning and prioritizing treatment.

If a problem cannot be alleviated and requires compensation, the goal(s) should reflect this as well. For example, a client with diabetes has progressive peripheral neuropathy with somatosensory loss and ineffective ankle strategy. If the client’s visual and vestibular sensory systems and proximal strength are relatively intact, however, then the goals might mention improved use of visual cues and successful substitution of hip and stepping strategies. Educational and environmental modification goals for safety also are appropriate in these situations.

Developing a Treatment Plan

Once the goals have been listed and priorities established, the treatment plan is developed. The most effective and efficient treatments focus first on those problems with the greatest impact on function and address more than one problem at a time. Training balance on an unstable surface contributes to the use of visual and vestibular inputs as well as to the use of hip strategy, increased lower-extremity strength, and increased motor control (skill) on that type of surface. Training gait on an inclined treadmill with eyes closed or head movement increases the use of somatosensory and vestibular inputs, endurance, postural control, ROM, and lower-extremity strength. Creative clinicians develop comprehensive treatment plans

with this type of multiple-problem approach to maximize the time available with clients.

The clinician must thoughtfully choose environments and tasks that together stimulate and challenge the appropriate postural control systems. To stimulate one sensory system, the other systems must be placed at a disadvantage to force reliance on the targeted system. The environment is then structured to put the other systems at a disadvantage (e.g., training with eyes closed or in the dark puts vision at a disadvantage and forces the use of somatosensory and vestibular inputs). If one side or limb is significantly more affected, such as in hemiplegia, then the other side must be disadvantaged to force reliance on the targeted side. Tasks are then selected to disadvantage the less affected side. For example, placing the less affected leg on a step or small ball makes it more difficult to use for balance and forces the transference of weight to the more affected leg. To achieve optimal function, however, all systems and all sides must be capable of working together, so training to improve balance impairments must be incorporated and interspersed with training functional tasks. For carryover of improvements into real-life situations, training tasks should be varied enough to promote motor problem solving on the part of the client.¹¹¹ For example, sitting balance and transfers should be taught using stable and unstable surfaces, with different heights and firmnesses, with and without armrests and back supports, and using both right and left sides. This technique may improve the client’s abilities to perform safe sitting and transfers in new situations not previously practiced in therapy.²⁴

Tables 22-5 through 22-7 illustrate the process of test choice, problem identification based on test results, goal setting based on impairments and disabilities, and treatment planning based on goals in three different types of clients. Note that only selected tests were performed for each client. Goals were directly related to the problems that were identified by the tests, and treatment plans followed directly from the goals.

BALANCE RETRAINING TECHNIQUES

Motor Learning Concepts

Although covering the principles of motor learning is not within the scope of this chapter (refer to Chapter 4), the discussion of balance retraining methods is not possible without some consideration of several motor learning concepts that must be incorporated into treatment. The clinician must remember that successful treatments address the interaction of the individual, the task, and the environment (Figure 22-18).^{12,24}

Individual

Therapists should know their clients’ impairments: sensory and motor, peripheral, and central. Whenever possible, therapists should know which impairments can be rehabilitated and which require compensation or substitution. Because of the nature of neurological insult, this includes an awareness of cognitive and perceptual impairments that may affect the ability to relearn old skills or develop new ones. Optimal learning of skilled movement requires that the client have (1) knowledge of self (abilities and limitations), (2) knowledge of the environment (opportunities and risks),

TABLE 22-5 ■ AN EXAMPLE OF TEST SELECTION, PROBLEM IDENTIFICATION, GOAL SETTING, AND TREATMENT PLANNING IN A CLIENT WITH PERIPHERAL VESTIBULAR DEFICIT

Patient profile: 50-year-old woman

Diagnosis: Uncompensated (R) unilateral peripheral vestibular deficit for 6-7 years

Course of examination and treatment: Otolaryngologist → psychologist → neuro-otologist → outpatient physical therapy

TEST	PROBLEMS IDENTIFIED	GOALS SET	TREATMENT PLAN
Visual acuity	Four-line drop on Snellen eye chart	Able to read chart with only one-line drop	Gaze stabilization exercises
Oculomotor Saccades Pursuit Nystagmus	Positive nystagmus with Frenzel lenses		
Gaze stabilization Visual-vestibular interaction VOR cancellation Hallpike	Unable to perform test ↓ Fixation with horizontal + vertical head movements after 5-10 s	Able to rotate head horizontally 2 min without problems	Gaze stabilization exercises
SOT	Decreased use of somatosensory inputs 70/100 Decreased use of visual inputs 55/100 Absent use of vestibular inputs 0/100 Unable to resolve visual conflict 0/100	Somatosensory use 100/100 Vision use 90/100 Vestibular use 70/100 Visual conflict resolution 90/100	Sensory environment stimulation
Limits of stability	Restricted anteriorly and posteriorly to 35% limit of stability Slow movement time	Limits of stability expanded to 85% anterior and posterior at 5-s pacing	COG control training
ROM and strength Gait	None		Gait training
Eyes open Eyes closed Head turning	Weaves side to side Deviates to (R) with eyes closed Dizzy with horizontal head turns	Walks in a straight line with eyes closed Walks with only slight deviation with eyes closed and head turning	
Pivots	Loss of balance and dizzy with (R) pivot	Spins to (R), (L) with eyes closed	
Abrupt stops	Very unsteady with abrupt stop; feels "off"	Comes to abrupt stop steadily

(3) knowledge of the task (critical components), (4) the ability to use those knowledge sets to solve motor problems, and (5) the ability to modify and adapt movements as the task and environment change. To the extent that a client is missing these characteristics, the clinician should attempt to support his or her development or even supply them until they are present. Different types of clients vary with regard to which characteristics are likely to be missing. For example, a cognitively impaired, head-injured client may lack awareness of self and environment, even though his or her physical abilities make modifying and adapting movements possible. Conversely, a quadriplegic client may be aware of his or her limitations, the environment, and the task demands but may initially have limited experience to know how to solve a motor problem and limited physical ability to modify movements.

The clinician must also ask what motor learning stage the client is in for different tasks. Skill acquisition is the first stage. The objective is for the client to "get the idea of the movement" to begin to acquire the skill.¹¹² In this stage,

errors are frequent and performance is inefficient and inconsistent. Within the nervous system only temporary changes are occurring. Skill refinement is the second stage. The goal is for the client to improve the performance, reduce the number and size of the errors, and increase the consistency and efficiency of the movements. Skill retention is the final stage. The ability to perform the movements and achieve the functional goal has been accomplished, and the new objective is to retain the skill over time and transfer the skill to different settings. Retention and transfer are the hallmarks of true learning, in which some relatively permanent changes have occurred within the nervous system. A client may have attained the skill retention phase for sitting balance tasks, be in the skill refinement stage for standing balance tasks, and be in the skill acquisition stage for locomotor balance tasks.

Therapists use practice and feedback to teach motor skills. Repetition is necessary to develop skill; feedback is necessary to detect and correct errors. During skill acquisition, frequent repetition of a movement or task and frequent feedback are beneficial to help the client begin to be able to

TABLE 22-6 ■ EXAMPLE OF HOW TREATMENT PLANNING FLOWS FROM TEST RESULTS IN AN ELDERLY CLIENT WITH FREQUENT FALLS

Patient profile: 72-year-old woman

Diagnosis: Disequilibrium of aging, frequent falls

Course of examination and treatment: Cardiologist → neurologist → outpatient physical therapy

TEST	PROBLEMS IDENTIFIED	GOALS SET	TREATMENT PLAN
Peripheral sensory	Mildly decreased vibration sense bilateral lower extremity	Compensate for permanent sensory loss	Educate about safe surfaces and lighting Home safety evaluation
Somatosensory	↓ Acuity, cataracts		
Vision	↓ Depth perception		
SOT	Absent use of vestibular inputs 0/100 Decreased use of somatosensory inputs 60/100 Dependent on vision	Increase use of vestibular inputs to 30/100 Increase use of somatosensory inputs to 75/100	Somatosensory and vestibular stimulation*
Static postural sway	Excessive sway—2 standard devia- tions outside normal range for age	Standing sway within normal limits for age	COG control training
Nudge or push test	No use of ankle or hip strategy Steps immediately	Survives 5/10 pushes with hip strategy	Hip strategy exercises*
LOS	No ankle strategy—uses hip strategy Sway to 45% LOS anterior, 35% LOS posterior Slow movement time	Uses ankle strategy to reach 40% LOS anterior and posterior Reaches 8/8 targets at 75% LOS using hip or ankle strategy within 4 s	COG control training
ROM	↓ Neck extension 0-10 degrees ↓ Lumbar extension 1-15 degrees ↓ Hip extension 0-5 degrees	↑ Spinal extension neck 0-20 degrees ↑ Lumbar extension 0-20 degrees ↑ Hip extension 0-10 degrees	ROM exercises*
Strength	Flexion 4/5 (B) Hip abduction 3+/5, extension 3/5 (B) Knee extension 4+/5, flexion 4/5 (R) Ankle dorsiflexion 3–/5 (L) Ankle dorsiflexion 2/5 (B) Ankle plantarflexion 3+/5	↑ (B) Hip abduction and extension to greater than 4/5 ↑ (B) Ankle dorsiflexion and plantarflexion to 4–/5	Progressive resistive exercises, including bicycle*
Gait (GARS)	Score 35/48 Deviations Forward flexed trunk Double limb stance prolonged bilaterally Short step length	GARS scales 25/48 (I) Ambulation with walker in home, community	Gait training* 1—starts, stops, turns 2—treadmill 3—uneven surfaces, curbs, stairs, carpet, outdoors
Endurance	Fatigue after ambulating 60 ft	Ambulates more than 200 ft without stopping	Gait training as earlier
Tinetti balance scale	6/16 score	Tinetti balance score 10/16	Gait training as earlier
Tinetti gait scale	5/12 score Falls and catches self	Tinetti gait score 8/12	Gait training as earlier

perform the desired movements and tasks. As soon as the client progresses to the skill refinement stage (the clinician observes reduced errors and less variable performance), however, then practice should be varied and feedback briefly delayed. For example, the task of standing and reaching to one side to take an object from the therapist might initially be repeated to the same side and at the same height several times. Then the therapist should begin to vary the task demands gradually: reach farther or faster; take different

objects of various weights, shapes, and sizes; and take the object from higher and lower heights and alternately reach to right and left sides. This variation introduces a problem-solving demand for the client: modifications in timing, force, and sequencing are now necessary.¹¹¹

Feedback, which is especially helpful for those with sensory reception or perception problems, initially may contain information to assist the client in detecting errors about the goal achievement (knowledge of results, such as “you did

TABLE 22-7 ■ AN EXAMPLE OF HOW TREATMENT PLANNING FLOWS FROM TEST RESULTS IN A CLIENT WITH RIGHT HEMIPARESIS

Patient profile: 69-year-old woman

Diagnosis: Left cerebrovascular accident with right hemiparesis

Course of examination and treatment: Acute rehabilitation → home health → outpatient rehabilitation

TEST	PROBLEMS IDENTIFIED	GOALS SET	TREATMENT PLAN
Peripheral somatosensory SOT	Average overall stability 47/100 Absent use of vestibular inputs 0/100	None Average stability 60/100 ↑ Use of vestibular inputs 15/100	Vestibular stimulation with forced use and head movements COG control training
Postural sway			
Functional reach	Forward lean restricted to 5 inches	Able to reach forward 8 inches	
Static balance	Weight shift asymmetry to left in static standing and medial or lateral sway, 25% LOS to left of midline	↑ Control of COG Stands midline	
Limit of stability	Forward weight shift restricted to 25% LOS	↑ Forward LOS to 50% ↑ Right LOS to 50%	
Rhythmic weight shift	Extraneous sway off desired path	↓ Extraneous sway scores by 50%	
OLST	Unable on right leg, 30 seconds on left leg	Stands on right leg, 10 seconds	COG control training
Nudge, push (motor strategy selection)	Switch from ankle to hip strategy noted but unable to withstand perturbation	Able to stand upright after mild perturbations 5/10 times Able to “catch” self by stepping or reaching 5/10 times	Hip and stepping strategy training
Range of motion	None		
Strength: right leg	4/5 Knee extension 3/5 Knee flexion 2/5 Ankle dorsiflexion 3/5 Ankle plantarflexion	↑ RLE strength 5/5 Knee 4/5 Ankle	Progressive resistive exercises
Endurance	Standing tolerance less than 10 minutes	Able to stand unaided for 15 minutes	Standing tolerance tasks
Gait	↓ Step length—RLE ↓ Step height—RLE ↓ Heel strike—RLE ↓ Toe-off—RLE	Symmetrical step height and length 5/10 times ↑ Heel strike RLE 5/10 times	Gait training on treadmill
Tinetti Gait Subscale	Unable to turn, reach, or bend without loss of balance Falls: Uneven surfaces Low lighting Head turning No community ambulation Requires cane Requires supervision for household ambulation	8/12 score No falls Gait independent without cane in household; with cane in community	Gait training on uneven surfaces, with head movements, with low lighting Safety education

not lean far enough to reach this last time”) or about a movement error (knowledge of performance, “you did not straighten your knee enough last time”).¹¹³ Early feedback also may contain cues about what to do better next time, such as “straighten your knee before you shift weight onto that leg.” If feedback is always provided by an external source, such as the therapist, a mirror, or a computer monitor, then the client is not given the opportunity to develop internal error detection and error correction mechanisms and will not be as likely to retain or transfer the skill. By delaying the feedback and asking the client to estimate or

describe her or his own errors, and afterward providing the feedback, the therapist allows the client to compare her or his own developing internal frame of reference with the correct external frame of reference. By asking clients to suggest what might be done to correct the errors, the therapist shifts the error correction process from the external source to the clients, supporting motor problem-solving processes. As clients progress to the skill retention level, variations should increase (including task and environmental demands) and feedback delays should be longer. The clinician must develop a sense of how to use practice variation and feedback

Figure 22-18 ■ Interactions of the individual, the environment, and the task are critical to postural control skills. Although they may be isolated in the mind of the clinician for assessment purposes, they are never isolated in the function of the client.

delay therapeutically to progress clients through the stages of motor learning. Too much variation and too little feedback early on impede skill acquisition; insufficient variation and excessive feedback later on hamper skill retention and transfer.

Task

Functional rating scales performed as a part of the evaluation yield information about what tasks, or functional activities, are limited by the postural control impairments. Bed mobility, sitting, sitting to standing, transfers, standing, walking, working, and sports participation may be affected. Repeating the problematic tasks over and over is one approach; however, analyzing the problematic tasks to determine what postural control demands are placed on the client when undertaking those tasks is far more productive for the clinician. Does a task demand predominantly stability? Mobility? Both? For example, standing to take a photograph demands the ability to hold still, standing to move laundry from the washer to the dryer requires weight shifting, and standing to don a pair of pantyhose calls for both steadiness and movement. All three are standing tasks, but each places different postural control demands on the client. By using task analysis, the therapist may consciously select or design tasks to place specific demands on the client such that the postural control systems that need improvement will be challenged to respond.

Analysis of mobility tasks includes attention to timing, force, and duration of movements. Consider the different timing demands for weight shifting and reaching to catch an item falling from a shelf, take a hot casserole out of the oven, or open a door. Compare the different amounts of force necessary to pick up a heavy suitcase, pick up a baby from a crib, or replace a ceiling light bulb. The duration of a balance demand may be brief, as in recovering from a trip, or extended, as in walking across an icy parking lot. Clinicians should choose tasks that vary these parameters to prepare clients for activities with various mobility demands. Activities that incorporate changing head positions will further challenge the individual with vestibular insufficiency.

Therapists also need to consider whether the elements of the task are predictable or unpredictable. In other words, will the postural control demand be a voluntary movement (e.g., sweeping the porch), an automatic postural response (e.g., missing the last step on a flight of stairs), or an antici-

patory postural adjustment (e.g., preceding a lift)? Clients need to learn to respond in all three conditions, which are often combined. For instance, lifting is a voluntary movement. Predicting the load to be lifted leads to anticipatory postural preparation. Counteracting the destabilizing force of a greater-than-predicted load requires an automatic postural response. If, during therapy, the clinician says “don’t let me push you” before nudging the client, the demand is for anticipatory postural adjustment. If the disturbance is provided without warning, the demand calls for APRs. If the clinician requests a lean to the right, that is a voluntary postural adjustment. Activities that demand all three types of balance control, either one at a time or in combination, should be included in balance retraining programs.

Environment

Just as tasks can be purposefully selected to promote postural control responses, environmental conditions also must be included in the design of the therapy plan to stimulate the necessary systems. Gravity cannot be manipulated by the clinician, but the client needs to learn to counteract it at different speeds and from different positions, among other things. Familiarity with how gravity can aid movement, as in walking, is also important. The therapist can vary the surface conditions. They may be stable, even, and predictable (hospital hallway, sidewalk), unstable (boat, subway, gravel driveway), uneven (grass, curbs, stairs), or compliant (beach, padded carpeting). Visual conditions also may be manipulated. Visual cues may be available and accurate (daylight, fluorescent lighting), unavailable (darkness or poor lighting, or lack of environmental cues such as a busy carpet pattern on a stairway), unstable (moving crowd, public transportation), used for purposes other than balance (fixation on a ball in tennis), or dependent on head movements. Clinicians should help prepare their clients to function in the real world by training them to maintain balance under different combinations of surface and visual conditions. This includes situations in which cues from the environment agree—that is, visual, somatosensory, and vestibular inputs are all sending the same message, so to speak—as well as in sensory conflict environments, where cues from one system may disagree with (not match) cues from the other sensory systems. Functional situations in which sensory conflicts may exist include elevators, escalators, people movers, airplanes, and subways. An emphasis on being able to adapt to changes in environmental conditions rapidly and effectively is important.

Intervention

Successful intervention for the individual with a balance disorder depends on the ability of the *clinician* to identify the components of the problem. The therapist must create a program that addresses several components at a time, not just for efficiency, but because these systems should be able to function together to perform functional activities in real-world environments. Treatment is oriented toward multiple impairments, with tasks and environments selected to best correct involved or facilitate compensatory systems.

The intervention must be matched to the level and combination of body system impairments. For example, tasks related to the different functions of the sensory systems should be identified and not treated as a single body system

problem. The clinician should have a good idea of the level of stimulus during each exercise program so that the facilitation is as accurate as possible. Progression of the program follows the changes seen from one intervention to the next to promote carryover and retention of learning. The exercise progression integrates activities that reflect those changes. This usually involves more complex movement skills in a greater range of gradually more challenging environments.

Sensory Systems

In general, the less sensory information available, the more difficult the task of balancing. A treatment progression might therefore start with full sensory inputs (vision, somatosensory, and vestibular: 3/3) available in the environment and perhaps augmented feedback if intrinsic sensory channels are deficient, as with somatosensory loss or a vestibular disorder. Challenge is added by manipulating either visual or somatosensory inputs, so that equilibrium must be maintained by using only two of three senses (vision and vestibular or somatosensory and vestibular). If both vision and somatosensory inputs are manipulated, then only the vestibular inputs are a reliable source of sensory information and balance is accomplished with only one of three senses.¹¹⁴

Most patients with permanent or progressive vestibular or somatosensory losses naturally compensate and become visually dependent. In cases in which improving the use of somatosensory or vestibular inputs is necessary, the training of vision for stability can be counterproductive, teaching compensation versus improvement of normal function. On the other hand, visual retraining is entirely appropriate for the client with severely compromised somatosensation that cannot be changed, as is common in persons with diabetes.

To stimulate the use of visual inputs, environments are designed to disadvantage somatosensation while providing reliable visual cues (stable visual field with landmarks). Somatosensation cannot be removed as can vision, but it can be destabilized by having the client sit or stand on unstable surfaces (rocker board, biomechanical ankle platform system [BAPS] board, randomly moving platforms) or confused by having the client sit or stand on compliant surfaces that give way to pressure, such as foam, “space boots,” or responsively moving platforms.

To stimulate the use of somatosensory inputs, environments are designed to disadvantage vision while providing reliable somatosensory inputs (stable surfaces, level or inclined). Having the client close the eyes or practice in low lighting or darkness removes or decreases visual inputs. For clients with an overreliance on visual input for balance, the somatosensory system needs to be facilitated while the visual system is disrupted. This can be accomplished by having the client sit or stand on a stable surface while performing quick head turns. For the client with self-limited head movement, the intervention may begin with head movement during quiet standing and progress to head movements during weight shifts and then walking. Eyes-closed standing and weight shifting also increase the use of somatosensation for balance. Optokinetic stimuli in the visual surround also stimulate use of somatosensory inputs.

To stimulate the use of vestibular inputs for adaptation of the CNS, environments are designed to disadvantage both vision and somatosensation while providing reliable vestibular cues (detectable head position). Practicing on unstable

or compliant surfaces, with vision either absent (eyes closed), destabilized (eye movements or head movements), or confused (e.g., optokinetic stimulation) provides challenging combinations. Adding neck extension and rotation to place the vestibular organs at a disadvantaged angle can increase difficulty. Gaze stabilization with head turns while standing on an uneven surface or while walking creates a higher-level challenge. Quick movements of the head, head tilts, or forward bending trigger vestibular signals to add input to the system. Combining these types of activities can create progressively more complex challenges. Standing or weight shifting on foam with eyes closed, and head and eye movement while walking all require vestibular input for successful performance.

Additional vestibular challenge can be added by including activities that require quick changes of position in a superior or inferior direction, such as a lunge or going up and down stairs. Other exercises involving up-and-down body movements, such as sitting to standing, seated bouncing on a Swiss ball, and standing bouncing on a mini-trampoline, all with eyes closed to eliminate use of vision for stability, increase the demand on the vestibular system. To train the client who is overreliant on vision to improve the use of vestibular inputs versus vision, activities such as watching a ball being tossed from hand to hand while walking, walking backward, or walking with eye movements can be used. Reading while walking requires the use of vision for reading so that it cannot be used for postural orientation, forcing the other sensory sources to be used for orientation.

Multisensory and Motor Control Dysfunction

Older clients often have dysfunction in all three sensory systems—that is, a multisensory balance disorder. Disease-related disruptions of the somatosensory or visual system (e.g., a peripheral neuropathy or cataracts) are combined with age-related declines in the vestibular system. In some cases therapy aimed at increasing vestibular function can have a significant impact on postural stability. If sensory loss is permanent or progressive, safe function may require the use of an assistive device.¹¹⁵ Choosing an assistive device for these clients can be a challenge. An individual with cerebellar or visual-perceptual problems may have more difficulty using an assistive device, and thus it may be contraindicated. For these clients, careful assessment of safety and gait both with and without the device is demanded. A single cane often does not allow for compensation for changes in direction of an impending fall, and a standard aluminum walker does not provide support when changing directions because it must be lifted. The ideal walker has four rotating wheels and thus the ability to change direction without being lifted. This device greatly increases stability, and the client usually describes a significant increase in confidence. Of course, the use of a walker also limits normal use of the upper extremities and trunk during gait and restricts the types of environments that can be negotiated. Making sure the client stands erect in walking versus leaning forward into a permanent flexed position is important in order to retain and/or improve existing postural function.

Many clients with neurological conditions have temporary difficulty with head control early in their recovery, and others have chronic head control problems. Their ability to orient the vestibular organs, eyes, and neck proprioceptors

properly is impaired, which negatively affects the ability to perceive internal and environmental cues that could assist in balance maintenance. Thus, developing head control is very important. (Refer to Chapter 9 for examples of how to improve head control.) Clients with spasticity or contractures of the ankles and feet who cannot place their feet in full contact with the floor are at a biomechanical disadvantage and also have difficulty receiving somatosensory inputs that could support postural control processes. The more accurate and reliable sensory information available, the greater the chances that the sensoriperceptual processes that contribute to balance can fulfill their role. Treatment progressions should include attention to increasing the client's ability to receive and process sensory information pertinent to balance control through oculomotor, head, and peripheral limb positioning and movement.

Control of the Center of Gravity

Effective control of the COG depends on accurate awareness of body position and motion in space and the relation between body parts (perception) as well as biomechanical and musculoskeletal systems (execution). Trunk and head control abilities are primary. For clients with paralysis or degenerative disease that limits the ability of arms and legs to assist with postural stability, head and trunk control may be the dominant means of balance. Both the head and neck and the trunk need to be able to achieve and hold a midline position, rotate around this midline axis, and move away from and return to the midline without loss of balance. The term *midline* here refers not to a line between right and left sides but to a point at which the right and left and forward and backward components are centered in all planes—medial-lateral, anterior-posterior, rotary, and side bending (shortening and elongation on either side). Midline problems can certainly be caused by body system problems such as weakness, pain, or sensory deficits but can also be caused by perceptual problems that have nothing to do with balance deficits but do cause balance problems.

Sitting Balance. In sitting the pelvis and posterior thighs form the primary base of support, with additional stability provided by the feet in contact with the floor. The axis of anteroposterior movement rotates around the greater trochanter, and forward and backward leans are achieved through pelvic and trunk movement. Anterior pelvic tilt with upper trunk extension allows forward reaching and begins the sitting-to-standing transition. Lateral weight shifts with trunk elongation precede right and left reaching and scooting. Lateral weight shifts with trunk rotation permit cross-midline reaching and begin the sitting-to-supine progression. The use of arms to prop in sitting is an extension of the base of support.

Standing Balance. In standing, the feet form the base of support. The axis of anteroposterior movement rotates around the medial malleolus. Mediolateral movement occurs with weight shifts from foot to foot. Weight shifts move the COG through space for reaching and lifting tasks as well as in preparation for stepping. Ankle strategy is most effective for forward and backward movement of the COG through the limits of stability on a stable surface. As the COG nears the sway boundary, hip strategy works to restrict its travel. If this fails, stepping or reaching strategies are used to reestablish a new base of support.

Balance during Gait. During gait, the COG follows a sinusoidal path as forward progression of the body mass combines with alternating lateral weight shifts to the stance foot (Figure 22-19).²³ Each step creates a new base of support. Assistive devices such as canes, walkers, and crutches extend the base of support and thus reduce the demands on the intrinsic balance control system. In sitting, standing, and walking, control of the COG involves the ability to establish a stable base of support and transfer weight over it. Treatment progressions for COG control then involve training to establish, maintain, and reduce the base of support and to

Figure 22-19 ■ The trajectory of the center of gravity (*C of G*) and the center of pressure (*C of P*) during a gait cycle. *LHC*, Left heel contact; *LTO*, left toe-off; *RHC*, right heel contact; *RTO*, right toe-off. (From Palia AE, Winter DA, Frank JS, et al: Identification of age-related changes in the balance control system. In Duncan P, editor: *Balance: proceedings of the APTA forum*, Alexandria, VA, 1990, American Physical Therapy Association.)

produce automatic, anticipatory, and voluntary postural responses to restrict or produce weight shifts.

Early treatment progression for COG control may include “neurodevelopmental sequence activities” (e.g., prone on elbows, all fours, kneeling, right or left side sitting, half-kneeling), not for the purpose of “reflex development” in the traditional sense but because the task demands are to balance with progressively less surface contact (i.e., shrinking the base of support). Additional benefits include greater control, coordination, and generation of power of the neck, trunk, and axial muscles. It also is useful for simultaneously addressing impairments such as lower-extremity extensor tone, trunk weakness and asymmetries, and head and neck extensor weakness. Functionally, bed mobility and floor-to-stand transfers are related to these progressive position exercises and should be practiced concurrently in low- and high-level clients, respectively.

Sitting balance can be progressed by (1) removing upper-extremity support (hands on firm surface to moveable surface [e.g., ball, bolster, rolling stool], one hand free and both hands free); (2) making the seating surface less stable (mat to bed to rocker board to Swiss ball); and (3) removing the use of one foot by crossing the leg or of both feet by raising the height of the seat so they do not touch the floor. Tasks might include multidirectional weight shifts with the hands in contact with a bolster or ball that is pushed or pulled to and fro, reaching or passing objects, performing upper body tasks (grooming, dressing), managing socks and shoes and wheelchair armrests and footrests, and so forth.

Sitting to Standing and Transfer Balance. Transitional movements such as sitting to standing and transfers involve large COG excursions over a stable base of support. For sitting to standing, the base of support must change from the seat to the feet. The feet begin to accept the weight first by downward pressure through the heels as the pelvis rolls anteriorly. The weight moves to the front of the feet as the trunk comes forward and the pelvis lifts from the surface, then backward toward midline as the trunk extends into standing. The COG stays near midline if both legs are participating equally, but it will often deviate to a preferred side during the transition in clients with hemiplegia. Training should include disadvantaging the preferred leg (perhaps by moving it a bit forward) to allow the more affected leg and foot to experience the weight transference. During transfers, a lateral weight shift is required in addition to the partial stand. The COG does not remain near midline; it instead moves forward to load the feet and then laterally toward the side of the transfer. Progression of balance skills in sitting to standing and transfer tasks may involve gradually lowering the height of the surface, removing armrests to preclude upper-extremity assistance, and transferring to surfaces of different heights and firmnesses. Remember that velocity is a normal part of sitting-to-standing movements because the momentum is used to assist the weight transfer from seat to feet, so the clinician must allow some speed during this task. If the client is unsteady on arising (cannot dampen or slow the speed in a controlled manner), working gradually from standing to sitting initially may be beneficial before progression to sitting to standing. Practice of sitting to standing with the eyes closed can be an effective way to train clients who are overdependent on vision for balance. Without the use of vision for stability, integration of vestibular and somatosensory systems can be facilitated.

Standing Balance. Standing balance tasks also can begin with finding midline and becoming stable there. Controlled mobility (volitional) should be encouraged as soon as possible, first on a stable surface with slow, small weight shifts. Challenge is added by increasing the distance traveled away from midline, moving toward restricted regions of the limits of stability, altering speed of sway, adding combined upper-extremity activities (e.g., dribbling a basketball, reaching), or adding resistance (manual, flexible bands). Narrowing the base of support (Romberg, tandem, single leg) makes control of the COG more demanding. Placing the feet in a diagonal stride position is more desirable for pre-gait weight shifting than is symmetrical double stance. Attention should be given to the stance (loading) leg with regard to pelvic protraction, hip and knee extension, and ankle dorsiflexion, with the tibia traveling forward over the foot. Focus on the swing (unloading) leg should include pelvic drop with knee flexion as the heel comes up and pressure through the ball of the foot and toes to load the opposite leg maximally. Standing balance exercises can be made more difficult by training on a less stable surface (carpet, foam, rocker board, BAPS board) and by adding combined head and eye movements or closing the eyes. The goals for dynamic sitting and standing balance exercises are to increase the size and symmetry of the limits of stability and improve the ability to transfer weight to different body segments with control at different speeds and with varied amounts of force. To facilitate somatosensory and vestibular integration, these activities can be performed with decreased or distorted visual cues. Closing the eyes, turning the head quickly, turning the lights down low, or wearing sunglasses may decrease the use of vision for stabilization.

Strategy Training. Training ankle, hip, and stepping strategies may begin in a voluntary manner but must progress to an automatic level of use to develop more normal balance and for real-life prevention of balance loss. Before strategy training, the clinician should be sure that the client has the ability to develop the desired strategies. The observed dominance of other strategies is appropriately compensatory, not dysfunctional, if a missing strategy cannot be effectively executed. Clients use these strategies to prevent loss of balance, so the clinician must take care not to reduce reliance on an effective strategy but to add additional strategies to the repertoire.

Ankle strategy should be practiced on a firm, broad surface. Clients can be asked to sway slowly in anterior-posterior, right-left, and diagonal directions, first to and from midline, progressing to passing midline, and finally progressing to sway toward the periphery without return to midline. Head and pelvis should be traveling in the same direction at the same time. Clients can practice standing near a wall with a table in front of them, swaying forward to touch the table with the stomach (leading with the pelvis) and backward to touch the wall with the back of the head. Cues are given not to “bow” to the table and not to touch the wall with the buttocks. As soon as the client is able to perform this protocol, functional meaning should be added with maneuvers such as forward or lateral reaching tasks, hands over head to take things off shelves, and leaning backward to rinse hair in the shower. To improve anticipatory and automatic ankle strategy use, add slight perturbations to the body or the surface when midline, progress to gentle

perturbation when away from midline, and finally progress from predictable to unpredictable perturbations.

Hip strategy is practiced on either a narrow or an unstable surface, such as standing sideways on a balance beam, a two-by-four, a half-slice foam roller, foam, or a rocker board. The head and pelvis travel in opposite directions to counterbalance each other, in a forward bow–backward bending motion for anterior–posterior sway. Rapid sway is requested in forward–backward, right–left, and diagonal directions. By using the wall and table setting previously mentioned, clients can be cued to how to touch the nose toward the table while simultaneously touching the wall with the buttocks. Lateral hip strategy can be trained similarly, with the client standing sideways to the wall, touching the table with one hip and the wall with the opposite shoulder. Sway close to the edge of the client’s limit of stability should produce a shift from ankle to hip strategy, so to enhance the use of hip strategy the client should practice sway control as far away from midline as possible without stepping. As soon as the client demonstrates the ability to perform this strategy, it should be incorporated into functional tasks such as low reaching (e.g., trunk of car, laundry dryer). To promote anticipatory and automatic use of hip strategy, the client is in midline and given moderate, rapid perturbations to the body or the surface such that ankle strategy will be insufficient to counteract the force. Then the size of the disturbance is increased, and the client is positioned away from midline when the perturbation is given so that righting to midline is appropriate. The shift should be made from predictable (“don’t let me make you step or fall”) to unpredictable perturbations.

Stepping strategy can be practiced first from atop a step, curb, or balance beam. Both legs should be included in training because real-life situations such as a slip or trip often preclude the use of one limb and demand the use of the other. It may be necessary to fix one foot in position to prevent stepping by the less affected leg in order to allow a stepping response on the more affected leg to emerge (a forced-use paradigm). Progress is made by stepping on a level surface and then to stepping up onto a step or curb or over progressively larger obstacles (appliance cord, shoe, phone book). All directions should be practiced, including lateral and diagonal perturbations, if safe recovery from real-life unexpected balance losses is to be learned. Large, rapid perturbations are given such that ankle and hip strategies will be inadequate and stepping or reaching is demanded. Again, progress should be made from predicted to unpredictable disturbances. For any automatic postural response—ankle, hip, stepping, protective reaching—to be effective in real life, successful demonstration of the response to *unexpected* perturbations is imperative.

Many clients, especially those who are fearful of falling, are dependent on the use of hands for stability. Therapeutic balance retraining activities should provide the maximal level of challenge that can be managed without the need for upper-extremity support. If the client physically needs to hold on, then the activity is at too high a level and should be modified. Otherwise, what is being taught is a “hand strategy” that will not be useful if the client experiences loss of balance when nothing firmly fixed is available to grasp for stability. Extremely anxious clients may initially benefit from training with an overheard harness system that will

permit hands-free motion but provide tangible reassurance that a fall will be prevented if balance loss occurs. In this case, treatment progression would include weaning the client off the use of the harness. If the only harness available is on a body-weight support treadmill or gait system, move the balance retraining to that harness. The treadmill does not need to be moving.

Gait Training. The initial focus for controlling the COG during gait is a stable base of support that can be continually reestablished quickly and reliably through stepping. Unlike standing balance, in which the base is stable and the COG moves over it, during locomotion the base is moving and the COG moves to stay over the base. Achieving a symmetrical, smoothly oscillating COG movement is the objective, with the forces of gravity and momentum being exploited.

The training is begun first in the forward direction but also includes backward and sideways directions (sidestepping, braiding, or carioca) to increase postural control demands. Challenge can be added by narrowing the base of support (tandem) or reducing the foot-surface contact (walk on toes or heels). Training to integrate postural control with locomotor skills is best accomplished not through continuous, steady-pace walking, but by starting, stopping, turning, bending, varying the speed, and avoiding or stepping over obstacles. Difficulty is added by increasing the abruptness, frequency, and unpredictability of these types of tasks and by adding tasks such as carrying or reading while walking. Altered surface conditions (carpets, ramps, curbs, stairs, grass, gravel) or reduced lighting conditions also heighten the challenge. Head and eye movements while walking should be added as the client improves. Walking quickly while reading signs on the wall or room numbers, for example, or looking toward and away from the therapist while walking makes vision more difficult to use for stability. Walking in crowds or in busy, cluttered environments is also challenging. Locomotion training on the treadmill reduces some abnormal asymmetries and increases control of gait with increased extension of the trailing limb.¹¹⁶ Again, gait training specifically for balance enhancement should occur without holding onto fixed surfaces with the hands, for example, parallel bars or the side rails of the treadmill. This is because the nervous system needs to learn to solve the balance problem using the legs and trunk, not the hands.

Clients with somatosensory loss in the feet should use a cane or walker. They may not need the device for biomechanical support, but they do need to obtain as much information about the surface as possible. Through use of a cane or walker, preserved somatosensation in the hands can detect surface information that is important for balance control, and biomechanical support is available if needed in case of balance loss.

Other Considerations

Treatment Tools

Therapists use both high-technological and low-technological equipment in the remediation of balance deficits; each has advantages and disadvantages. High-technological options include accelerometers with motion biofeedback, forceplate systems with postural sway biofeedback, electromyographic biofeedback, optokinetic visual stimulation (from visual

surround or moving lights), videotaping, and treadmills with biofeedback. Options for the evaluation and treatment of balance and gait deficits are expanded with the addition of advanced technology such as forceplate measures of postural sway and pressure mat measures of gait, giving the therapist a more quantitative and sensitive measurement than visual observation or timed measures. Most high-technological systems provide computer-generated reports with charts and graphs quickly. For training, overhead harness systems allow safe, hands-free practice, and computerized sway feedback supports motor learning (Figures 22-20 through 22-23). Computerized systems allow advanced monitoring of progress and biofeedback, which supports motor learning.¹¹⁷ Figure 22-20 is an example of technology in which forceplates measure pressure-generated signals (center of force [COF]). The systems shown use height and COF data to calculate the COG, which is used to measure postural sway. The COG icon may be displayed on the monitor screen for feedback to the individual if desired. Figure 22-21 is an example of how surface motion provides both biomechanical and somatosensory challenges. Balance measurement characteristics vary: some systems measure the motion of the surface (Figure 22-21, A), whereas others use motion sensors on the body placed at the level of the COG (Figure 22-21, B). Other systems provide the ability to generate visual motion. Figure 22-22, A, shows a system with a three-sided booth with unidirectional motion combined with a moveable forceplate with unidirectional motion. Both visual and somatosensory inputs can be manipulated for testing (e.g., SOT) and training. Omnidirectional visual motion (Figure 22-22, B) can be produced by rotating display systems that are used in a dark room.

The ability to challenge balance during gait training is improved if the client is secure in an overhead harness system as seen in Figure 22-23, A and C. These systems allow

Figure 22-20 ■ Advanced technology to support balance and gait retraining. The forceplates shown here are static, or fixed. They are somewhat portable. **A**, Balance Master Basic. **B**, Balance Master. (Courtesy NeuroCom, a division of Natus, Clackamas, Ore.)

hands-free training as soon as possible, to increase reliance on the lower extremity and trunk reactions critical for balance recovery strategies. Rapid and recordable measurement of gait characteristics (e.g., velocity, step length, step width) is possible with instrumented systems. Some systems are made for overground walking (Figure 22-23, B) and are portable. Other systems are incorporated into treadmills and provide feedback during gait training. All motorized systems provide the ability to manipulate the environment easily and efficiently and to graduate tasks and environmental challenges safely. Drawbacks to high-technological equipment include cost, space requirements, and operator training requirements.

Low-technological options include mirrors, soft foam pads, hard foam rollers, rocker boards, BAPS boards, tilt boards, Swiss balls, mini-trampolines, balance beams, and wedges or incline boards. All these items are accessible (low cost, easy to obtain), portable, and easy to use. The main drawbacks for low technological equipment are that it does not provide novel feedback, objective scoring, or graphic recording, and clinicians must be skilled and creative in the use of such equipment in order to provide appropriate gradation of task difficulty and environmental conditions.

Safety Education and Environmental Modifications

Remediation of balance deficits is not always possible, but the clinician is always responsible for ensuring the safety of each client. When permanent deficits exist, the client and the family should be taught in what environments the client is at risk (e.g., a client with vestibular loss on a gravel driveway at night), what tasks are unsafe (e.g., ladder climbing, changing ceiling light bulbs), how the client can compensate (e.g., use a cane at night or in crowds), and what changes in the home or workplace are needed (e.g., night lights, stair stripes, raised toilet seats). Clinicians can ask the client (or family) to problem solve risky situations: “What would the client do?” Home evaluations should be followed by a list of recommended safety modifications. Falls are frightening and dangerous; clinicians should do their utmost to prevent them. If falls are likely, clients and families should be taught what to do if a fall occurs and, once the client is on the floor, how to perform floor-to-standing or floor-to-furniture transfers. Home monitoring services such as Lifeline may be indicated if the client lives alone and is prone to falling. Hip protectors will not prevent falls but do significantly reduce the risk of hip fracture.

Home Programs

Strengthening, stretching, posture, and endurance exercises can all be performed safely at home so that time in the clinic can be spent on balance-challenge exercises requiring supervision. Improvements in strength, ROM, posture, and endurance support improvements in balance. Many balance exercises can and should be performed at home if safety and adherence can be ensured; however, *unstable clients should always be supervised*. Standing balance tasks can be completed in a corner or near a countertop so that in case of balance loss the client can use the hands (reaching strategy) to prevent a fall if other automatic postural response strategies are inadequate. However, balance exercises should not be routinely done while holding onto countertops, furniture, or other surfaces. If the client needs to use her or his hands to perform the balance task, the task is too difficult and

Figure 22-21 ■ Advanced technology to support balance and gait retraining. Other systems provide surfaces that can be made unstable (**A**) or made to move (**B**). The surface motion provides both biomechanical and somatosensory challenges. Amplitude and velocity capacity also vary from system to system. Both systems shown here provide omnidirectional motion. **A**, Biodex Balance System SD measures the motion on the surface, **B**, Proprio Reactive Balance System uses motion sensors on the body placed at the level of the COG (**A**, Courtesy Biodex Medical Systems, Shirley, NY; **B**, Courtesy Perry Dynamics, Decatur, Ill.)

should be modified so that it can be safely performed without needing to hang onto a stable object. The community setting is ideal for postural control gait training. Grocery or library aisles, public transportation, elevators, escalators, grass, sandboxes or beaches, ramps, trails, hills, and varied environmental conditions in general provide both challenge and functional relevance.

Concurrent Tasks

Normal balance is largely subconscious. One objective in balance retraining is to force the nervous system to solve postural control problems at the automatic, subconscious level. A great deal of practice and dual-task training are

necessary to accomplish this; the conscious brain is focused on accomplishing some other goal(s) and thus balance control must be achieved at a less conscious level. Alternative tasks can be physical in nature, such as carrying a tray or dribbling a basketball, or cognitive, such as conversing or solving verbal or math problems, or a combination of physical and cognitive demands.

This objective is not universal. Clients with permanent or progressive deficits in automatic motor processing, particularly those with Parkinson disease, lose automaticity. They must learn to produce motor actions volitionally, with attention and intention, unless there are external sensory cues to drive the motor system.

Figure 22-22 ■ Advanced technology to support balance and gait retraining. Visual motion may provoke instability for certain individuals. Some systems provide the ability to generate visual motion. **A**, SMART Balance Master is a system with a 3-sided booth with unidirectional motion combined with a unidirectional movable forceplate. Fall Prevention

Client safety is always paramount; for any client with balance deficits the risk of falls is increased and must be addressed in every clinical management program. In older adults without documented neurological conditions, falls are prevalent and lead to severe injury (including head trauma) and death. Fall risk is even greater and is especially high in persons with stroke and Parkinson disease. Fall prevention is a critical primary objective for clinicians serving clients with neurological conditions who have impaired balance and gait.

Fall risk factors are categorized as intrinsic, relating to the individual, and extrinsic, relating to the environment. Intrinsic risk factors include but are not limited to medical conditions (e.g., stroke, Parkinson disease); medications; impaired balance and gait; somatosensory, visual, or vestibular sensory loss; central processing problems; slow reaction time and other central motor deficits; lower-extremity weakness and decreased ROM; cognitive deficits; depression; urinary urgency or incontinence; and footwear. Extrinsic risk factors are hazards in the environment, such as inadequate lighting or excessive glare, slippery or cluttered surfaces, lack of handrails or grab bars, attention distracters, and timing demands (e.g., hurrying to answer the phone). The more risk factors present, the greater the likelihood of falls. Most falls in community-dwelling older adults are trips and slips and

occur because of a combination of intrinsic and extrinsic risk factors. For example, a client with hemiplegia who has limited ability to rapidly and maximally dorsiflex the ankle who encounters a trip hazard such as a rumpled doormat may not be able to clear the obstacle by lifting the hemiplegic leg and foot quickly. If the number and/or severity of intrinsic risk factors is great, falls may occur without any provoking extrinsic hazard.

Additional factors influence fall risk levels. The location of the client may have an effect on fall risk. While in an institutional setting, the physical environment may be safer and the level of supervision and assistance higher, thus lowering risk. Yet if the surroundings are unfamiliar or confusing to the client, the client does not remember to call for assistance before getting up, or the environment holds barriers such as bedrails, wheelchair footrests, and so on that must be dealt with when hurrying to the bathroom, then an institutional setting may pose increased risk. The amount of supervision or assistance the client receives may alter risk level. Confused or forgetful clients in facilities with high staff-to-client ratios or who have family or caregiver supervision most of the time will have lower risk than those in facilities or homes where supervision and assistance are sparse. Lastly, the relative dependence-independence level of the client, both physical and cognitive, affects risk level. Very dependent clients who cannot get up by themselves, and very independent clients with high-level balance and

Figure 22-23 ■ Advanced technology to support balance and gait retraining. High technology used to challenge gait. The ability to challenge balance during gait training is improved if the client is secure in an overhead harness system. These systems allow hands-free training to increase reliance on the lower extremities and trunk reactions critical for balance recovery strategies. Rapid and recordable measurement of gait characteristics is possible with instrumented systems. **A**, Biomed FreeStep SAS uses overhead harness system to challenge balance during gait. **B**, GAITrite Portable Walkway System challenges gait during overground walking. **C**, Biomed Gait Trainer 3 with Unweighting System is another example of how to challenge balance during gait training. (**A** and **C**, Courtesy Biomed Medical Systems, Shirley, NY; **B**, courtesy CIR Systems, Havertown, Pa.)

gait skills, are both at lower risk than clients in the middle of that spectrum. Clients who have sufficient ability to get up out of the bed or chair, and perhaps to walk, but who have impaired balance and gait skills and poor judgment or memory are at a much higher risk level.

A separate but equally important risk to consider is the risk of injury from a fall. Injury risk also depends on both intrinsic and extrinsic factors. Clients with low bone mineral density, low body mass, and impaired protective responses (automatic postural responses, especially reaching or protective extension) are more likely to be injured. Falls that occur from a greater height onto a harder surface are more apt to result in injury. An overweight client with adequate bone mineral density (BMD) who, while in her yard gardening, stumbles and falls to the grassy ground from standing height with both arms out to break her fall would have a lower risk of injury. A thin client with osteoporosis who, while at the store shopping, stumbles off a curb and falls to

the concrete parking lot without getting her arms out in time to protect her would have a higher risk of injury.

Clinicians should consider fall risk and injury risk factors as they carry out their assessments and evaluation. This would begin with the chart review or history taking; as problems are noted, the clinician should be “red-flagging” those that are risk factors for falls. For example, you might note that the client is on more than six prescription medications; polypharmacy is a risk factor for falls. You also note that one of the medications is a drug to remediate bone loss, and further inquiry reveals that the client does have a diagnosis of osteoporosis, a risk factor for injury. During your own therapy assessment, you find substantial lower-extremity weakness, balance impairments, and gait limitations requiring the use of an assistive device, all major risk factors for falls. One of the identified balance impairments includes deficient automatic postural responses, a risk factor for injury. Later, during a team meeting to discuss the new client,

you learn from the occupational therapist that the home safety survey completed by the client's spouse indicates numerous safety hazards, extrinsic risk factors for falls and perhaps injury. For fall prevention and injury prevention purposes, a list of all fall and injury risk factors pertaining to that client should be generated for use in treatment planning.

The aim of intervention for fall prevention is to eliminate or minimize risk factors, with emphasis on four risk factors that appear to be more influential than others (in community-dwelling older adults). These four interventions are exercise, medication management, home safety modification, and vision management. The single best intervention for fall prevention is exercise—specifically, individualized exercises that target balance, gait with balance challenges, and leg strength. The challenge level of the balance and gait exercises should be high. The balance and gait training program must be of high intensity and frequency and of long duration. For a reduction in fall rates in community-dwelling older adults, a bare minimum of 5 to 6 weeks, with sessions two to three times a week, is required. For more neurologically involved clients, the overall amount of practice would need to be greater. Gains that are made during therapy will not be maintained unless exercise or physical activity that includes balance challenge is continued after therapy. Clients should be intentionally transitioned from therapy to a community-based balance exercise or physical activity program as an integral part of their discharge plan. Clinicians may consider doing their last treatment or two at the community-based program to support the client through the transition and increase the probability of follow-through. It is critical for clients to persist with physical activity to maintain or even further lower their fall risk level.

The second area of intervention is medication management. This requires a team approach and tactful, professional communication with the client's physician(s). The goal is to have the client take as few medications as possible, in the smallest doses possible, and to eliminate or when necessary replace certain drugs that are known to raise the risk of falls substantially (e.g., benzodiazepines). (Refer to Chapter 36 for a discussion of the impact of drug therapy on patients undergoing neurological rehabilitation.) Clinicians must understand that medication management for fall prevention is a difficult balancing act for the physician. For example, antidepressants and sleeping pills raise the risk of falls. Yet depression and sleep disorders are serious conditions with many negative effects, and depression, inattention, and fatigue are all risk factors for falls. Both the condition and its treatment increase risk! Clients on blood-thinning medication who are at risk for falls are also at risk for serious bleeding problems should a fall occur; the physician, client, and family or caregiver should all be alerted to this risk. Medication management guidance for fall prevention directed to physicians is available from the American Geriatrics Society.

Home safety modification is an effective intervention for those who are already at high risk for falls. Ideally an in-person home safety evaluation is performed by a trained professional, usually a physical or occupational therapist. If this is not possible, a home safety survey may be completed by a reliable source (client, family member, or caregiver). The clinician and client or their responsible decision makers

should then have a frank discussion about recommended home safety modifications. The clinician should convey what is recommended and why, highlighting the benefits. However, factors such as time, expense, and personal preference also influence client and family decisions. Identification of barriers to safety modification implementation is helpful and may lead to solutions that permit initial resistance to be overcome.

Vision management is critical for any client with visual deficits. (Refer to Chapter 28 for a discussion of disorders of vision and visual-perceptual dysfunction.) These visual impairments might be at the peripheral level, such as macular degeneration, or the central level, such as homonymous hemianopsia. Occupational therapy is recommended for a visual-perceptual evaluation and potentially for low-vision rehabilitation if needed. Vision professionals (ophthalmologists, developmental optometrists), preferably those with specialization in neurological populations if indicated (e.g., TBI, cerebrovascular accident [CVA], MS), should also be involved. Objectives include maximizing vision for the client and including visual support within the home safety modification plan if needed.

Footwear assessment is important. Walking indoors barefoot or in socks is associated with increased fall risk. The footwear most highly associated with hip fractures is slippers. Shoes and slippers that do not provide adequate foot support, or that have slick soles, are unsafe and not recommended. Footwear lacking a secure back (flip-flops, mules, or sling-backs), high-heeled shoes, and platforms are poor choices for clients at risk for falls. Running shoes with very thick, cushioned soles and a heavy tread are also not ideal. The optimal shoes for fall risk reduction are well fitted with thin, hard soles. Shoes with a tread sole and a tread beveled heel are more stable on wet or slippery surfaces.¹¹⁸ Just as with home safety modifications, factors such as expense, habit, and personal preference may create obstacles to client adoption of suggested footwear changes. These obstacles should be recognized, respected, and addressed directly with professional communication strategies designed to facilitate positive behavior change.

Clinicians should assume that clients at risk for falls will fall when they are discharged home. Though we work to ensure this will not happen, we also prepare for the possibility that it will. Clients who are able must be taught how to get up from the floor independently, with and without furniture if the latter is possible. If clients cannot get up from the floor by themselves, then family members or caregivers should be taught how to assist clients to get up from the floor. This may be as simple an act as bringing a chair close to the client so the client can use the chair to get up independently. Clients at risk for falls who will be home alone for extended periods of time would benefit from a wearable home alerting system. If such a system is cost-prohibitive, the client should develop the habit of carrying a cell phone at all times. For clients without cell phones, a landline phone should be left on the floor or a chair seat so that it is within reach from the floor should a fall occur. Older clients with osteoporosis should consider wearing hip protectors. Hip protectors do not reduce the risk of falls but when properly fitted and worn may reduce the risk of hip fracture. Adoption of and adherence to wearing hip protector apparel is typically low and requires commitment and effort.

The combined aim of balance retraining and fall prevention is to assist the client to become as active as is safely possible. With improved balance and gait skills, the client achieves higher levels of function and physical activity. With attention to and emphasis on fall prevention, safety is maintained, injury is prevented, and the opportunity for improved quality of life is preserved.

Vestibular System

Kenda Fuller, PT, NCS

OVERVIEW: THE ROLE OF THE VESTIBULAR SYSTEM

The CNS integrates the information from visual, somatosensory, and vestibular inputs to determine the most appropriate response to maintain stability and homeostasis.¹¹⁹ These three senses play an important role in dynamic equilibrium (Figure 22-24). In fact, the somatosensory system is necessary to interpret vestibular information.¹²⁰ The activity of the vestibular system must be recognized in order to interpret balance testing. This chapter provides background information that has been incorporated into the earlier portion on balance.

Figure 22-24 ■ The otoliths register linear acceleration and static tilt of the head. (From Hain TC, Ramaswamy TS, Hillman MA: Anatomy and physiology of the normal vestibular system. In Herdman SJ, editor: *Vestibular rehabilitation*, ed 3, Philadelphia, 2007, FA Davis.)

The role of the vestibular system is to maintain clear vision during head motion as well as to orient head and trunk in space with respect to gravity when the visual and surface references are not sufficient. Horizontal and vertical accelerations, as in riding in a car or an elevator, are also detected by the vestibular otolith mechanism as seen in Figure 22-24.¹²¹ The vestibular system is critical for postural control because it uniquely identifies self-motion as different from motion in the environment. Recognition of self-movement as it relates to visual movement can be disrupted momentarily in a normal individual experiencing unexpected movement in the peripheral visual environment. This is a common sensation noticed, for example, when the car next to you moves backward, and you press the brake, thinking that you are rolling forward. Unless the system fails, the vestibular system is noticed only when it is stimulated beyond the level at which it is typically activated, as in a fast spin or the drop of a roller coaster. The dizziness that occurs in the normal individual when the vestibular system is overstimulated is reflective of the dizziness that occurs when the brain encounters sudden changes or losses of input from the vestibular system.¹²²

Disorders of the vestibular system can cause devastating lack of visual stability, loss of balance, and inaccurate sense of movement. There is an initial loss of trunk and gaze stability with vestibular dysfunction that improves as a result of CNS adaptation. The CNS adaptation is critical to recovery of function.¹²³ In the course of recovery, the visual or somatosensory systems may be chronically used in preference to the vestibular system, causing abnormal sensory dependence patterns.^{123,125} Comorbid dysfunction can affect functional recovery, especially if it affects the visual or somatosensory inputs. Prior trauma, either physical or psychological, can cause maladaptation resulting in responses to intervention that are inconsistent with typical recovery patterns.¹²⁶⁻¹²⁸

Clinicians are exposed to patients at many different levels of adaptation, from the ones who show adequate adaptation with minimal intervention to those who have recovered only limited independence after disruption of vestibular system inputs. Successful intervention is achieved by accurately analyzing both the missing and the available components of the system, facilitating adaptation, avoiding excessive sensory substitution, and determining appropriate compensatory strategies.¹²⁹ If maladaptation is not understood and treated properly, it can lead to frustration for the patient and clinician, resulting in less than optimal outcomes.

VESTIBULAR SYSTEM DISORDERS

There are many types of common vestibular disorders. This chapter cannot provide a total discussion of all these disorders. They have been summarized in Appendix 22-A.

RECOVERY OF FUNCTION: NEUROSCIENCE OF THE VESTIBULAR SYSTEM

Recovery of function is related to the mechanism of injury and where the damage is located. In order to understand how the system recovers, we must first understand how it works. The end organ of the vestibular system is basically a mechanical, fluid-filled system activating afferent signals that travel through the vestibular nerve to the brain stem nuclei.^{130,131} Figure 22-25 shows the relative relationship of the canals to the otoliths and the cochlea. This demonstrates

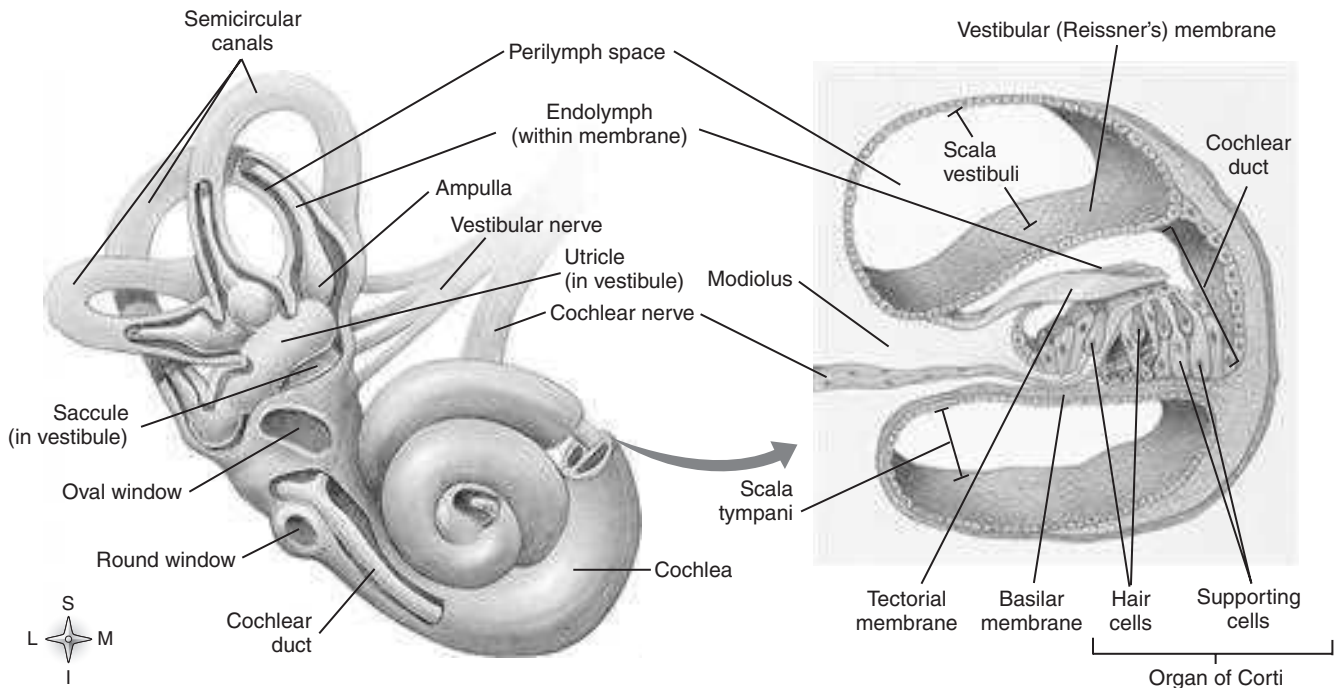

Figure 22-25 ■ Components of the vestibular system and cochlea with distribution of neural connections. (From Thibodeau GA: *Anatomy and physiology*, ed 6, St Louis, 2006, Mosby.)

why there is often a connection between loss of hearing and vestibular dysfunction, especially when the fluid mechanism is part of the impairment. **Box 22-1** describes the sensory components of the vestibular system. At the level of the nuclei, the brain stem receives input from the other sensory systems related to orientation of the head and body. The combined input is further modulated by the cerebellum, providing further calibration. Purkinje cells in the cerebellum provide inhibitory control of the vestibular nuclei. The flocculonodular lobe and medial zone of the cerebellum affect postural control.¹³² Input continues to the cortex via the vestibular projections (**Box 22-2**).

Recalibration at Rest

The tonic firing of the vestibular system when the head is in a neutral nonmoving state is symmetrical on both sides of the system at approximately 50 spikes per second. The brain is able to compare this symmetrical resting level tone to the information coming from the visual and somatosensory systems' feedback about the position and movement of the head.

BOX 22-2 ■ POTENTIAL LOCATION OF LESIONS THAT MAY AFFECT THE VESTIBULAR SYSTEM

- Vestibular end organ and vestibular nerve terminals
- Vestibular ganglia and nerve within the internal auditory canal
- Cerebellopontine angle
- Brain stem and cerebellum
- Vestibular projections to the cerebral cortex

From Goodman CC: *Pathology: implications for the physical therapist*, ed 3, Philadelphia, 2008, WB Saunders.

When there is disruption of signal from one side of the vestibular pathway, it will change the relative input into the CNS, resulting in a perception of the head rotating toward the intact side when the head is not actually moving (**Figure 22-26**). Initially, as well, there will be a phenomenon of spontaneous nystagmus, a reflex-driven movement of the eyes. In an acute asymmetrical vestibular system disruption, the eyes will move away from the perceived direction of head motion, and that movement of the eyes will cause a sensation of dizziness with the head still, eyes open. The brain quickly identifies this as an abnormal state and begins CNS recalibration so that the vestibular system input from each side becomes calibrated to match the visual and somatosensory system input. The system is able to determine that despite the uneven signals, the head is not really moving.¹³³ There is usually adequate central adaptation to stop the spontaneous nystagmus in a lighted environment within 3 days.¹³⁴ The spontaneous nystagmus may continue to be active in a dark room, and there may still be a sensation that the head is rotating when the eyes are closed for weeks after the insult. Increasing somatosensory input about stability can help in the central recalibration process. Input through the joint surfaces by establishing a stable joint reference can facilitate calibration. This appears to be most effective through mechanical pressure through the top of the head or with the use of weights on the shoulders to increase the vertical reference of the spine in a neutral position. **Figure 22-27** shows how weights are placed on the shoulder to provide somatosensory input. The brain can then match or recalibrate the abnormal perception of head movement induced by the inaccurate vestibular system to the correct reference of the stable somatosensation. It is critical in the rehabilitation process to achieve accurate CNS recalibration with the head at rest before initiating intervention that requires movement of the head.

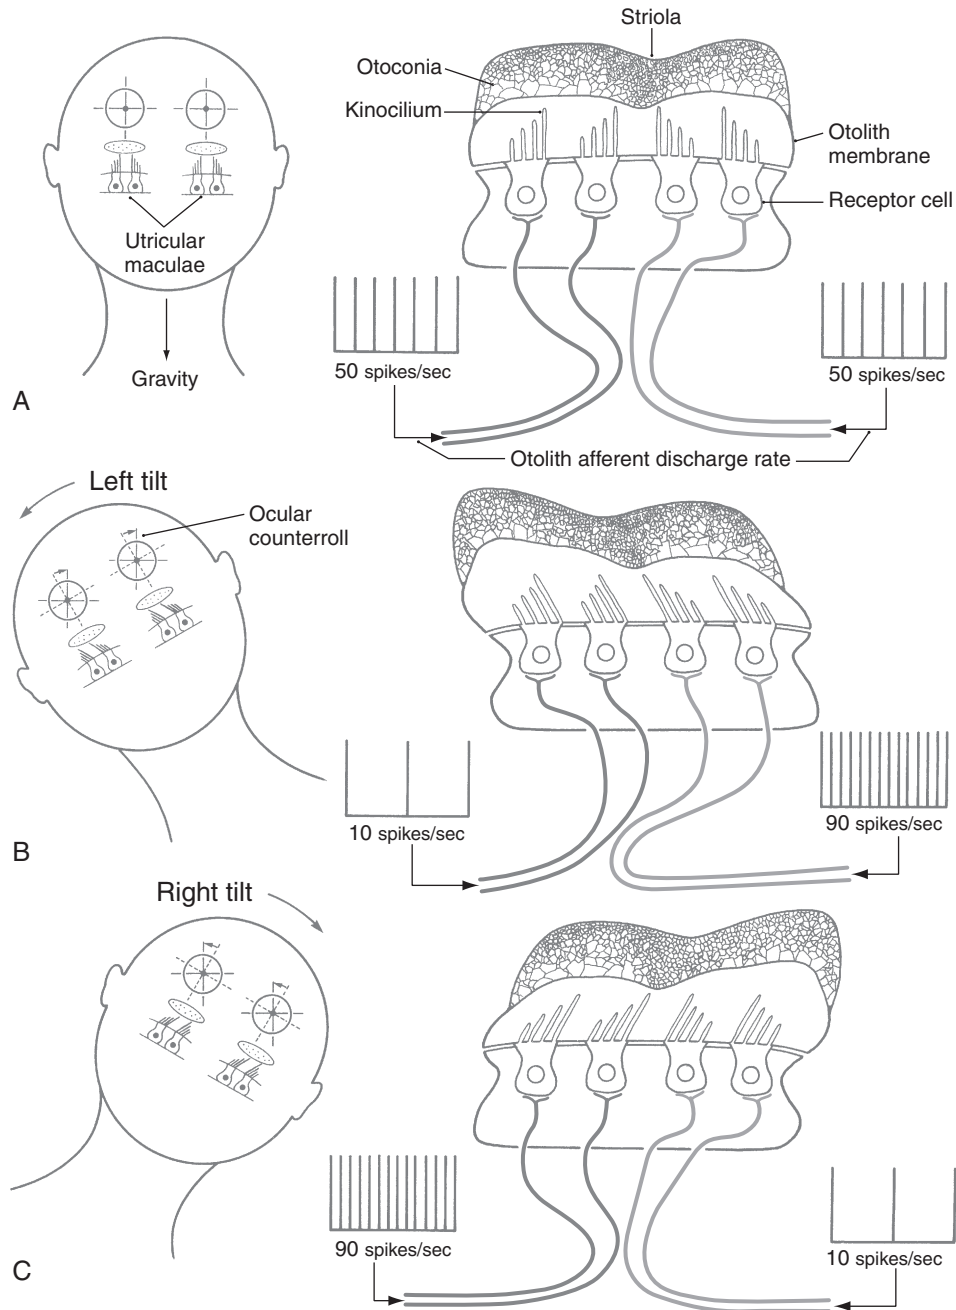

Figure 22-26 ■ Patterns of excitation and inhibition for the left utricle and saccule when the head is upright (A), tilted with the left ear 30 degrees down (B), and tilted with the right ear 30 degrees down (C). The utricle is seen from above and the saccule from the left side. (From Haines DE: *Fundamental neuroscience for basic and clinical applications*, ed 3, Philadelphia, 2006, Churchill Livingstone.)

Head Movement and Gaze Stability

As the head starts to move, the signal from each part of the vestibular system activates as a result of fluid movement against the cupula. The direction of movement is determined by the relative firing pattern of the vestibular system from each side of the head. The vestibular system on the side toward the movement increases in firing, and the side opposite decreases its firing rate. The resulting signal to the brain stem drives the VOR to move the eyes in opposition to

the head movement, and the gain remains 1:1. [Figure 22-28](#) shows the neural connections involved in activation of the VOR. If the vestibular system does not drive the eyes to the correct position for stable gaze, the result is vestibular-driven oscillopsia, and again, objects can appear to move as the head moves. This disorder has significant functional implications and works in conjunction with both smooth pursuits and saccades to interpret the relationship of the body to the environment ([Figure 22-29](#)).

Figure 22-27 ■ Use of 5-pound weights on each shoulder to increase the somatosensory reference allows the vestibular system to recalibrate to the body reference. Eyes are closed so that head position is not referenced by vision.

The VOR is reported as abnormal only if there is loss of gaze stability, or blurring of target objects with head movement at 1 to 3 Hz. Rotation or pitch of the head during testing of the VOR may cause dizziness because of the differences in firing patterns from each ear that are not yet efficiently calibrated. This is especially noted when the head is moving in the direction of the abnormal ear. It is important to note that head motion–provoked dizziness can persist even when gaze stability has normalized.

The clinician must also be aware that the peripheral visual field will appear to move in the opposite direction as head movement during these testing procedures. This normal visual phenomenon can cause dizziness in the patient with visual dependence or visual motion sensitivity (described later). It is the vestibular system that provides the

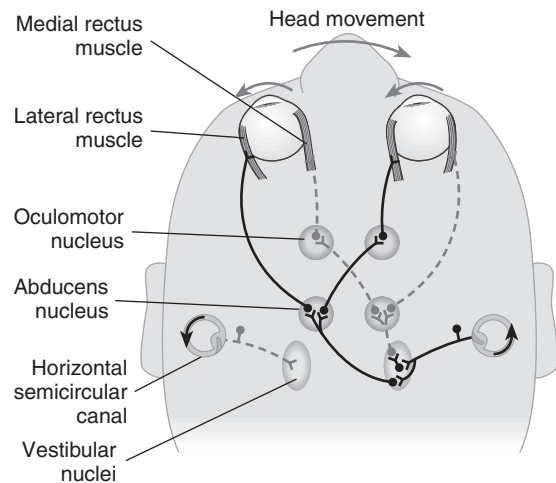

Figure 22-28 ■ Vestibuloocular reflex. When the head is turned to the right, inertia causes the fluid in the horizontal semicircular canals to lag behind the head movement. This bends the cupula in the right semicircular canal in a direction that increases firing in the right vestibular nerve. The cupula in the left semicircular canal bends in a direction that decreases the tonic activity in the left vestibular nerve. Neurons whose activity level increases with this movement are indicated in solid lines. Neurons whose activity level decreases are indicated in dotted lines. For simplicity, the connections of the left vestibular nuclei are not shown. Via connections between the vestibular nuclei and the nuclei of cranial nerves III and VI, both eyes move in the direction opposite to the head turn. (From Lundy-Ekman L: *Neuroscience: fundamentals for rehabilitation*, ed 3, Philadelphia, 2007, Saunders.)

reference of head movement and position so that the perceived movement in the environment is properly identified.

The quality of somatosensation in the spine and muscles of the upper body can contribute to dizziness with head motion. The vestibular nuclei have the job of integrating somatosensory information on its way to the cortex. There must be adequate input from both systems to distinguish between head-on-body and body-on-head movement. Impaired somatosensation, pain, and guarding of movement will disrupt the accuracy of calibration related to head movement. The patient who has an abnormal VOR will be constantly decelerating head movement to less than 2 Hz in order to prevent blurred vision. That unconscious deceleration by the muscles in the neck can cause stiffness and decrease the sensitivity of the somatosensory mechanisms in the neck. Two simple tests will alert the therapist to abnormalities of head motion related to the quality of somatosensation. Holding the head upright and still, in gravity-neutral position, while the patient rotates in a chair (body on head) provides information about the somatosensory reference. The movement may elicit dizziness if the somatosensation is impaired. If the patient has been relying on somatosensation as a primary reference for head position, there may be resistance or guarding against allowing the body to move in a direction different from the direction of the head movement.

Rotating in a chair at 1 to 3 Hz and allowing the head to move at the same speed as the body will eliminate somatosensation reference through the neck receptors and isolate the vestibular system response to rotation of the head. This should

Dynamic Acuity Ranges

Figure 22-29 ■ Dynamic acuity ranges. (From NeuroCom beta-testing data and analysis (2004-2008), used by permission.)

be done with the eyes closed to eliminate the sense of visual motion. Movement at this speed will cause an increase in dizziness even in a normal system, but it should resolve in less than 10 seconds. If the dizziness persists for longer than 15 seconds, it is considered to indicate abnormal vestibular calibration.

Head Position Changes

Head position changes in reference to gravity can cause dizziness as a function of the vestibular system under certain circumstances. The most common form of head position dizziness in adults is BPV (see [Appendix 22-A](#)). In this condition, debris (otoconia) from the utricle moves into the semicircular canal, and there is suddenly mass in a system that is designed to calculate only fluid pressure changes in response to head movement. The added mass causes excessive deflection of the hair cells in the cupula when the head is moved into a gravity-dependent position. The otoconia move in the direction of gravity through the endolymph, causing a pull on the cupula and increased firing of the hair cells as if the head were moving quickly in that direction. [Figure 22-30](#) shows the movement of the otoconia in relationship to head movement in a gravity-dependent state. The brain activates the VOR in response to the message that the head is moving quickly, and there is nystagmus based on the same mechanism as described previously. The nature of this nystagmus reflects the canal in which the debris is floating. As soon as the otoconia come to rest, the pressure on the hair cell is gone, and the nystagmus subsides. This takes about 20 seconds. There is no nystagmus until the head is moved into another gravity-dependent position causing the otoconia to roll through the canal.

Top-down Reference for Postural Control

The most important role of vestibular information for postural control relates to orientation of the head and trunk in space with respect to gravitational forces.¹³⁵⁻¹³⁷ Orientation

to gravity is most critical when balancing on unstable surfaces when vertical and horizontal visual reference is not adequate. The vestibular system provides a top-down reference for the head and trunk stability in line with gravity while the leg segment is coordinated to maintain surface reference. Vestibular inputs are critical to determine whether the body is swaying or the surface is perturbed.¹³⁸ The conscious perception of verticality used to orient to gravity when the support surface is perceived to be unstable is provided by the vestibular system. Vestibular inputs are used in order to recognize the changes in angle of the support surface.¹³⁹⁻¹⁴¹

Surface perturbations or oscillations provide a method to examine the ability of the vestibular system to maintain the head and trunk in gravity-neutral position as the legs move in reference to the platform movements. When standing on a surface that tilts both anteriorly and posteriorly at 4 degrees per second, patients with bilateral vestibular loss will lose balance and fall.^{120,140,141} A normal person should be able to position a hand-held rod in vertical while standing or sitting on an oscillating surface, irrespective of the angle of the surface, even with eyes closed. Individuals with loss of orientation to gravity will orient the hand-held rod with respect to the angle of the moving surface.¹⁴²

It is important to remember that at the same time the vestibular system is activated in this moving surface condition, the somatosensory system is still providing feedback about the relationship of the head that is provided by vestibular inputs to the base of support.² Resulting patterns of muscle activation reflect vestibular and somatosensory integration to maintain continuous upright postural control. As a surface rotates to greater degrees, there is more weighting of the system away from the somatosensory reference toward the gravity reference.^{138,143} Patients with noncompensated vestibular dysfunction will report lack of awareness of angle changes when standing on an oscillating support surface. Therefore, instead of changing the ankle angle to

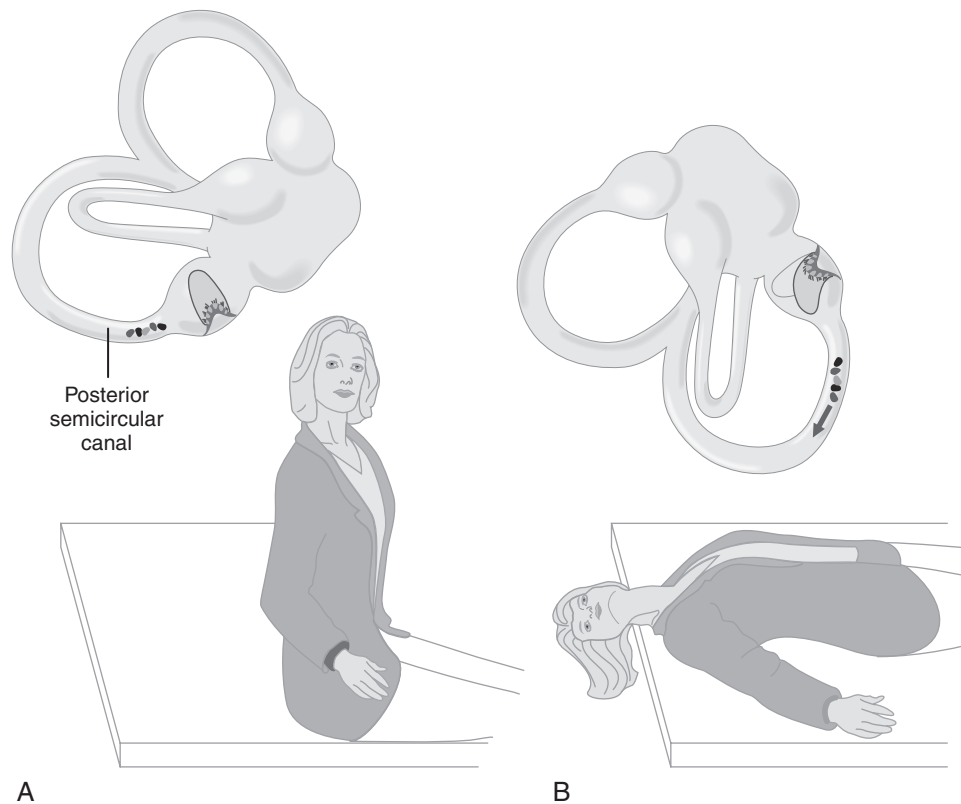

Figure 22-30 ■ The Hallpike-Dix maneuver. **A**, Starting position with head rotated toward the side to be tested. **B**, Lowering the patient's head backward and to the side allows debris in the posterior canal to fall to its lowest position, activating the canal and causing eye movements and vertigo. (From Lundy-Ekman L: *Neuroscience: fundamentals for rehabilitation*, ed 3, Philadelphia, 2007, Saunders.)

adjust to the tilt, the torque around the ankle remains locked, holding the leg, trunk, and head at 90 degrees to the surface. The head then follows the direction of the surface tilt as seen in Figure 22-31. As the surface tilt angle exceeds 8 degrees, the individual who cannot activate gravitational reference or adjust the ankle angle will be unable to maintain balance.¹⁴³ Lateral tilt can activate the system in the same way; with the head following the direction of the downward tilt, the weight is typically shifted to the downward-most leg. Patients report lack of awareness of the movement generated. Figure 22-32 shows the abnormal shift of weight as the patient attempts to orient to the surface rather than gravity.

Bottom-up Reference for Postural Control

The somatosensory system can determine the orientation of the head in reference to the surface through cutaneous, proprioceptive, pressure, and stretch receptors of the muscles and joints, primarily related to pressure through the balls of the feet. Although overreliance on this surface reference can be destabilizing in some conditions, it contributes to balance when the surface is stable or moving slowly (at less than 4 degrees per second). At the other end of the spectrum, in very fast oscillations the muscle spindles provide stabilizing information that can contribute to head and trunk stability.¹⁴⁴

It is critical to remember that the vestibular spinal system also activates the neck muscles in response to head perturbations and modulates somatosensory-driven activity of

muscles in the neck. When the vestibular system function is missing or inaccurate, there is abnormal muscle activation in the muscles of the neck.¹²⁰ One way this function can be tested is by observing head-righting response when a patient has vision blocked and is tilted while sitting on a tilt board so that the perturbation starts at the surface instead of the head. In the patient with vestibular dysfunction, when gravity vertical reference is lacking, lateral head righting back to center, or neutral is inadequate. This can be a result of co-contraction of the neck muscles to lock the head into position, with the trunk maintaining the same tilt as the trunk. The head stays in reference to the surface in much the same way as described earlier regarding locking of the ankle joints. This is evidenced in higher-level activities that require gravity reference such as tandem walking in visually stimulating environments or with vision occluded. As the patient tries to use somatosensation to determine head position instead of gravity reference, the head becomes locked onto the trunk through abnormal muscle activation. The narrow stance limits the contribution of surface reference in the lateral plane, and the patient must take a step out to control the excessive lateral tilt of the trunk and head. Figure 22-33 represents the abnormal and normal views of head righting in both sitting on a tilted surface and standing in tandem. It is the vestibular inputs that should drive the appropriate head righting and resulting postural strategies that are required in these conditions.

Figure 22-31 ■ In anterior tilt of the platform, the head and trunk follow the reference of the platform rather than maintaining a gravity-neutral position. This is reported as surface reference. (Courtesy Perry Dynamics, Decatur, Ill.)

Having even the slightest touch reference so that the somatosensory system can orient the trunk through upper-extremity joint position sense is another way to substitute somatosensation for vestibular reference.¹⁴⁵ The position of the head and trunk can be determined by this touch even when the vestibular system function is missing and eyes are closed. Because the arm stabilizes the trunk more than the legs do, reaching for a stable surface is a common way to maintain balance when challenged. The therapist must recognize when the patient is using this touch reference to substitute for gravity. This is why allowing a patient to touch a stable surface during balance training should be quickly eliminated from intervention to avoid dependence on surface reference when attempting to activate the vestibular system.

When the brain is not able to use somatosensation to identify the relationship between appropriate body segments

Figure 22-32 ■ **A**, The patient references her trunk to the platform, shifting weight downhill to the downhill leg. **B**, The patient has referenced her trunk and head to gravity, resulting in improved postural control. (Courtesy Perry Dynamics, Decatur, Ill.)

and the surface, the patient often will report feeling light-headed or having the sense of floating. When somatosensory inputs from the neck are reduced, absent, or distorted, the result is poor spinal segment stabilization. Excessive muscle activity, including co-contraction of the sternocleidomastoid (SCM), levator scapulae, upper trapezius, and superficial neck extensors indicates poor stability, altered afferents, and recruitment patterns that are ineffective. Nociception from cervical segments can create “noise” in the postural control system contributing to dysmetric postural responses and nausea. Impaired cervical afferents will cause changes in cadence and length of stride when neck motion is introduced to gait. Diminished gait measures have been seen on the DGI in the presence of neck pain. When abnormal somatosensation is concurrent with CNS vestibular adaptation, the result is less than satisfactory. Because brain pattern learning is task specific and dependent on high repetition, it is not helpful to practice poor motor recruitment patterns during balance retraining.

Visual Reference for Postural Control

Orientation of the head in space is possible through predictive control of vision. A stable environment provides visual vertical and horizontal references for balance. Patients with vestibular loss are able to substitute vision for vestibular reference, even during surface perturbations.^{146,147} Destabilization occurs when the peripheral visual references are moving slowly or are not in alignment with gravity. When eyes are tracking something moving in central gaze field, the background or peripheral visual field will appear to move in the opposite direction. In the patient with lack of gravity reference, when performing diagonal smooth pursuits, postural adjustment patterns are activated as if the room were tilting, because that is the dominant sensory reference being used. The patient is pulled off balance when aligning himself or herself with the apparent visual vertical. This is most pronounced and can be tested easily when a patient is standing

Figure 22-33 ■ **A**, When surface reference is used in preference to vestibular cue, the head remains in alignment with the surface. **B**, As the patient is able to regain vestibular function and gravity reference, the head remains in alignment with gravity, as a head-righting response. **C**, Lack of head-righting responses can cause excessive use of upper-extremity activity to try to reference to the surface, with bottom-up firing patterns; hip strategy is activated but inefficient. Abnormal reference patterns result in loss of balance in tandem stance with eyes closed. **D**, When the vestibular reference is restored, the head remains over the feet, so balance is restored. This is why it is important to observe the angle of the head during examination of tandem stance or gait. (Courtesy Ray Hedenberg, IRB Solutions, Silverthorne, Colo.)

on a compliant surface, tracking a target moving in a figure-of-eight configuration. Head and trunk sway match the apparent visual field movement instead of actual gravity vertical in the patient who is visually dependent. This test can be used in a clinical battery to determine the level of visual dependence or substitution related to lack of gravity reference. **Figure 22-34** shows the effect of visual dependence on head position and the resulting balance responses.

Visual disorders can disrupt balance, cause sensation of dizziness, and lead to limitation of function. Accurate evaluation of the visual system is critical in differential diagnosis (see Chapter 28 on disorders of vision and visual perception). Disorders of convergence are common in the vestibular-deficient patient and can cause delay in the process of adaptation. Sensitivities to physiological diplopia develop, causing visual motion hypersensitivity during daily activity (**Box 22-3**). Remember, too, that abnormal responses in neck muscle activity associated with eye motion have implications for control of posture and movement. The smooth pursuit neck torsion test (SPNT) is used to delineate abnormal cervical afferent influences on oculomotor function from vestibular influences (**Box 22-4**).

Figure 22-34 ■ When the visual reference is dominant for head position, the position of the head changes to match the tilted peripheral visual reference that results from the eye following the thumb in a figure-of-8. **A**, The head tilts off center as the perception of the visual field tilts. **B**, If the vestibular system is dominant, suppression of the apparent shift in the visual field allows the head to stay in alignment over the base of support. Sensory Substitution for Postural Control

When, as noted several times earlier, critical information from one system is absent or inaccurate, the CNS will begin to rely more heavily on the other systems for necessary reference. Although this is used initially to provide stability during the recalibration process, it can limit adaptation over the course of recovery.¹²⁵ Visual or somatosensory dependency patterns develop when the patient persistently makes use of either or both of those systems in preference to vestibular references when the most efficient reference for the environmental condition would be the vestibular system. This phenomenon has been identified in individuals with unilateral vestibular loss, thought to be compensated for. On testing there was an average of only 50% use of vestibular system weighting (trunk in gravity neutral), resulting in trunk sway in reference to the surface tilt, when tested on a rotating (tilting) surface at 8 degrees. Individuals with normal functioning systems showed 100% reliance on gravity by the time the surface made the 8-degree rotation, with minimal head and trunk sway following the surface tilt.¹²⁰

Dependency patterns are typically observed in an individual who does not recover satisfactory adaptation and integration of the sensory systems required for normal balance responses in a variety of environmental conditions. Clinically, these substitution patterns often manifest as hyperreliance on vision or somatosensory cues even when the vestibular system may have adequate potential for recovery. When given standard vestibular rehabilitation, these patients often do not recover a full return to activity and are left with functional limitations or symptoms that have a negative impact on their lives. They may experience discomfort every time they close their eyes or may find it impossible to walk down an incline in a visually challenging environment. Increased vestibular weighting can improve the ability to accomplish ADLs and improve balance confidence.¹⁴⁸ Interventions are now possible that provide both the therapist and the patient with feedback regarding trunk movement during surface perturbations.

Inadequate Use of Available Sensory Reference

Central maladaptation is a term used for what appears to be a condition that limits the use of any of the sensory systems so that each system seems to be inadequate for reference. The vestibular, visual, and somatosensory systems may test normal, but the individual is not able to use them adequately for functional activity. Patients report chronic subjective dizziness and have a tendency to develop hypersensitivities to stimuli in their environment.^{149,150}

Hypersensitivity patterns result in a patient who is intolerant of typical environmental conditions that include apparent visual motion, ground vibrations, or conflict between

sensory references. Avoiding provoking environments such as airports or malls, wearing dark glasses inside, limiting driving, and using bracing techniques for balance are common behaviors in this group of patients. **Box 22-5** presents conditions that may drive hypersensitivities. These patients have typically lost their jobs and generally underperform in life roles. Routine vestibular rehabilitation is usually not successful. Unless sensitivities are identified at initial presentation, a patient in this category may become recognized only when several treatment regimens fail. Based on the status of normal test results for individual systems, the patient has often been told that there is nothing wrong and therefore the problem is “in his head.” Indeed, this category of patient often has an overlapping psychological disorder that should be treated concomitantly. Anxiety, depression, posttraumatic stress disorder, and a history of physical or verbal abuse are common comorbidities that will affect intervention and successful outcomes. It is sometimes possible to identify the condition within the initial evaluation. These patients often report abnormal sensations with the head at rest with eyes closed, such as “flickers,” “explosions,” or “racing,” that do not reflect vestibular or somatosensory deficits. These patients will often demonstrate fear of the testing process but perform better on the higher-level tests of balance, such as eyes closed on foam, especially when distracted by a concurrent mental task. Visual motion hypersensitivity during oculomotor testing is common, and excessive startle is often seen during tests of head righting.

Vestibular Contributions to Movement

Vestibular system losses can result in motor responses that are larger than necessary for the task, which can predispose a patient to falling. This can be seen in the gait cycle when the body’s center of mass moves faster and farther than the individual can control. This movement appears similar to that of the patient with cerebellar dysfunction (see Chapter 21), and indeed may represent the loss of vestibular input to the Purkinje cells in the cerebellum that would normally modulate vestibular pathways.^{120,151} The earlier portion of Chapter 22, which discusses balance, describes automatic postural responses and describes balance testing in detail. It is important to understand the role of the vestibular system in movement

disorders related to balance. Patients with vestibular deficits typically rely primarily on their ankle strategy, which permits the head to remain aligned with the body and sustains congruence between vestibular and somatosensory inputs, with the somatosensory system being the dominant reference. Use of hip strategy may be modified or limited in the vestibular-deficient patient because when the head is moving in the opposite direction as the COG, vestibular and somatosensory inputs are not congruent.¹²⁶

Activities that require use of hip strategy, such as standing in tandem or on one leg, can be a problem for clients with bilateral vestibular loss or an uncompensated vestibular lesion.¹⁵² However, some patients demonstrate excessive use of hip strategy on a level surface when an ankle strategy would suffice. This often is related to a maladaptation or somatoform dizziness.

The vestibulospinal system is responsible for initiation of muscle activity in the neck in response to perturbations of the head as stated earlier. Abnormal integration of the vestibular responses can be seen in excessive co-contraction of the muscles of the neck when attempting to stabilize on unsteady surfaces. Responses to postural perturbations that start at the surface instead of the head may be exaggerated and poorly timed in the patient with insufficient use of vestibular system input. Understanding the critical link between the sensory input and motor output of the structures in the neck in relation to VSR activity is critical. Comorbid dysfunction of the cervical spine can negatively affect the reactions driven through the vestibular and somatosensory systems.

EXAMINATION OF THE VESTIBULAR SYSTEM AND DEVELOPMENT OF SPECIFIC MOVEMENT DIAGNOSES

Assessment of eye movement control can help diagnose dysfunction of the peripheral and central vestibular pathways. In particular, tests for a specific type of abnormal eye movement called *nystagmus* should be performed in clients with dizziness and those with known neuropathology involving these pathways. Nystagmus is involuntary, rhythmic oscillation of the eyes, with movement in one direction clearly faster than movement in the other direction. The client with nystagmus will also usually report vertigo. There is more than one type of nystagmus; identification of the particular type can direct the clinician toward the area of dysfunction. Visually induced, optokinetic, and end-gaze nystagmus should not be confused with conditions having a vestibular cause.^{134,153}

Spontaneous Nystagmus

Spontaneous nystagmus results from imbalance in the vestibular signals through their transmission to the oculomotor neurons. This imbalance produces a constant drift of the eyes in one direction interrupted by brief, fast movement in the opposite direction. Spontaneous nystagmus occurs after acute vestibular lesions and usually lasts approximately 24 hours. Peripheral versus central lesions may be distinguished by asking the patient to fix his or her gaze on a stable target. Nystagmus from peripheral vestibular lesions is easily inhibited with visual fixation. Nystagmus caused by central lesions of the brain stem or cerebellum is not easily inhibited with visual fixation.

Positional Nystagmus

Positional nystagmus is induced by a change in head position. Nystagmus caused by stimulation of the peripheral semicircular canals from movement of the otoconia or canaliculi typically lasts up to 30 seconds and then dissipates. Static nystagmus occurs with lesions to the peripheral otolith system through connections in the vestibular nuclei and cerebellum. It is provoked with change of head position in relation to gravity and continues as long as the position is maintained, although it can fluctuate in frequency and amplitude. Nystagmus caused by central vestibular system damage lasts minutes or longer before abating.

Gaze-Evoked Nystagmus

Gaze-evoked nystagmus occurs when clients shift the eyes from a primary central position to a second location. It is caused by the inability to maintain stable gaze position, and the eye drifts back toward the center or primary position. Usually indicative of a CNS problem, it is common in MS, brain injury, and congenital lesions.

Video Nystagmography

Video nystagmography (VNG) captures eye movements related to vestibular dysfunction using video goggles or electrodes surrounding the orbit of the eye. Oculomotor testing is performed to determine the ability to move the eye at normal speeds. Abnormal responses can indicate central dysfunction. Another component of the VNG is the caloric test, in which warm and cold air are introduced into the external ear canal to manipulate the fluid in the horizontal canal to isolate the ear and indicate the relative function on one side compared with the other. Central disorders will produce nystagmus patterns that are different from those related to a peripheral lesion.

Vestibular-Evoked Myogenic Potential

Vestibular-evoked myogenic potential (VEMP) is based on the principle that the saccule is sensitive to sound and responds in a similar fashion to clicking sounds as it does to tilt. A click produced in the ear stimulates the saccule, which in turn inhibits the synchronous discharges of muscles in the SCM on the same side. The rate of firing or tone of the SCM is inhibited during the recorded sounds, and this change is captured using surface electromyography (sEMG). The response in one ear can be compared with the response on the other side in the same person. VEMP findings are considered to be abnormal when they are very asymmetrical such that one side is more than twice as large as the other, low in amplitude, or absent. It is thought that this inhibition allowed the head to turn reflexively to sound, as was critical for survival of early humans.¹³¹ An abnormal VEMP can indicate ipsilateral lesion in the saccule, the inferior vestibular nerve, the lateral vestibular nucleus, or the medial vestibulospinal tract. Conversely, dysfunction of the motor neurons of the SCM will cause abnormal findings that are not related to vestibular disorder.

Subjective Visual Vertical

Subjective visual vertical (SVV) is used to test the degree of ocular torsion present in unilateral lesions. The SVV is tested in absolute darkness or an environment that prevents visual reference to vertical. The patient is asked to orient a rod to gravity, and the degree of off-axis tilt represents

the torsion of the eye that is common in acute unilateral lesions.¹⁵⁴

Gaze Stability and Vestibuloocular Reflex

The ability to hold the eyes fixed on a target while the head is moving is known as *gaze stabilization*. To test the accuracy of the vestibular system gain, the head is rotated or moved up and down at a rate of about 2 Hz. This is the rate at which the head moves during typical daily tasks, moving up to about 3 to 4 Hz with activities such as sports. When an individual is unable to achieve similar clarity of vision at rest and at 2 Hz, it would be expected that the VOR is not sufficiently calibrated.¹⁵⁵ If the image blurs, the gain of the system is abnormal, meaning that the vestibular system is unable to move the eyes at the exact speed in the opposite direction as the head movement. The ratio of eye velocity to head velocity is known as the *gain* of the VOR. The gain of an intact VOR is usually equal to one, which means movement of the eyes is equal to the movement of the head.¹⁵⁶ Testing of dynamic visual acuity assesses the acuity that can be obtained during a specific rate of rotation of the head. It can be tested with manual head turn using a Snellen eye chart (the same chart that is used to determine visual acuity, with normal vision recorded as 20/20) with the patient reading the smallest line that is comfortable, then having the head moving at 2 Hz in attempts to read the same line.¹⁵⁷ When acuity drops more than three lines, it is clear that the patient will be unable to maintain visual acuity during typical daily activity. Quantified dynamic visual acuity can be recorded as the logarithm of minimal angle of resolution or LogMAR. This can be tested and quantified by use of equipment such as inVision (NeuroCom International). Gaze stability can also be quantified using the same equipment, but the measure is one of function, reporting the head speed that can be obtained while maintaining gaze stability. This is a good way to clarify the amount of deceleration that is necessary in order for the patient to maintain proper vision. [Figure 22-35](#) shows testing and treatment available using quantified dynamic visual acuity.

Figure 22-35 ■ Quantified dynamic visual acuity is possible with systems such as inVision. (Courtesy NeuroCom International, Clackamas, Ore.)

Vestibuloocular Reflex Cancellation

VOR cancellation reflects the ability to synchronize simultaneous eye and head movements in the same direction and is associated with the ability of the brain to suppress the VOR. This function allows an individual to track an object while moving the head at the same speed. Testing results are reported as normal if the eye can remain in the center of the orbit as the head and eyes track an object as it moves across the visual field. If the central integration capabilities are abnormal, the client will not be able to override the reflex activity and cannot keep the eye and head moving at the same rate in the same direction.

Gait

Vestibular control of position for the upper body and head appears to be separated from the lower body in gait in a similar pattern as noted during perturbed stance. Head and trunk stability remain constant throughout the phases of gait, and vestibular inputs appear to be most critical during initiation of gait, toe-off, and heel strike. Vestibular information contributes to the planned foot trajectory and placement of the foot to prevent disequilibrium. It is interesting to note that during steady-state gait, and even more so with running, vestibular contribution appears to diminish in importance. This may be because running is so highly automated and the trajectory remains fairly steady.¹⁵⁷

The gait pattern reflected by vestibular dysfunction, or lack of integration, involves flat-foot gait with minimal heel strike, abnormal foot placement requiring larger-than-normal trunk adjustment. In order to control the position of the trunk, the base of support is widened. Speed of gait is another indication of vestibular function from the perspective that patients with bilateral vestibular loss demonstrate a slower self-selected speed. Typically, increased double-limb stance time and decreased stability at heel strike are present.¹⁵⁸ Walking with head turns becomes even more challenging as the vestibular system is activated and the somatosensory and visual systems are disadvantaged. Vestibular contributions to stability during transitions from sitting to standing, initiation of gait, and abnormal foot placement can be identified during standard tests such as the TUG, the Tinetti, and the DGI. Scores are adversely affected when vestibular system functions are diminished. The FGA was developed specifically for use with patients with vestibular disorders.¹⁵⁹ For a more complete description of tests of balance, see the earlier portion of Chapter 22.

Movement diagnoses related to vestibular examination are presented in [Box 22-6](#).

BOX 22-6 ■ MOVEMENT DIAGNOSES RELATED TO VESTIBULAR EXAMINATION

- Spontaneous nystagmus inhibited by fixation
- Sensation of motion with body held still
- Instability or dizziness during head motion
- Loss of adequate head righting
- Head position dizziness
- Dependency patterns
- Inadequate use of available sensory reference

INTERVENTION

Positional Dizziness

The Hallpike-Dix maneuver is a positional test used to determine if otoconia are present in the posterior or anterior semicircular canal. Figure 22-30 demonstrates the position of the head and movement of the otoconia. A positive response is a delayed nystagmus of about 3 to 15 seconds, which determines potential diagnosis of BPV.

To test, the client is positioned in long sitting on a mat or plinth such that, when supine, the head and neck extend over the upper edge of the surface. The examiner holds the head of the sitting client between both hands and then rapidly moves the client backward and down with the head turned to the side and the neck extended 30 to 45 degrees below the horizontal position. The head is held in this position for 20 to 30 seconds. The examiner monitors for symptoms of vertigo and observes the eyes for nystagmus.¹²¹

When the Hallpike-Dix test position indicates BPV, specific, highly effective procedures can be performed in the clinical setting to remediate the disorder.¹⁶⁰

Canalith repositioning is a series of passive movements designed to move loose debris (otoconia) through the canal and back into the otolith. The client is first brought down into the extended and rotated position that causes the nystagmus and vertigo (the positive Hallpike-Dix position). The head is held in that position until the symptoms fade completely or for 60 to 90 seconds. The head is maintained in extension and then slowly rotated toward the unaffected side and kept in that position for an additional 1 to 2 minutes to allow movement of the otoconia through the canal. The client then rolls so that she or he is side-lying and the head is turned to a 45-degree position relative to the ground. This position often produces more vertigo and nystagmus as the otoconia continue to move through the canal. In the next movement, the head is tipped toward the chest and the client is assisted into the sitting position. Figure 22-36 shows the sequence of the Epley maneuver. The client must then follow specific instructions for 24 hours.¹⁶¹ These include avoiding forward, backward, or lateral head tilts or bending activities. Clients should also sleep with the head elevated to at least 30 degrees and avoid turning to the involved side.¹⁶²

When the BPV is within the horizontal canal, dizziness or vertigo is reported when rolling, especially if the head is elevated on a pillow because that puts the canal in a position perpendicular to the ground. The symptoms are reported when the head is turned in either direction, but the side that triggers the worse symptoms is thought to be the side of the dysfunction.

Horizontal canal BPV is tested for in the supine position with the head held in 30 degrees of flexion to keep the lateral canal perpendicular to the ground or in the neutral position for ease of positioning. The head is then turned in each direction and the eyes observed for horizontal nystagmus. This must be distinguished from static positional nystagmus by the fact that the nystagmus will fatigue if it is caused by movement of the otoconia but otherwise persists.¹⁶³

The repositioning intervention then begins with the client supine with the head turned toward the more affected ear. The head is then turned away from the affected ear and the client is slowly rolled 360 degrees (essentially staying in the same place) until the head is returned to the original

position. The client sits back up with the head tucked. Side tilts of the head, as well as forward and backward movements of the head and trunk, are avoided for 24 hours.¹⁶⁴

Position-provoked dizziness may alternatively be related to canal sensitivity or abnormal firing through the brain stem when BPV is not found to be the cause. In this case, exercises should be done to increase the client's tolerance to the provoking position(s). This involves having the client perform the provoking positions to give the CNS the opportunity to adjust to the sensation that the position triggers. Rolling on a bed or spinning in a chair can help adapt when stimulation to the horizontal mechanism is disrupted. In cases of maladaptation causing sensitivity of head position, moving gradually into the position of discomfort while minimizing input from the other sensory systems can be successful. In addition to exercise sessions, incorporating the provoking positions into daily activities is also important

Adaptation

Adaptation represents the highest level of recovery in the patient with a vestibular dysfunction, and therefore as much adaptation as possible should be facilitated for the final outcome.^{129,133} As noted earlier, the patient may be at any level of adaptation when intervention is initiated, and it is critical to be able to recognize the symptoms and behaviors associated with lack of adaptation and those that represent sensory substitution. Overdependence on nonvestibular sensory reference must be extinguished. Isolating specific components of the symptoms reported and understanding how impairments can manifest across several different testing procedures will guide intervention. Activation of an error signal starts the recovery process, and the environment must be carefully manipulated to challenge the patient at the right level for the correct impairment. Substitution strategies must be eliminated during exercise even if they are still in use during activity. To stimulate the use of vestibular inputs for adaptation of the CNS, environments are designed to disadvantage both vision and somatosensation. Practice can be on unstable or compliant surfaces, with vision either absent or destabilized by eye and head movements, progressing to optokinetic stimulation.^{140,165-168} Central dysfunction will negatively affect recovery rate, and knowledge of the degree and form of central disorders is important to determine prognosis and modify interventions. Psychogenic disorders will also affect the process of recovery and need to be addressed with the appropriate professional support.

When the integration of vestibular and somatosensory inputs is not congruent even at rest, there is a reported sensation of movement inside the head when the body is held at rest in supported sitting. In this instance, enhancing the somatosensory input by weighting through the spinal column or having the patient lie on a firm surface should be part of the initial intervention. This allows the vestibular system to calibrate using somatosensory input as a reference. This activity, known as *settling*, is a good way to allow the patient to manage symptoms when they have been exacerbated by activity. Use of distracting mental tasks pushes the adaptation to the subconscious level. Figure 22-27 shows the setup of weighting the spine to encourage settling of symptoms.

On the other hand, if the use of weights increases the sensation of movement, the clinician should suspect abnormal central sensory weighting of somatosensory inputs.

Figure 22-36 ■ Epley maneuver: Canalith repositioning maneuver for the patient with posterior canal benign positional vertigo (BPV). Figure represents procedure for right-side BPV. Movement of particles through the canal is shown in each position. (From Furman JM, Cass SP: Benign paroxysmal positional vertigo. *N Engl J Med* 341:1590–1596, 1999. Slow progressive introduction of weights may be necessary to achieve decreased sensation of movement.

VOR adaptation requires movement of images on the retina, or retinal slip. Therefore intervention begins with head movement at the speed that allows stable vision.^{156,169} Adaptation of the VOR is accomplished by having the patient move his or her head while trying to maintain gaze stabilization by keeping a stationary object in clear focus.¹²⁸ As the system adapts, speed of head movement increases, with the goal of achieving head movement at 2 Hz without the object blurring. Initially the client can focus on the thumb or a business card held at arm's length. The activity is progressed to a higher level of difficulty by adding a background visual stimulus such as a television set or a visually complex environment. Gaze stabilization with head turns while standing on an uneven surface or while walking creates a higher-level challenge. Many clients have avoided head movement, so simply turning the head may initially trigger dizziness. As stated previously, dizziness with head motion should not be confused with abnormal VOR; in VOR dysfunction the visual image blurs as the head moves.

As stated previously, the vestibular system provides a top-down point of reference that the somatosensory system uses to prevent the head and trunk from aligning with surface changes. Perturbations in the form of oscillating surfaces provide a mechanism to activate the gravity receptors, and feedback about the alignment of the trunk to gravity neutral can help to discourage surface dependence when it should not be the dominant reference.¹⁴⁰

Ineffective head-righting responses observed during sharpened Romberg or standing on a narrow surface should be treated as such and activated for efficiency starting in a sitting tilt. Activities that require quick changes of position in a superior or inferior direction, such as a lunge or going up and down stairs, can be difficult when the otoliths are damaged. Good program components for otolith stimulation are activities involving up-and-down body movements. Examples include sitting to standing, seated bouncing on a Swiss ball, and standing bouncing on a mini-trampoline, all with eyes closed to eliminate use of vision for stability. Certain positions or movements of the head during upright activities can affect balance if just one part of the vestibular system has abnormal function. If the otoliths are damaged or hypersensitive, a voluntary lateral tilt of the head when standing with the eyes closed can cause destabilization.

A vestibular adaptation program should challenge the patient at the limit of his or her ability. Clients often choose

to do the easiest exercise and avoid the more difficult exercises if they are not educated about the need to trigger the symptoms. Conversely, if the challenge is too far above the ability of the patient, the CNS will fail to adapt and symptoms will not decrease.

Elimination of Visual Dependence

When the use of vestibular inputs has been minimized through self-limitation of head and eye movements to control dizziness and imbalance, the visual system often becomes dominant for balance. Testing as identified in [Figure 22-34](#) can be used for intervention. Another way to train the client to use vestibular input versus vision is watching a ball being tossed from hand to hand while standing on a compliant surface ([Figure 22-37](#)). This can also be done while walking. Clients with visual dependency often report excessive fatigue after activity because of the strain of using vision for postural stability. When these clients are in situations with excessive visual stimulation, reports of dizziness increase. The subtle eye movements associated with viewing a computer monitor cause more fatigue for the individual with vestibular disorder. These individuals also often avoid crowds as in a mall, grocery store, or airport. Attending church services, which are often characterized by low lighting, visual stimulation, and the need to stand with eyes closed or read a hymnal while singing challenges the vestibular system. [Figure 22-38](#) shows the use of optokinetic stimulus to decrease visual dependence and to improve the

Figure 22-37 ■ Keeping the gaze directed at the moving ball while standing on a compliant surface eliminates the primary use of visual targets to stabilize the head and is an effective way to shift reference from visual to vestibular. (Courtesy Ray Hedenberg, IRB Solutions, Silverthorne, Colo.)

Figure 22-38 ■ Projecting peripheral movement activates the optokinetic response. Individuals with visual dependence for balance, or visual motion hypersensitivity are not able to adequately achieve gaze stability of the central object or will lose balance as they match head position to the peripheral reference. In the patient with maladapted responses, this stimulus can cause significant nausea and other abnormal autonomic nervous system (ANS) responses.

ability to maintain gaze reference when there is movement in the visual background.

Gait

Gait with head motion is important for the individual with vestibular dysfunction. Because head movement causes visual disturbances and dizziness, the client with a vestibular disorder will significantly limit head movement while walking. When visual cues are used predominantly for balance, the client will try to keep the body in line with vertical and horizontal visual targets. This will decrease the small, natural movements typically made during the gait cycle. Patients with potentially recoverable vestibular function should be trained to walk with eye and head movements, trunk rotation, and arm swing. [Figure 22-39](#) shows abnormal placement of the foot for stability when the individual is unable to use the head orientation to gravity as the primary reference.

When the vestibular system does not accurately inform the client about the speed and direction of head movement, visual cues are used to determine movement speed and direction in relation to nonmoving objects. However, in environments with a lot of motion, or when someone approaches in the opposite direction, determining speed and direction of self-movement becomes more difficult. Clients often report dizziness and imbalance in a crowd. Changing visual environments can trigger imbalance in the client with visual dependency. Walking into a darkened room, especially if the surface is uneven (as in a theater), can often trigger a fall or stumble. Clients with permanent vestibular loss should be educated about these potentially high-risk environments and taught compensatory strategies to ensure safe mobility. If improvement in vestibular function is anticipated, however, then progressive exposure to these busy environments is needed to prepare the client for real-world mobility.

To increase somatosensory input, clients with a vestibular disorder often put the whole foot down at once to get better input on the position of the body relative to the ground. The normal heel-toe weight progression over the ball of the foot

Figure 22-39 ■ **A** and **B**, When the vestibular, visual, and somatosensory systems are integrated properly, the movement of the head does not change the pattern of the step. **C** and **D**, When the vestibular system is not primary for reference, step outs occur during head rotations. This demonstrates the foot moving in the direction of head turn, causing a staggering gait pattern seen often with patients with lack of ability to activate primary dominance of the vestibular system. (Courtesy Ray Hedenberg, IRB Solutions, Silverthorne, Colo.)

is diminished. This is often seen in conjunction with increased step width while walking. This compensatory strategy is acceptable in clients with permanent loss but should be discouraged in clients who do not need to be overreliant on somatosensation for balance control during walking. Walking on uneven surfaces can be a challenge if the client is primarily reliant on somatosensory input and has poor visual-vestibular interaction. This is one reason why walking indoors is less of a problem than walking outdoors. Again, clients who are not expected to recover vestibular function should be educated about these potentially hazardous environments and encouraged to develop compensatory mechanisms to permit safe mobility. Gait training on progressively less stable surfaces is appropriate for clients who need to reduce dependence on somatosensory cues and improve visual-vestibular interaction.

Substitution

Permanent bilateral vestibular loss, however, requires substitution of somatosensation and vision to orient to the environment. Use of a cane or walking stick to increase use of somatosensation and allow more time to prepare for the next step can increase confidence in gait. Control of turns can be achieved by a quick stop while the head is turning, rapid saccade to stable target, and then completion of the turn with a fixed gaze. **Figure 22-40** shows the sequence of the spot turn. This process can become second nature and can be performed on a regular basis to increase stability during daily tasks.¹⁷⁰ Driving can be trained in a safe manner in reference to head turns and visual references by doing a slow blink to decrease distracting visual flow.¹⁷¹

Maladaptation

Clinical interactions have an important influence on the course of maladapted responses. Explaining the psychosomatic connections in detail can be the first step in recovery. This is critical in order to engage the patient who demonstrates strong avoidance behaviors. Successful outcomes are possible; however, the process may take longer because the central modulation of sensory input is compromised, and therefore adaptation will occur in smaller increments. Proper referral to someone to assist with the management of the psychological or psychiatric condition should always be considered.

Figure 22-40 ■ The “spot turn” for the patient with bilateral vestibular loss. **A**, When the patient is ready to turn, the front foot is planted to provide somatosensory reference. **B**, Once the foot is planted, the head is turned. **C**, Visual reference on a nonmoving target is maintained while the body turns under a stable head. (Courtesy Ray Hedenberg, IRB Solutions, Silverthorne, Colo.)

FEEDBACK

Biofeedback can be used in a variety of ways. Feedback about correct postural responses remains the task of the therapist in the training paradigm. Visual feedback has been used to supplement center of pressure reference for control of weight shifting using vision to supplement vestibular integration to somatosensory inputs. Visual feedback about the head and trunk movement versus total movement on a perturbed surface is available on the Proprio 5000 (Figure 22-41).

Use of the Nintendo Wii Fit has been popular and provides information about results of weight shifting integrated into games that integrate a balance task into an activity that may represent another activity. Training is performed on a nonmoving surface, so somatosensory drive is activated. Patients with visual motion hypersensitivities may find the games overstimulating at the beginning of the session, but playing them may also be an appropriate method to increase adaptation so that more visual stimulus can be tolerated.

Audio feedback has long been used in the patient with vestibular system loss to provide information about sway when surface and visual reference is lacking. It can be used in many different ways for intervention.

Vibrotactile feedback using accelerometer or gyroscopic information has emerged in recent years. This has been successful on many levels, and the modes of input are becoming less intrusive to those who wear them. The input typically provides immediate positive changes in performance of a task, with behaviors that represent improved postural re-

sponse to gravity reference; however, the rate of retention or carryover may still be related to available plasticity within each system.

CONCLUSION

This chapter has been divided into two sections owing to the specificity and amount of information specific to both areas. Balance was presented first because of the general nature of this topic and because it lays the foundation for discussion of vestibular problems. Although vestibular disorders have a direct effect on balance, not all balance dysfunction is caused by vestibular problems. With the amount of research available in both areas and the areas of specialization separating, the chapter was separated to aid the readers in focusing on specific problem areas. The references have been placed chronologically as appearing in the chapter, but the reader will see that the two portions have been clearly identified to assist in finding materials specific to the topic of interest. The complexity of these two topic areas has grown as new research and new technology have become available. Outcomes of treatment once thought unrealistic have become reality. Many patients who once thought their quality of life was permanently diminished and their ability to participate in meaningful activities had been taken away now show tremendous improvement in functional movement. The effectiveness of therapists working with these patients depends on understanding the specificity of the clinical problems and applying interventions that show measurable change. The importance of active patient participation cannot be overemphasized when discussing motor control and motor learning principles needed to optimize positive changes in balance and in specific vestibular disorders. These problems dramatically affect an individual's quality of life, and the role occupational and physical therapists play in providing appropriate interventions has established efficacy in practice.

Acknowledgment

Thanks to Janet Helminski, PT, PhD; Linda Horn, PT, NCS; Pat Huston, MS, PT; Leslie Allison, PT, PhD, NCS; and Kenda Fuller, PT, NCS, for their significant contributions to the development of this chapter. Gratitude is also extended to Darcy Umphred, PT, PhD, FAPTA, and our families for their patience and support.

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 182 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

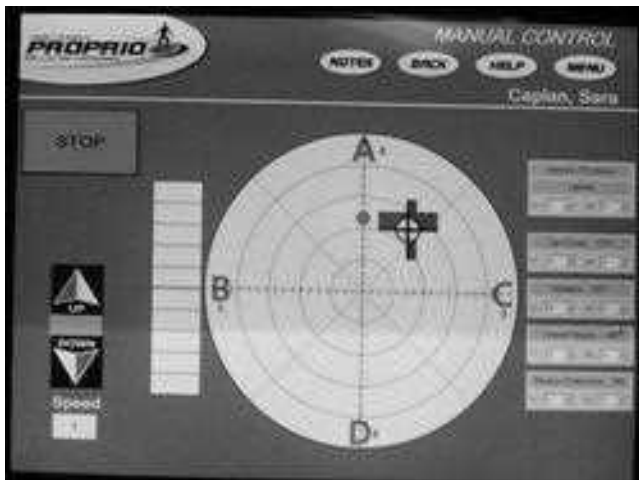

Figure 22-41 ■ Feedback about the position of the trunk in relation to the center of the platform, as well as feedback about the amount of trunk flexion and extension and rotation, can be provided to the patient during the perturbations. The patient can also receive summary feedback after sessions performed with the eyes closed. (Proprio 5000, Perry Dynamics, Decatur, Ill.)

CASE STUDY 22-1 ■ ANDY

Andy is a 27-year-old man who sustained a severe closed-head injury in a skiing accident. He was hospitalized for 2 months and resided at a long-term care facility for 6 months before cranial surgery for removal of bilateral subdural hygromas and revision of a ventriculoperitoneal shunt. After surgery he demonstrated marked improvement and was transferred to a rehabilitation unit. His initial physical therapy assessment revealed the following impairments, which had a negative effect on postural control:

1. Oculomotor deficits (difficulty tracking to the right and upward)
2. Disorientation
3. Delayed and slow motor responses
4. Bilateral ankle plantarflexion contractures (1 to 10 degrees left, 1 to 15 degrees right); limited right shoulder flexion (0 to 100 degrees) and external rotation (0 to 20 degrees)
5. Hypotonic trunk (right, moderate; left, mild), hypertonic (extensor) lower extremities (right, moderate; left, mild), hypertonic right upper extremity (mild)
6. Fair head control
7. Poor trunk control with right scapular atrophy, shortened right side, strength 3–/5
8. Left upper and lower extremity movement isolated and coordinated but slow, strength 4/5 at shoulder, 4+/5 elbow, wrist, hand, 4/5 hip and knee, 3+/5 ankle, able to place and hold for weight bearing
9. Right upper extremity rests and moves in synergistic pattern but can move out of synergy with request or demonstration; strength 3–/5 at shoulder and 4–/5 distally; coordination is poor; can place and hold for weight bearing if cued but not spontaneously
10. Right lower extremity moves in flexor-extensor pattern, grossly 3+/5 in hip and knee flexion, 2+ hip extension, 3+/5 knee extension, no isolated ankle movement, cannot place or hold for weight bearing

Functional tests found the following activity limitations:

1. Minimum assist supine-to-sit
2. Sitting balance, poor
3. Moderate assist sit-to-stand
4. Standing balance, unable
5. Moderate assist transfers
6. Nonambulatory

Body system impairment goals were the following:

1. Increase ROM to within normal limits throughout
2. Increase trunk tone to normal and strength to 4+/5
3. Decrease right-sided tone to normal
4. Increase spontaneous use, isolated movement, and strength (4+/5) in right extremities
5. Able to place and bear weight on right lower extremity

Short-term functional goals were the following:

1. Independent in all bed mobility
2. Independent in wheelchair transfers

3. Good static and fair dynamic sitting balance
4. Contact guard sit-to-stand
5. Minimal assist static standing balance

Note: Ambulation goals were temporarily deferred because of the ankle contractures and balance deficits.

Early treatments included the following:

1. Standing frame activities for head control, visual tracking, trunk control, reduced lower-extremity extensor tone, and heel cord stretching with ultrasound
2. Neurodevelopmental sequence activities for head and trunk control; trunk strengthening; decreased lower-extremity extensor tone; balance on all fours, heel-sitting, kneeling
3. Supine to and from sitting, especially over the right arm
4. Sitting balance with upper-extremity functional tasks (e.g., putting glasses on and taking them off, taking shirt off and putting it on, wiping nose with tissue), with focus on right visual tracking, right trunk elongation, and incorporation of right lower-extremity ground pressure for stability
5. Transfer training with incorporation of right upper extremity to push up, reach and grasp, and right lower-extremity placing and weight bearing

As soon as Andy's ankle dorsiflexion ROM was near neutral on the right (was then 0 to 5 degrees on the left), neurodevelopmental activities were phased out and standing balance and pre-gait activities in the parallel bars were initiated with moderate assistance. He rapidly progressed to minimal-assistance gait in the parallel bars but with significant scissoring of the lower extremities. Gait outside the bars was begun with a quad cane on the left, but Andy was not able to organize the sequence for cane use and did not use the cane when loss of balance occurred, so use of the cane was discontinued. Gait without an assistive device required moderate assistance from the therapist for balance. A line drawn on the floor provided a visual cue to remind him to keep his feet apart; when walking without this cue, approximately 25% of his steps were close or crossed.

At discharge, 2 months after admission, Andy had good visual tracking; normal ROM with the exception of right lower-extremity dorsiflexion, which was limited to 0 to 5 degrees; normal tone in the left extremities; mildly increased tone in the right extremities with slight extensor patterning in the leg; good head and trunk control; and strength grossly 4+/5 throughout. Functionally, he was independent in bed mobility, wheelchair mobility, and sitting balance. He required supervision for safety in transfers and standing activities and minimal to moderate assistance for indoor ambulation without an assistive device depending on his fatigue level.

CASE STUDY 22-2 ■ DORIS

Doris is a 73-year-old woman with a long history of Parkinson disease who had fallen four times within the 6 months before referral to physical therapy. As a result of her most recent fall, during which she hit her head, Doris had ear pounding, lightheadedness, and headaches. After referral to an otolaryngologist, she was diagnosed with unspecified peripheral vestibular dysfunction and referred to outpatient therapy. Her therapist found that Doris reported increased lightheadedness and dizziness, with anterior-posterior head movements, rolling in bed, sit-to-stand, and the Hallpike-Dix maneuver (worse to the right). Multiple impairments that could be contributing to her instability and falls, as well as symptoms related to the vestibular disorder, were also noted. Doris had mildly decreased ROM in her left ankle, shoulders, and neck; mild left-sided weakness and lack of coordination; marked bilateral upper-extremity tremor; and moderately forward-flexed posture.

She could not perform an ankle strategy at all and continually used hip strategy; she also used stepping strategy frequently with the least shift or sway. Static postural sway tests indicated that Doris had excessive sway when attempting to stand still and that she kept her COG slightly posterior and to the right of midline. Sway increased tenfold with eyes closed, indicating poor use of somatosensory inputs for postural control. Doris could not perform repeated weight shifts in either anterior-posterior or medial-lateral directions. Her limits of stability were severely restricted to less than half of normal sway range anteriorly, and her movement time was slow.

Functional testing revealed that Doris had several disabilities. She had to use a walker or have manual assistance to ambulate and could negotiate level surfaces only. Without her walker or handhold assistance, Doris could stand for less than 30 seconds and take a maximum of 10 steps. For community ambulation, Doris needed minimum assistance with her walker and could go only short distances. She also required minimum assistance with bathing and household tasks.

Doris participated in therapy twice a week for 6 weeks and also performed a home exercise program daily. Her

treatment plan included vestibular exercises for the dizziness and balance retraining exercises for instability and falls. The vestibular exercises she was given were designed to provoke her symptoms repeatedly and included head turning in supine and sitting (progressed to standing), rolling in bed, rocking in a rocking chair, and sit-to-stand practice. As her dizziness subsided, her home program was modified to increase the number and rate of head movements. To improve her use of somatosensory and vestibular inputs, Doris also practiced standing on a firm surface with eyes closed (with family supervision). In the clinic, Doris did stretching, strengthening, and postural extension exercises to address her musculoskeletal limitations. For increased use of somatosensory and vestibular inputs, she practiced standing and weight shifts with optokinetic stimulation. By using postural sway biofeedback, she practiced achieving the midline position, controlled anterior and left-sided weight shifts at progressively faster speeds, and ankle strategy. Gait training included starts, stops, turns, and obstacle avoidance and progressed to community ambulation tasks such as curbs and ramps. As her endurance improved, she also did gait training on the treadmill to increase the gait speed, stride length, hip strength, and use of vestibular inputs.

Despite her multiple problems, Doris was able to reduce the severity of her impairments and consequently improve her functional level. Her dizziness resolved completely. Although she still had excess sway during static standing, she was able to achieve and hold a midline position, and her sway with eyes closed reduced by more than half. Doris could shift her weight in both anterior-posterior and medial-lateral directions at moderate speeds by using ankle strategy without stepping. Her limits of stability were expanded from 35% to 80% of normal, and she was able to shift her weight much more quickly. Functionally, she could stand without the walker for 8 minutes and walk independently indoors on level surfaces without the walker for short distances. She was independent in community ambulation with the walker. At a 3-month follow-up visit, Doris reported that she had experienced no more falls.

APPENDIX 22-A ■ Common Vestibular Disorders

Benign Positional Vertigo (BPV)

The otoconia in the otolith can become loose, clump together, and form densities known as *canaliths*, which can move into a semicircular canal and become a cause of vertigo. In cases of BPV, the involved side is distinguished by which ear is toward the ground when the symptoms occur. The critical hallmark of BPV is that the vertigo usually starts after 5 to 10 seconds and resolves or fatigues within 20 to 40 seconds. A less common variant of BPV, cupulolithiasis reflects the adherence of the otoconia to the cupula. The vertigo associated with change of head position is caused by the direct pressure deflection of the cupula. The vertigo appears with less latency and is often more persistent, taking up to 60 seconds to resolve after change of head position.

Benign positional nystagmus or vertigo is a common sequela of head concussion, viral labyrinthitis, hydrops, and vascular occlusion in the distribution that feeds the inner ear. It can also develop without a known external cause and is the most common cause of vertigo.¹⁷² Other conditions that can cause head position dizziness are described in [Appendix Box 22-1](#).

BPV may involve any semicircular canal, although the posterior canal is most common because of its relationship to the otoliths when the person is in the recumbent position. The horizontal canal can also collect otoconia, and the result is horizontal nystagmus generated with head movement; dizziness often occurs as the head is going backward, when the horizontal canal moves into the gravity-responsive position. The dizziness is also triggered in the head rotated and flexed position.

Despite the use of the term *benign*, the symptoms related to positional vertigo are intense and can cause significant disability. There is often a strong sense of falling or spinning out of control, even when the individual is lying on a bed. Before the individual is

APPENDIX BOX 22-1 ■ ALTERNATIVE CAUSES OF HEAD POSITION DIZZINESS AND NATURE OF DIZZINESS

Unilateral vestibular dysfunction: Dizziness when changing head position while supine

Vestibular migraine: Episodic dizziness that can usually be related to specific triggers

Cerebellar nodulus: Nystagmus is downbeat without torsion without fatigue or habituation

Vertebral artery compression: Nystagmus with extreme rotation or extension of neck

Central vestibular pathways: Nystagmus without dizziness, usually unidirectional

Geriatric supine nystagmus: Vertical nystagmus when supine

Perilymph fistula: Episodic dizziness after trauma, increases with Valsalva or head hanging

Superior canal dehiscence: Dizziness with loud noises or change of head position

Hypermobile stapes: Unstable at oval window; allows fluid pressure changes that cause dizziness with head positions

Head extension: Otoliths outside of functional range, causing dizziness

Orthostatic intolerance: Dizziness when bending or quickly standing from sitting, never when lying

aware of the mechanism, it seems to be something that is uncontrollable because it is associated with head movement. Spontaneous remissions are common and may reflect an underlying disorder such as hydrops or migraine-induced ischemia. Infections or inflammations may occur months or years before the onset of BPV. Adverse life events are reported to trigger an event, especially in individuals with an underlying disorder.

Infection

Acute unilateral vestibulopathy affects the vestibular nerve. Most often the infection is viral in nature and is known as *neuritis* or *neuritis*. It can also be caused by bacterial infection from a variety of causes, either as a primary infection or secondary to bacterial meningitis or encephalitis. Vestibular neuritis can be partial, affecting the superior afferents from the horizontal and anterior semicircular canals primarily.

The infection often is preceded by a systemic illness or an upper respiratory tract infection, but it can be an isolated infection affecting the nerve or labyrinths. This causes an acute, severe dizziness often accompanied by nausea and vomiting. Initial impairment may include ocular tilt, skew deviation, or lateropulsion. Recovery reflects central adaptation to loss of input on one side of the vestibular system.

Endolymphatic Hydrops

Increased fluid pressure within the labyrinth, known broadly as *hydrops*, will cause vertigo. The fluid pressure may increase because the fluid cannot move out of the system through the endolymphatic sac, which normally absorbs excess fluid. As the fluid pressure increases, the brain receives abnormal signals from the cupula of the labyrinth on one side, and the result is the sensation of spinning. There is often concurrent low-frequency loss of hearing related to the fluid pressure in the cochlea. The episode can last from just a few minutes to a day but usually lasts 2 to 4 hours. The use of diuretics can control the fluid changes and decrease the number and intensity of symptoms. Meniere disease is a type of hydrops that occurs intermittently; the person has normal balance when not having an episode.

Over time there appears to be a gradual degradation of the vestibular system, resulting in symptoms associated with chronic unilateral vestibular loss. These patients often have a diffuse dizziness and report imbalance between episodes. Intervention is targeted at adaptation of the abnormal vestibular responses, and this can improve symptoms, although it cannot remedy the disease itself. Traumatic hydrops can be the result of a blow to the head during a fall or whiplash injury. The mechanism is not fully understood, but it may be related to damage to the endolymphatic sac during the trauma, resulting in inflammation or scarring that limits the regulation of fluid in the sac. Patients often appear drunk during an episode and therefore may limit social interactions or driving for fear of an attack. In some individuals an attack can include the “crisis of Tumarkin,” resulting in feeling as if they have been thrown to the ground without a sensation of dizziness.

Perilymph Fistula

Fistula, or an abnormal communication of the inner and middle ear, can occur at the round or oval windows. This may have a congenital cause or may be related to trauma through the middle ear from surgery, blasts, head injury, or even sneezing. The Valsalva maneuver can trigger an intense sensation of dizziness owing to increased pressure in the system, and daily activity can produce an almost

Continued

APPENDIX 22-A ■ Common Vestibular Disorders—cont'd

persistent sense of dizziness that is relieved by recumbent positions with minimal head movement. Typical vestibular testing is nondiagnostic, but use of pressure in the ear may assist this diagnosis. Vestibular rehabilitation for adaptation fails because the system has a persistent fluctuating nature. Successful surgical repair of the fistula produces the stability needed to resume rehabilitation efforts.

Superior Semicircular Canal Dehiscence Syndrome

Dehiscence or thinning of the bone overlying the superior (anterior) semicircular canal creates a “third mobile window,” and the effect of change in pressure of the canals appears to be similar to the fistula. Loud noise or pressure can cause disequilibrium. Surgical repair usually produces good results.

Vertiginous or Vestibular Migraine

The aura or even the primary symptom of migraine may be dizziness. Diagnosis is based on the episodic nature, recognition of triggers, history of migraine, and combination of dizziness with the other typical prodromes of migraine including photophobia, nausea, and vestibulocochlear symptoms of tinnitus and sensitivity to sound. The pathophysiology follows that of migraine headache, in which there are multiple levels of dysfunction from gene defects that drive familial autosomal disorders and an inherited migraine threshold, brain stem activity that can trigger vascular responses of dilation or restriction, serotonin platelet activity, and spreading neuronal depression. Medical management follows the criteria for migraine. Rehabilitation is indicated when avoidance of activity has changed the sensory integration, or when multiple episodes have influenced the system toward dependency or hypersensitivity patterns.¹⁷³

Vascular Disorders

Ischemia in the areas of the vestibular system (brain stem, cerebellum, parietal-insular cortex) can cause dizziness and imbalance. Vertebral basilar artery insufficiency syndrome, for example, classically produces these problems. Ischemia is usually seen in individuals older than 50 years, but it can also be associated with bleeding disorders such as leukemia. Migraine headache can cause intermittent dizziness from compromise of blood flow in the areas of the vestibular system.

Neoplasia

Neoplasia can compromise vestibular function when it occurs near any part of the vestibular system. Vestibular schwannoma (commonly but mistakenly known as *acoustic neuroma*) can cause damage as it slowly grows on the sheath of the vestibular nerve. The schwannoma can grow into the pontocerebellar angle and cause symptoms typically associated with cerebellar lesions. Meningiomas (encapsulated tumors found most often deep in the brain) growing in the area of the temporal lobe can cause pressure on the vestibular mechanism. In some cases, damage to the vestibular nerve occurs as a result of surgical removal of the tumor.

Ototoxicity

Aminoglycosides, antibiotics used in cases of massive or systemic infection, can be ototoxic (causing damage to the vestibular hair cells). Although a small percentage of users experience this adverse effect, it can affect both sides of the bilateral vestibular apparatus and cause significant disability. Often the client does not begin to experience the symptoms until the medication has been used for more than a week.

Traumatic Brain Injury (TBI)

TBI can affect the vestibular system in several ways. It can cause direct damage to the vestibular end organ (in the temporal bone); BPV; and, in many cases, disruption of the integration of the vestibular nuclei (in the brain stem) and cerebellum. Sensorimotor disturbances are common with TBI involving the cerebellum or parietal lobe. Visual dysfunction results from damage to brain stem areas such as the pontine gaze centers or central damage in the medial longitudinal fasciculus. Frequently the third, fourth, or sixth cranial nerve is damaged, and this affects the ability to move the eyes for conjugate gaze. In some extensive TBI cases the brain loses its ability to use any of the three sensory systems accurately. Dizziness and imbalance are prevalent complaints from client with TBI because there are often situations in which they cannot acquire accurate sensory information.¹⁷⁴

Each system should be evaluated individually for its function. In patients with TBI, the adaptation of the vestibular system occurs more slowly and with more effort than in other clients with vestibular deficits. The client with vestibular problems associated with TBI requires significantly more intervention initially, and the outcomes are less favorable than for other clients experiencing vestibular dysfunction.¹⁷⁵

Allergies

Persons with allergies are often predisposed to episodes of dizziness. Foods, airborne allergens, and chemicals can trigger dizziness in these individuals.

Metabolic Disorders

Vertigo and dizziness are often reported with metabolic disorders such as diabetes. Autoimmune diseases such as rheumatoid arthritis, lupus, and human immunodeficiency virus infection can also cause symptoms when the disease process damages components of the vestibular system.

Autoimmune Ear Disease

Autoimmune responses may result in rapid decline of hearing with intermittent symptoms of vertigo, aural pressure, and tinnitus. It is caused by the deposition of antibody-antigen complex in the capillaries or basement membranes of inner ear structures. It can appear in the same manner as hydrops, with fluctuations of hearing loss and vestibular function. The Western Blot is one of the most widely used diagnostic tools.

Autonomic Related Vertigo

The autonomic and vestibular systems are physiologically connected, and significant activation of the vestibular system will cause nausea, pallor, sweating, and clamminess. Autonomic dysfunction can contribute to dizziness and is reported in conjunction with palpitations, chronic fatigue, sleeping disorders, cold extremities, headaches, gastrointestinal disorders, medication intolerance, and fainting.

Mitral valve prolapse can be found in patients with such signs and symptoms, and disorders of circulation should be considered. Orthostatic concerns should be considered, and often patients are found to have abnormal tilt-table test results. Often patients will have been diagnosed with Meniere disease but do not respond to diuretics and, when observed carefully, have signs as described previously, with lightheadedness a component of the dizziness, along with vertigo.¹⁷⁶

APPENDIX 22-A ■ Common Vestibular Disorders—cont'd**Mal de Debarquement (Disembarkment Syndrome)**

The symptoms of continued rocking or a sensation that one has just gotten off a boat is the hallmark of disembarkment syndrome. Indeed it comes often after a long boat or airplane ride, often when there is turbulence. The vestibular system seems to be activated to a high degree, then is unable to calibrate back to normal in reference to the somatosensory input available.¹⁷⁷

The sensation is greater when the patient is at rest, and movement is actually preferable to standing or sitting. The system remains maladapted, and the condition can persist over months and years, causing significant disability and frustration. Rehabilitation is directed toward recalibration of the somatosensory and vestibular systems.

Somatoform Dizziness

Forty percent of dizzy patients have psychological disorders, and individuals with psychological disorders report more disability related to dizziness. There are connections between the locus coeruleus and lateral vestibular nucleus within the brain stem, and both nuclei are affected by serotonergic processes. Primary somatoform disorders, dissociative (conversion) disorders, and anxiety disorders produce dizziness without organic cause.¹⁷⁸ Secondary, reactive, or comorbid disorders can emerge as a consequence of identifiable organic dysfunction, but the recovery process is derailed owing to an underlying psychiatric disorder. Vestibular disorders

have an influence on autonomic regulation, and symptoms such as heart palpitations, fainting spells, and chronic fatigue are reported to a higher degree when there is an additional psychogenic component. Vertiginous migraineurs have a higher frequency of comorbid anxiety disorders. The common neuroanatomic pathways provide focus for interventions. Antivertiginous medications are not effective, and challenging the vestibular pathways can often lead to increased avoidance behaviors, more dizziness, and actual decline in function.¹⁷⁹ Determination that there is a psychogenic or somatoform component of the disorder is often made late in the diagnosis when treatment from the ear, nose, and throat specialist, neurologist, or internist has failed.¹⁸⁰⁻¹⁸² Appendix Box 22-2 describes the relationship of the disorders.

APPENDIX BOX 22-2 ■ RELATIONSHIP BETWEEN OTOLOGICAL CONDITIONS AND ANXIETY

- Otogenic:* Primary otological conditions that can trigger secondary anxiety disorders
- Psychogenic:* Anxiety disorders as primary cause of dizziness
- Interactive:* Otological conditions that exacerbate preexisting anxiety

KEY TERMS

atypical movements
 clinical hypertonicity
 composite impairments
 edema
 evaluation of movement control
 goal setting
 hemiplegia
 movement deficits
 muscle activation deficits
 orthoses
 postural control
 predictors of recovery
 primary impairments
 secondary impairments
 shoulder pain
 shoulder subluxation
 significant impairments
 standardized evaluations of function
 trunk and arm linked movements
 trunk control
 trunk and leg linked movements
 undesirable compensations

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify the various types of neurovascular disease.
2. Identify the atypical patterns of movement in clients with residual hemiplegia.
3. Identify significant primary and secondary body system problems (impairments) that interfere with functional movement patterns and limit ability to participate.
4. Describe a reeducation intervention strategy for improving functional movement in clients who have had a stroke.

OVERVIEW

The treatment of hemiplegia from vascular insult is controversial. Various treatment methods have been devised and advocated. Recent scientific theories have changed the focus of treatment from one of inhibition of abnormal tone and facilitation of normal movement to reeducation of control and weakness, and functional retraining. In this chapter, pathological conditions, body system problems (impairment), functional limitations, and intervention strategies for clients with hemiplegia from stroke are reviewed. Although hemiplegia from neurovascular pathological conditions is the focus of the chapter, therapists can use this information and apply it to adults with hemiplegia caused by other central nervous system (CNS) pathological conditions, such as tumor (see Chapter 25), trauma (see Chapter 24), multiple sclerosis (see Chapter 19), and demyelinating diseases (see Chapter 17). Movement components and their relationship to functional performance are used as the basis for selection of therapy techniques and training.

Definition

Hemiplegia, a paralysis of one side of the body, is the classic sign of neurovascular disease of the brain. It is one of many manifestations of neurovascular disease, and it

occurs with strokes involving the cerebral hemisphere or brain stem. A stroke, or cerebrovascular accident (CVA), results in a sudden, specific neurological deficit and occurs when a brain blood vessel is either occluded by a clot or bursts. It is the suddenness of this neurological deficit—occurring over seconds, minutes, hours, or a few days—that characterizes the disorder as vascular. Although the motor deficits of hemiplegia may be the most obvious sign of a CVA and a major concern of therapists, other symptoms are equally disabling, including sensory dysfunction, aphasia or dysarthria, visual field defects, and mental and intellectual impairment. The specific combination of these neurovascular deficits enables a physician to detect both the location and the size of the defect. CVAs can be classified according to pathological type—thrombosis, embolism, or hemorrhage—or according to temporal factors, such as completed stroke, stroke-in-evolution, or transient ischemic attacks (TIAs).

Epidemiology

In the United States, stroke is the third ranking cause of death—more than 137,000 people die each year—and is the leading cause of adult disability.¹ The National Stroke Association estimates that 795,000 new or recurrent strokes

occur each year. The incidence of stroke rises rapidly with increasing age: two thirds of all strokes occur in people older than the age of 65 years; and after the age of 55 years, the risk of stroke doubles every 10 years. With the over-50-years age group growing rapidly, more people than ever are at risk. In the United States, the incidence of stroke is greater in men than in women, and it is twice as high in blacks as in whites. Cerebral infarction (thrombosis or embolism) is the most common form of stroke, accounting for 70% of all strokes. Hemorrhages account for another 20%, and 10% remain unspecified. Stroke is the largest single cause of neurological disability. Approximately 4 million Americans are dealing with impairments and disabilities from a stroke. Of these, 31% require assistance, 20% need help walking, 16% are in long-term care facilities, and 71% are vocationally impaired after 7 years.¹ One study reported that 12% of subjects have complete functional arm recovery and 38% have some dexterity 6 months after stroke. In addition, loss of leg movement in the first week after stroke and no arm movement at 4 weeks are associated with poor outcomes at 6 months.²

The three most commonly recognized risk factors for cerebrovascular disease are hypertension, diabetes mellitus, and heart disease. The most important of these factors is hypertension.³ Because high blood pressure is the greatest risk factor for stroke, human characteristics and behaviors that increase blood pressure, including increased high serum cholesterol levels, obesity, diabetes mellitus, heavy alcohol consumption, cocaine use, and cigarette smoking, increase the risk of stroke.

Ostfeld⁴ noted that mortality rates for stroke declined, slowly at first (from 1900 to 1950) and then more quickly (from 1950 to 1970), with a sharp drop noted around 1974. Experts have speculated that the greater use of hypertensive drugs in the 1960s and 1970s started this decline, and the creation of screening and treatment referral centers for high blood pressure may account for the marked decline in the late 1970s.

Outcome

The long-term follow-up on the Framingham Heart Study revealed that long-term stroke survivors, especially those with only one episode, have a good chance for full functional recovery.⁵ For people left with severe neurological and functional deficits, studies have demonstrated that rehabilitation is effective and that it can improve functional ability.^{6,7} It has been demonstrated that age is not a factor in determining the outcome of the rehabilitation process.⁸ Currently it is thought that clients should be given an opportunity to participate in the rehabilitation process, regardless of age, unless it is medically contraindicated.

The prediction of ultimate functional outcome has been hampered by the inaccuracy of commonly used predictors (medical items, income level, intelligence, functional level). Computed tomography (CT), functional magnetic resonance imaging, and regional cerebral blood flow studies are used in diagnosis and increasingly as predictors of functional recovery after stroke. Positron emission tomography and single-photon emission CT are newer techniques that are used in research centers to define areas of dysfunctional but perhaps “salvageable” tissue.^{2,9}

Pathoneurological and Pathophysiological Aspects Classification

The pathological processes that result from a CVA can be divided into three groups—thrombotic changes, embolic changes, and hemorrhagic changes.

Thrombotic Infarction. Atherosclerotic plaques and hypertension interact to produce cerebrovascular infarcts. These plaques form at branchings and curves of the arteries. Plaques usually form in front of the first major branching of the cerebral arteries. These lesions can be present for 30 years or more and may never become symptomatic. Intermittent blockage may proceed to permanent damage. The process by which a thrombus occludes an artery requires several hours and explains the division between stroke-in-evolution and completed stroke.¹⁰

TIAs are an indication of the presence of thrombotic disease and are the result of transient ischemia. Although the cause of TIAs has not been definitively established, cerebral vasospasm and transient systemic arterial hypotension are thought to be responsible factors.

Embolic Infarction. The embolus that causes the stroke may come from the heart, from an internal carotid artery thrombosis, or from an atheromatous plaque of the carotid sinus. It is usually a sign of cardiac disease. The infarction may be of pale, hemorrhagic, or mixed type. The branches of the middle cerebral artery are infarcted most commonly as a result of its direct continuation from the internal carotid artery. Collateral blood supply is not established with embolic infarctions because of the speed of obstruction formation, so there is less survival of tissue distal to the area of embolic infarct than with thrombotic infarct.²

Hemorrhage. The most common intracranial hemorrhages causing stroke are those resulting from hypertension, ruptured saccular aneurysm, and arteriovenous (AV) malformation. Massive hemorrhage frequently results from hypertensive cardiac-renal disease; bleeding into the brain tissue produces an oval or round mass that displaces midline structures. The exact mechanism of hemorrhage is not known. This mass of extravasated blood decreases in size over 6 to 8 months.

Saccular, or berry, aneurysms are thought to be the result of defects in the media and elastica that develop over years. This muscular defect plus overstretching of the internal elastic membrane from blood pressure causes the aneurysm to develop. Saccular aneurysms are found at branchings of major cerebral arteries, especially the anterior portion of the circle of Willis. Averaging 8 to 10 mm in diameter and variable in form, these aneurysms rupture at their dome. Saccular aneurysms are rare in childhood.

AV malformations are developmental abnormalities that result in a spaghetti-like mass of dilated AV fistulas varying in size from a few millimeters in diameter to huge masses located within the brain tissue. Some of these blood vessels have extremely thin, abnormally structured walls. Although the abnormality is present from birth, symptoms usually develop at ages 10 to 35 years. The hemorrhage of an AV malformation presents a pathological picture similar to that for the saccular aneurysm. The larger AV malformations frequently occur in the posterior half of the cerebral hemisphere.¹⁰

Clinical Findings

The focal neurological deficit resulting from a stroke, whether embolic, thrombotic, or hemorrhagic, is a reflection of the size and location of the lesion and the amount of collateral blood flow. Unilateral neurological deficits result from interruption of the carotid vascular system, and bilateral neurological deficits result from interruption of the vascular supply to the basilar system. Clinical syndromes resulting from occlusion or hemorrhage in the cerebral circulation vary from partial to complete. Signs of hemorrhage may be more variable as a result of the effect of extension to surrounding brain tissue and the possible rise in intracranial pressure. Table 23-1 summarizes the clinical symptoms and the anatomical structures involved according to specific arterial involvement.

The frequencies of the three types of cerebrovascular disease—thrombosis, embolism, and hemorrhage—vary according to whether they were taken from a clinical study or from an autopsy study, but they rank in the order presented in this section. Ischemic strokes, thrombotic or embolic, account for 80% of strokes, and hemorrhagic strokes account for 20%.¹¹ The clinical symptoms and laboratory findings for each type are condensed in Table 23-2.

Medical Management and Pharmacological Considerations

Acute Medical Care

Thrombosis and Transient Ischemic Attacks. Although infarcted tissue cannot at present be restored, medical management of the acute stroke from thrombosis or TIA is geared toward improving the cerebral circulation as quickly as possible to prevent ischemic tissue from becoming infarcted tissue. Cells that have 80% to 100% ischemia will die in a few minutes because they cannot produce energy, specifically adenosine triphosphate. This energy failure results in an activation of calcium, which causes a chain reaction resulting in cell death.¹ Around this area of infarction is a transitional area where the blood flow is decreased 50% to 80%. Cells in the transitional area are not irreversibly damaged.^{12,13}

One of the newer drugs available for immediate stroke treatment is tissue plasminogen activator (t-PA) (see Chapter 36). It is approved for use within 3 hours of symptom onset but is most effective if used within the first 90 to 180 minutes. Recent studies indicate that 42% of patients who have sustained a stroke wait 24 hours before getting care, with the average being 13 hours.¹³ The importance of community-wide programs to increase awareness of symptoms and effectiveness of emergency medical responses is immense for this drug's usage. The American Heart Association and the National Stroke Association are creating community campaigns to increase awareness of the medical emergency nature of stroke symptoms. These campaigns encourage people to call 911 immediately when any of the following warning signs occur:

- Sudden numbness or weakness of the face, arm, or leg, especially on one side of the body
- Sudden confusion or trouble speaking or understanding
- Sudden trouble walking, dizziness, loss of balance or coordination

- Sudden severe headache with no known cause
- Sudden trouble seeing with one or both eyes

Anticoagulant drugs are used to prevent TIAs and may stop a stroke-in-evolution. Before anticoagulant drugs are used, an accurate differential diagnosis is necessary because of the danger of excessive bleeding if hemorrhage is present. Heparin is often used in the early stage of the stroke, and warfarin (Coumadin) or dabigatran (Pradaxa) is commonly used in the months after the stroke. Cerebral edema, if present, is managed pharmacologically during the first few days. Antiplatelet drugs such as aspirin, dipyridamole (Persantine), and sulfapyrazone (Anturane) are used to prevent clotting by decreasing platelet “stickiness.”¹⁰

Surgical treatment (thromboendarterectomy or grafting) is used when TIAs are the result of arterial plaques. Areas accessible to and suitable for surgery include the carotid sinus and the common carotid, innominate, and subclavian arteries. Although both surgery and anticoagulant therapy are used for TIAs, Adams and Victor¹⁰ extensively reviewed the wide divergence of opinions. For clients who have had a stroke yet recovered quickly and well, medical care focuses on prevention. Prevention usually includes maintaining blood pressure and blood flow, monitoring hypotensive agents (if given), and avoiding oversedation, especially for sleep, to prevent cerebral ischemia.

Embolic Infarction. Management of embolic infarction is similar to that of thrombotic infarction. The primary emphasis is on prevention. Long-term anticoagulant therapy is effective in preventing embolic infarction in clients with cardiac problems such as atrial fibrillation, myocardial infarction, and valve prostheses. The diagnostic use of CT is important in anticoagulant therapy to rule out hemorrhage after the infarct.

Hypertensive Hemorrhage. Medical procedures for hypertensive hemorrhage parallel those for thrombosis and embolism. Surgical removal of the clot and lowering of the systemic blood pressure to decrease hemorrhage have generally not been helpful. Again, the preventive use of antihypertensive drugs in clients with essential hypertension is the soundest medical management available.¹⁰

Ruptured Aneurysm. Comatose clients are not good candidates for surgery. However, if the client survives the first few days and if the state of consciousness improves, surgical intervention, whether extracranial or intracranial, is the treatment of choice. Medical treatment consists of lowering arterial blood pressures. Bed rest for 4 to 6 weeks with all forms of exertion avoided is prescribed. Antiseizure medication may be used. Often a systemic antifibrinolytic is given to impede lysis of the clot at the site of rupture. Vasospasm, resulting in severe motor dysfunction, occurs with the use of drugs such as reserpine (Serpasil) and kanamycin (Kantrex) (see Chapter 36).

Regardless of the cause of the stroke, comatose clients are managed by (1) treatment of shock; (2) maintenance of clear airway and oxygen flow; (3) measurement of arterial blood gases, blood analysis, CT, and spinal tap; (4) control of seizures; and (5) gastric tube feeding (if coma is prolonged). Hypertensive hemorrhage is one of the most common vascular causes of coma.¹⁴

TABLE 23-1 ■ CLINICAL SYMPTOMS OF VASCULAR LESIONS

AFFECTED VESSEL	CLINICAL SYMPTOMS	STRUCTURES INVOLVED
Middle cerebral artery	Contralateral paralysis and sensory deficit Motor speech impairment “Central” aphasia, anomia, jargon speech Unilateral neglect, apraxia, impaired ability to judge distance Homonymous hemianopia Loss of conjugate gaze to opposite side Avoidance reaction of opposite limbs Pure motor hemiplegia Limb—kinetic apraxia	Somatic motor area Broca area (dominant hemisphere) Parieto-occipital cortex (dominant hemisphere) Parietal lobe (nondominant hemisphere) Optic radiation deep to second temporal convolution Frontal controverse field Parietal lobe Upper portion of posterior limb of internal capsule Premotor or parietal cortex Motor area—leg Arm area of cortex
Anterior cerebral artery	Paralysis—lower extremity Paresis in opposite arm Cortical sensory loss Urinary incontinence Contralateral grasp reflex, sucking reflex Lack of spontaneity, motor inaction, echolalia Perseveration and amnesia	Posteromedial aspect of superior frontal gyrus Medial surface of posterior frontal lobe Uncertain Uncertain
Posterior cerebral artery Peripheral area	Homonymous hemianopia Bilateral homonymous hemianopia, cortical blindness, inability to perceive objects not centrally located, ocular apraxia Memory defect Topographical disorientation	Calcarine cortex or optic radiation Bilateral occipital lobe
Central area	Thalamic syndrome Weber syndrome Contralateral hemiplegia Paresis of vertical eye movements, sluggish pupillary response to light Contralateral ataxia or postural tremor	Inferomedial portions of temporal lobe Nondominant calcarine and lingual gyri Posteroventral nucleus of thalamus Cranial nerve III and cerebral peduncle Cerebral peduncle Supranuclear fibers to cranial nerve III
Internal carotid artery	Variable signs according to degree and site of occlusion—middle cerebral, anterior cerebral, posterior cerebral territory	Uncertain
Basilar artery Superior cerebellar artery	Ataxia Dizziness, nausea, vomiting, horizontal nystagmus Horner syndrome on opposite side, decreased pain and thermal sensation Decreased touch, vibration, position sense of lower extremity greater than that of upper extremity	Middle and superior cerebellar peduncle Vestibular nucleus Descending sympathetic fibers Spinal thalamic tract Medial lemniscus
Anterior inferior cerebellar artery	Nystagmus, vertigo, nausea, vomiting Facial paralysis on same side Tinnitus Ataxia Impaired facial sensation on same side Decreased pain and thermal sensation on opposite side	Vestibular nerve Cranial nerve VII Auditory nerve, lower cochlear nucleus Middle cerebral peduncle Fifth cranial nerve nucleus Spinal thalamic tract
Complete basilar syndrome	Bilateral long tract signs with cerebellar and cranial nerve abnormalities Coma Quadriplegia	

TABLE 23-1 ■ CLINICAL SYMPTOMS OF VASCULAR LESIONS—cont'd

AFFECTED VESSEL	CLINICAL SYMPTOMS	STRUCTURES INVOLVED
Vertebral artery	Pseudobulbar palsy Cranial nerve abnormalities Decreased pain and temperature on opposite side Sensory loss from a tactile and proprioceptive Hemiparesis of arm and leg Facial pain and numbness on same side Horner syndrome, ptosis, decreased sweating Ataxia Paralysis of tongue Weakness of vocal cord, decreased gag Hiccups	Spinal thalamic tract Medial lemniscus Pyramidal tract Descending tract and fifth cranial nucleus Descending sympathetic tract Spinal cerebellar tract Cranial nerve XII Cranial nerves IX and X Uncertain

TABLE 23-2 ■ CLINICAL SYMPTOMS AND LABORATORY FINDINGS FOR NEUROVASCULAR DISEASE—RUPTURED SACCULAR ANEURYSM

DISEASE TYPE	CLINICAL PICTURE	LABORATORY FINDINGS
THROMBOSIS	<i>Extremely variable</i> Preceded by a prodromal episode Uneven progression Onset develops within minutes or hours or over days (“thrombus in evolution”) 60% occur during sleep—patient awakens unaware of problem, rises, and falls to floor Usually no headache, but may occur in mild form Hypertension, diabetes, or vascular disease elsewhere in body	Cerebrospinal fluid pressure is normal Cerebrospinal fluid is clear Electroencephalogram: limited differential diagnostic value Skull radiographs not helpful Arteriography is definitive procedure; demonstrates site of collateral flow CT scan helpful in chronic state when cavitation has occurred
TIA	Linked to atherosclerotic thrombosis Preceded or accompanied by stroke Occur by themselves Last 2-30 min A few attacks or hundreds are experienced Normal neurological examination findings between attacks If transient symptoms are present on awakening, may indicate future stroke	Usually none
EMBOLISM	<i>Extremely variable</i>	
Cardiac	Occurs extremely rapidly—seconds or minutes	Generally same as for thrombosis except for the following:
Noncardiac	There are no warnings	If embolism causes a large hemorrhagic infarct, cerebrospinal fluid will be bloody
Atherosclerosis	Branches of middle cerebral artery are involved most frequently; large embolus will block internal carotid artery or stem of middle cerebral artery	30% of embolic strokes produce small hemorrhagic infarct without bloody cerebrospinal fluid
Pulmonary thrombosis	If embolus is in basilar system, deep coma and total paralysis may result	
Fat, tumor, air	Often a manifestation of heart disease, including atrial fibrillation and myocardial infarction Headache As embolus passes through artery, client may have neurological deficits that resolve as embolus breaks and passes into small artery supplying small or silent brain area

CT, Computed tomography; TIA, transient ischemic attack.

Medical Management of Associated Problems

Spasticity. Spasticity and its treatment constitute a major medical problem after stroke because clients complain about it, it may fluctuate, and it does not respond to one fixed treatment. The relationship between spasticity and movement after stroke is an area of continued interest for researchers. Recent studies have refuted the earlier belief that spasticity was inversely related to voluntary movement.^{15,16} Although therapists are more hesitant to treat spasticity now, physicians continue to treat it aggressively. Various pharmacological, surgical, and physical means are used to decrease spasticity. The pharmacological and surgical means are examined here, and therapy management is discussed later.

Two types of drugs are used to counter the effects of spasticity: centrally acting and peripherally acting agents. Centrally acting drugs, such as diazepam, have been used to depress the lateral reticular formation and thus its facilitatory

action on the gamma motor neurons. This form of drug is used widely to treat spasticity, although the greatest disadvantage of centrally acting drugs is that they depress the entire CNS. Drowsiness and anxiety are common side effects.

Peripherally acting drugs are used to block a specific link in the gamma group. Procaine blocks selectively inhibit the small gamma motor fibers, resulting in a relaxation of intrafusal fibers. The effect of procaine blocks is transient. Intramuscular neurolysis with the injection of 5% to 7% phenol has been used to destroy the small intramuscular mixed nerve branches.¹⁷ Phenol blocks relieve hypertonicity and improve function, especially when followed by an intensive course of therapy.¹⁸ It can provide relief for 2 to 12 months, and the effects have been documented to last as long as 3 years.^{17,18} Disadvantages of phenol use include its toxicity to tissue and the complications of pain that occasionally result.

Botulinum toxin type A (Botox) is also used to decrease the effects of hypertonicity on functional movement in

hemiplegia.¹⁹⁻²¹ Local injection of the toxin into spastic muscles produces selective weakness by interfering with the uptake of acetylcholine by the motor end plate. The effect of the toxin is temporary, depends on the amount injected, and is associated with minimal side effects. Repeat injections are recommended no sooner than 12 to 14 weeks to avoid antibody formation to the toxin. Researchers report positive functional results when botulinum toxin A injections are followed by intensive muscle reeducation and appropriate splinting.²²

Dantrolene sodium is used to interrupt the excitation-contraction mechanism of skeletal muscles. Trials have shown that it has reduced spasticity in 60% to 80% of clients while improving function in 40% of these clients. The side effects—drowsiness, weakness, and fatigue—can be decreased through titration of dosage. Serious side effects, including hepatotoxicity, precipitation of seizures, and lymphocytic lymphoma, have been reported when the drug has been used in high doses over a long time.¹⁷

Baclofen, in pill form, is used as a skeletal muscle relaxant to decrease spasticity. It can now be delivered intrathecally into the spinal cord with a pump that is surgically inserted into the body. It relieves spasticity with a small amount of medication (10 mg/20 mL, 10 mg/5 mL). Intrathecal baclofen has had dramatic results in cases of severe spasticity because it acts directly on the affected muscles instead of circulating in the blood. It is used for extremity spasticity that interferes with the ability to assume functional positions in patients with severe stroke, multiple sclerosis, head injury, and cerebral palsy.²³

The surgical treatment of spasticity through tenotomy or neurectomy is considered when all other treatments fail, and it is used to correct deformity, especially of a hand or foot. A peripheral nerve block is often used as a diagnostic tool to evaluate the effect of surgical treatment. If anatomical or functional gains are made through a temporary nerve block, consideration is given to surgical release. The surgical treatment of spasticity does not necessarily result in increased movement control and, with the increased understanding of the causes of spasticity, does not seem appropriate in stroke.

Seizures. The highest risk for seizure after a stroke is immediately afterward; 57% of seizures occur in the first week and 88% occur within the first year.²⁴ Seizures after thrombotic and embolic stroke are usually of early onset, whereas seizures after hemorrhagic stroke are of late onset. The management of seizures after stroke is usually with antiseizure medication. Commonly used drugs include phenytoin (Dilantin), carbamazepine (Tegretol), gabapentin (Neurontin), and divalproex (Depakote).²⁵ Side effects that interfere with movement therapy include drowsiness, ataxia, distractibility, and poor memory.

Respiratory Involvement. Fatigue is a major problem for the person with hemiplegia. This fatigability, which interferes with everyday life processes and active rehabilitation, is attributed to respiratory insufficiency resulting from paralysis of one side of the thorax. Haas and colleagues²⁶ studied respiratory function in hemiplegia and found decreased lung volume and mechanical performance of the thorax to be significant factors, in addition to abnormal pulmonary diffusing capacity. Clients with hemiplegia consume 50% more oxygen while walking slowly (regardless of the presence or absence of orthotic devices) than that used

by subjects without hemiplegia.²⁶ The decreased respiratory output and the increased oxygen demand that result from atypical movement patterns are responsible for early fatigue in persons with hemiplegia. Treatment objectives and techniques must reflect the understanding of this respiratory problem. For clients who walk at velocities greater than 0.48 m/s, a gain in walking capacity is associated with an increased peak VO_2 . Research exploring the role of exercise after stroke indicated that gains in respiratory fitness were associated with increased walking capacity. In clinical practice, therapists should remember to include standard respiratory measures and functions to evaluate the efficacy of treatment techniques.²⁷

Cardiovascular Health. In the chronic stage of recovery, clients may have significant cardiovascular deconditioning with half the fitness levels of age-matched controls. This decrease in fitness affects the performance of daily activities and adds to these clients' morbidity and mortality risk. This decreased fitness results in part from decreased mobility of the leg, muscular atrophy, altered muscle physiology, increased muscular fat, and altered peripheral blood flow.^{28,29}

Fractures. If the hemiplegic client has severe extremity or trunk weakness and relies heavily on the nonparetic extremities for function, poor balance and falls are possible. After a stroke the risk of hip fracture is greatest in the first year of recovery. Eighty percent of hip fractures occur on the paretic side and are the result of bone loss or falls. In addition, other common fracture sites are the humerus and wrist.³⁰

Therapy intervention for a hip fracture with a hemiplegia is complicated by increased difficulty sustaining a symmetrical trunk posture over the fractured hip, decreased strength in the leg, pain, and spasticity. In addition to the loss of balance and protective mechanisms, the development of osteoporosis from disuse is a limiting factor for functional recovery after a fracture.³¹

Thrombophlebitis. Thrombophlebitis may occur in the early stages of rehabilitation. Vascular changes are often premorbid. Deep vein thrombosis is caused by altered blood flow, damage to the vessel wall, and changes in blood coagulation times. The vascular changes are aggravated by the inactivity and dependent postures of the weak extremities. Deep vein thrombosis is many times more common in the weak leg.³²

Complex Regional Pain Syndrome. Formerly known as reflex sympathetic dystrophy, *complex regional pain syndrome* is a chronic pain condition affecting the paretic arm or leg. The extremity pain is reported as intense and burning and may be accompanied by swelling and redness. It leads to changes in bone and skin and, if left untreated, becomes debilitating. Medical treatment includes the use of chemical sympathetic blocks and oral or intramuscular corticosteroids. The use of blocks and corticosteroids often stops the burning pain. The length of time of the relief varies from client to client. Adverse reactions from blocks and corticosteroids occur about 20% of the time^{33,34} (see Chapter 32).

Pain. The pharmacological management of joint pain after stroke (usually shoulder pain) includes the local injection of corticosteroids. (For additional information regarding pain and its management, see Chapter 32.)

Sequential Stages of Recovery from Acute to Adaptive Phase

Evolution of Recovery Process

The evolution of the recovery process from onset to the return to community life can be divided into three stages—acute, active (rehabilitation), and adaptation to personal environment.

The acute state involves the stroke-in-evolution, the completed stroke, or the TIA and the decision whether to hospitalize.

The stroke-in-evolution develops gradually with distinct demarcation of the damaged area over 6 to 24 hours. Thrombosis, the most common cause of stroke, results first in ischemia and finally in infarction. Its gradual onset has led researchers to believe that a “cure” may be found for this type of stroke. If ischemic tissue can be treated and saved before infarction occurs, the neurological damage may be reversible. Small hemorrhages also may become a stroke-in-evolution by effusing blood along nerve pathways and by attracting fluid.³⁵ A completed stroke has a sudden onset and produces distinct, nonprogressive symptoms and damage within minutes or hours. In contrast, the TIA has a brief duration of neurological deficit and spontaneous resolution with no residual signs. TIAs vary in number and duration.

The physician decides the extent of hospitalization. The trend to hospitalize is more common today than years ago.³⁶ However, a mild stroke or TIA may produce minimal physical and mental symptoms, and the person may not even seek medical help. Cost-containment measures in hospitals and managed care have led to decreased lengths of stay and the development of critical pathway plans to deliver services more efficiently. Critical pathways are plans that describe the duration and extent of services after a stroke. The inpatient length of stay for acute stroke is currently 2 to 4 days. After the inpatient stay, the client follows one of four pathways: he or she returns home with or without home care services, goes to a rehabilitation hospital for a 2- to 4-week stay, goes to a subacute facility to become strong enough for the rehabilitation regimen, or goes to a long-term care facility for rehabilitation or maintenance care.

Once the stroke is completed, the clinical symptoms begin to decrease in severity. A person with a stroke caused by an embolic episode may have symptoms that reverse completely in a few days; more frequently, however, improvement takes place very slowly with a marked deficit. The fatality rate is high within the first day but decreases substantially in the following months of recovery.³⁶ Evidence from efficacy studies of rehabilitation programs that aim at improving functional performance is limited. Studies by Bamford and colleagues³⁷ indicate that early rehabilitation intervention reduces disability and improves compensatory strategies.

The Framingham Heart Study has revealed that long-term stroke survivors have a good chance of returning to independent living. The greatest deficit in persons with hemiplegia who have recovered basic motor skills and who have returned home is in the psychosocial and environmental areas.⁵

Recovery of Motor Function

Recovery of motor function after a stroke was thought historically to be complete 3 to 6 months after onset. More recent research has shown that functional recovery from a stroke can

continue for months or years.^{38,39} Measuring recovery is difficult because the definition of “successful” or “complete” recovery varies greatly. Duncan reports that if recovery is defined at the disability level (Barthel score greater than 90), 57% of stroke survivors have a complete recovery. However, if impairments are measured, less than 37% recover fully. And if recovery is related to prior physical functioning, less than 25% are considered completely recovered.⁴⁰

The initial functional gains after the stroke are attributed to reduction of cerebral edema, absorption of damaged tissue, and improved local vascular flow. However, these factors do not play a role in long-term functional recovery. The brain damage that results from a stroke is thought to be circumvented rather than “repaired” during the process of functional recovery. The CNS reacts to injury with a variety of potentially reparative morphological processes. Two mechanisms underlying functional recovery after stroke are collateral sprouting and the unmasking of neuropathways: regeneration and reorganization.³⁸ Research continues to provide important insights into the fundamental capabilities of the brain to respond to damage. Methods of intervention that use the environment and help the client learn lead to long-term improved recovery.

The CNS has some predictable traits in response to injury. Twitchell, in his classic study, first documented the initial loss of voluntary function.⁴¹ Although paralysis with flaccidity initially exists, there is seldom, if ever, total paralysis. He reported both an increase in deep tendon reflexes after 48 hours and the emergence of synergistic patterns of movement.⁴¹ The synergistic movement patterns of the upper extremity and lower extremity have been described in detail by many.⁴²⁻⁴⁴ Verbal description of a visual phenomenon often leads to differences in written and spoken communication, yet the visual array or behavioral patterns may be exactly the same.⁴⁵ Synergistic patterns may not be the same as movement combinations necessary for function. Although it is stated that the leg recovers more quickly or better than the arm, a leg that is bound by an extensor synergy and that is as “rigid as a pillar” during gait has not recovered more quickly and has no better function than an arm that is flexed and held across the chest and that can only grasp in a gross pattern with no ability to release.

Although studies are investigating the exact nature of the relationship between voluntary movement and spasticity, clinical evidence demonstrates that as voluntary function increases, the dependence on synergistic movement decreases.¹⁶ With the knowledge that the CNS is capable of reacting to injury with a variety of morphological processes, we should no longer view the effect of a stroke as a fixed event. Because the brain immediately institutes neuromechanisms that reconstitute typical functions, therapy interventions should emphasize use of movement patterns on the affected side to maximize return and to help the client achieve the highest level of function.

Predictors of Recovery

Research in motor recovery shows that although motor recovery may continue after 6 months, the functional status usually remains constant, and that 86% of the variance in 6-month recovery is predictable at 1 month.⁴⁶

In one study, although 58% of the patients regained independence in activities of daily living (ADLs) and 82% learned to walk, 30% to 60% of patients had no arm function.⁴⁷ Initial return of movement in the first 2 weeks is one indicator of the possibility of full arm recovery. But failure to recover grip strength before 24 days was correlated with no recovery of arm function at 3 months.⁴⁷ In another study that used the modified Rankin scale as the outcome measure, half of the patients recovered within 18 months with the greatest amount of recovery present at the 6-month mark. Predictors of recovery in this group included stroke severity, no previous ischemic stroke, peripheral artery disease, or diabetes.⁴⁸

One problem inherent in prognostic research is the lack of a movement-based classification system. The clinical “predictors” in regression models are assumed to be static, whereas in fact they may change over time. Another problem is that there may be a lack of accuracy because of differences in researchers’ objectives.⁴⁹

As clinicians we can help minimize the problems in research methods by precisely formulating functional goals, stating movement components and significant impairments that interfere with functional performance, and following a model when making clinical decisions to postulate cause and effect during intervention.

Classification of Atypical Movement Patterns

Although the *Guide to Physical Therapist Practice* groups patients with neurological dysfunction according to pathological condition, therapy intervention rarely is directed by the diagnosis of stroke and resultant hemiplegia.⁵⁰ The World Health Organization (WHO) classification system, the International Classification of Function (ICF-2), provides a structure that allows us to evaluate by health condition, impairment, or activity or participation limitation.^{51,52}

Impairment-related classification systems for stroke are just beginning to be researched.⁵³ Currently, atypical movement patterns in stroke are classified according to type of lesion (embolism, thrombosis, TIA) or side of weakness. The classification models make it easier for therapists to identify and define the focus of their intervention for the neurological patient. These models help us organize our interventions into two categories: (1) interventions that aim at improving relevant impairments that contribute to functional limitations and disability and (2) interventions that focus on the activity or participation limitations. The treatment interventions in this chapter try to relate limitations in activities to relevant underlying impairments.

Although the main focus of this chapter is the evaluation and treatment of activity limitations and impairments resulting from a loss of movement control, a stroke may result in damage to other systems that affects the client’s ability to perform functional skills. There may be deficiencies in sensory processing (vision, somesthetic sensation, and vestibular systems) and disorders of cognitive integration (arousal and attention, awareness of disability, memory, problem solving, and learning), which all have a large impact on functional retraining. Depression and, most important, problems of language and communication also affect the client’s ability to participate in a therapy program.

Impairments Contributing to Activity and Participation Limitations

Clients with hemiplegia from stroke have movement problems—impairments—that lead to activity and participation limitations. These movement problems manifest themselves as loss of movement in the trunk and extremities, atypical patterns of movement, and involuntary nonpurposeful movements of the affected side that lead to compensatory functional strategies. These impairments interfere with normal functional movements and may lead to loss of independence in daily life.

Impairments are the signs, symptoms, and physical findings that relate to a specific disease pathology. Schenkman and Butler were the first to apply a model of impairments to neurological physical therapy practice. Ryerson and Levit, using a similar format, specifically defined the impairment categories as primary, secondary, and composite^{54,55} (Box 23-1).

Primary Impairments. Primary impairments are physical findings that are associated with the specific brain lesion. The primary impairments of stroke that relate to functional recovery of movement include changes in strength, changes in muscle tone, muscle activation or control changes (sequencing, firing, initiation), and changes in sensation. Cognitive and perceptual, emotional, and speech and language changes are also primary impairments that have an effect on function but are less of a focus of this chapter.

Secondary Impairments. Secondary impairments involve systems of the body other than the neurological system. They occur as a consequence of the stroke or because

BOX 23-1 ■ IMPAIRMENTS THAT INTERFERE WITH FUNCTIONAL MOVEMENT

PRIMARY IMPAIRMENTS

- Changes in muscle strength
 - Paralysis or weakness
- Changes in muscle tone
 - Hypotonicity
 - Spasticity
 - Clinical hypertonicity
- Changes in muscle activation
 - Inappropriate initiation
 - Difficulty sequencing
 - Inappropriate timing of firing
- Changes in sensation
 - Awareness
 - Interpretation

SECONDARY IMPAIRMENTS

- Changes in alignment and mobility
- Changes in muscle and soft tissue length
- Pain
- Edema

COMPOSITE IMPAIRMENTS

- Movement deficits
- Atypical movements
- Undesirable compensations

Modified from Ryerson S, Levit K: *Functional movement reeducation: a contemporary model for stroke rehabilitation*, New York, 1997, Churchill Livingstone.

of other medical and environmental influences, such as a fall, pneumonia, or phlebitis. As they develop, they influence one another and the primary impairments. Secondary impairments influence the client's level of disability by contributing additional physical problems. There are four major categories of secondary impairments: orthopedic changes in alignment and mobility, changes in muscle and soft tissue length, pain, and edema.

Composite Impairments. Composite impairments are the combined effects of the primary and secondary impairments, motor recovery, treatment, and behavioral factors. Movement deficits are the missing pieces of movement control that the client needs to move normally. Atypical movements are movements that deviate from normal coordinated movement. Undesirable compensations are alternative, severely one-sided strategies used to perform a functional activity because of loss of normal movement patterns.

Patterns of Recovery

In the 1970s, “neurophysiological” theories and approaches changed therapy treatment for adults with CNS lesions. The founders of these approaches described positions and patterns of trunk and extremity movement.⁴²⁻⁴⁴ These patterns were described in terms of spastic synergies, reflexive patterns, and position. Extremity movements were described as patterns of flexor or extensor synergies, arm and leg patterns were changeable according to the influence of tonic reflexes, and trunk position was always short on the affected side with scapular and pelvic retraction. The intervention techniques followed the descriptions and understanding of the movement problems. As knowledge from orthopedics, manual therapy, and motor control grew, therapists looked more closely at movement patterns and body position in clients with hemiplegia and expanded the categories. As early as 1982, new descriptions emerged that combined synergistic patterns and biomechanical influences on the musculoskeletal systems.⁵⁶ Today, descriptions of position and patterns of movement follow the impairment categories. The composite impairment category used in this chapter has three generalized movement patterns that create one model of classification: (1) movement deficits, (2) atypical movements, and (3) undesirable compensatory patterns.⁵⁴

Movement deficits result from severe weakness or paralysis with either gradual, balanced return or no significant return. Functional movement patterns and levels of independence are based on the distribution and amount of return: trunk control greater than extremity control, extremity control greater than trunk control, distal extremity return greater than proximal extremity return or vice versa, and arm control greater than leg control or vice versa. These clients do not have problems with spasticity but, when weakness is severe, have long-term problems with the secondary impairments of muscle shortening and loss of joint range.

In the acute stage, the arm hangs by the side, the humerus is internally rotated, the elbow is extended, and the forearm is pronated. Inferior shoulder subluxation is common. The trunk is weak, the ribs flare, and posture is impaired, with a convex lateral curve seen on the affected side. (Appearances of lateral trunk flexion with the concavity on the affected side exist with compensatory upper- and lower-trunk movements.) In standing, the client has problems recruiting strength on the affected leg. The pelvis lists downward, and

the hip and knee flex. The hip and knee flexion combined with a tendency to place more weight on the stronger leg places the ankle in plantarflexion, and no weight is borne on the heel. As the client learns to walk, either the knee flexes because of weakness or the patient compensates and “locks” the knee in extension.

Over time, the heavy arm pulls the upper body into flexion, creating an appearance of a low shoulder. To stand and walk, a compensatory shift of the upper body onto a cane helps the client balance. This overshifting of the upper body also makes it easier for these clients to initiate stepping with the use of pelvic elevation (Figures 23-1 and 23-2).

Atypical movement patterns are found in clients with unbalanced muscle return and deficits in muscle activation. These clients have difficulty organizing and sequencing muscle return, quieting muscles after active firing, and grading strength of contractions. Clients with unbalanced return can be further divided into two subcategories: (1) those with greater weakness, that is, unbalanced return, with secondary

Figure 23-1 ■ **A**, Client with right hemiplegia. Movement deficit: paralysis; client was unable to move arm or leg in standing or sitting. **B**, Client uses cane and tries to shift to the right as he gets ready to step forward with the left leg. Note how the heavy weight of the right arm pulls the upper body into forward flexion and rotation left. **C**, Client prepares to step forward with the right leg. Note that his attendant has corrected his upper-body position. **D**, Client leans heavily onto cane (his upper body translates laterally to the left) to lessen weight on the right leg. He will accomplish the “step” by rotating his upper body to the left, a compensation for the loss of leg control in standing.

Figure 23-2 ■ **A**, Client with right hemiplegia. Movement deficit: weakness; client is able to walk with a brace and does not need a cane. **B**, During stance, his upper body moves laterally to the right and his right femur internally rotates as his knee hyperextends. **C**, He has enough trunk control to stand and balance and sufficient leg control to lift the leg with knee flexion.

problems of muscle shortening and poor alignment, and (2) those with greater return, with more problems of hypertonicity in the arm and leg.

These clients move and function with patterns that were formerly described as “spastic” or “synergistic.” They have either anterior or superior shoulder subluxations, which determine the possibilities for fractionated movement in the arm. Common atypical leg movement patterns used for walking include *swing*—proximal initiation patterns of pelvic hiking or rotation toward the affected side, hip flexion with internal rotation and knee extension, or pelvic posterior tilting with hip abduction and knee flexion—and *stance*—contact with ground via toe strike or foot flat, loss of hip extension, and using excessive forward trunk flexion to initiate forward progression instead of moving the shank and lower leg over the foot.

Regardless of the proximal trunk and extremity patterns, the ankle-foot and wrist-hand patterns are predictable on the basis of the amount of distal return and the effects of proximal alignment. With weakness, the ankle plantarflexes and the wrist flexes. The foot or hand rotates on the ankle or wrist according to the pattern of and amount of return of proximal movements. Finger and toe patterns (curling or fisting, clawing) follow biomechanical rules of compensation or correlation (Figure 23-3).

Although the main movement problems of stroke occur because of weakness and atypical muscle activation patterns (e.g., sequencing, initiation), other movement disturbances, such as ataxia, may occur. In clients with ataxia, the main movement problem is one of wide swings of tone and muscle activation disturbances with fewer problems of weakness.

These clients demonstrate trunk instability, excessive extremity movement, and overshooting of distal targets. Voluntary extremity movements are usually present but uncoordinated (see Chapter 21).

Undesirable compensatory patterns are patterns of function that may arise from either of the two previously described movement categories. Compensations are alternative movements or movement substitutions used to circumvent the challenge to the impaired side during daily activities. Although compensatory movements may be necessary and desirable to achieve the highest level of activity performance when there is no ability for recovery to occur, some may be more desirable than others. Undesirable compensatory patterns are noticeably one sided; they rely on movements of the uninvolved arm and leg and are accompanied by asymmetrical postural trunk movements. They lead to unsafe patterns, or to secondary impairments, or contribute to strategies that may have the potential to block or hinder future motor recovery. These undesirable compensatory patterns create “learned nonuse” of the affected arm and leg and foster asymmetrical postural patterns. Recent research findings indicate that limiting compensatory trunk movements may actually increase the performance of arm-reaching activities.

Patients who come into therapy with strongly established undesirable compensatory patterns do not respond quickly to any type of intervention. Although therapists may be tempted to train a one-sided pattern in early rehabilitation to quickly meet a stated goal, the long-term effects of learned nonuse of one side of the body include increased severity of secondary impairments and poor balance with an increased chance of falls (Figure 23-4).

Figure 23-3 ■ A, Client with right hemiplegia. Movement deficit: loss of control of firing patterns, timing, and sequencing. B and C, Client walking.

Figure 23-4 ■ Client with right hemiplegia. Severe compensatory patterns. She walks with a quad cane and standby assistance. Pelvis rotates to the right, upper body rotates to the left, hip flexes, and knee hyperextends. There is strong lateral translation of upper body to the left (to the stable cane).

EVALUATION PROCEDURES

Evaluation is a process of collecting information to establish a baseline level of performance to plan interventions and to document progress. This section reviews medical evaluations, standardized evaluations of functional performance (disability scales), evaluation of motor function and balance, and evaluation of secondary impairments that interfere with motor performance.

Medical Evaluation

After or during the evolution of a stroke, a thorough medical examination is conducted. All systems are surveyed, with emphasis placed on the level of consciousness; mental, affective, and emotional states; communication; cranial nerves; perceptual ability; sensation; and motor function. The National Institutes of Health (NIH) Stroke Scale is often used to evaluate the level of these common impairments poststroke.⁵⁷

Levels of Consciousness

Scales of varying types are used to measure the client's level of consciousness, to assess the initial severity of brain damage, and to prognosticate recovery curves. The Glasgow Coma Scale, devised by Teasdale and Jennett in collaboration with Plum,⁵⁸ has been used for nontraumatic comas caused by stroke, head injury, and cardiac disease. This scale records motor responses to pain, verbal responses to auditory and visual clues, and eye opening. It assigns numerical values according to graded scales. Plum and Caronna⁵⁹ and Levy and colleagues⁶⁰ have also established criteria for correlating clinical signs of coma with prognosis.

The standard descriptions of level of consciousness—normal, semistupor, stupor, deep stupor, semicomma, coma, deep coma—are categorized by objective medical data but often leave a gap in the understanding of how the client functions in life.⁵⁸ This gap was closed by the creation of a

scale, Levels of Cognitive Functioning, at Rancho Los Amigos Hospital. This behavioral rating scale is not a test of cognitive skill but an observational rating of the client's ability to process information⁶¹ (see Chapter 24).

Mental, Emotional, and Affective States

The history portion of the neurological evaluation leads to an assessment of the mental, emotional, and affective states. The client's ability to describe the illness gives information on memory, orientation to time and place, the ability to express ideas, and judgment. If the examiner suspects a particular problem, a more thorough review is undertaken of the higher cortical function: serial subtraction, repetition of digits, and recall of objects or names. Clients with right hemiplegia may be cautious and disorganized in solving a given task, and clients with left hemiplegia tend to be fast and impulsive and seemingly unaware of the deficits present. These different response patterns stem from hemispheric involvement and prior hemispheric specialization.

Loss of emotional control often exists after a stroke. Crying is a common problem. Although excessive, inappropriate, or uncontrollable crying is usually a result of brain damage and a sign of emotional lability, crying can also be an expression of sadness as a result of depression. This difference is distinguishable by the ease with which the crying can be stopped. Other signs of emotional lability in persons with hemiplegia from stroke include inappropriate laughter or anger.

Communication

A general evaluation of communication disorders is noted while taking the history. Cerebral disorder resulting from infarct or hemorrhage can produce a loss of production or comprehension of the spoken word, the written word, or both. The therapist should be familiar with all types of communication disorders and with alternate modes of communication to establish a good client relationship.

Cranial Nerves and Reflexes

Thorough cranial nerve evaluation is necessary in hemiplegia because a deficit of a particular cranial nerve helps to determine the exact size and location of the infarct or hemorrhage. In hemiplegia, it is imperative to check for visual field deficits, pupil signs, ocular movements, facial sensation and weakness, labyrinthine and auditory function, and laryngeal and pharyngeal function.

Standard areas of reflex testing include the triceps, biceps, supinator, quadriceps, and gastrocnemius muscles. According to Adams,¹⁰ there are four plantar reflex responses: (1) avoidance–quick, (2) spinal flexion–slow, (3) Babinski–toe grasp, and (4) positive support.

Perception

Perceptual deficits in clients with hemiplegia are complex and intimately linked to the sensorimotor deficit. Sensory integration theory has begun to establish normative values and objective data for testing and documenting perceptual deficits in children. Currently, norms and testing procedures for adults have not been standardized, but perceptual deficits have been identified in clients with hemiplegia. Common perceptual deficits found in left and right brain damage are listed in [Box 23-2](#).

BOX 23-2 ■ PERCEPTUAL DEFICITS IN CENTRAL NERVOUS SYSTEM DYSFUNCTION

LEFT HEMIPARESIS: RIGHT HEMISPHERE—GENERAL SPATIAL-GLOBAL DEFICITS

Visual-perceptual deficits

- Hand-eye coordination
- Figure-ground discrimination
- Spatial relationships
- Position in space
- Form constancy

Behavioral and intellectual deficits

- Poor judgment, unrealistic behavior
- Denial of disability
- Inability to abstract
- Rigidity of thought
- Disturbances in body image and body scheme
- Impairment of ability to self-correct
- Difficulty retaining information
- Distortion of time concepts
- Tendency to see the whole and not individual steps
- Affect lability
- Feelings of persecution
- Irritability, confusion
- Distraction by verbalization
- Short attention span
- Appearance of lethargy
- Fluctuation in performance
- Disturbances in relative size and distance of objects

RIGHT HEMIPARESIS: LEFT HEMISPHERE—GENERAL LANGUAGE AND TEMPORAL ORDERING DEFICITS

Apraxia

- Motor
- Ideational

Behavioral and intellectual deficits

- Difficulty initiating tasks
- Sequencing deficits
- Processing delays
- Directionality deficits
- Low frustration levels
- Verbal and manual perseveration
- Rapid performance of movement or activity
- Compulsive behavior
- Extreme distractibility

Perceptual retraining without standardized norms for the deficit is at best difficult. The soundest course currently available appears to be one that relates perceptual and motor learning rather than retraining perception in isolation (see Chapters 4 and 14).

Sensation

Traditional sensory testing is used to assess sensory deficits in the adult with hemiplegia: light touch, deep pressure, kinaesthesia, proprioception, pain, temperature, graphesthesia, two-point discrimination, appreciation of texture and size, and vibration. A comparison of the differences in the two sides of the body and qualitative and quantitative measurements are

important features of sensory testing. Sensory testing is difficult because it relies on the client's interpretation of the sensation, the client's general awareness and suggestibility, and the client's ability to communicate a response to each test item.

The presence and quality of sensory loss must be considered during the process of reeducating motor control. Although Sherrington established the principle of interdependence of sensation and movement, current researchers have refined the concept and hypothesize that sensation modifies continuing movement by providing feed-forward information, feedback, and corollary discharge. They have provided evidence that sensation is not an absolute prerequisite for movement.⁶²

Evaluation of motor function includes both standardized evaluation of functional performance and evaluation of movement control. Manual muscle testing, although used by physicians to determine a general level of strength, is not widely used by therapists to measure strength in individuals with CNS dysfunction because of the insensitivity of the test to loss of trunk and limb linked control. New measures of manual muscle testing for stroke are now beginning to be investigated.

Standardized Evaluations

Functional Performance

During the initial interview the therapist and the client together form a list of limitations and relate them to the client's goals and needs. The client can state his or her perceived functional limitations, or the therapist can ask the client to perform tasks. Commonly used standardized tests and scales for activity and participation limitations are listed here. Additional information can be found in Chapter 8.

Scales

The *Barthel Index* is one of the oldest measures of disability.⁶³ It has excellent validity and reliability and is simple to use, but it does not discriminate at higher levels of activity.

The *Motor Assessment Scale* (MAS) comes from the intervention theory of Carr and Shepherd.⁶⁴ Its reliability is high, it is simple to administer, and it takes only 15 minutes to perform. Although it mainly evaluates mobility skills, there is an arm and hand function section. The tests of arm function include movement patterns without tasks, and the hand function section uses object manipulation.

The *Functional Independence Measure* (FIM) is commonly used in rehabilitation centers, takes 45 minutes to perform, and measures ADLs, mobility, cognition, and communication.^{65,66} It has good to excellent reliability.

The *Rivermead Mobility Index* measures common mobility functions, takes 5 minutes to perform, and has been tested for reliability and validity.⁶⁷

The *Assessment of Motor and Process Skills* (AMPS) is a standardized test that measures task-performance abilities and efficiency during instrumental ADLs (IADLs).⁶⁸

Tests of Motor Function and Balance

The *Fugl-Meyer Assessment* is a measure of extremity impairment severity. It is weighted, with more items measuring arm movement than leg movement. The test factors in reflexes and sensation and has good validity and reliability. It requires from 45 minutes to 1 hour to perform.⁶⁹

The *Berg Balance Scale* is easy to administer, takes 5 to 10 minutes, and has norms specific to clients who have had a stroke.^{70,71}

The *Balance Evaluation Systems Test* (BESTest and Mini-BESTest) is a balance evaluation that helps clinicians identify the impaired underlying system that is contributing to poor dynamic balance. The mini-BESTest is composed of 14 items and can be administered in 10 to 15 minutes.^{72,73}

The *Postural Assessment Scale for Stroke* is a clinical balance measure that has been found to have better psychometric characteristics than the Berg Balance Scale or the balance subtest of the Fugl-Meyer test for people with severe stroke during the acute recovery phase. It has excellent reliability and validity and is easy to perform.^{74,75}

The *Functional Reach Test* provides a measure of balance in standing. It measures control only during anterior (forward reach) weight shifts. Reliability is high, and the test is fast and easy to perform.⁷⁶

The *Wolf Motor Function Test* is used to measure upper-extremity movements and functional tasks. It is a timed test, has been tested for reliability and validity, and is the assessment used in constraint-induced treatment studies.⁷⁷

The *Trunk Impairment Scale* measures trunk movement patterns and dynamic and static sitting balance. It has high test-retest reliability and excellent concurrent validity.⁷⁸

Gait

The evaluation of gait patterns includes the assessment of gait speed, a description of gait deviations, and, ideally, the assignment of a value representing the efficiency of ambulation.⁷⁹ Therapists are encouraged to measure gait speed throughout the rehabilitation process to quantitatively identify improvement in walking ability.^{80,81}

The 5-meter walk test is responsive to changes in the acute phase of recovery especially the first 5 weeks post-stroke. The 10-meter walk test has excellent reliability in the chronic recovery phase and is correlated with walking parameters and endurance.⁸²

The 2-, 6-, and 10-minute walk tests are measures of walking endurance with high reliability and validity.⁸³

The *Functional Ambulation Profile* is a system that attempts to relate the temporal aspects of gait to neuromuscular and cardiovascular functioning and converts this relationship to a single numerical score.⁸⁴

The *Timed Up-and-Go Test* measures (in seconds) the ability to rise from a chair, walk 3 meters, turn, walk, and return to a seated position. It is frequently used in geriatric populations, but there is no validity testing for people poststroke.⁸⁵

The temporal characteristics of gait—step time, cycle time, step length, and stride length—can be measured with a piece of chalk and a stopwatch or with more sophisticated equipment such as a gait analyzer. These parameters provide an objective measurement of performance and a baseline from which the efficacy of treatment procedures and client progress can be assessed.

Gait deviations in persons with hemiplegia have been described according to their biomechanical and kinesiological abnormalities and in terms of the loss of centrally programmed motor control mechanisms.^{86,87}

Perry⁸⁷ described common problems of the hemiplegic person's gait as loss of controlled movement into plantarflexion at heel strike, loss of ankle movement from heel

strike to midstance (resulting in loss of trunk balance and forward momentum for pushoff), and loss of the normal combination of movement patterns at the end of stance (hip extension, knee flexion, and ankle extension) and at the end of swing (hip flexion with knee extension and ankle flexion).

Knutsson and Richards⁸⁶ classified the motor control problems of the hemiplegic gait into three descriptive types. Type I is characterized by inappropriate activation of the calf muscles early in the gait cycle with corresponding low muscular activity in anterior compartment muscles. In the type I activation pattern, the calf musculature is activated before the center of gravity passes over the base of support. This thrusts the tibia backward instead of propelling the body forward in a pushoff as normally occurs. The client with hemiplegia compensates for the backward thrust of the tibia by anteriorly tilting the pelvis or flexing forward at the hip. Type II consists of an absence of or severe decrease in electromyographic activity in two or more muscle groups of the involved lower extremity. This pattern of markedly decreased muscular activity results in the adoption of compensatory mechanisms to gain stability. Type III activation patterns consist of abnormal coactivation of several limb muscles with normal or increased muscular activity levels in the muscle groups of the involved side. This type of pattern results in a disruption of the sequential flow of motor activity.

The Stroke Impact Scale (SIS) and the short version, the Stroke Impact Scale–16 (SIS-16) are measures with high reliability and validity for people poststroke. The long version assesses eight domains: strength, emotion, hand function, memory, physical function and mobility, communication, ADLs, and social participation. The SIS-16 includes most of the original items in the SIS physical function and mobility domain.^{88,89}

Evaluation of Movement Control

After the standardized testing has been performed, the therapist continues to a subjective evaluation of movement components to gather information to answer the question “why” it is difficult for the client to perform specific movements or tasks.

Clients who have sustained a stroke have difficulty moving the trunk and the arm and leg on the affected side because of the presence of primary and secondary impairments. Objective standardized measures for the primary impairments are few; standard muscle testing has been questioned for CNS deficits because of the numerous degrees of freedom available and the discrepancy in functional strength on the basis of the increasing degrees of difficulty of controlling linked trunk and extremity patterns as the body moves from function in supine to function in sitting to function in standing.

Active Movement and Strength

When active movement patterns in the trunk and extremities are assessed, the therapist measures both strength and control. Paralysis, weakness, and imbalanced return are determinants of strength. Initiation pattern, sequencing, and control of firing patterns are indicators of control. Weakness and paralysis after stroke have been largely ignored because of a lingering focus on spasticity. Some recent studies have shown that muscle weakness is, in fact, present and interferes with the ability to generate enough force to achieve

functional performance.⁹⁰⁻⁹² Motor weakness is present in 75% to 80% of clients after a stroke. There appears to be no difference in clients with left- or right-sided hemiplegia in terms of frequency or severity of weakness.⁹³ In contrast to these studies, Landau and Sahrmann⁹⁴ investigated the degree of functional impairment in strength that was a result of deficits in the contractile element of the affected muscles. Their findings from comparisons of maximal tetanic contraction of the anterior tibialis muscle suggest that maximal voluntary muscle strength was *not* impaired. Although recent research has moved weakness back into the impairment list, there is much more to be learned about the nature of weakness in CNS dysfunction.

The objective assessment of active movement in hemiplegia is commonly documented by therapists through the use of the Fugl-Meyer assessment scale, derived from synergistic stages as outlined by Brunnstrom,⁴³ and is similar to a version of Bobath’s long evaluation form, which gradually builds series of selective or fractionated movement in the arm, trunk, and leg.⁹⁵

When clinically assessing weakness and control of active movement patterns, the therapist analyzes and identifies the client’s patterns of posture and movement in the trunk and extremities by position (supine, side lying, sitting, and standing) and in linked combinations. Active movement control is evaluated in individual muscles, movement components, and movement sequences.⁵⁴ Verbal directions or demonstrations may be necessary to help the client understand what is desired. In this phase of the evaluation, the therapist should not physically assist the client’s movement but should be prepared to prevent loss of balance.

While evaluating force production or weakness in all these categories, the therapist gathers information about sequencing movements in increasingly complex patterns, timing of muscle firing, and speed of movement. Muscle activation deficits in these categories may explain why some clients with minimal weakness do not regain spontaneous functional use of the extremities.⁵⁴

Assisted Movement

After the evaluation of active movement, therapists use their hands while retesting the movements to gain additional information about the relationships between impairments. Whereas the use of handling must be judicious, handling is used during an assessment for the following purposes:

1. To correct alignment to gather additional information about strength, control, and orthopedic impairments (Figure 23-5)
2. To limit degrees of freedom of one of the joints to assess relationships between intralimb segments
3. To assist the movement of a weak muscle
4. To block or stabilize a joint to assess the performance of a weaker muscle group or to limit the degrees of freedom of an intralimb segment⁵⁴ (Figure 23-6)

Example

Step 1. *Assessment of forward reach in sitting by client with left hemiplegia.* Active movement patterns on left: client initiates movement proximally; shoulder flexes to 60 degrees, with internal humeral rotation; abducted, downwardly rotated scapula elevates during the movement; elbow flexes, forearm supinates to 10 degrees; wrist remains in flexion and radial deviation. Client leans trunk

Figure 23-5 ■ **A**, Client with right hemiplegia trying to perform an upper-body-initiated lateral weight shift to the left. Note that the spine is straight and the right hip is off the surface. **B**, Therapist uses her hands to correct and stabilize the lower trunk as the client initiates the upper-body lateral movement to the left. The therapist gains information about trunk and hip control and secondary impairments of trunk muscle tightness. Note that the spine is beginning to curve as the client uses eccentric activity of the right lateral musculature to control the movement. Active stretching of the right quadratus lumborum and latissimus occurs if tight muscles are present.

Figure 23-6 ■ **A**, Client with right hemiplegia moving from sitting to standing. Note the tendency to use the left leg more than the right, the left rotation of the upper body, and the position of the right arm. **B**, Therapist uses her hands to stabilize the lower leg and to assist lower-leg movements as the client initiates sit to stand. Note the change in upper-body position and the decrease in arm posturing.

forward to assist with task but cannot reach arm forward to place it on table.

Step 2. Clinical judgment or hypothesis 1: Weakness of scapula and humeral external rotators prevents antigravity use of elbow extensors during forward reach. Supination of forearm comes from strong proximal initiation

and use of elbow flexors to lift arm. *Clinical judgment or hypothesis 2:* Forearm, wrist, and hand position prevents distal initiation and biases shoulder in internal rotation, thus blocking use of elbow extensors.

Step 3. Test hypothesis 1: Therapist uses her or his hands to externally rotate the humerus to neutral and asks client to reach again. *Result:* Client activates elbow extension halfway through range with shoulder forward flexion and places wrist and hand on table. *Clinical intervention implication:* Increased control of humeral external rotation and increased control of accompanying scapular pattern are important intervention goals to regain forward reach of arm. Retrain trunk, scapular, and humeral movement patterns, with emphasis on shoulder external rotation and scapular upward rotation. Assess secondary impairments of pectoral and rotator cuff tightness (rotator cuff is shortened if scapula is in an abducted position). *If result is unchanged, test hypothesis 2:* Therapist supports wrist and hand with wrist splint or with his or her hand and asks client to reach again. *Result:* Client activates elbow extension and places the wrist and hand on the table. *Clinical intervention implication:* Prevention or blocking of wrist flexion limits the degrees of freedom, changes the internal rotation moment on the distal portion of the lever arm, and allows use of existing elbow extensors. Use small wrist splint during independent practice or use object to assist or preset distal segment during practice.

Tone

The evaluation of extremity tone, sometimes referred to as *spasticity*, continues to be an integral part of poststroke movement research and is part of the physician's neurological examination. Over the years, leading physiologists have split into two camps over the definition of tone. During the beginning of the 20th century, tone was thought of as postural reflexes. In the 1950s the concept of tone was thought of as a state of light excitation or a state of preparedness.⁹⁶ Granit⁹⁷ later encouraged us to think of the relatedness of both these views. He believed that the same spinal organization is mobilized by the basal ganglia to produce both manifestations of tone: a state of preparedness and the postural reflexes.⁹⁷ In the 1980s, scientists challenged the concept that what led to a spastic movement pattern was hypertonicity resulting from an exaggerated stretch reflex.^{98,99} A new construct emerged in the following years that acknowledged the contribution of both neural and nonneural elements to the phenomenon of "spasticity." This newer concept of spasticity explains why the stretch reflex or tendon tap response (performed in a passive condition—during rest) is an "epiphenomenon and is not the cause of the "spastic movement problem" that interferes with movement."¹⁰⁰ Although the Modified Ashworth Scale is an objective measure of spasticity caused by the stretch reflex,¹⁰¹ it is not a measure of the functional problem that interferes with skilled movement. It is heartening to hear such discussions occurring among physiologists because therapists are also questioned about their notations of and changes in tone and they often have no objectively derived standard clinical system for measurement. The debate over tone continues, but clients with CNS dysfunction clinically display changes of muscle tone that result in

longer rehabilitation stays and problematic secondary impairments.¹⁰²

The response of a spastic muscle to stretch differs during passive and active movements, leading some to question the usefulness of the classic numerical test of spasticity, the Ashworth Scale. The Ashworth Scale rates the severity of tone from 1 to 5.¹⁰³

The first noticeable change in tone is the change from the premorbid state. Clients in the acute phase of hemiplegia exhibit, for varying periods of time, a lower than normal tonal state. Clients with paralysis of the extremities exhibit low tone or hypotonicity. The extremities feel like “dead weight” as the therapist moves them. As neuromuscular return slowly begins, the extremities feel heavy, but some “following” of passive movement patterns is detected.

As the client becomes more active, he or she uses all available movement patterns. Ryerson and Levit have described three specific situations, which in reality have overlap, wherein tone increases (see page 23 for a detailed discussion).⁵⁴ This increased tone, or clinical hypertonicity, occurs in the arm and leg if the client’s trunk control is less than the demand of the task, if altered joint alignment increases the tension of the muscle, or if the voluntary movement pattern of the extremity is unbalanced and disorganized.^{54,104}

One clinical description of increased extremity tone put forth in the 1970s is still somewhat useful today: severe hypertonicity makes coordinated movements impossible; moderate hypertonicity allows movements that are characterized by great effort, slow velocity, and abnormal coordination; slight hypertonicity allows gross movement patterns to occur with smooth coordination, but combined, selective movement patterns are uncoordinated or impossible.¹⁰⁵

Equilibrium and Protective Reactions

Equilibrium reactions help us to maintain or regain balance by keeping the center of gravity within the base of support. Equilibrium reactions are often referred to as the body’s “first line of defense” against falling. They occur when the body has a chance of winning the battle against gravity. If equilibrium reactions cannot preserve balance, the second line of defense emerges: protective reactions. One of the best known protective responses in the arm is the “parachute reaction.” Protective responses in the leg in standing positions include hopping and stepping.

When assessing equilibrium or balance reactions in clients with hemiplegia, the therapist remembers the distinction between equilibrium reactions and protective reactions. Equilibrium reactions should be assessed while slowly moving either the limb or trunk away from the base of support. The amount of control in the trunk and supporting limb, the size of the base of support, and the available range of motion as well as the evaluator’s handling skills affect the response (see Chapter 22).

Descriptive Analysis of Functional Activities

When evaluating functional activities, the therapist assesses three phases of the movement pattern. The first phase is the *initiation* of the act, which includes the body segment initiating the movement, the direction of movement, and the

establishment of antigravity control. *Transition*, the second phase, represents the point in the functional activity at which there is a switch in the muscle groups that provide antigravity control. The third phase is the *completion* of the activity, involving a final weight shift and the ability to maintain postural control.⁵⁴

If assistive devices are used, the following questions should be asked: Is the device always used? If not, when is it used? How is the device used? Could the device be used another way that would foster trunk symmetry and allow activity of the affected extremities?

Evaluation of Secondary Impairments

Loss of Joint Range and Muscle Shortening

In hemiplegia, loss of joint range is caused by muscle shortening from poor alignment that is the result of weakness or muscle activation problems. Loss of alignment occurs early in recovery, whereas muscle shortening and loss of range occur over time. When measuring joint range of motion and muscle shortening, the therapist must remember to consider the functional consequences of two-joint (multijoint) muscle tightness.

Example 1. In sitting (knee bent), the client has ankle joint dorsiflexion range from 0 to 10 degrees; but in standing (knee and hip straight), ankle joint dorsiflexion range is –20 degrees. This functional loss of ankle range causes significant problems for standing and walking. Loss of ankle joint range in standing may be the result of gastrocnemius and soleus, tensor fasciae latae, or hamstring muscle tightness (Figure 23-7).

Range-of-motion measurements should be documented in terms of functional position. Extremity muscles that cross multiple joints are the most common groups to shorten and limit joint range in hemiplegia. Muscle shifting (changes in the resting position of muscle bellies and tendons) occurs with prolonged changes in alignment and loss of joint range.

Example 2. Long-standing wrist flexion may cause the ulnar wrist extensor to slip volarly and function as a wrist flexor. Similarly, a position of knee flexion with ankle plantarflexion and subtalar varus may lead to lateral shifting of the anterior tibial muscle belly. As the muscle shifts laterally, the tension increases distally and foot supination becomes more pronounced.

Pain

Two commonly used standardized pain measurement scales are the visual analog pain rating scale and the McGill Pain Questionnaire.^{106,107} These scales focus primarily on the intensity of pain but provide an objective measure of intervention effectiveness. For an in-depth discussion of the topic of pain management, see Chapter 32.

The presence of pain in hemiplegia is devastating for the client and makes movement reeducation difficult. Shoulder pain is the most frequent pain complaint after stroke.^{11,108} Pain must be evaluated specifically and should not be allowed to occur during intervention; the “no pain, no gain” message that is sometimes used in sports or orthopedic intervention should not be used in neurorehabilitation. Pain is an indicator that joint alignment or movements are incorrect. See Box 23-3 for general questions.

Figure 23-7 ■ **A**, Client with right hemiplegia with limited range in hamstring, tensor fasciae latae, and gastrocnemius and soleus muscles. **B**, Client has sufficient range at ankle to keep foot on the floor in sitting and as she initiates the rise to standing. **C**, As she stands and reaches the limit of range of these two muscle groups, her body compensates. The pelvis rotates right, and the tight medial hamstring adducts and internally rotates the femur and pulls the knee into extension as its medial insertion becomes more anterior to the joint. **D**, As the knee extends more, the calcaneus moves into equinus and varus. The foot supinates as a result of calcaneal varus and external tibial rotation from the tight tensor fasciae latae.

Motor Evaluation Forms

The foregoing information, once gathered, can be placed on an evaluation form in many ways. Every medical institution seems to have its own evaluation form and its own system of recording data. Active movement at the shoulder joint may be described in one institution in terms of percentages of synergistic stages, at another institution by a narrative of degrees and planes of movement, and at still another by functional outcomes of shoulder movement. At one hospital the documentation of pain may be descriptive, and at another it may be numerical. It is important to keep in mind the substance of the evaluative material, not the form in which it is described. A detailed motor evaluation form is necessary for the establishment of realistic goals and for subsequent treatment planning, but the specific form depends both on the needs of the specific clinical setting and on the clinician's choice.

BOX 23-3 ■ QUESTIONS FOR SUBJECTIVE EVALUATION OF PAIN

Location: Where is the pain? Pinpoint the location.

Type: What does it feel like?

- Pins and needles
- Sharp and stabbing
- Aching
- Dull
- Pulling

Occurrence: When does the pain occur?

- At rest
- During movement
 - Range-of-motion exercises
 - Weight-bearing exercises
 - A specific part of the movement

Recognizing Needs

The information obtained from the total evaluation provides the basis for answers to the following questions:

- What activities are possible?
- What activities are not possible?
- How do the movement impairments and secondary impairments relate to activity performance?

By understanding the impairments and their relationship to activity limitations, the therapist can answer the following question: What significant movement components are missing? The answer to this question becomes a hypothesis for intervention planning. How the possible is accomplished and why the impossible exists provide logical suggestions for selection of intervention techniques.

Therapy intervention occurs at either the level of activity limitation or the level of movement-related primary and secondary impairments. The process of establishing goals and selecting activities for intervention begins with clinical decision making or problem solving.

CLINICAL DECISION MAKING AND PROBLEM SOLVING

Problem solving is a process of gathering and analyzing evaluation information from movement analysis, organizing and reflecting on this information to develop hypotheses for causal relationships between activity limitations and significant impairments, and establishing and prioritizing goals for therapeutic intervention. The problem-solving process is also used to hypothesize how the movement problems of the trunk, arm, and leg are interrelated and how these problems relate to the ability to perform tasks. Movement control deficits, secondary impairments, and compensatory or atypical movement patterns should be identified in relation to each significant activity limitation.

Analyzing Evaluation Material

The relationship between activity performance and primary and secondary impairments in stroke has not been researched. Therefore, this relationship, which is the basis for therapy intervention, must be derived from clinical experience and judgment. Clinical reflection guides the evaluation process—what should be evaluated and how. As a result of the evaluation, the therapist has a list of functional skills that are difficult or impossible for the client to perform and a list of primary and secondary impairments that relate to the attempted performance of that task. The therapist analyzes this information with the goal of identifying common impairments in categories of tasks: Which primary impairments are major impediments in each task analyzed? Are there secondary impairments that interfere with the client's ability to perform specific critical movement components? What is the level of trunk-extremity control during task performance in each functional position evaluated? While analyzing the evaluation material, the therapist pays attention to all significant factors that limit performance of tasks, including environmental, cognitive, perceptual, and emotional barriers.

Example

A patient after an acute stroke with left hemiplegia cannot perform morning daily care activities at the sink while sitting in a wheelchair, cannot transfer from bed to chair, and

cannot rise to stand. Common primary impairments include paralysis or weakness of the left arm and leg, a loss of muscle activation resulting in an inability to coordinate trunk and lower-body movements to allow forward weight shifts in sitting and/or to perform transfers from bed to chair and/or inability to sequence forward arm movements, and impaired proprioception in the extremities. Secondary impairments that begin to appear by the end of the acute recovery phase might include trunk asymmetries (lateral trunk flexion with a left spinal convexity; inferior shoulder subluxation; loss of ankle joint dorsiflexion range; muscle shortening in the pectoralis, wrist flexors, and gastrocnemius; and edema in the hand and foot.

In the rehabilitation phase of care, the primary impairments of weakness and loss of muscle activation pattern (motor control) begin to improve. As the client performs tasks that exceed his or her level of trunk strength and control, clinical hypertonicity in the arm and leg may increase as a strategy for maintaining balance or reinforcing trunk control. Secondary impairments of shoulder pain increase, along with increasing instances and degrees of muscle tightness and continued loss of trunk-extremity alignment.

Developing Hypotheses for Significant Impairments

The process of motor performance evaluation results in a list of activities and related impairments. However, not all these impairments directly relate to each activity limitation of the client. The therapist, using clinical judgment, hypothesizes a causal relationship between frequently occurring impairments and activity limitation. These impairments, called *significant impairments*, are the ones that must be changed for measurable changes in movement and function to occur.⁵⁴ The other impairments are not forgotten but are re-evaluated later as improvement begins and new activity goals are chosen. The significant impairments are often used as the focus of short- and long-term goals because they are the underlying building blocks of the selected activity goal. Because functional movement depends on the linkage of trunk and extremity movements, the therapist develops hypotheses between impairments in the extremities and specific levels of trunk control to set goals that result in improved activity performance. If weakness and control deficits of the trunk, arm, and leg are treated separately, the client may see improvement in the impairments but not see a change in function (Box 23-4). (See Chapters 4 and 9 for further discussion.)

Goal Setting

Once the therapist reviews the desired functional goal and identifies the underlying significant impairments, the intervention plan is created and discussed with the client.

Functional Goals

Functional goals are based on the needs and desires of the client and on the functional impairments that were identified by the therapist during the initial assessment. Functional goals should represent a significant change in the patient's level of independence, be practical, and reflect improvement in a specific activity limitation. They state the desired function and the expected level of performance.⁵⁴

BOX 23-4 ■ MOVEMENT COMPONENT CONTROL MODEL OF POSTURAL CONTROL

Postural tone and stability
 Trunk control
 Level I: Basic movement components
 Upper-body– and lower-body–initiated movement
 Anterior
 Posterior
 Lateral
 Level II: Coordinated trunk and extremity patterns
 Level III: Power production
 Equilibrium and protection

Example. Client will stand independently and safely while performing self-care activities at the bathroom sink.

Long-Term Goals

A long-term goal should reflect a major improvement in a primary or secondary impairment or an increase in level of performance of an existing skill. The accomplishment of a long-term goal brings the client closer to the functional goal. The time it takes to accomplish a long-term goal varies tremendously depending on the frequency of treatment and the length of time after stroke. The therapist may set many short-term goals to achieve one long-term goal. Long-term goals may be stated in functional terms, but they usually reflect a change in a primary impairment: an increase in strength, movement control, or balance.⁵⁴

Examples

Functional Goal. Client will be able to perform meal preparation activities in the kitchen safely (while standing).

Long-Term Goals

1. Client will perform upper-body–initiated movement (lateral and rotational) while standing, supporting hips against a kitchen counter.
2. Client will safely stand near the kitchen counter and maintain balance during far-reach movements of the uninvolved arm.

Short-Term Goals

A realistic short-term goal should be achievable quickly and should be based on the result of the patient's response to handling during the evaluation of movement. Short-term goals should directly relate to the accomplishment of the long-term goal. There are multiple short-term goals that relate to one long-term goal. Short-term goals are compiled from the list of relevant secondary impairments or desired increases of strength or movement control. These goals are measurable but do not in and of themselves result in a functional change.⁵⁴

When stated in terms of movement control rather than functional performance, these goals include the reestablishment of generalized movement patterns that link movement patterns of the trunk and extremities (Box 23-5).

Example. Decrease tight hamstring and gastrocnemius muscles in standing position to allow the foot to remain flat on the floor during assisted and independent upper-body movements while standing (e.g., forward reach beyond arm's length).

BOX 23-5 ■ COMPONENT GOALS IN FUNCTIONAL TRAINING

Component goal (power): Restore strength in trunk and extremity patterns (individual muscles, components, sequences)
 Component goal (structure): Minimize or eliminate secondary impairments
 Component goal (control): Reeducate patterns of control (sequencing and timing)

Choosing Intervention Techniques

Once the problem-solving process of goal setting is finished, therapists can select specific intervention techniques and activities. Therapists have many techniques to choose from to meet their goals. After a stroke, most clients will not fully regain normal movement patterns regardless of the type of intervention they receive.

Controversy exists as to the means of increasing functional mobility and performance in clients who have had a stroke. One school of thought teaches compensatory patterns or hopes for some use of the affected side through task-specific practice without direct intervention for the neurological impairments. The other prevalent practice pattern is to increase functional movement patterns on the affected side to help achieve an activity goal by increasing control and strength of movement sequences of the trunk and limb through specific levels of reeducation.^{54,109-111}

A combination of these two practices may be useful: impairment-based intervention strategies to reeducate movement and training strategies to foster desirable compensations—a functional reeducation strategy. This type of intervention includes strengthening trunk and extremity linked patterns of movement, minimizing or eliminating secondary impairments that interfere with regaining control, teaching appropriate compensations, and training the client to practice functional movement patterns in the context of daily tasks^{54,112} (Box 23-6). Research findings support a link between the trunk and upper extremity and the trunk and lower extremity during reaching activities.^{113,114} One result of this research has been to design treatment interventions that restrain trunk movements during forward reach retraining to increase control of elbow extension movement in the paretic arm.^{115,116}

For reeducation to be effective, therapists must allow the patient to initiate the active trunk and extremity pattern,

BOX 23-6 ■ REEDUCATION STRATEGY FOR INTERVENTION

Reeducating basic trunk movement components
 Linking coordinated trunk and extremity patterns

- Weight bearing
- Movements in space

 Preventing, minimizing, eliminating secondary impairments
 Teaching appropriate compensations
 Teaching independent practice routines

must move from assisted practice to independent practice with the assistance of appropriately selected objects or verbal cues, and must teach the patient appropriately staged practice patterns. Studies based on the “learned nonuse” phenomenon described by Taub have shown that when patients are encouraged to use the affected arm rather than receiving pessimistic messages about its potential, movement and functional use, even if limited, are possible.^{117,118}

Regardless of intervention type used, task-performance practice or a reeducation strategy, there comes a time in the recovery process when therapists help the client select practical compensatory strategies. Compensatory strategies are taught when the client needs to function independently and cannot yet use the affected arm because of insufficient recovery or the severity of damage. To be appropriate, the strategy should incorporate the use of the involved extremities and use appropriate trunk movement patterns to maximize future return of movement. Undesirable compensations are patterns that are so asymmetrical that they fail to incorporate available movements of the affected trunk and extremities (Figure 23-8).

Although current literature generally applauds function-based techniques, therapists in clinical settings use hands-on approaches to increase muscle strength and control and to decrease impairments that block the emergence of new functional patterns.⁵⁴ As research in movement science and

recovery of movement increases, therapists must critically analyze research findings and judiciously integrate them with their clinical experience and judgment.

COMMON IMPAIRMENTS AND INTERVENTION SUGGESTIONS

Weakness and Loss of Control

Diminished muscle strength, either paralysis or weakness, is an important category of impairment in hemiplegia. A paralyzed muscle is unable to contract to produce enough force for movement. A weak muscle contracts insufficiently for joint or body segment movement or to allow functional performance.⁹⁰⁻⁹² In a client who has sustained a severe, acute stroke, the paralysis or weakness affects the majority of muscles and results in a loss of functional movement in the face, trunk, arm, and leg. In clients who have had less severe strokes, some muscle groups are weak and produce movement, whereas other muscles are paralyzed and cannot be activated.¹¹⁹

Weakness from stroke differs from generalized weakness and orthopedic weakness: it involves one entire side of the body and includes the trunk and extremities. After a stroke, the trunk, perhaps because of its bilateral cortical innervation, does not display the degree of weakness found in the extremities. As a result of differences in testing methods,

Figure 23-8 ■ **A**, Client with left hemiplegia using his right side to move to sitting and not incorporating movement of the left side—an undesirable compensation. **B to D**, Client moving to sitting while using as much control as possible on the left side to assist the movement to sitting.

position, and design, there is no consensus on the degree of trunk muscle weakness after a stroke: some research findings indicate a loss of lateral paretic-side trunk strength,¹²⁰ others report no significant difference in lateral trunk strength,^{121,122} and others find slight weakness in the trunk extensors.^{123,124} However, it is clear that weakness in the extremities interferes with functional use in either weight bearing or movement in space.^{54,125}

Model of Postural Control

Trunk control allows the body to remain upright, to adjust to weight shift, to control movements against the constant pull of gravity, and to change and control body position for balance and function. Therapy based on neurophysiological models stressed facilitation of trunk rotation to gain trunk control. Newer clinical models of postural and trunk control began appearing around 1990.^{104,126,127} Information from motor control science has resulted in revision of therapists' thoughts on trunk control.¹²⁸⁻¹³⁰

In a movement component model of postural control, trunk control has levels of increasing difficulty¹³¹ (see Box 23-4). Trunk control not only helps us remain upright but also allows weight transfer to free an arm or leg for function. For some functional movements, such as sitting, trunk control keeps the upper and lower trunk stable during weight shifting and balance. For other tasks, such as reaching forward beyond the length of the arm, the upper trunk is stable and adjusts to the lower-body-initiated anterior weight shift.⁵⁴

Additional postural control models, based on a developmental or systems model, are well documented.^{105,132-134} Research in the field of postural control shows that the level of trunk control and trunk strength correlates with sitting balance, that extremity function correlates with trunk control, and that loss of trunk strength occurs in all planes.¹³⁵⁻¹³⁷

Postural Tone and Stability. Clients with hemiplegia frequently have alterations in both muscle tone and postural tone. *Postural tone* refers to the overall state of tension in the body musculature. Postural tone is tone that is “high” enough to keep the body from collapsing into gravity but “low” enough to allow the body to move against gravity. It

is influenced by the input from the corticospinal tracts, the vestibular system, the alpha and gamma systems, and peripheral-tactile and proprioceptive receptors.¹³⁸ Normal postural tone allows a constant interplay among the various muscle groups in the body and imparts a constant readiness to move and to react to changes in the environment (internal and external). It provides an ability to adjust automatically and continuously to movements. These adjustments provide the proximal fixation necessary to hold a given posture against gravity while allowing voluntary and selective movements to be superimposed without conscious or excessive effort.

Trunk Control. Trunk control can be divided into levels of increasing complexity. The first level of trunk control is the ability to perform the basic movement components. Trunk strength and control at this level provide a base that allows extremity movement to be combined and used for function. Retraining strength and control of basic trunk movements in the three cardinal planes is a prerequisite for the coordination of trunk and extremity patterns for tasks.

Trunk movements in sitting are initiated from the upper trunk or the lower trunk according to the demands of the task. In standing, functional trunk movements are initiated from the upper trunk (if the head or arm is initiating a task) or the lower extremity. The two initiation patterns result in different spinal patterns, different types of muscular activity, and changes in the distribution of weight⁵⁴ (Tables 23-3 and 23-4). These basic movement patterns allow the body to be positioned for functional use.

The second level of trunk control, coordination of trunk and extremity patterns, may best be explained through the concept of anticipatory postural control. Anticipatory control allows the coordinated linkage of trunk and extremity patterns before the activation of extremity movements: it allows us to sit and reach beyond arm's length without falling forward or to step forward with one leg as walking is initiated. Researchers have identified altered anticipatory postural responses in people after stroke in both sitting and standing positions. The pattern of anticipatory responses poststroke appears to be preserved, but the timing of the response is slowed.^{139,140}

TABLE 23-3 ■ UPPER-BODY-INITIATED WEIGHT SHIFT PATTERN: SITTING

WEIGHT SHIFT	SPINAL PATTERN	MUSCLE ACTIVITY
Anterior movement—reach down to floor	Flexes	Eccentric extensor activity
Posterior—to sit back up	Extends	Concentric extensor activity
Lateral—reach sideways and down to right	Laterally flexes with concavity on right	Eccentric lateral activity on left
Lateral—comes back up to middle	Spine moves back to neutral	Concentric lateral activity on left

TABLE 23-4 ■ LOWER-BODY-INITIATED WEIGHT SHIFT PATTERN: SITTING

WEIGHT SHIFT	SPINAL PATTERN	MUSCLE ACTIVITY
Posterior weight shift	Flexion	Concentric flexor activity
Anterior weight shift	Extension	Concentric extension activity
Lateral weight shift to right	Lateral flexion—convexity to right	Eccentric lateral activity on right Concentric lateral activity on left

This level of trunk control allows the trunk to remain stable yet adapt to movement of the arms and legs. There are two different ways this happens: trunk movements occur as postural adjustments to extremity movement around midline, or trunk movements can precede voluntary movements to help extend the reach of the extremities. These coordinated movements can occur in supine, sitting, or standing positions as demonstrated in the following three examples.

1. While sitting, the client reaches down or sideways to the floor to pick up an object. As the arm reaches down, the upper body initiates the anterior weight shift. To extend the reach of the arm, the lower body provides stability yet adjusts and adapts.
2. When the client lifts up a leg to tie a shoe, the lower body initiates a posterior weight shift. The upper body adjusts to the weight shift and to the demands of the arm and hand as they tie the shoe.
3. In standing, upper-trunk movements occur as postural adjustments as the legs initiate both the stance phase (forward weight shift) and swing phase (stepping) of walking.

The third level of trunk control allows strength and stability for power production from the arm or leg. The movement and control of the trunk are used to support power production in the extremities for propulsive activities such as stair climbing, jumping, running, throwing, hitting, and rowing.

The entire model is summarized in [Box 23-4](#).

Extremity Weakness

Weakness in the arm and the leg results in ineffective and inefficient functional patterns in daily life. Intervention for weakness in the extremities includes reeducation of movements in space, reeducation of weight-bearing movements, and training of and appropriate initiation and sequencing of movement. Most clients with hemiplegia regain enough control in the leg to stand and walk, but those same patients may not be able to use the arm for any purpose. Today the concept of “learned nonuse” may help therapists understand why the discrepancy between arm and leg recovery exists. Wolf and colleagues¹¹⁸ conclude from studies of hemiplegic patients that learned nonuse does exist in some patients who have had a stroke and suggest a program of “forced use” training. Although the research training model may not be directly transferable to the clinic, this study points out the benefits of incorporating the use of the affected side in intervention strategies.

Distal reeducation is an important component of early reeducation that has been neglected by therapists because of a previous belief that proximal return comes before distal. Distal reeducation trains the client to be able to initiate movements from the hand or foot, instead of the common proximal initiation patterns seen during attempted reach or stepping ([Figure 23-9](#)).

Weight bearing on either the forearm or the extended arm is used as a postural assist during transition activities such as side lying to sitting, or as a means of supporting the weight of the upper trunk in sitting or standing, and is used to stabilize objects during task performance. The activity of accepting weight through the arm is not passive but extremely active and dynamic. Forearm weight bearing in sitting or standing is used to activate trunk movements, to re-establish scapulohumeral rhythm, to maintain range of

motion in the arm, or to strengthen movement sequences in the arm. It is not used to inhibit tone ([Figure 23-10](#)). The muscles of the arm are linked with trunk weight shifts during active weight bearing.⁵⁴ [Table 23-5](#) presents the linked trunk and arm muscle activity during active weight bearing for one functional task.

The ability to support body weight on both legs for stability and movement control is important in sitting, standing, and walking retraining. Movements of the trunk in sitting and standing occur with constant changes of muscle activity in the legs as part of the base of support, to adjust to demands of weight shifts, and to increase activity levels of leg muscles to initiate standing weight shifts. Loss of control of weight bearing on both legs or on one leg has an immediate effect on balance. Problems of weight-bearing control of the leg may exist because of weakness; because of muscle shortening in the pelvis, hip, knee, or ankle; or because of posturing. When the leg cannot actively support body weight, undesirable asymmetrical compensations result. A significant and often overlooked prerequisite for active control of the leg in weight bearing is a stable, aligned upper body. The use of forearm or extended-arm weight bearing in standing provides external stability to the upper body while allowing the therapist to reeducate control of bilateral or unilateral weight-bearing movements in the leg.

Muscle Activation (Motor Control) Deficits

Common muscle activation deficits include improper initiation, the inability to grade timing and force production, and the inability to sequence muscles for task performance.

Improper Initiation

Improper initiation of movement occurs when the client attempts to move the arm or leg in space and substitutes the stronger proximal muscles for weaker distal muscles.⁵⁴

Example 1. If we ask a client to lift a hemiplegic arm and reach forward for an object, she or he often initiates the movement proximally instead of distally with the hand and forearm, using the stronger elevators and abductors instead of the weaker hand and forearm muscles.

This is also seen during walking.

Example 2. The client initiates the swing phase of gait proximally instead of distally with the foot, using the stronger pelvic elevators or rotators instead of the weaker ankle and foot muscles.

Inappropriate Muscle Selection

Inappropriate muscle selection for the task occurs when the client substitutes a strong muscle group for a paralyzed muscle although it is inappropriate for the function.

Example. When the hamstrings are weak, the client may use the quadriceps to lift the leg up a step. This results in strong overshifting in the trunk and makes balance precarious.

Inappropriate Sequencing

Inappropriate sequencing includes improper initiation and excessive co-contraction. Excessive co-contraction occurs when the client activates too many muscles either at the same time or out of sequence for the task.

Figure 23-9 ■ A to C, Client with left hemiplegia. Therapist assists movements of forearm, wrist, and hand as client practices increasing distal arm control. D to F, Therapist introduces object and assists client as he learns to control the object and the movement. G, Independent practice. H, Client uses same movements with a similar object.

Excessive Force Production

Excessive force production occurs when the patient activates muscles with inappropriate effort during voluntary movement. When force is excessive, the movement pattern is slow and the extremity feels stiff. Frequently, these muscles easily fatigue and the extremity slowly falls back to the starting position. Therapists often label this movement a “spastic” pattern and intervene with inhibition techniques. However, if this pattern is not from spasticity but from a muscle activation pattern, the intervention should focus on reeducation of control, not inhibition.⁵⁴

Hypotonicity

Hypotonic muscles offer no resistance to passive movement and are clinically associated with paralysis and weakness. Clients who have had a severe stroke may have no visible movement in the extremities; the extremities display no resistance to passive movement and feel heavy. As strength and control in the muscles of the trunk and extremities increase, the hypotonicity lessens. If weakness persists, the secondary impairments of poor joint alignment, muscle and soft tissue tightness, and eventually joint deformity or contracture will be more predominant than problems of spasticity.

Spasticity

There is considerable debate in the academic and clinical therapy community over the clinical relevance of spasticity and the need to address it in treatment.^{90,141} Characteristics of a spastic muscle include increased velocity-dependent resistance to stretch, a clasp-knife phenomenon, and hyperactive tendon responses. It is important to remember that spasticity is the increased tension in a muscle when it is passively stretched. The type of high tone that occurs with active, voluntary movement is a different phenomenon: it is the result of both neural and nonneural changes in the muscle. As described earlier in this chapter, Dietz¹⁰⁰ recommended that we assign different names to these two different phenomena of increased tone: he suggested “spasticity” and “spastic movement disorder.” Clinicians realize that although movement interventions may not change spasticity, if the “spastic movement disorder” is left untreated the task of muscle reeducation becomes more difficult. Additional, secondary problems such as joint dysfunction, pain, and undesirable compensatory movements may result. I suggest renaming Dietz’s second category of spastic movement disorder to *clinical hypertonicity*.

Figure 23-10 ■ Client performs lower-body-initiated posterior movement during forearm weight bearing at a table. The therapist uses her hands to stabilize the humerus, and as the patient moves back, the therapist's left hand slowly stretches or releases tight tissue in the rotator cuff.

TABLE 23-5 ■ TRUNK AND ARM-LINKED MOVEMENTS IN FOREARM WEIGHT BEARING

FUNCTIONAL TASK

Sit at a table with both forearms supported on the table. Keeping both arms on the table, move forward toward the table, and then move body back away from the table.

TRUNK AND ARM LINK	BODY MOVES FORWARD	BODY MOVES BACK
Spine	Extends	Flexes
Scapula	Adducts and depresses	Abducts and elevates
Glenohumeral joint	Less flexion	More flexion
Elbow	Flexes	Extends

Clinical Hypertonicity

Clinical hypertonicity can be separated from spasticity, in part, because clinical hypertonicity responds to movement interventions. Research findings have helped clinicians realize that spasticity is not the *major* problem in hemiplegia. However, for interventions to be successful, it is important to understand the situations in which hypertonicity occurs. At least three different situations result in an increase in

clinical hypertonicity: (1) increased tone as a result of proximal instability, either insufficient trunk control for the task or instability of proximal limb musculature (e.g., hip weakness), (2) increased tension on a two-joint muscle caused by poor joint alignment and the resultant shortening or shifting of muscles, and (3) increased tone that is voluntarily produced during attempts at active movement, especially in the extremities.⁵⁴

These situations are divided into three groups for ease of description, but, in reality, overlap occurs between groups. *Insufficient postural stability and control* in the trunk is the first explanation for arm and leg clinical hypertonicity. The extremity patterns of arm flexion or leg extension occur as an atypical balance strategy when the body is unstable.

Example 1. If a client has sufficient trunk control in sitting, the arm and leg display normal resting positions. However, during the rise to stand, the arm postures in flexion. The arm postures most obviously during the transition phase of the stand when the hips are off the surface and the center of gravity of the body is behind the feet, the new base of support.

Treatment of the increased tone, in this case, would not be directed at the arm. Rather, intervention would focus on increasing stability of the upper body during lower-trunk-initiated sit-to-stand patterns and on increasing strength and control of the leg in weight bearing. As the trunk and leg gain more control, the arm posturing decreases (see Figure 23-6).

A second situation in which clinical hypertonicity exists is when muscle tension increases in a two-joint muscle because of changes in alignment of one of the joints.

Example of Second Situation. In sitting, tightness in the gastrocnemius muscle across the knee may not affect the ability to keep the heel on the floor. However, as the client extends the knee, the limit of tightness in the gastrocnemius is reached and the distal end of the tendon shortens and the ankle plantarflexes. When gastrocnemius tightness pulls the calcaneus into equinus, it also moves the calcaneus into varus because of the position of its insertion on the sustentaculum tali. The resultant position, ankle plantarflexion and foot supination, has been labeled a “spastic foot position” (see Figure 23-7).

However, after lengthening of the gastrocnemius across the ankle and knee in standing and correction of the calcaneal position, the patient can stand and keep the foot on the floor.

Example 2 of Second Situation of Clinical Hypertonicity. In an anterior shoulder subluxation, the anterior movement of the humeral head increases tension on the biceps proximally, resulting in elbow flexion. As the tension increases, the forearm begins to supinate. As the humeral head and scapula are repositioned, the tension on the biceps is diminished. If the therapist holds this proximal correction, the elbow and forearm posturing activity stops; the forearm slowly pronates and then the elbow extends.

For the posturing to permanently stop, therapy intervention must help increase strength and control in linked trunk and scapulohumeral patterns to prevent the malalignment.

The third situation, *inappropriate voluntary muscle activation*, occurs when the client is trying to move the arm or leg. The client uses the muscles that have returning strength in the only way he or she knows how. Historically, these

patterns were labeled “synergistic or spastic.” This label resulted in intervention strategies of inhibition. If these patterns are thought of as unbalanced or inappropriately initiated, or inappropriately sequenced, therapy intervention is more appropriately directed. The abnormally extended or flexed leg movement changes when the patient learns new activation patterns or strengthens weaker muscle sequences. Often, these are “learned” patterns and are difficult to change. Early reeducation should include training in these skills of controlling sequencing, intensity, and duration of firing.

The underlying cause of each of these situations is weakness or loss of control. Therefore, for changes in clinical hypertonicity to last, treatment interventions must address the underlying causes. In each of these situations, the cause is weakness or loss of control of activation patterns.

In this model, generalized inhibition is inappropriate because it does not focus on the underlying cause. Intervention techniques that focus on global inhibition of extremity tone—maximal elongation, vibration, biofeedback, cold, or relaxation—rarely result in a permanent change in the tone. The temporary decrease of clinical hypertonicity that occurs with any of these methods does not by itself directly lead to an increase in function. If used, they must be immediately followed by therapeutic exercise to create a learning environment that improves motor performance.^{142,143}

Toe Posturing

There are two patterns of toe posturing: toe clawing and toe curling. Toe clawing, metatarsal hyperextension with phalangeal flexion, is a result of loss of alignment; and toe curling, metatarsal and phalangeal flexion, is a response to instability of the trunk and leg during standing, that is, part of a balance response.⁵⁴

Toe curling and toe clawing interfere with comfort during standing and walking. Problems of blistering on pads of the toes and on the top of the proximal interphalangeal joint and toe pain occur in the intermediate and long-term stage of hemiplegia as the result of the toes rubbing on the tops of the shoes and digging into shoe soles. Relief from pressure and pain on the toe pads (tips) comes with use of commercially available “hammertoe crest pads” available from distributors (e.g., AliMed) or from medical pharmacies.

Loss of Alignment

Muscle weakness or atypical anticipatory control in the trunk leads to atypical alignment patterns in the trunk and shoulder and pelvic girdle. This loss of alignment creates an atypical starting position for functional movement, interferes with muscle activation patterns, and limits weight transfer between extremities. Loss of alignment in the trunk in sitting and standing is analyzed and incorporated into intervention goals to reeducate functional trunk and limb coordinated movements. The commonly described pattern of trunk shortening (lateral flexion with the concavity) on the affected side is only one of the possible alignment problems. More routinely, weakness of the trunk on one side results in a flaring of the rib cage and lateral flexion of the spine with the *convexity on the affected side*. The “appearance” of shortening on the side comes from a number of compensatory adjustments to balance or as a result of the heavy weight of a weak arm. Often therapists confuse the

lower contour of the shoulder on the hemiplegic side with shortening of the trunk and concavity of the spine. The heavy weight of the weak arm pulls the upper quadrant into *excessive forward flexion*. In this position, the scapula elevates and tips forward on a flexed, rotated thoracic spine (Figure 23-11).

Another compensatory pattern is excessive spinal flexion throughout the spine, the convexity on the weak side, and *spinal rotation toward the affected side*. Clients with this asymmetry usually shift weight onto the stronger hip. This pattern viewed from the front or rear gives the appearance of

Figure 23-11 ■ **A**, Client with right hemiplegia. Contour of right shoulder appears lower and longer than on the left. Pelvis lists downward on the right. **B**, Therapist lifts the client’s upper body up out of forward flexion and corrects the position of the glenohumeral joint. Note that the contour of the right shoulder is now higher and shorter than the left shoulder contour. The trunk is laterally flexed with the convexity on the right. These movement components, convexity of a lateral curve, high shoulder, and low pelvis, are compatible. **C**, Client’s arms are supported symmetrically by a table. Note the convexity of the curve on the right and the low pelvis on the right. **D**, Same client moving forward and down with an upper-body anterior weight shift. This position allows the therapist to evaluate the position of the trunk. Note the tendency to avoid weight on the right hip. The trunk is laterally flexed with the convexity on the right, and the right shoulder is higher than the left shoulder.

a low shoulder. This pattern of rotation to the weak side does not occur acutely but develops over time in clients who sit more than they stand or walk.

Lateral translation of the thoracic spine from the hypermobile point of T10 occurs as a means of balancing when trunk weakness results in a lateral curve, with the convexity on the affected side. This asymmetry is common in sitting when the client is encouraged to stand by pushing up with the good arm without putting any weight on the affected leg. It occurs in standing when quad canes or hemiwalkers are used before standing control on both legs is reeducated. The stable external cane acts as a “third stable leg,” and the “long, weak” side translates laterally as the unaffected arm pushes down into the cane for stability. This pattern creates a “skinfold” on the affected side that has been confused with shortening of the affected side (see Figures 23-1 and 23-4).

In standing, because the need for leg stability and movement control is much greater than in sitting, the trunk compensates to accommodate the demands of the leg. Often the upper-body and lower-body patterns are opposite one another (i.e., counterrotational). If the leg is in a position of ankle plantarflexion and knee extension, the hip flexes with pelvic rotation toward the affected side. The upper body then counterrotates to provide an equal and opposite balance pattern to allow the client to stand. The opposite may also occur: if the pelvis and hip rotate toward the unaffected side because of learned compensatory swing and/or stance patterns, the upper body rotates toward the affected side to provide a counterrotation for balance (see Figure 23-4).

The atypical alignment pattern in one client may be different in sitting and standing as a result of the pattern of loss of control in the leg. In sitting, the hip is in flexion and provides support, a base, for the upper and lower trunk. Weakness in the knee and lower leg is not as critical to sitting balance and function as it is to standing functions. In standing, the hip demand is one of neutral extension to support the trunk; and complex combinations of knee, ankle, and foot movements are necessary for functional activities.

Shoulder girdle asymmetries are described in the sections on shoulder subluxation, and pelvic girdle and leg asymmetries are described in the sections on standing and walking.

Alignment problems in the distal extremity segments are related to loss of movement control and proximal alignment changes. Patterns in the distal arm and distal leg are strikingly similar. When the midjoint, elbow or knee, is extended, the proximal rotational alignment asymmetry translates down the lower segment into the hand or foot. Shoulder internal rotation translates across an extended elbow, causing the forearm to pronate and the hand to fall into carpal pronation (often confused with ulnar deviation) (Figure 23-12, A). Similarly, with knee extension, hip internal rotation asymmetries translate across the knee and cause tibial internal rotation and midfoot pronation. However, as the midjoints gain flexion activity, the proximal pattern no longer dictates distal asymmetries. The distal weight-bearing pattern or active initiation pattern causes a distal rotation that may be opposite to the proximal rotational pattern. When this occurs, the midjoint may posture with a result of incompatible intra-limb alignment.

Figure 23-12 ■ **A**, Client with left hemiplegia and severe weakness. The left arm and hand are in shoulder internal rotation, elbow extension, and forearm pronation. The left wrist flexes, and the hand pronates and radially deviates on the wrist. **B**, Client with left hemiplegia with atypical movements. The left arm is positioned in shoulder internal rotation and elbow flexion. As the elbow flexes, the forearm begins to supinate on the internally rotated humerus. The wrist flexes and radially deviates with finger flexion.

Example

A client has a shoulder subluxation resulting in humeral internal rotation. This tendency for internal rotation places tension on the biceps tendon, resulting in beginning elbow flexion and forearm supination. With unbalanced return and weakness of arm muscles, the emerging biceps activity predominates and reinforces a posturing pattern of shoulder internal rotation, elbow flexion with forearm supination (Figure 23-12, B).

The weakness pattern of ankle plantarflexion and calcaneal equinovarus biases return in the anterior and posterior tibialis. During movements of the leg in space with hip and knee flexion, this distal supination pattern pulls the tibia into external rotation. To place the supinated foot on the ground, the client compensates proximally by rotating the pelvis and femur, as a unit, toward the unaffected side. This incompatible tibial external rotation and femoral internal rotation result in knee hyperextension.

Muscle and tissue tightness is a common result of alignment problems. Techniques of lengthening muscle and tissue tightness must be balanced with muscle reeducation. Isolated stretching does not result in a lasting improvement in range and may decrease functional ability if not combined with activities designed to increase control. In hemiplegia, slow stretching in functional positions through active weight shifting (i.e., functional stretching) is more effective than

“orthopedic” stretching because it reeducates the weakness that underlies the loss of muscle length (Figure 23-13).

Because weakness is the underlying cause of loss of alignment and joint range, in the acute phase the *joints are hypermobile*. Over time the tissues tighten around some joints, and therapists often confuse that “feel” with joint hypomobility. Joint mobilization techniques are rarely needed because the weakness in hemiplegia renders the joints hypermobile. It is important to avoid excessive mobility in the intricate joints of the hand and foot. Tightness around a joint may indicate the need for lengthening exercises, but the joint almost never requires mobilization.

Pain

In the client with hemiplegia, arm pain can be caused by an imbalance of muscles, improper movement patterns, joint dysfunction, improper weight-bearing patterns, and muscle shortening, or it may be related to diminished sensation and sensory interpretation. Although evidence-based approaches should be used to manage shoulder pain after stroke, systematic reviews show that there are few rigorous studies that can be used to guide treatment.¹⁴⁴

Joint Pain

Joint pain is caused by poor shoulder joint mechanics during movement. Two common alignment problems are loss of scapular and humeral rhythm and insufficient humeral external rotation.^{108,145} With a shoulder subluxation, the humeral head is not seated in the fossa and passive movements of the shoulder will not occur with scapulohumeral rhythm. At 60 to 90 degrees of forward flexion, impingement of the capsule will occur and the client will report sharp pain on the superior aspect of the shoulder joint. The pain ceases when the arm is lowered. The subluxation and loss of scapulohumeral rhythm result from loss of trunk and arm movements or muscle tightness from either persistent arm posturing or weakness.

Figure 23-13 ■ **A**, Client with right hemiplegia practicing home program. During standing forearm weight bearing (providing upper-body stability), she initiates a lower-extremity forward-backward movement. As she moves her hips and lower leg forward, she thinks of keeping her knee straight and stretching her calf. **B**, As she moves her hips backward, she may feel a stretch in the back of her thigh, on the lateral aspect of her trunk, or under her axilla.

If the client reports joint pain, the therapist should lower the humerus immediately, reestablish the mobility of the scapula, reseat the humerus if necessary, and maintain appropriate humeral rotation while moving the arm up again. Trunk movements in forearm weight bearing are used to teach a self-ranging practice routine that ensures scapulo-humeral rhythm.

Muscle and Tendon Pain

When a shortened or posturing muscle is stretched too quickly or beyond available length, a strong “pulling” type of pain is often reported in the region of the muscle belly being stretched. If the amount of stretch is decreased a few degrees, the reported pain subsides.

If the inappropriate stretching is not stopped, muscle pain progresses to tendon pain. Proximal biceps tendonitis, distal biceps tendonitis radiating into the forearm, and wrist flexor tendonitis are most common. The usual cause of tendonitis is improper weight bearing, with an inactive trunk and “hanging” on the arm with forced elbow extension and shoulder internal rotation. The treatment of tendonitis is rest and modalities (i.e., heat, ultrasound, or electrical stimulation) or injection of corticosteroids. When movement reeducation is restarted, it is important to avoid the “exercise” that caused the pain and to create a new intervention plan.

Complex Regional Pain Syndrome—Shoulder-Hand Syndrome

One type of complex regional pain occurs in the shoulder and hand. It begins with tenderness and swelling of the hand and diffuse aching pain from altered sensitivity in the shoulder and entire arm.¹⁴⁶ This pain interferes with the reeducation of movement patterns and causes a general desire on the part of the client to “protect” the arm by not moving it. Limited shoulder, wrist, and finger range of motion soon occurs.

The second stage includes further loss of shoulder and hand range of motion, severe edema, and loss of skin elasticity. This is followed by the third stage, which includes demineralization of bone, severe soft tissue deformity, and joint contracture.^{146,147}

Not every edematous hemiplegic hand leads to shoulder-hand complex regional pain syndrome. Hand edema results from an upper extremity that remains dependent and that does not move for long periods of time. It is essential to teach the person with hemiplegia how to properly care for the hand and to give the responsibility for the care of the hand and arm to the client.

Ryerson and Levit⁵⁴ propose five steps for intervention for severe or chronic arm pain: (1) eliminate pain from intervention or the home program, (2) desensitize the arm and hand to touch, (3) eliminate hand edema, (4) introduce pain-free arm movements by reestablishing scapular mobility, and (5) beginning with guided arm movements below 60 degrees, gradually increase the variety and complexity of arm movements.

Edema

Edema in the hand and foot is another common secondary impairment that develops as a consequence of loss of movement control and hospitalization factors such as intravenous infiltrates and limb positioning. Edema limits joint range and tissue mobility. The edematous fluid places the skin on stretch and acts as an interstitial “glue” that bonds the skin,

fascial tissue, muscle tissue, and tendons. Hand edema is associated with the development of shoulder-hand syndrome. Foot edema is as common as hand edema, limits ankle joint dorsiflexion range, and is often ignored during intervention programs. Edema begins on the volar surface of the hand and foot, progresses dorsally, and then continues proximally across the wrist or ankle.

Edema interferes with the retraining of functional movement patterns by preventing the smooth glide of tissues. It must be eliminated before active reeducation begins.

Edema has defined stages. When the involved tissue feels soft and fluid, the condition responds to retrograde massage and elevation. When the tissue is gelatinous and pitting, the edematous fluid cannot be physically expressed. At this stage, it begins to adhere to underlying tissues. The edema must be softened and liquefied through transtissue massage. The last stage of edema is characterized by hard, lumpy tissue that does not “pit” in response to manual pressure. This stage of edema requires gentle bilateral compression to break up the hard, solid areas into regions of softness. The soft regions then act as open spaces into which fluid released by massage of hard tissue is directed. The goal is to reverse the process of hardening—from hard, to pitting, to soft and fluid. In the pitting and hard stages, when the edematous tissue is not fluid, elevation, elastic gloves, bandaging, and retrograde massage are not effective. When edematous tissue is soft and fluid, active and active assistive extremity movement patterns produce muscular contractions that assist venous and lymphatic return of the fluid.⁵⁴

Shoulder Subluxation

Shoulder subluxation occurs when any of the biomechanical factors contributing to glenohumeral joint stability are interrupted. In persons with hemiplegia, subluxation is related to a change in the angle of the glenoid fossa occurring because of muscle weakness. In the frontal plane the scapula is normally held at an angle of 40 degrees. When the slope of the glenoid fossa becomes less oblique (and more vertical), the humerus will “slide” down and out of the fossa.¹⁴⁸ Ryerson and Levit¹⁴⁹ first described three types of subluxation in clients with hemiplegia: inferior, anterior, and superior.

Inferior Subluxation

The most common type of subluxation is an inferior subluxation. It occurs in clients with severe weakness and it is present in the acute stage. Weakness and the weight of a heavy arm result in downward rotation of the scapula. Downward rotation orients the glenoid fossa vertically, the unlocking mechanism of the capsule is lost, and the humerus subluxates inferiorly with internal rotation. As the humerus internally rotates, the bicipital tuberosity rolls anteriorly; this anterior prominence is often confused with an anterior subluxation.⁵⁴ As subluxation occurs, the shoulder capsule is vulnerable to stretch, especially when the humerus is dependent and resting by the side of the body. In this position the capsule is taut superiorly, so any downward distraction of the humerus will place an immediate stretch on the upper part of the capsule. The coracohumeral ligament reinforces the superior portion of the capsule, which is crucial for shoulder stability. Jenson¹⁵⁰ has discussed the implications of rupture of this ligament as a result of forced abnormal passive motion as a cause of shoulder pain in subluxation.

Anterior Subluxation

Anterior subluxation occurs when the humeral head separates anteriorly from the glenoid fossa. Anterior shoulder subluxation occurs when the downwardly rotated scapula elevates and tilts forward on the rib cage and the humerus hyperextends with internal rotation. In an anterior subluxation, as tension increases on the proximal biceps tendon, the elbow flexes and the forearm supinates. This subluxation is found in clients with atypical patterns of return and trunk rotational asymmetries.⁵⁴

Superior Subluxation

A superior subluxation occurs when the humeral head lodges under the coracoid process in a position of internal rotation and slight abduction. The humeral head is “locked” in this position so that every movement of the humerus is accompanied by scapular movement. The scapular position in this subluxation is one of abduction, elevation, and neutral rotation. The forearm adducts across the body as the humeral abduction and elbow flexion increase. A superior subluxation occurs in clients with inappropriate muscle firing and co-contraction.

Subluxation is not painful but results in changes in muscle length-tension relationships, muscle shortening, and permanent stretch of the joint capsule. If a subluxation exists, the therapist reduces the subluxation by correcting trunk, scapula, and humeral alignment patterns before attempting to reeducate arm movement patterns. A discussion of these subluxations, accompanying trunk movement patterns, and intervention suggestions can be found in therapy literature.⁵⁴ As the client learns to move the arm in patterns of functional coordination, subluxation and associated arm posturing decrease.

Prevention of subluxation requires (1) proper assessment of secondary alignment problems (rib cage, scapular, humeral position), (2) early reeducation of trunk and arm linked patterns in sitting and standing, and (3) prevention of shoulder capsule stretch, including support and positioning as the client sits, stands, and practices walking.

FUNCTIONAL ACTIVITIES

Functional mobility movement analysis, intervention techniques, unilateral compensatory strategies, and suggestions for task practice are documented in therapy literature.¹⁵¹⁻¹⁵³ In this section, representative mobility skills are selected in three functional positions: supine, sitting, and standing. For each task selected, the focus is on the basic trunk and extremity control patterns used, significant impairments in addition to weakness that make it difficult for the client to perform the task, and observations from the clinic that relate to intervention and practice. Detailed descriptions of each trunk pattern and trunk and extremity linked pattern can be found in the literature.⁵⁴

Supine Rolling

Basic trunk movement patterns for rolling include (1) upper-trunk flexion and rotation initiation, (2) lower-trunk extension and rotation initiation, and (3) symmetrical (log-rolling) lateral flexion initiation. These patterns link the trunk with either the arm or leg during the roll.

Trunk and Extremity Linked Patterns. The *upper-trunk flexion-rotation initiation pattern* links upper-trunk flexion-rotation with arm reach across the body. Active assistive patterns, with the client holding both hands together for a bilateral arm reach, are encouraged when strength is insufficient to lift the arm against gravity or, through therapist handling, when arm muscle weakness results in such a heavy feeling that the patient cannot control the extremity with the unaffected hand. If the therapist assists the arm, the goal of practice is for the client to initiate the active anti-gravity trunk pattern.

A *lower-trunk extension-rotation initiation pattern* is coordinated with either a leg-reach pattern or a flexed-leg “push” pattern. Active assistive patterns can be implemented through therapist handling to help train the sequencing or to grade the firing patterns of the leg when it is pushing into the bed. As the lower body moves from supine toward side lying, the upper body and arm follow the movement. The client is encouraged to practice independently with a focus on the sequence. During independent practice, the therapist may provide verbal cues to help the client time the movement of the upper body.

The *symmetrical lateral flexion initiation pattern* is known as “log rolling.” In this pattern, the trunk does not rotate but is active in a coordinated fashion with the arm and leg on the same side; the arm and leg “reach or push” on the leading side. In rolling from supine to side lying, the trunk flexors initiate the antigravity movement, and when rolling from side lying to supine, the trunk flexors are the antigravity movement initiators.

Impairments that Interfere. Shoulder joint pain may occur when the client rolls onto the affected side. Pain occurs if the shoulder is trapped under the trunk as the client moves to side lying or when the humeral-scapular alignment causes the shoulder capsule to be impinged. If pain occurs during the roll, the therapist should teach the client to stop, roll back a few degrees, adjust the position of the arm away from the trunk, and then continue the roll. Therapists should teach their clients how to avoid shoulder pain during all activities, especially during rolling or when lying on the more affected side.

In rehabilitative or outpatient care, muscle tightness in the latissimus, quadratus lumborum, biceps, or tensor fasciae latae may limit trunk rotation or trunk and extremity linked movements.

Clinical Observations. Weakness in the extremities is a significant factor during rolling because the arm and the leg assist the trunk initiation patterns. Rotational patterns are difficult in the acute stage because they require an integration and sequencing of flexor and extensor muscle patterns. Symmetrical rolling may be an easier independent pattern to train. Therapists should incorporate active assistive strategies and extremity strengthening in the early recovery period. Clients have an easier time rolling to the affected side because they use the strength of the unaffected side to initiate the roll. But they may not want to stay on that side because of shoulder pain, instability of the hip, or decreased sensation and the fear that ensues. The client may prefer rolling to the unaffected side because it is easier to rest on, but initiating the movement is difficult because of loss of control on the affected, leading side.

The family is educated to understand the nature of the loss of movement and sensation and the effects of these losses on body awareness and early bed mobility. Family members are encouraged to sit with, visit, talk to, feed, and touch the person from the client’s affected side. They are instructed in simple movements such as rolling to promote symmetry, midline control, and activation of trunk and extremity muscles.

Feeding and Swallowing

Although detailed facilitation and inhibition of oral and neck muscle movement for feeding and articulated language are a specialty of speech pathologists, the movement therapist activates upper-body control to prepare for more automatic chew and swallow.

Basic trunk patterns to be reeducated include (1) lower-body anterior and posterior movement control to move toward a table and back into a chair and (2) upper-body anterior and posterior and lateral movement control to provide control for head and arm movements.

Impairments that Interfere

Oral problems include the following:

- Forward head, poor lip closure, loss of saliva and food
- Facial asymmetry during function greater than at rest
- Inability to swallow
- Inability to chew
- Inability to lateralize foods
- Inability to take liquids from cup or spoon
- Muscle weakness

Central problems are as follows:

- Poor postural control
- Inability to feed self

Compensations include the following:

- Use of gravity—head and neck extension
- Chewing on one side only
- Using the hand to place food in the mouth
- Using the hand to pull food from the cheek
- Using thicker food than liquids

Clinical Observations

Excessive drooling occurs with loss of head control and a decreased ability to automatically close the mouth and swallow. If the client tries to lift the head from a flexed position and the cervical spine remains flexed, the head may jut forward into a position of axial extension. As a result of the biomechanics of the forward head position, the jaw opens, automatic swallowing becomes difficult, and saliva runs out of the open mouth.

Drooling from one side of the mouth is annoying and embarrassing. The client may not be able to maintain lip closure and, in addition, may not feel the saliva running out or may not identify a need to swallow. Drooling lessens as upper-body control increases.

In the majority of cases, swallowing problems are transient in persons with hemiplegia. After the initial insult, many clients exhibit a decreased gag reflex. In acute care settings, where liquid diets are often routinely given to persons with hemiplegia, education of hospital staff regarding the merits of using thicker foods should be considered. Thicker, chopped food is easier to swallow than soft food. Soft food is easier to swallow than liquids. Liquids with

distinct taste or texture are easier to swallow than water. Specific feeding programs are noted in Chapters 9, 11, and 12.

Sitting

Function in sitting is based on the ability to maintain the trunk in an upright position, to automatically adjust the trunk when the arms or one leg moves around midline, and to follow movements of the arm and leg as they extend their reach. Control in sitting is also used to help change position, such as moving from sitting to standing, or lying down. The reestablishment of control in sitting for function is an important early goal in rehabilitation care.

Basic trunk movement patterns include the following:

1. Anterior, posterior, and lateral upper-body-initiated movements. Upper-body movements are easier to retrain than lower-body movements because the base of support (contact of the buttocks and thighs) remains on the surface.
2. Anterior and posterior lower-body-initiated movements. With lower-body-initiated movement, the upper body needs to be stable yet adjust to and follow the movement of the lower body. The reeducation of upper-body control allows the therapist to begin retraining lower-body control.
3. Lateral lower-body-initiated movements. These movements are more difficult to reeducated than upper-body movements because as the movement begins, the base of support narrows.
4. Rotational movements. In sitting, upper-body rotational movements are easier to perform than lower-body rotational patterns for the reason noted previously.

Trunk and Arm Linked Patterns (Representative Examples)

Postural adjustments to arm movements around midline require the trunk to be upright, to be active, and to perform small adjustments. When the hand functions in front of the body, the trunk adjusts with small posterior weight shifts and increased flexor control, whereas as the hand(s) move to function behind the body, the trunk adjusts with a small anterior weight shift.

The trunk moves with an arm to extend reach. If the reach is forward and down to the floor, as if to reach a shoe, the upper body initiates an anterior weight shift and the spine moves into flexion with control from eccentric contraction of the spinal extensors. If the reach is forward as if to grab an object on the far side of a table, the lower body initiates an anterior weight shift as the upper body remains stable and adjusts to the demands of the arm movement.

Trunk and Leg Linked Patterns (Representative Examples)

Small trunk adjustments occur with leg movements around midline. If the feet move back under the hips, the trunk adjusts with a small amount of anterior weight shift. When one foot is lifted up to slide into a slipper, the lower body adjusts with a small lateral weight shift. Upper-trunk stability allows lower-trunk-initiated patterns when rising to stand. As the legs extend and the buttocks lift off the chair, trunk adjustments accompany the changing leg pattern to control trunk position over the legs.

Impairments that Interfere

Changes in alignment of the arm resulting from weakness and muscle shortening affect the position of the thoracic spine and rib cage. The weight of an extremely weak arm pulls the upper trunk into forward flexion; an increase of flexor tone in the arm influences scapular and rib cage positions.

Shoulder subluxation results in muscle shortening (biceps, pectorals, latissimus, subscapularis), alters the line of muscle pull, and interferes with scapulohumeral rhythm. Muscle shortening contributes to loss of upper-body alignment and interferes with reestablishing arm and trunk control.

Loss of trunk alignment as a result of extremity weakness and loss of trunk control creates an atypical starting position for movement and can become an undesirable compensation.

Clinical Observations

Alignment changes in the arm influence strength and control of the upper body. Therefore intervention techniques to restore alignment and control of the arm in relation to the upper trunk must be included in the list of short-term goals to achieve the functional goal of safe, independent task performance in sitting.

Active control of the pelvis in a neutral position is necessary for the reeducation of lower-body lateral and rotational weight shifts. Pelvic position influences leg position. If the pelvis is held in a posterior tilt, the leg initially tends to abduct; and if it is held in an anterior tilt, the leg initially adducts.

Clients with poor hip control do not regain functional trunk patterns while sitting until they can activate and strengthen hip muscles for stability during weight shifts. Weakness of the hip joint results in a desire to shift weight to the stronger side, thus creating a spinal or pelvic asymmetry. Clients who push to the affected side in sitting need strength from the weak leg for stability as a prerequisite for midline control of the trunk.

Lower-body-initiated lateral weight shift patterns are difficult to train because they require a narrowing of the base of support. Forearm weight-bearing movement patterns are used to increase the base of support to allow practice of these patterns, which are needed for functional activities such as scooting, toileting, and lifting one leg off the surface. This movement is difficult to practice without upper-body stability (external or internal).

Transfers

Transfers in the half-stand, pivot pattern require upper-body control over the lower body and combined trunk and leg control patterns. The squat, pivot position is trained when leg strength and control are weak and the goal is to train the client to use the affected leg. Transfers involve interim patterns that are trained before safe standing is possible.

The client practices transfers to different objects (chair, bed, toilet) to either side. This promotes symmetry, encourages the use of the affected leg, and allows practice with varying environmental constraints. Transfers to the unaffected side have the advantage of being familiar to hospital staff because they are the “traditional” textbook way of transferring the person with hemiplegia. Nevertheless, transfers to

the affected side need to be trained by therapists to allow function in either direction.

Sitting to Standing

Moving from sitting to standing is an important skill to retrain early after a stroke because it is used many times a day during functional activities. In a study investigating the relationship between sitting to standing and walking, Chou and colleagues¹⁵⁴ found that a critical component of sitting to standing was vertical force displacement, the amount of weight transferred down into the floor. Those who had a maximal vertical force difference of less than 30% body weight between both legs displayed faster walking speeds and more typical gait parameters.

Two initiation patterns are commonly used, with or without the use of momentum, to train sitting to standing. A *lower-body-initiated* anterior weight transfer occurs with a straight spine as the shoulders move forward. Therapists should emphasize the forward weight shift component of this pattern rather than the anterior pelvic tilt component; the requirement of sitting to standing is a forward shift of the upper body and shoulders. An anterior pelvic tilt usually results in a backward movement of the shoulders. The confusion over this movement occurs because clients often sit in a position of flexion with a posterior pelvic tilt. To come to upright, they must extend the spine and move the pelvis to neutral. Although individuals with a tendency for lumbar extension may have an anterior pelvic tilt as they shift forward, the anterior pelvic tilt is not as important a component as is a forward weight shift.

An *upper-body-initiated* anterior weight transfer during sitting to standing requires control in spinal flexion. This pattern keeps body weight over the feet, the new base of support, but does not link the extension of the legs with the lower trunk. The demand on the trunk from liftoff to standing is greater than in the previous pattern because of the need to move the spine from flexion to upright neutral. In the previous pattern the spine starts and remains in a neutral position through to standing. The upper-body-initiated pattern is used in rehabilitative and extended care centers because it allows caregivers to keep weight firmly over the feet, thus allowing a safe, maximal-assistance transfer.

During transfer and sitting-to-standing training, techniques of directing manual pressure from the top of the knee through the tibia into the foot help the client remember to keep weight on both feet and increase the dorsiflexion movement at the ankle. Full standing should not be attempted if loss of control in the leg results in nonuse. If the client cannot activate leg muscles in a weight-bearing position in attempts to stand, the standing position will be precarious with undesirable trunk compensatory patterns.

Standing

Standing Control

Control in standing is a difficult early goal to achieve because not only is there a need for trunk and leg coordinated movements, but there is also a prerequisite need for upper-body (trunk and arm) control over the lower body. Control of basic movement patterns in standing is divided into upper-body-initiated control patterns and lower-extremity-initiated control patterns.¹³⁴ Upper-body control in standing includes the ability

to move the upper trunk and arm in all planes with appropriate leg responses and the ability to respond and adjust to weight transfer to each leg and to provide postural stability for movements of each leg in space. Lower-extremity control in standing has a weight-bearing component and a movement in space component. As a prerequisite for reeducation of these movements, the upper body must have enough strength and control to provide stability and postural adjustments for movements of the leg.

Basic trunk movements to be reeducated include the following:

1. Upper-body-initiated anterior, posterior, lateral, and rotational patterns with critical corresponding adjustments in the leg (either hip, knee, or ankle strategies).
2. Control of the upper body over the lower trunk during lower-extremity-initiated weight-bearing movements.
3. Linked trunk and leg patterns during movements of the leg in space. These are easiest when the leg moves around midline and increase in difficulty as movement in space increases in amplitude or speed.
4. Increased upper-body control to support power production of the arms for pushing, pulling, or lifting objects and increased lower-body control to support power production of the legs for jumping, running, and stair climbing.

Trunk and Arm Linked Patterns

Trunk and arm linked patterns include the following:

1. Upper-body-initiated flexion movements that occur with forward and downward arm-reach patterns
2. Upper-body-initiated extension that occurs when the arm reaches up or up and back
3. Upper-body-initiated lateral flexion when the arm reaches down and to one side
4. Upper-body flexion and rotation when the arm reaches down and to one side.
5. Upper-body extension and rotation when the arm reaches up and back to one side

Trunk and Leg Linked Patterns in Weight Bearing

Control of the upper and lower trunk during unilateral stance on either leg is one of the most difficult patterns to retrain. Control of the trunk in unilateral stance is linked with the need for abduction control on the stance leg. In clients with hemiplegia, the complicated control demands for leg and trunk control in standing combined with the presence of weakness and control problems result in loss of alignment in multiple joints and undesirable compensatory patterns.

Trunk and Leg Linked Patterns as the Leg Moves in Space

When the leg moves in space in small ranges, the movement of the upper trunk is small and occurs as a postural adjustment. The movement pattern of the femur and pelvis has a linked rhythm similar to that of scapulohumeral rhythm: the first 30 to 45 degrees of hip flexion occurs with no pelvic movements; from 45 to 90 degrees the pelvis flexes (posteriorly tilts) with the flexing hip; with continued hip flexion the upper trunk flexes. This pelvic-hip relationship occurs in

the other planes of movement as well and is seen during the following functional movements:

1. Pelvic and lower trunk flexion occurs when the leg reaches forward and up; stepping up.
2. Pelvic and trunk extension occurs when the leg reaches back.
3. Pelvic elevation or depression with trunk lateral flexion occurs when the leg moves laterally.

Impairments that Interfere

In standing, loss of alignment in the upper body on the hemiplegic side may result in undesirable compensatory patterns that interfere with functional standing movements and balance. These patterns include (1) forward flexion of the upper trunk, (2) upper-body rotation toward the affected side, and (3) upper-body rotation away from the affected side.

Ankle range may decrease within a few days after stroke and needs to be minimized to allow early standing functions. Loss of ankle joint dorsiflexion range interferes with the ability of the body to recruit ankle strategies, and limited ankle joint dorsiflexion range is one cause of knee hyperextension in standing.

Loss of knee control during standing may result from leg weakness or loss of intralimb sequencing. Loss of knee control is also influenced by the position and movement control of the hip and ankle joints. Initially the knee flexes as more weight is shifted to the unaffected side, and the pelvis lists downward. If the pelvic position is not corrected (leveled) and the client actively straightens the knee, a compensatory pelvic rotation (toward the affected side) may occur. Because of the instability of a weak, flexing leg, the client may learn to “lock” the knee in hyperextension as a means of gaining stability (Figure 23-14).

Figure 23-14 ■ **A**, Client with left hemiplegia with knee hyperextension wearing a lightweight prefabricated posterior leaf-spring brace that does not control his knee hyperextension. **B**, A solid ankle brace with foot control that decreases knee hyperextension by providing distal stability.

Clinical Observations

In the acute phase, therapists can help the client practice standing with the hips and shoulders back against a wall to provide support for the trunk and pelvis while creating a safe situation for practicing active self-initiated leg weight-bearing movements. The client can slide down the wall, activating eccentric control in the legs, and then slide back up, activating concentric control. By using the wall to assist the stand, the therapist frees his or her hands to help correct leg alignment problems and lets the client practice the initiation of movement early, independently, and safely.

The client can practice controlled lateral weight transfer with appropriate trunk activity in this position. Whereas one study concluded that there is no relationship between lateral weight shift and walking, therapists should not conclude that unilateral weight acceptance is inappropriate functional training.¹⁵⁵ What may be more important than the lateral weight transfer over the leg is learning to depress the foot into the floor, as it equalizes weight between the two legs.¹⁵⁶

Upper-extremity forearm or extended-arm weight bearing provides upper-trunk stability for lower-extremity-initiated practice. This practice pattern also allows a means of self-ranging for the ankle, knee, hip, and pelvis. This position is used not to inhibit tone in the extremities but to activate and strengthen the trunk and legs in linked patterns.

Walking

Independent, functional, and safe walking is difficult to retrain in the early phases of intervention because it requires refined degrees of trunk and extremity control. It requires an advanced level of trunk control, linked trunk and leg movements, and enough strength and control in the leg to support body weight, to move the multiple joints of the leg in complex patterns, and to control speed, momentum, and balance. Walking patterns in clients who have experienced stroke are characterized by slow speed, uneven step and stride lengths, impaired balance with resulting arm and leg posturing, and reliance on adaptive equipment.

In the current health care environment with the emphasis on limited therapy visits, therapists are confronted with major intervention dilemmas: Should they force the client to walk without minimal prerequisites? Should they allow undesirable compensations although they predict future secondary problems? Should they use the benefits of the large health care systems to divide responsibility for continued gait training among therapy divisions (inpatient, rehabilitation, home care, outpatient)?

Prerequisites for functional, safe walking include the following:

- Upper-body control to support leg movements in unilateral stance and during swing
- Lower-trunk control to prevent atypical pelvic patterns
- Strength and control of the leg to initiate weight shifts
- Strength and control of the leg to move in space

Because gait is the most extensively studied, analyzed, and discussed in terms of intervention, this section describes the prerequisites for walking training and common impairments that interfere with walking.¹⁵⁷⁻¹⁵⁹ Common impairments that interfere with walking are separated into three

divisions of the walking cycle: (1) forward progression, (2) single- and double-limb support, and (3) swing.^{160,161}

Impairments that interfere with functional walking are summarized in [Box 23-7](#).

Research on and equipment for partial-body-weight supported treadmill walking training with or without robotic assistance have increased over the past 10 years.¹⁶²⁻¹⁶⁶ In a 2004 review of randomized controlled studies, there was strong evidence for poststroke treadmill training with or without body-weight support¹⁶⁷ ([Figure 23-15](#)). Task specificity, speed, intensity, and symmetry of practice in this type of equipment were thought to contribute to improved over-ground walking performance.¹⁶² However, the most recent Cochrane review reports no statistically significant effect of treadmill training with or without body-weight support.¹⁶⁸ A

BOX 23-7 ■ SUMMARY OF SIGNIFICANT FUNCTIONAL IMPAIRMENTS

FORWARD PROGRESSION—HEEL STRIKE TO MIDSTANCE

Poor trunk control

- Loss of alignment of upper trunk over lower trunk
- Loss of control of upper trunk as leg initiates weight shift forward

Lack of proper initiation pattern and direction

- Excessive forward trunk flexion
- Excessive lateral weight shift

Insufficient ankle joint dorsiflexion range

- Muscle tightness
- Loss of control
- Edema

Inappropriate foot contact

- Weakness of foot and ankle muscles
- Muscle tightness
- Foot posturing

SINGLE AND DOUBLE LIMB SUPPORT

Insufficient trunk control to maintain position over one leg

- Asymmetries during unilateral stance
- Loss of control of upper trunk over lower trunk

Poor lower-extremity control

- Hip instability
- Loss of knee control in unilateral stance
- Loss of ankle joint dorsiflexion range
- Toe clawing or curling

Loss of ability to transfer weight through foot

- Inability to maintain leg on floor behind body
- Muscle tightness
- Weakness or inappropriate activation of leg muscles

SWING—EARLY AND LATE

Atypical leg muscle firing patterns

- Lack of proper initiation
- Loss of ankle and foot dorsiflexion
- Inability to control trunk and lower-extremity initiation pattern
- Initiation pattern

Inability of the body to continue to move forward as leg swings

Foot posturing

A

B

Figure 23-15 ■ A and B, Client with right hemiplegia walking on a treadmill with partial body weight support.

2011 randomized controlled trial comparing body-weight-supported locomotor training with a therapist-supervised home progressive exercise and balance program reports improvements with both training methods.¹⁶⁹

Clinical Observations

If weakness in the foot and ankle creates difficulty clearing the foot during stepping, compensatory strategies of hip hiking, circumduction, or posterior pelvic tilting arise. If allowed to persist, these atypical initiation strategies become difficult to retrain. This points to a need to consider minimal ankle and foot support during early walking as a means of creating appropriate distal initiation patterns and limiting the need for proximal compensatory strategies ([Figure 23-16](#)). (See Chapter 34 for additional suggestions.)

After the identification of significant impairments in swing phase and stance phase, specific intervention techniques are chosen. See example.

Example. After the description set forth by Knutsson and Richards,⁸⁶ in a type I motor control problem with premature activation of the calf muscles, intervention may stress lower-extremity-initiated forward weight shift. Control of the ankle with appropriate knee activity allows the center of gravity to advance ahead of the foot before the activation of calf muscles pulls the lower leg backward. With a type II disturbance, training to improve control and power of the leg while standing or during sitting to standing under varied conditions may be indicated. In a type III problem, intervention is directed at achieving stability control of the upper trunk during lower-extremity-initiated patterns.

EQUIPMENT

Equipment for persons with CNS dysfunction can be thought of as supports or extra help to allow better alignment or stabilization so that the client can move and function more

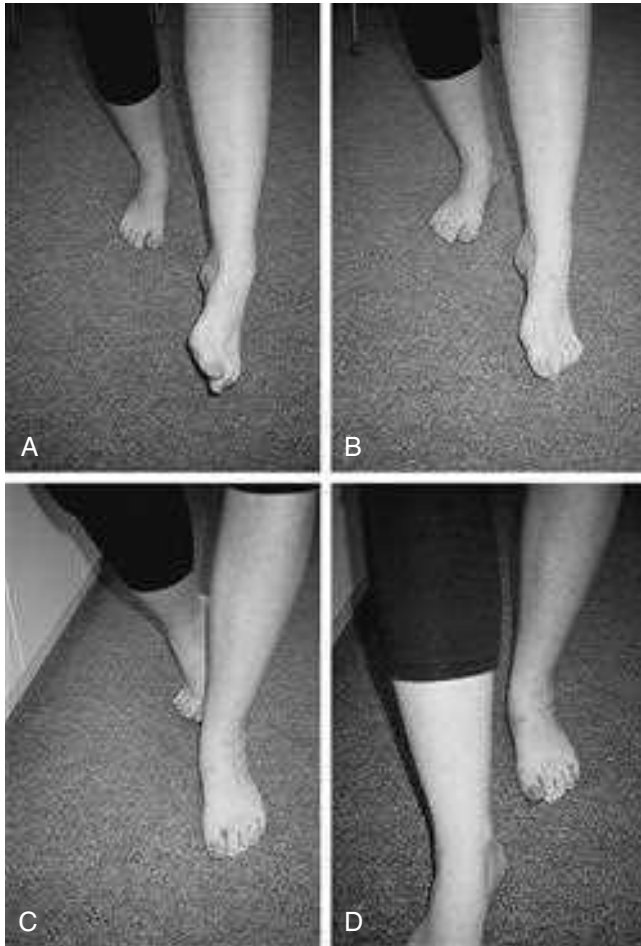

Figure 23-16 ■ **A and B**, Client with left hemiplegia. Supination of the foot during swing and during foot contact with ankle joint plantarflexion and calcaneal varus. **C and D**, Compensatory pronation of the midfoot to allow the foot to contact the ground during stance.

independently. Too much support or equipment may hinder the development of new movement control. Equipment should never be a substitute for treatment and should not be given without practice during treatment. One-handed equipment that is used as a compensation for trunk control is less successful than equipment that is used to compensate for loss of extremity function. Therapists should perform continuing assessments of the appropriateness of the equipment in relation to gains made in therapy.

Example

A “reacher” compensates for loss of trunk and limb linked control (reach beyond arm’s length), but use of a reacher may prevent the development of this control; whereas an electric can opener designed for one-handed use substitutes for the ability to use the affected hand (when recovery is not possible).

Bedside Equipment

In acute and rehabilitation settings, pillows, blankets, or towels are used to position the client in bed. With the client in the supine position, the head pillow can be angled so that

it slips under the shoulder and scapula to prevent loss of alignment: to prevent humeral hyperextension and internal rotation. A soft towel roll or pillow under the leg—greater trochanter or knee—maintains alignment of the leg in the first few days after a stroke. Once the client begins to move to both sides in bed, the use of pillows for support is not necessary.

Wheelchairs

Wheelchairs must have a solid surface and, when possible, a supportive backrest. The soft leather seats and backs of transport chairs act as slings and allow the pelvis to posteriorly tilt and the spine to flex. Solid seats and backs allow the pelvis, trunk, and extremities to be more normally aligned. Wheelchairs specifically for clients with hemiplegia who are not expected to become household ambulators have lower seat heights and one-armed drive (two hand rims on one wheel). These adaptations make it easier for clients to propel the chair with the unaffected hand and foot.

Support for the hemiplegic arm when the client is sitting in a wheelchair reduces the effect of the downward pull of gravity on the weak or paralyzed arm. Lapboards support both arms and provide symmetry for the upper body. However, in some health care settings, they are considered a form of restraint and cannot be used. The use of a pillow in the lap is another option for bilateral support of the arms. Half-lapboards or arm troughs are used to support the arm. If an arm support is used, the client should be taught how to protect the arm and hand while on the support.

Slings

Slings are used to support the glenohumeral joint to prevent capsular stretch, to temporarily maintain alignment that is gained in treatment, and to take some of the weight of the paralyzed arm off the upper trunk as the client begins to learn to stand and walk. Capsular stretch accompanies shoulder subluxation, and it is difficult to reverse an existing subluxation once the capsule is stretched. Because subluxation is not inherently painful, a sling is not used to prevent pain. However, use of a sling can help break the cycle of pain from shoulder-hand syndrome.

Various reviews and comparisons of slings are available.^{170,171} Shoulder subluxation is the result of loss of strength and control in the shoulder girdle and trunk, especially scapular upward rotation. There is no sling available that corrects a subluxation because no existing sling provides scapular upward rotation control. Slings act as an assist to “hold” a scapulohumeral position that has been restored in treatment.

The ideal shoulder sling helps maintain the normal angular alignment of the glenoid fossa, decreases the tendency of the humerus to internally rotate, takes some of the weight of the arm off the upper trunk, and allows the upper extremity freedom of movement. Therapists should not prescribe slings that cradle the arm in front of the body, prevent any movement, and in effect teach learned nonuse. The orthopedic-type *envelope arm sling* was used in the 1950s and 1960s. In the 1970s, influenced by Bobath,¹⁰⁵ sling use was thought to be undesirable. As more information about tone and movement became available, new slings were designed to allow the arm to be supported while movement was reeducated. Slings have different suspensions, provide different means of

control for the arm, give differing “messages” to the arm and trunk, and have individual uses. Table 23-6, adapted from the work of Levit,¹⁷² lists available slings and their characteristics.

Clients who come into therapy with a sling but who do not require one are weaned from a supportive sling into a less controlling one. Clients state that the *clavicle support* provides support during household tasks that require upper-body flexion, such as bed making or vacuuming. Clients who complain of “aching” in the arm at the end of the day may relieve this ache by using a support for a few hours around midday.

If the arm dangles or bangs against the body during active periods, the *shoulder saddle sling* can be adjusted to protect the arm from bruising. This sling is also helpful to clients with severe shoulder-hand pain because it allows full support of the arm and can be adjusted by the client to allow the elbow to extend as the pain subsides. The *GivMohr sling* combines a humeral cuff with a hand support. *Humeral cuff slings* are the least practical from a functional standpoint because they do not affect scapula or trunk position.

Canes

Canes are given to clients with hemiplegia to provide extra balance, not as a means to support body weight. Canes should be used after upper-body control and lower-extremity-initiated movements have been practiced.

If quad canes or hemiwalkers are used before trunk and leg activity is minimally established, they encourage lateral translation of the spine or rotation of the spine and ribs. When clients shift off the weak leg onto the stable cane, the

cane acts functionally as a third leg. This one-sided compensation encourages learned nonuse of the affected leg.

Single canes provide a balance assist. Often clients use the cane while walking outdoors or in crowded situations but not inside their homes. Reliance on a cane for walking eliminates the possibility of carrying objects and makes it difficult to perform one-handed tasks such as opening a door. Wrist loops allow the client to use the unaffected hand without having to put the cane aside. Weighted cane tips, such as the AbleTripod cane tip, are a bridge between quad canes and straight canes and allow a standard cane to remain upright.

Orthotics

Ankle-foot orthoses (AFOs) are used to allow foot clearance during walking, to ensure heel strike, to provide distal stability for early standing and walking in clients with severe weakness, to provide lateral lower-leg stability in clients who need an assist because of lateral hip weakness, and to control knee hyperextension caused by loss of ankle dorsiflexion control. Different design types provide different functions. Solid ankle bracing with plastic beyond the malleoli limits distal freedom but allows clients with severe weakness to practice gaining control of trunk and hip movements.

The use of polypropylene bracing to control foot posturing in adults began in the 1970s with information from pediatrics and podiatry. Foot control in a brace stops supination of the foot in swing and compensatory pronation of the foot in stance. This control is achieved through neutral rear foot positioning and long medial and lateral foot counters.

TABLE 23-6 ■ AVAILABLE SLINGS AND THEIR CHARACTERISTICS

BASIC TYPE	SUPPLIER	SUSPENSION	MESSAGE	COMMON USE
Clavicle support	DePuy (clavicle fracture sling with 1-inch soft foam axilla pad)	Figure-of-8 between scapulae Support under axilla	“Spine extend, scapula adduct”	Acute care Minimal support To wean out of other supports
Humeral cuff	Rolyan Hemi Arm Sling	Figure-of-8 between scapulae Velcro cuff support to humeral shaft	“Arm up”	Rehabilitative care
Unilateral shoulder orthosis	Bauerfeind Rolyan	Across body Elastic or spandex cuff support to humeral shaft	“Lift humerus up”	Rehabilitative care
Shoulder-saddle sling	Sammons	Saddle sits on top of shoulder Strap across body Forearm cuff—adjustable straps allow changes in elbow position	Maximal support of arm	To prevent “banging” of flaccid arm in active patients or during sports activities To provide support for painful arm
GivMohr sling	GivMohr	Figure-of-8 between scapulae Plastic cone in palm of hand	“Arm up”	To relieve weight of “heavy” flaccid arm

Techniques of Aquaplast fabrication have created new possibilities for inexpensive, immediate, remoldable bracing for the foot and ankle.¹⁷³

Custom-made AFOs provide the best fit and control, but excellent prefabricated polypropylene braces are available through companies such as Friddle's Orthopedic Appliances, Orthomerica, or Wheaton Brace. These orthoses have long medial and lateral foot edges for control of foot posturing, come in multiple models and sizes, and can be ordered with regular or long foot plates or as blanks that can be self-trimmed (see Chapter 34).

Functional electrical stimulation foot-drop systems, the Bioness L300 and the WalkAide, are now available for clinical use. These systems use low-level electrical activity to stimulate the nerves that lift the foot and are timed with walking stance and swing patterns.

Clients should be encouraged to spend time standing or walking short distances without the brace so that dependence is not established. Clients like to be able to walk to the

bathroom at night without a brace. Orthopedic ankle and foot supports provide alternatives to plastic bracing. The MalleoLoc ankle support controls rear foot equinus and varus while allowing ankle and forefoot movement (Bauerfeind USA/Alimed). Clients with moderate supination posturing report a reassuring feeling of security with this support while walking short distances and during sports participation. This support, a substitute for the Aircast and Ace support, is a good choice for sports activities such as golfing, bicycling, jumping, and running.

Functions and limitations of commonly used braces are found in Table 23-7 and orthotic manufacturers in Appendix 23-A.

Movable Surfaces

Movable surfaces such as gymnastic balls of varying sizes, large rolls, and adjustable stools with casters are used as assistive devices to help clients increase trunk and extremity strength and control. To encourage trunk and leg activity, the

TABLE 23-7 ■ ANKLE-FOOT ORTHOSES (AFOs) USED IN CLIENTS WITH HEMIPLEGIA FROM STROKE

ORTHOTIC DESIGN	FUNCTION	LIMITATIONS	PATIENT TYPES (CATEGORIES)
Solid ankle with foot control	Heel strike Distal stability Lateral hip stability Assists forward progression Assists knee control Stops foot posturing	No ankle mobility No toe break	Severe weakness in trunk and leg Need for distal stability
Modified solid ankle with foot control	Heel strike More distal mobility, less ankle control Stops foot posturing	Less knee control Reduced message of forward progression No control of knee	Increasing leg strength Increasing trunk and leg control
Posterior leaf spring	Toe clearance	No control of foot posturing	Good return of control in trunk and leg Need for minimal dorsiflexion assistance
Articulated ankle	Free dorsiflexion Heel strike if plantar stop used	Limited control of foot posturing Bulky at ankle	Normal ankle range—if range is limited, the movement of brace is translated into foot Functional needs; climb hills, stairs, move to and from ground
Supramalleolar foot orthoses in Aquaplast	Foot control Assist heel strike Used for weaning from AFOs Sports	No knee control Short shelf life of material	Increasing leg control Desire to begin increasing activity level
Foot orthoses	Balance small asymmetries of foot	No control of foot posturing No ankle or knee control	Persistent but minimal rear foot–forefoot asymmetries
Klenzak metal, double upright	Toe clearance Reminder of forward progression	No foot control Control of ankle and foot through shoe	Used before creation of polypropylene to provide heel strike and stop foot supination
ALTERNATIVE FUNCTIONAL ELECTRICAL STIMULATION FOOT DROP DEVICES			
Bioness L300	Foot control Knee control assist Operates via heel pressure switch	Expensive Requires cognitive ability to don and adjust settings	
WalkAide	Foot control Operates via tibial tilt	Requires cognitive ability to don and adjust settings	

See Chapter 34 for additional suggestions.

client sits on the ball and moves it in small ranges to the limits of perceived balance. This is an activity that increases trunk and leg control but does not lead directly to improvements in standing or walking. Gymnastic balls provide symmetrical support to the rib cage when used in the hands-and-knees position and are used to stretch specific tight tissues. Routines of lifting the ball with either the arms or legs strengthen extremity movements in space.

When spasticity was considered the major impairment in hemiplegia, therapists often placed clients prone over balls to “inhibit” tone. This is an inappropriate technique, considering advances in understanding of movement control and recovery.

Hand Splints

The practice of splinting the hemiplegic hand is controversial. Historically, the hand in clients with hemiplegia was splinted in a “resting” position. After the introduction of neurophysiological approaches, splinting became “inhibitory” in design.¹⁷⁴⁻¹⁷⁶ Now, with the understanding that spasticity is not the major problem, splinting the wrist and hand has undergone another change. A splint designed in 1982 by Levit¹⁷⁷ as a neutral functional splint promotes functional retraining and hand use while minimizing secondary impairments. This splint, designed to hold the wrist and hand in a position of orthopedic neutral, decreases clinical hypertonicity that occurs either from poor alignment or unbalanced muscle return. The splint promotes support of the wrist and hand to avoid the secondary impairments of muscle tightness, muscle shifting, and overstretching of weak wrist and finger muscles. This type of splinting has been reported to decrease hand edema and pain.¹⁷⁸

Therapists custom make the splints with the goals of supporting the wrist in neutral, preventing radial or ulnar deviation with long, high sides, and maintaining the palmar arches. The fingers are not incorporated into the splint but are left free, to allow movement reeducation and practice.

The increased tone in finger flexors, previously labeled “spasticity,” comes in part from incomplete return or weakness of finger muscle activity on a poorly aligned wrist. A position of wrist flexion results in a drop of the proximal row of carpals and a flattening of the palmar arches. If the wrist is supported in neutral and the arches are preserved, returning muscle activity is reeducated in functional patterns. Finger support in a splint should be used only when there is a serious deformity with a need to serially, systematically, and slowly lengthen tight tissues.

This functional type of splint is worn mainly during the day when arm posturing is greater and when support of critical joints allows beginning hand use. Hand posturing is less of a problem when the patient lies down because of decreased demands on the trunk and legs. Clients are instructed not to wear the splint at night.

Design Considerations

If joint range is limited, the therapist makes the splint to support available range. The splint can be revised as range increases. Alignment is corrected in three steps: (1) keeping the wrist in flexion, the lateral deviation is corrected by aligning the third metacarpal with the middle of the radius; (2) the carpal position is corrected (usually by gently lifting up from a low position under the radius); and (3) the hand is moved to wrist neutral (see *Functional Movement*

*Reeducation*⁵⁴ for a step-by-step analysis). The warmed, soft splinting plastic captures this corrected position as it cools. The length of palmar support is decided by the therapist after assessment of degree and distribution of muscle return and muscle tightness patterns. The thumb is supported at its base in a neutral position, not one of abduction. As beginning grip returns, the thumb hole is widened to allow function.

A variety of neutral functional splints have been designed. The neutral wrist and thumb hole splinting design makes the splint hard to keep on the hand of patients with severe weakness. They sometimes find ulnar or radial trough splints or wide opponens splints easier to keep on.

As wrist extension control against gravity emerges, the therapist can fabricate a wide opponens splint to maintain the palmar arches as the client begins practicing finger movements. The wide opponens splint supports the base of the hand and assists in maintaining carpal alignment. Patients can switch between the two splints as needed.

Clients with severe hand pain prefer a neutral wrist splint with a resting area for the thumb. This splint is fabricated with little or no correction initially but with gentle support for the wrist and palmar arches. As the pain decreases, this splint is modified to become the original neutral functional splint.

Although the move away from “inhibitory” splints and from night splinting to daytime functional splinting breaks many of the “rules” from the past, it is more compatible with concepts from research and clinical experts.

Recommended resources for practical solutions to one-handed functioning and devices that assist in independence are listed in [Appendix 23-B](#) at the end of this chapter.

PSYCHOSOCIAL ASPECTS AND ADJUSTMENTS

The suddenness of a stroke and the dramatic change in motor, sensory, visual, and perceptual performance and feedback may leave the person with hemiplegia confused, disoriented, angry, stressed, frustrated, and fearful.

Psychosocial issues may be more detrimental than any functional disability to long-term stroke survivors.¹⁷⁹ Decreased interest in social activity inside and outside the home and decreased interest in hobbies as a result of psychosocial disability hamper the hemiplegic person’s return to a normal social life.¹⁸⁰ Feelings of rejection and embarrassment may interfere with the hemiplegic person’s interaction with people outside the home environment. Individuals with long-standing hemiplegia often become clinically depressed with symptoms of loss of sleep and appetite, self-blame, and a hopeless outlook. The usual psychosocial adjustments to disability are compounded in persons with hemiplegia resulting from stroke by the issues associated with aging.

Family members and spouses may have difficulty assessing the capabilities of the hemiplegic person and may be overprotective. Overprotection among spouses may be a sign of affection and support or a sign of guilt.¹⁸¹ Long-standing marriages do not tend to dissolve when one member has a stroke. However, previous marriage problems and personality traits may become exaggerated as a result of the presence of increased and changing demands and stresses that occur when the person returns home.

A comparison of occupational status of long-term stroke survivors in the United States and in Sweden reveals that 40% of the Swedes returned to a form of employment (including part-time work) but none of the U.S. group returned to work.¹⁸² The scarcity of part-time work and a shorter treatment period dictated by third-party payers in the United States may account for this discrepancy.

Age is a general predictor for return to employment, and younger people are more attractive to employers. Barriers to return to work for the person with hemiplegia include speech, perceptual, and cognitive deficits along with a need for psychosocial support. Architectural barriers also can create severe problems for hemiplegic clients with regard to both work and recreational activities. Stroke clubs, usually organized through hospitals, the National Stroke Association, or the American Heart Association, provide educational, social, and recreational support for the hemiplegic person and her or his spouse.

The impact of psychosocial disability and the need for its long-term treatment is great. Programs need to be established and continued for years to allow clients and their families to deal with the many problems that result from the stroke. Refer to [Appendix 23-C](#) for resources.

Sexuality

Most persons with hemiplegia experience a decline in sexuality through a decrease in frequency of sexual intercourse without a change in the level of prestroke sexual desire.¹⁸³ On return home, the person with hemiplegia faces uncertainty about sexual skills and the risk of failure. Sexual dysfunction that results from a stroke depends on the amount of cerebral damage and includes a decreased ability to achieve erection and ejaculation in men and decreased lubrication in women.¹⁸⁴ The sensory, motor, visual, and

emotional disturbances of hemiplegia may cause awkwardness, but these disturbances can be overcome through the education of the spouse in alternate positioning and ways to provide appropriate sensory experiences. The normal factors of aging also interfere with the sexual performance of persons with hemiplegia. A person's prestroke sexual activity is a good indicator of poststroke sexual activity. The closeness between partners achieved through a satisfactory sexual relationship can add to the quality of life after stroke (see Chapter 6).

SUMMARY

This chapter reviews the neuropathology of stroke, the evaluation of impairments that interfere with functional movement patterns, and intervention planning. Both evaluation of outcomes and evaluation of movement components are described. The chapter highlights significant impairments and provides clinical observations on critical areas of intervention. A detailed process of clinical problem solving helps the therapist organize and prioritize impairments to plan intervention programs that retrain movement components and train desirable compensatory patterns to help the client gain the highest level of functional performance and independence in daily life. An example of the synthesis of this chapter's concepts and ideas can be found in Case Study 23-1.

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 184 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

CASE STUDY 23-1

A client with left hemiplegia was seen 4 days after stroke on admission to a rehabilitation center. The classification of movement disorder was composite movement category with severe movement deficits.

FUNCTIONAL LIMITATION 1: CLIENT IS UNABLE TO PERFORM MORNING SELF-CARE AT BEDSIDE OR SITTING IN WHEELCHAIR IN FRONT OF A SINK **Why?**

Client cannot perform anterior and posterior or lateral trunk movements in sitting without loss of balance and falling to left. Client cannot feel left arm, and it hangs by side.

Evaluation

Primary Impairments

Weakness in left arm and leg

Impaired motor control: inability to coordinate trunk–limb movements

Decreased sense of touch in left arm, trunk, and leg

Loss of postural control

Secondary Impairments

Loss of trunk alignment in sitting

Left shoulder subluxation

Muscle tightness—pectorals, latissimus, wrist flexors, ankle dorsiflexors

Loss of alignment of lower trunk and pelvis in sitting—spine

laterally flexed, convexity on left, left pelvis lists downward

Loss of 10 degrees of left ankle joint dorsiflexion range

FUNCTIONAL LIMITATION 2: CLIENT IS UNABLE TO TRANSFER FROM BED TO CHAIR INDEPENDENTLY **Why?**

Client cannot control upper body while trying to activate bilateral leg activity when initiating transfers to either side. Left arm hangs by side with an inferior shoulder subluxation. Cannot lift left leg against gravity in sitting. Cannot depress left leg into surface. Tends to use right side exclusively during transfer with loss of balance. Client uses right arm to support self at edge of bed.

Primary Impairments

Weakness in upper trunk

Weakness in left leg and trunk–leg patterns

Inability to coordinate trunk–limb patterns in weight bearing

Inability to sequence movement patterns in left leg in weight bearing

Continued

CASE STUDY 23-1—cont'd

Secondary Impairments

Loss of upper-body alignment

Loss of left ankle joint dorsiflexion range

FUNCTIONAL LIMITATION 3: CLIENT IS UNABLE TO STAND UP FROM CHAIR INDEPENDENTLY

Why?

Client is unable to control upper body over lower trunk during lower-body-initiated transfers and sit to stand. Client is unable to use left leg for support and movement during the transition of sit to stand. Client is unable to keep weight (depress leg into floor) on left foot in standing.

Primary Impairments

Inability to control upper body over lower body, resulting in an inability to initiate lower trunk and leg movements

Weakness in left leg

Inability to coordinate trunk-leg patterns in weight bearing

Secondary Impairments

Loss of left ankle joint dorsiflexion range

Tightness in left gastrocnemius

SIGNIFICANT IMPAIRMENTS FOR FUNCTIONS EVALUATED

1. Loss of upper-body control during lower-body-initiated movements, especially anterior-posterior plane
2. Shoulder subluxation contributes to loss of upper-body control
3. Loss of control and weakness of left arm and leg
4. Loss of ankle joint dorsiflexion range

Treatment Goals

I. Functional Goals

- A. Perform morning self-care activities in wheelchair in bathroom independently

- B. Transfer from chair to bed and back with contact guarding
- C. Rise to standing with assistance of one person

II. Long-Term Goals

- A. Sit safely while performing tasks with right arm and leg around midline; that is, perform upper-body- and lower-body-initiated trunk movements in sitting independently
- B. Increase upper-body control to prepare for independent, safe, lower-body-initiated movement patterns (extended-arm reach, sitting to standing, and standing balance)
- C. Increase leg strength and establish trunk and leg coordinated patterns in weight bearing (to allow transfers, rising to stand, and standing with minimal assistance to the upper body)
- D. Establish a home or bedside program that the client can perform independently

III. Short-Term Goals

- A. Perform basic trunk movement patterns in sitting with contact guarding
- B. Increase control in upper body and shoulder girdle to decrease shoulder subluxation
- C. Protect shoulder joint from excessive capsular stretch
- D. Strengthen left arm, be able to lift weak arm up onto sink with unaffected arm, maintain sitting balance during morning ADL activities
- E. Increase ankle joint dorsiflexion range in standing
- F. Increase strength in leg and in trunk and leg linked patterns during lower-body-initiated transfers, during sitting to standing, and in supported standing to allow lower-extremity-assisted practice

CHAPTER 24 Traumatic Brain Injury

PATRICIA A. WINKLER, PT, DSc, NCS

KEY TERMS

anticipatory responses
knowledge of results
learning theory
motor control
motor learning
motor skill
neuroplasticity
systems theory
traumatic head injury

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe the application of current concepts in motor control and motor learning theories for clients with traumatic brain injury.
2. Understand the meaning of *impairment*, *activity limitation*, and *participation limitation* and their interrelationships as they apply to clients with traumatic brain injury.
3. Prescribe methods of examining, evaluating, and developing interventions for clients with brain injuries on the basis of task, impairment, and activity limitation analysis.
4. Describe prognosis and outcomes for clients with traumatic brain injury.
5. Differentiate between development of basic movement patterns and motor skills.
6. Understand the role of synergy formation, synergy selection and modification, and anticipatory and feedback information as used in motor skills.
7. Describe the long-term effects of different types of feedback and practice on learning.

Traumatic brain injury (TBI) is defined as a blow or jolt to the head or a penetrating head injury that disrupts the function of the brain. Not all blows or jolts to the head result in a TBI. The severity of such an injury may range from mild—a brief change in mental status or consciousness—to severe—an extended period of unconsciousness or amnesia after the injury. A TBI can result in short- or long-term problems with independent function.¹

OVERVIEW OF BRAIN INJURY

Epidemiology of Traumatic Brain Injury

One and three-quarter million people sustain a TBI every year.¹ Of these, 1.3 million are treated in emergency departments and 275,000 injuries are severe enough to require hospitalization.² Fifty-two thousand people die yearly of TBI, 80,000 injuries result in disabilities, and 5.3 million people are living with permanent disabilities from TBI. It is the leading killer and disabler of children and young adults. Motor vehicle crashes cause 20% of all TBIs, falls cause 28%, violence causes 11% (the majority from firearms), and sports and recreation account for 10%. Child abuse accounts for 64% of infant brain injuries.¹ Fifty-thousand children sustain bicycle-related brain injuries, and 400 of them die.³ Two thirds of firearm-related TBIs are suicidal. Falls are the leading cause of TBI in people aged 65 years and older, with 11% proving fatal. The incidence of TBI is 506.4 per 100,000 population, with 43% of those hospitalized having long-term activity limitation.⁴

Population of Clients with Brain Injury

The incidence of brain injuries is higher for the male population than for the female population by more than 2:1. Most of those injured are 15 to 24 years old.⁴ The greatest risk of

injury is for those younger than 10 years old or older than 74. American Indians and African Americans have the highest rate of TBI. People in lower socioeconomic status also have a higher rate of injury.

Cost

The estimated lifetime cost for each individual with severe brain injury exceeds \$4 million. Annual costs for all TBIs in the United States exceed \$60 billion.

Mechanisms of Injury

There are four main types of injury, as follows:

1. Those from external forces hitting the head or the head hitting hard enough to cause brain movement. Injuries include those with skull fracture and those without skull fracture (closed head injuries). Direct blows to the head can cause coup injuries (at the site of impact) and contrecoup injuries (distant from the site of impact).
2. Severe acceleration and deceleration of the head can cause TBI without the head hitting an object. An example is shaken baby syndrome.
3. Blast injuries have become very common in the past 10 years, mainly affecting military personnel.
4. Penetrating objects cause direct cellular and vascular damage. Injuries to the face and neck can cause brain injury by damaging the blood supply to the brain.⁵

Pathophysiology of Injury

Acceleration, deceleration, rotational forces, and penetrating objects cause tissue laceration, compression, tension, shearing, or a combination, resulting in primary injury.

Primary Damage

Contusions—a bruise or bleeding on the brain—and lacerations can occur with or without skull fractures. Either an object hits the head, neck, or face, or the head hits an object. Damage can be to any area of the brain. Occipital blows are more likely to produce contusions than are frontal or lateral blows. Areas in which the cranial vault is irregular, such as on the anterior poles, undersurface of the temporal lobes, and undersurface of the frontal lobes, are commonly injured. Lacerations of blood vessels within the brain itself or of blood vessels that feed the brain from the neck or face reduce the flow of blood carrying oxygen to the brain. Contusions and lacerations can also injure the cranial nerves. The most commonly injured are the optic, vestibulocochlear, oculomotor, abducens, and facial nerves. Lacerations of the dura or in the arachnoid space may cause cerebrospinal fluid to discharge from the nose (cerebrospinal fluid rhinorrhea discharge increases with neck flexion, coughing, or straining).⁶ An example of a computed tomography (CT) scan of a cerebral contusion can be found in Chapter 37, Figure 37-17, B.

Epidural hematomas or hemorrhages occur mostly in adults when tearing of meningeal vessels results in blood collecting between the skull and dura. Skull fracture is present in the majority of cases. This is accompanied by intervals of lucidity and can result in death unless treated early.

Subdural hematomas occur with acceleration-deceleration injuries when bridging veins to the superior sagittal sinus are torn. Blood accumulates in the subdural space. Symptoms include weakness and lethargy. Symptoms such as weakness and lethargy that come on acutely are life-threatening. Symptoms caused by slow bleeding may not be present for several weeks. A CT scan of this problem can be found in Chapter 37, online image Figure 37-17, A. Also, note on the same figure the midline shift of the brain.

Diffuse axonal injuries, or shearing injuries, are among the most common types of primary lesions in patients with brain trauma.^{7,8} Brain tissues that differ in structure or weight experience unequal acceleration, deceleration, or rotation of tissues during rapid head movement or during impact, causing diffuse axonal injury and changes in chemical processing. Refer to Chapter 37, Figure 37-17, D for an illustration of what axons are most affected by this shearing motion. Severing of the axons may be severe enough to result in coma. In milder forms, more spotty lesions are seen, including deficits such as memory loss, concentration difficulties, decreased attention span, headaches, sleep disturbances, and seizures. Damage often involves the corpus callosum, basal ganglia, brain stem, and cerebellum.^{6,8} For a complete image of how the axons diffuse throughout the entire CNS, refer to Figure 37-17, C.

Penetrating objects with high velocities, such as bullets or shrapnel from explosives, can cause additional damage remote from the areas of impact as a result of shock waves. Foreign objects such as sticks and sharp toys cause low-velocity injuries, directly damaging the tissues they contact.

Blast injuries occur when a solid or liquid explosive material explodes, turning into a gas. The expanding gases form a high-pressure wave (overpressure wave) that travels at supersonic speed. Pressure then drops, creating a relative vacuum (blast underpressure wave) that results in a reversal of air flow, which is in turn followed by a second overpressure wave. Blast-related injury can occur through several

mechanisms. The primary blast wave generates extreme pressure changes that can cause stress and shear injuries. For example, rupture of the tympanic membranes is very common after blast injury, and lung and gastrointestinal injuries also occur. The exact mechanism of injury to the brain is unknown, with speculation about both axonal shearing and shearing of vasculature.^{9,10}

Secondary Damage

Secondary injuries are mainly caused by a lack of oxygen in the highly oxygen-demanding brain. Secondary problems may result from the following:

- **Increased intracranial pressure (ICP)** (resulting from swelling or intracranial hematoma). Swelling of the brain causes distortion because the brain is held in the skull, a rigid, unyielding structure. The resultant increased ICP can lead to herniation of parts of the brain. The most often seen herniations include cingulate herniation under the falx cerebri, uncus herniation, central (or transtentorial) herniation, and herniation of the brain stem through the foramen magnum.¹¹ Acute hydrocephalus occurs when blood accumulates in the ventricular system, expanding the size of the ventricles and causing increased pressure on brain tissue being compressed between the skull and the fluid-filled ventricles. The increased pressure can then result in changes in PCO₂, which is also harmful to nervous tissue. Increased ICP has been correlated with poorer outcomes and higher mortality rates.¹²
- **Cerebral hypoxia or ischemia** (occurring when blood vessels are ruptured or compressed). Hypoxia can occur from a lack of blood to the brain or from lack of oxygen in the blood as a result of airway obstruction or chest injuries.
- **Intracranial hemorrhage** causes hypoxia to tissues fed by the hemorrhaging blood vessels and adds pressure and distortion to brain tissue. Metabolic products from damaged cells and blood bathe the brain. Cell death occurs within minutes after injury from ischemia, edema, necrosis, and the toxic effects of blood on neural tissues.
- **Electrolyte imbalance and acid-base imbalance.** Secondary cell death occurs either by swelling and then bursting of the cellular membrane (necrosis) or by destruction from within the cell through changes in the deoxyribonucleic acid (DNA) (apoptosis). Cell death can occur days, weeks, or months after injury.¹³
- **Infection from open wounds.** Infection in brain tissue may cause swelling and cell death.
- **Seizures from pressure or scarring.** Seizures are most common immediately after injury and 6 months to 2 years after injury. The seizures can cause additional brain damage owing to high oxygen and glucose requirements.

Physiological, Cognitive, and Behavioral Changes after Brain Injury

Autonomic Nervous System

Box 24-1¹⁴ lists possible autonomic nervous system symptoms resulting from brain injury.

BOX 24-1 ■ AUTONOMIC NERVOUS SYSTEM SYMPTOMS RESULTING FROM BRAIN INJURY

- Changes in pulse and respiratory rates or regularity
- Temperature elevations
- Blood pressure changes
- Excessive sweating, salivation, tearing, and sebum secretion
- Dilated pupils
- Vomiting

Motor, Functional, Sensory, and Perceptual Changes

Motor abnormalities after severe head trauma are common. More severe head injuries tend to manifest more persistent physical problems.⁶ In at least two studies^{6,15} a fourth of the cases had no neurophysical sequelae. Changes in muscle tone may reflect the physiological effects of changes in the amount of tissue compression or irritation.¹⁶ **Box 24-2** lists motor changes and provides symptoms of sensory and perceptible involvement.

Cognitive, Personality, and Behavioral Changes

Cognitive and behavioral sequelae can result from generalized or focal brain injuries. Memory impairments are an aftermath of generalized lesions. Emotional changes may be seen with lesions in the orbitofrontal areas. Behavior may be excessive and disinhibited. Septal area lesions result in rage and overall irritability. Pseudobulbar injuries can result in emotional lability of involuntary laughing or crying not associated with feelings of emotions. Behavioral changes can be present even without cognitive and physical deficits. Although actual psychoses can be sequelae, they appear to be neither common nor definitively related to the brain injury.

The social consequences of inappropriate behavior can be disastrous and a stumbling block to achieving therapy goals. A correlation between preinjury personality and postinjury changes has not been established.⁶ It does seem reasonable, however, that factors within an individual's psychological makeup may affect reaction to the injury. Brain trauma frequently happens to adolescents—an age group fraught with its own problems that may be aggravated by the injury. Outcomes at 1 year postinjury have shown the most common problems to be poor memory and problem solving, problems managing stress and emotional upsets, and an inability to control temper. Finally, managing money and paying bills were still a problem at the 1-year mark.¹⁷ **Box 24-3**¹⁸ lists both cognitive and behavioral changes resulting from brain injury.

Changes in Consciousness and Coma

Coma and changes in consciousness result from conditions in which there are diffusely extensive and bilateral cerebral hemispheric depression of function, direct depression or destruction of the brain stem—activating system that is responsible for consciousness or a combination of the two. In moderate or severe head injury, unconsciousness can be prolonged. Plum and Posner's definitions¹⁶ of various stages of acutely altered consciousness are briefly presented, intermingled with some insights from the descriptions offered by

BOX 24-2 ■ MOTOR, FUNCTIONAL, SENSORY, AND PERCEPTUAL CHANGES RESULTING FROM BRAIN INJURY

Motor changes may include any or all of the following:

- Paralysis or paresis such as monoplegia or hemiplegia.
- Cranial nerve injury resulting in paralysis of eye muscles, facial paralysis, vestibular and vestibuloocular reflex abnormalities, slurred speech (dysarthria), swallowing abnormalities (dysphagia), and paralysis of the tongue muscles.
- Poor coordination of movement.
- Abnormal reflexes.
- Abnormal muscle tone: flaccidity, spasticity, or rigidity. (The terms *decorticate rigidity* and *decerebrate rigidity* are often used to denote abnormal posturing. *Decerebrate rigidity* denotes extension in all four limbs. *Decorticate posturing* includes flexion of the upper extremities and extension of the legs.)
- Combinations of asymmetrical cerebellar and pyramidal signs and of bilateral pyramidal and extrapyramidal signs have all been reported.¹⁵
- Loss of selective motor control.
- Poor balance.
- Loss of bowel or bladder control.

Sensory and perceptible involvement may include any or all of the following:

- Hypersensitivity to light or noise
- Loss of hearing or sight
- Visual field changes
- Numbness and tingling (peripheral nerves are often injured)
- Loss of somatosensory functions
- Dizziness or vertigo
- Visuospatial abnormalities
- Agnosia
- Apraxia

Gilroy and Meyer.¹¹ Plum and Posner¹⁹ do not equate the presence or absence of motor responses with the depth of coma. These authors point out that the neural structures regulating consciousness differ from and are more anatomically distant from those regulating motor function.

Concussion. In mild concussion, the loss of consciousness may not occur or lasts a relatively short time (20 minutes or less) and there is little or no retrograde amnesia. A concussion can cause diffuse axonal injury and result in either temporary or permanent damage. The client may be irritable or distractible and have difficulty with reading and memory. There may be complaints of headache, fatigue, dizziness, and changes in personality and emotional disposition. This group of symptoms constitutes what is called *posttraumatic syndrome*. The effects of repeated concussions (second impact syndrome) are cumulative.²⁰

Coma. *Coma* is defined as a complete paralysis of cerebral function; a state of unresponsiveness. The eyes are closed, and there is no response to painful stimuli. Within

BOX 24-3 ■ COGNITIVE, PERSONALITY, AND BEHAVIORAL CHANGES RESULTING FROM BRAIN INJURY

Cognitive changes might include any or all of the following:

- Temporary or permanent disorders of intellectual function
- Memory loss
- Shortened attention span
- Concentration problems
- Confusion
- Changes in motivation
- Difficulty sustaining attention
- Executive function loss (executive functions are those that affect how behavior is regulated); Lezak¹⁸ outlined four functions:
 1. Choosing a goal
 2. Developing a plan
 3. Executing a plan
 4. Evaluating the execution of the plan
- Reduced problem-solving skills
- Lack of initiative
- Loss of reasoning
- Poor abstract thinking
- Shortened attention span

Behavioral changes could include the following:

- Lability
- Uncontrolled anger
- Irritability
- Euphoria
- Intolerance
- Inappropriate sexual behavior
- Perseveration (repetition of movements or sounds)
- Impulsiveness
- Hyperactivity

2 to 4 weeks, nearly all clients in coma begin to awaken. Oculomotor and pupillary signs are valuable in assisting with the diagnosis, localizing brain stem damage, and determining the depth of coma.¹⁹ In coma, brain stem responses may include grimacing to pain, which is frequently associated with a flexor or localizing motor response, loss of hearing or balance, abnormal palate and tongue movements, and loss or distortion of taste.

Stupor. Stupor is a condition of general unresponsiveness. The client is usually mute but can be temporarily aroused by vigorous and repeated stimuli.

Obtundity. *Obtundity* describes the condition of a client who sleeps a great deal and who, when aroused, exhibits reduced alertness, disinterest in the environment, and slow responses to stimulation.

Delirium. Delirium is often observed in recovery from unconsciousness after severe brain injury. Disorientation, fear, and misinterpretation of sensory stimuli characterize this state. The client is frequently loud, agitated, and offensive.

Clouding of Consciousness. Clouding of consciousness is a state of quiet confusion, distractibility, faulty memory, and slowed responses to stimuli.

Persistent Vegetative State. Finally, no discussion of changes in consciousness would be complete without mention of those unfortunate enough to remain in a “persistent vegetative state.” This state is characterized by a wakeful, reduced responsiveness with no evident cerebral cortical function. The vegetative state can result from diffuse cerebral hypoxia or from severe, diffuse white matter impact damage. The brain stem is usually relatively intact. Clients may track with their eyes and show minimal spontaneous motor activities that even appear purposeful, but they do not speak, nor do they respond to verbal stimulation.²¹ Life expectancy can be weeks, months, or years.^{22,23} Clients with brain injury who remain vegetative for 3 months rarely achieve an independent outcome. However, the term “persistent” should not be added to “vegetative state” until the injury has stabilized or the state has lasted for approximately 1 year.²⁴ Functional magnetic resonance imaging (fMRI) was recently used to test clients who were diagnosed as being in persistent vegetative states. Five of 54 clients diagnosed as in a persistent vegetative state demonstrated “willful, neuroanatomically specific blood-oxygenated-level-dependent responses when told to visualize one of two tasks.”²⁵ The diagnosis of persistent vegetative state indicates lack of cortical function, and fMRI may be useful in this diagnosis in the future. Recovery of consciousness, if it occurs, includes a gradual return of orientation and recent memory.¹⁹ The duration of each of these stages is variable and can be prolonged. Improvement can stop at any point.

Other Complications

A list of the complications that may accompany brain injury would be limitless. In addition to any concomitant injuries, some of the diagnostic, monitoring, and therapeutic procedures themselves carry hazards. So does prolonged bed rest. Catheters, nasogastric tubes, and tracheotomies can cause iatrogenic injuries. Infections, contractures, skin breakdown, thrombophlebitis, pulmonary problems, heterotopic ossification (HO), and surgical complications are but a few of the risks. Posttraumatic epilepsy is also a possible sequela. Depression occurs frequently after brain injury, and it can alter functional outcome. It appears that a combination of neuroanatomical, neurochemical, and psychosocial factors are responsible for the onset and maintenance of the depression.²⁶

Locked-in Syndrome. Locked-in syndrome occurs rarely and can be confused with coma. The client cannot move any part of the body except the eyes but is able to think and is conscious.²⁷

Communication Disorders. Communication disorders include expressive and receptive language aphasia and dysarthria.

Amnesia. Two types of amnesia are frequently associated with brain injury: retrograde and posttraumatic.²⁸ Cartlidge and Shaw¹⁴ define *retrograde amnesia* as a “partial or total loss of the ability to recall events that have occurred during the period immediately preceding brain injury.” The duration of the retrograde amnesia may progressively decrease. *Posttraumatic amnesia* (PTA) is defined “as the time lapse between the accident and the point at which the functions concerned with memory are judged to have been restored.”¹⁴ The duration of PTA is considered a clinical indicator of the severity of the injury.¹⁴ An additional deficit can

be the inability to form new memory, referred to as *anterograde memory*. The capacity for anterograde memory is frequently the last function to return after recovery from loss of consciousness.²⁹

Memory. The client's inability to develop continuing short-term memory can be quite frustrating for the rehabilitation team as well as for the client because memory is an important component of learning.³⁰ There are two types of memory: *declarative* and *procedural*. Memory in which the client can recall facts and events of a previous experience is declarative memory. Explicit learning, a conscious verbal learning, is based on declarative memory. However, many clients who cannot reproduce memories through conscious recollection do have the ability to learn new motor skills. Implicit learning, a noncognitive type of learning in which clients can show changes in performance after prior experience, is based on procedural memory. Clients can show the ability to change motor, perceptual, or cognitive behaviors with practice or training but may lack declarative memory. That procedural memory may be present without declarative memory in clients with TBI has been demonstrated.²⁸

Initial Care and Medical Interventions

On the client's admission to the hospital, a neurosurgeon usually assumes initial and primary responsibility for the client. The first priority in medical care is resuscitation, after which baseline assessments are made and a history is obtained. Immediate surgery may or may not be indicated. Surgery is indicated when blood and necrotic tissue are present in the cranial vault. Early concerns may include the management of respiratory dysfunction, cardiovascular monitoring, treatment of raised ICP by means of pharmacological, mechanical, or surgical procedures,¹⁴ and general medical care. Examples of general medical care are familiar: maintenance of fluid and electrolyte balance, nutrition, eye and skin care, prevention of contractures, postural drainage, and safety considerations.⁶ The need for this type of care gradually lessens as the client responds, or it may continue if unconsciousness persists. Initially, a determination of Glasgow Coma Scale³¹ (GCS) score (Box 24-4) is performed to test the function of the brain stem and the cerebrum through eye, motor, and verbal responses. It provides a measure of the level of consciousness. Scores range from 3 to 15, with lower scores associated with lower levels of function. Scores from 13 to 15 indicate a mild brain injury, 9 to 12 a moderate brain injury, and 8 or less a severe injury.

Several scales define TBI as mild, moderate, or severe based on specific measurements (Table 24-1). Because the definition of mild brain injury has varied so widely, the CDC convened a panel of experts to further define it. The new definition of mild TBI is an injury to the head (arising from blunt trauma or acceleration or deceleration forces) that results in one or more of the following: any period of

confusion, disorientation, or impaired consciousness; any dysfunction of memory around the time of injury; loss of consciousness lasting less than 30 minutes; or the onset of observed signs or symptoms of neurological or neuropsychological dysfunction.² According to the Brain Injury Association of America, with a moderate TBI the client experiences a loss of consciousness that lasts from a few minutes to a few hours; confusion that lasts from days to weeks; and physical, cognitive, or behavioral impairments that last for months or are permanent. A severe brain injury occurs when a prolonged unconscious state or coma lasts days, weeks, or months. With the possible exception of the diagnosis and hence prognosis of diffuse white matter impact damage,³² one third of clients hospitalized with brain injuries have extracranial injuries,⁶ which are explored with a physical examination and appropriate special tests. Additional testing depends on the client's particular dysfunctions. CT,³³ MRI, positron emission tomography (PET), radioisotope imaging, ventriculography, echoencephalography, electroencephalography, monitoring of ICP, measurement of cerebral blood flow and metabolism, monitoring of cardiorespiratory and cardiovascular function, and tests of cerebrospinal fluid and other biochemical studies all provide important information. Changes in electrocerebral potentials that occur in response to specific stimuli also are studied. Visual, auditory, and somatosensory evoked potential examinations are used with

clients with brain injury but are more effective when combined with other examinations.³⁴ These examinations make it possible to observe the presence, evolution, and resolution of a lesion.⁶ Reflex motor responses in unconscious clients are tested by applying a noxious stimulus, such as pressure on a nail bed with a pencil or supraorbital pressure, and observing the response. Most responses generally fall into three categories: appropriate, inappropriate, or absent.¹⁹ Testing for cognitive and behavioral functions is usually done via neuropsychological tests. In some circumstances the results of IQ tests, achievement tests, and Armed Forces tests may be available for comparison. Differentiating changes in cognitive and behavioral functions caused by brain injury from posttraumatic stress syndrome, conversion or hysterical reactions, malingering, depression, and anxiety is extremely important.

Surgical Interventions

Patients with epidural hematomas often undergo craniotomies with blood evacuation. Subdural injuries are frequently treated by removing the blood through bur holes.

Pharmacological Interventions

Medications are chosen according to symptoms to be treated. Many of these recommendations are from a meta-analysis of management of severe TBI published in 2007.³⁵⁻³⁹

Drugs that Decrease Intracranial Pressure. When ICP increases, changes in PCO_2 are seen. The maintenance of a PCO_2 at 30 to 40 mm Hg appears most appropriate. Osmotic agents such as mannitol are used to pull fluid from brain tissue back into the blood system, thus lowering ICP. Propofol, a barbiturate, is recommended for control of ICP if it cannot be controlled by other means.³⁵ Use of mannitol is recommended for clients who have profusion problems.³⁵ ICP has been lowered by intentional hyperventilation, which causes an increase in blood PCO_2 , resulting in vasoconstriction of the central vessels and reduced cerebral blood flow. However, Muizelaar and colleagues⁴⁰ as well as information from the Traumatic Coma Data Bank⁴¹ showed that dramatically reducing a client's PCO_2 in this manner resulted in a worse outcome than that in clients managed with medication. Therefore hyperventilation is currently used only for nonresponsive cases and for short durations. Glucocorticoids (dexamethasone [Decadron], methylprednisolone [Solu-Medrol]) have been used to treat cerebral edema, but most studies show no long-term changes in outcome, and methylprednisolone is contraindicated because it increases mortality.³⁹ See Chapter 36 for additional information.

Drugs that Control Blood Pressure. Blood pressure control is important in clients with brain injury. Cerebral perfusion pressure⁴² or adequate blood pressure to maintain cerebral blood flow against increased ICP is calculated by subtracting the ICP from the mean arterial pressure. If fluid management cannot keep the blood pressures elevated, then vasopressor drugs such as phenylephrine (Neo-Synephrine) are used to constrict peripheral vessels but not the vessels of the brain.

Drugs that Affect the Motor, Behavioral, and Cognitive Functions (See Chapter 36). Medications also may be prescribed for motor abnormalities involving increases in tone. Baclofen is now used more frequently

with clients with brain injury; however, it can produce lethargy, confusion,⁴³ and reduction in attention span⁴⁴ in some clients. These effects are greatly reduced with implantation of a pump to deliver the drug. Dantrolene sodium is another medication used to decrease spasticity and rigidity. This drug works directly at the muscle level and therefore is less likely to cause cognitive disturbances but more likely to cause generalized weakness.⁴⁵ Botulinum toxin type A (Botox) is widely used to inject into specific muscles, such as the finger flexors, biceps, or gastrocnemius, to decrease their tone. Diazepam (Valium) initially was the drug most commonly administered for spasticity or high tone. However, diazepam also promotes drowsiness and decreased responsiveness and can increase muscle weakness and ataxia.⁴³ These side effects actually hinder rather than assist in rehabilitation. Glenn and Wroblewski⁴⁴ conclude that "rarely, if ever, are the benefits of diazepam's antispasticity effect great enough to justify its use in the brain-injured population." Drugs to treat behavioral or cognitive dysfunction have not been particularly successful. Antidepressive drugs as well as carbamazepine (Tegretol) and propranolol (Inderal) have been used to treat aggression and agitation. Carbamazepine appears to reduce agitation or aggression in clients with brain injury.⁴⁶ Confusion and other neuropsychotic symptoms have been treated using neuroleptic medications. A recent review article suggests that these drugs may negatively affect motor outcomes.⁴⁷ Sedative drugs prescribed in an attempt to control delirium may add to the client's confusion and may also contribute to a decreased responsiveness. Later in the rehabilitative process, various antidepressants may be used to treat aggressive and disruptive behaviors. These, too, may have deleterious side effects. Antidepressants other than the tricyclics appear to be the most effective for treating depression.

Attention Deficits. Methylphenidate may increase information processing in some clients, but the evidence is still weak.⁴⁸ Traumatically acquired neuroendocrine dysfunctions, such as hyperphagia and thermal regulation, also may be treated with pharmacological agents.⁴⁹

Pain. Severe, intractable pain may be present in clients who have had injury to the thalamus. In these cases, some of the antiseizure drugs appear to be more effective, including phenytoin (Dilantin) and gabapentin (Neurontin). Late seizure control is usually through valproic acid (Depakote or Depakene).

Prevention of Brain Cell Death. Hypothermia is frequently used in acute severe TBI. Although it does not appear to change the mortality rate, it is associated with improved functional outcome on the Glasgow Outcome Scale (GOS) (Box 24-5).³⁶

For a variety of reasons, other pharmaceutical agents are prescribed as an adjunct to care. Antibiotics may be used with respiratory complications or with compound fractures and infections.

Prognostic Indicators

Numerous problems are encountered in trying to predict outcome. Included among these problems are the validity and reliability of the tests used, the uniform implementation and interpretation of predictive factors, the percentage of error in prediction, the possible effects of intervention strategies and

BOX 24-5 ■ GLASGOW OUTCOME SCALE**VEGETATIVE STATE**

A persistent state characterized by reduced responsiveness associated with wakefulness. The client may exhibit eye opening, sucking, yawning, and localized motor responses.

SEVERE DISABILITY

An outcome characterized by consciousness, but the client has 24-hour dependence because of cognitive, behavioral, or physical disabilities, including dysarthria and dysphasia.

MODERATE DISABILITY

An outcome characterized by independence in activities of daily living and in home and community activities but with disability. Clients in this category may have memory or personality changes, hemiparesis, dysphagia, ataxia, acquired epilepsy, or major cranial nerve deficits.

GOOD RECOVERY

Client able to reintegrate into normal social life and able to return to work. There may be mild persisting sequelae.

Modified from Jennett B, Bond M: Assessment of outcome after severe brain damage: a practical scale. *Lancet* 1:480, 1975.

bias in treatment on the basis of predictions, and, finally, the definition of what constitutes a “successful” outcome. Understanding these problems is imperative because the therapist can provide persuasive suggestions regarding the type and intensity of rehabilitative care after injury. The differences in operational definitions, types and sizes of populations, and length of time after injury when the outcome assessment was made contribute to the lack of consistency in studies of predictive factors for clients with brain injury. For example, several authors have found that clients younger than age 20 years usually recover better⁵⁰⁻⁵²; however, this has not been uniformly confirmed. A reason for caution in using tests for prediction is the percentage of error in prediction. If prediction is 80% or even 90% accurate, there are still 10% to 20% of the clients with head trauma whose outcome may be predicted incorrectly.⁵³

Lesion Size and Area

There is conflicting evidence regarding recovery outcomes on the basis of lesion size and area because the type of lesion and the rapidity with which lesions occur have an impact on both the deficits and the size. There is some evidence that lesion area rather than size is important. Van der Naalt and co-workers^{54,55} looked at 67 patients with brain injuries in the mild to moderate injury categories and found that frontal and frontotemporal lesions were predictive of poorer outcomes than lesions in other areas. However, Kurth and colleagues⁵⁶ looked at number of acute hemorrhages, lesion volume, and location in TBI using neuropsychological outcome measures and found no relationship between the numbers of hemorrhages and the volume of injury. Brain MRI in 80 adult patients (6 to 8 weeks after injury) was predictive of nonrecovery from persistent vegetative states at 12 months when the client had corpus callosum and dorsolateral brain stem lesions.⁵⁷ Lesion location is not a significant predictor

of GOS scores. Lesions in the brain stem do appear to cause poorer outcomes on the GOS than other lesions.^{58,59}

Time Since Lesion

Better functional outcomes were found in monkeys when rehabilitation occurred earlier after the lesion. Black and colleagues⁶⁰ created lesions in the motor cortices of 27 adolescent rhesus monkeys and then trained them in motor tasks involving the arm. Active postoperative training of the weak hand led to recovery of 82% of the preoperative function in 6 months if the therapy was initiated immediately. Recovery was only 67% of preoperative control if training was delayed 4 months.

Age

Age is an important factor in recovery. Beginning at age 40 years, older patients have significantly longer PTA and worse functional outcome at any severity.⁶¹

Posttraumatic Amnesia

PTA duration is better related to outcome than either lesion area or size.⁶¹ Postinjury amnesia had a predictable relationship to length of coma in patients with diffuse axonal injury. Duration of PTA was strongly correlated with the GOS score at 6 and 12 months after injury in patients with diffuse axonal injury but poorly correlated in patients with primarily focal brain injury. Van der Naalt and colleagues⁵⁴ study of the GCS indicates that this scale, applied 12 months after injury, is a simple and consistent predictor of outcomes in clients with a score of 9 to 11 (mild to moderate brain injury). PTA is a strong predictor of outcome as measured by the Functional Independence Measure (FIM) (an activity level measurement tool)⁶²; and when PTA is combined with age, sitting balance, and limb strength at admission, prediction of productive outcome is high.⁶³ Walker and colleagues⁶⁴ also found that when PTA lasted less than 4 weeks, a severe activity limitation was unlikely; and if longer than 8 weeks, a good recovery was unlikely when measured by GOS.

Sitting and Standing Balance

Age younger than 50 years had a significant association with normal sitting and standing balance. Measures of severity of TBI, including admission Glasgow Coma GCS score, length of PTA, length of coma, and acute care length of stay, were also each significantly related to impaired sitting and standing balance. Initial abnormalities in pupillary response, respiratory failure, pneumonia, soft tissue infections, and urinary tract infections had a significant relationship with impairment of sitting but not standing balance. Presence of intracranial hemorrhages did not have a significant relationship with either sitting or standing balance. Intracranial compression had a significant relationship with standing balance. Discriminant functional analysis showed no relationship between balance ratings and neurological or radiological findings, injury severity, or medical complications.⁶⁵

Other Factors

Finally, several studies have reported that absence of previous TBI,⁴² a higher level of educational achievement, and stable work history also are positive preinjury variables for

a better prognosis.⁶⁶ The Wechsler Adult Intelligence Scale (WAIS)—Revised IQ test may correlate with prognosis according to other studies.⁶⁶

Motor disturbances resulting from brain injury generally have a good prognosis.¹⁴ Of the physical deficits encountered, dysfunctions in the cerebral hemispheres and of the cranial nerves are the most common disorders, and these may partially resolve. Losses of these functions can be more permanent,^{11,14} especially without skilled rehabilitation interventions. Complete recovery is rare except with hearing, vestibular function, and smell. In one Glasgow study, some degree of hemiparesis was present 6 months after injury in 49% of the 150 clients who regained consciousness after severe brain injury.⁶

Psychosocial outcomes vary after severe brain injury.⁶⁷ Psychosocial variables that significantly increased life satisfaction for persons with TBI were total family satisfaction, being employed, being married, having memory, bowel independence, and not blaming oneself for the injury. Those who do not blame themselves show a greater number of functional activities as indicators for their self-satisfaction.⁶⁸

See Box 24-6 for factors that can influence recovery and management.

CONCEPTUAL FRAMEWORK FOR THERAPEUTIC INTERVENTION

Motor Control Theory

Motor control and learning theories try to explain how the central nervous system (CNS) accomplishes the miracle of coordinated, meaningful movement. Motor control theory and factors affecting effectiveness and speed of motor learning are reviewed in this section and are discussed in detail in Chapter 4. This chapter's examination, evaluation, and intervention technique sections are based on that framework. A quick review of basic principles follows.

Synergistic Organization

Synergies, or motor patterns, were viewed by Bernstein⁶⁹ as the basis of movement. The need for the brain to use synergistic organization comes from the infinite number of movement combinations that are available. By use of motor patterns, which decrease the number of degrees of freedom, speed and efficiency are added while flexibility of response is maintained. Force (amplitude) of contraction, velocity, and timing can still be changed to meet task demands. Research suggests that motor patterns are shaped

BOX 24-6 ■ FACTORS THAT CAN INFLUENCE MANAGEMENT AND RECOVERY AFTER A TRAUMATIC BRAIN INJURY

PREINJURY CHARACTERISTICS

Cognitive Factors

1. Intelligence*
2. Memory
3. Level of education

Behavioral Factors

1. Personality*
2. Psychological status

Social Factors

1. Vocational skills
2. Avocational skills
3. Interpersonal skills
4. Family and friends support systems

Physical Factors

1. Age*
2. General health and physical fitness
3. Existing physical deficits
4. Morphology
5. Level of motor skill development and capacity for motor learning

POSTINJURY CHARACTERISTICS

Static Factors

1. Trauma factors (neurological)
 - a. Location(s) and extent of injury
 - b. Cause and type of injury*
 - c. Immediacy of injury*
2. Cognitive factors
 - a. Ultimate duration of retrograde amnesia*
 - b. Ultimate duration of posttraumatic amnesia*
3. Physical factors: extracranial injuries

Dynamic Factors

1. Trauma factors (neurological)
 - a. Depth and duration of coma*
 - b. Secondary brain damage
 - c. Brain stem reflexes
 - d. Special investigations (radiological and laboratory tests)
2. Cognitive factors
 - a. Rate of recovery of intellectual and memory functions*
 - b. Quality of recovery of intellectual and memory functions*
 - c. Communication disorders
3. Behavioral factors
 - a. Primary personality changes*
 - b. Secondary personality changes*
 - c. Psychological status
4. Social factors
 - a. Opportunity to reenter occupation or school
 - b. Avocational reintegration abilities
 - c. Reaction to family and friends
 - d. Family adjustment and support capabilities*
5. Physical factors
 - a. Pattern and quality of sensorimotor recovery*
 - b. Rate of recovery of sensorimotor function*
 - c. Range of motion and muscle flexibility
 - d. Cranial nerve deficits
 - e. Concomitant disabilities
6. Environmental factors
 - a. Staff, facilities, equipment available
 - b. Attitude of health care providers
 - c. Expertise of health care providers
 - d. Room or housing and treatment settings

*Discussed in the text.

through experience and that they develop before birth (innate) and after birth (learned). Early experiments on motor learning demonstrate how motor patterns may develop. Payton and Kelley⁷⁰ showed that with practice of a novel motor task, movements become more organized and skilled.

Characteristics of a Learned Skill (Motor Pattern).

In learning a new skill, movement begins with a “gross approximation” of the movement that includes agonist-antagonist co-contraction. As movement is refined, reciprocal movement replaces co-contraction.⁷¹ In electrophysiological studies of skill acquisition, less electrical activity is seen on electromyography (EMG) and less time to peak activation of the muscle is noted in motor tasks after they become skillful. In addition, fewer muscles are recruited for the same movement.⁷² PET scans have confirmed these EMG findings, demonstrating decreasing areas of brain activity after skill acquisition. Neuronal changes brought about through long-term potentiation and long-term depression are a basis for learning new tasks and developing motor patterns and behavioral changes.⁷³ As neurons are repetitively fired at the same time, networks develop. These neuron networks, or cell assemblies, are formed with increasing complexity and self-organization. The more they are used, the stronger and more permanent are the changes that occur. Finally, a specific stimulus now provokes a learned or skilled response as an organized synergy. The output of the networks is not a summation of individual functions but has “emergent properties” that are more than the sum of the output of individual neurons.

The best understood motor patterns are the balance and reaching patterns. Both appear to be basic innate synergies. Quiet standing in humans is maintained by somatosensory, visual, and vestibular inputs (see Chapter 22). It requires the coordination of many muscles, especially those of the hips, knees, and ankles, to maintain the body’s center of gravity over its base of support. This complex coordination of muscle control is accomplished by sequences of stereotyped patterns mediated through the brain stem, cerebellum, and spinal cord. Somatosensory input during body sway stimulates the response in which posture is stabilized by small changes in the angle between the foot and the leg. For small and slower center of gravity movements, these synergies are sequenced in a distal to proximal manner. The direction of sway determines the particular synergy elicited to correct for the shift in the center of gravity. In forward losses of balance, the posterior extensor muscles of the legs and trunk respond at about 100 ms. In backward losses the anterior muscles respond, including the anterior tibialis, hip flexors, and abdominals. The timing between muscle contractions and the proximal-to-distal sequence are preset. The amplitude of contraction varies with the environmental demands and the amount and velocity of sway. In larger or more rapid sway, a different synergy is used; the person may bend at the hips and knees, or a hip strategy or a combination of hip and ankle strategies is used. If the balance loss is great enough, the person takes a step to maintain upright balance.⁷⁴ (For additional information, see Chapter 22A on balance and 22B on vestibular dysfunction). In gait, weight shifts from one leg to the other and stability after the weight shift are other aspects of dynamic balance performed through motor

patterns. The movement pattern of the swing leg in gait is limited in the number of degrees of freedom at each joint and the sequence of movement by motor patterns. There is also a specific coordination and timing of swing leg movement in relation to the stance leg movement (interlimb timing and coordination) accomplished through motor patterns. In gait, the sequence of contraction of the leg muscle from ankle to hip, the time of onset of the contraction of each muscle, and a ratio of force for each muscle is preset in the motor control program of the brain or spinal cord. If an increase in speed is needed, step length, cadence, and force can be increased within the synergy, but the basic synergies, or motor patterns, are what give identity to a gait pattern. Whether the person is walking quickly or slowly, there is an individually recognizable pattern.

In the reaching and grasping pattern, three components have been identified: the reaching portion (transport), the grasping or prehension portion, and the maintenance of balance. Reaching and maintenance of balance are accomplished through motor patterns.^{75,76} The target determines the reaching pattern. Characteristics of the reaching synergy include a distal-to-proximal sequence of firing, and movement is in a straight line with a bell-shaped velocity curve.⁷⁷ The prehension portion of reach and grasp is not a synergistic movement, and the motor-sensory cortex helps with force production and selection of muscles⁷⁸ during hand movement to meet task demands. This may be why more severe deficits are seen in the hand after cortical injury.

Anticipatory and Adaptive Responses

To meet the motor task (external) requirements, motor patterns are used and modified through a feed-forward and feedback system of control. The brain adapts motor patterns to environmental constraints, such as obstacles, by modifying the basic motor patterns’ velocity, intensity, or duration of contractions before the movement even begins. Feed-forward or anticipatory responses (often from vision and past memory of successful movements) are provided by muscles that will stabilize before the prime mover of a motion begins to fire and thus are the first muscle contraction that occurs during a movement that might disrupt stability. For example, before a rapid forward reach, the gastrocnemius muscles fire to reduce the amount of forward sway that would occur secondary to the forward movement of the center of gravity.⁷⁹

Adaptive responses use sensory feedback (visual or proprioceptive feedback is most commonly used) to improve the effectiveness of a response. After a movement, the brain checks to determine that the motor pattern matched the original “planned” pattern. Adaptive responses provide for modifications of movements, especially when the environment is changing. An example would be the ability to change the balance response when stepping from a firm surface onto a surface that is unexpectedly soft. A person will lose balance the first time but should be able to perform with good balance after several attempts. Sensory information helps fine-tune or adapt the subsequent movements within a synergistic movement. For gait, sensory impulses drive motor system adaptations to the environment. In the reaching-prehension pattern, tactile input from the fingertips (feedback) is used to make adjustments in grip force if the

initial grip was not effective.⁸⁰ Once movement occurs, there is a final comparison of the original planned pattern with the executed pattern to see whether they match; if not, then more adaptations are made.

Dynamic Pattern Theory and New Patterns

Once called *motor control theory*, the dynamic pattern theory^{81,82} addresses problems when motor behavior changes and also uses concepts of basic patterns of movement. This theory states that certain patterns are stable or unstable and that transition between patterns or to a new pattern depends on pattern stability. (See Giuliani⁸³ for a summary of this theory.) The challenge for therapists is to identify what makes these “stuck” behaviors become unstable and perhaps amenable to change. Patterns that are “set” are much more difficult to change than those that are more variable. In fact, phase transitions between old and new patterns are noted by periods of increased variability. The client appears to vacillate between the old and the new behaviors during transition phases and before new behavior establishment points. Transition phases are often frustrating for clients, as they feel unstable and may think that therapy is making them worse. Repetition is important to develop more consistent motor patterns and new establishment points; however, more important is preparing the client to expect this change.

Motor Learning

Three stages have been identified for motor learning: the cognitive stage, during which the performer begins to understand the task; the associative stage, in which performance is refined; and the autonomous stage, in which the task performance is skilled (a consistent motor pattern is formed).

Byl⁸⁴ noted that motor cortex (M1) changes occurred (motor learning) when (1) new or novel tasks were used, (2) movements were practiced together (spatial organization and temporal organization), (3) movements were frequently repeated, and (4) movements were important to the individual.

Interventions are designed to produce a task-oriented behavioral change that becomes permanent without continued therapist help or intervention. When this does not happen, the client performs well during therapy but does not seem to carry the improved performance outside the clinic. This difference between performance and learning is discussed by Schmidt.^{85,86} Many things affect motor learning, among which are knowledge of results (KR) and type of practice. (See Chapter 4.)

Knowledge of Results

Information on how successful the movement was in meeting the task goal is basic to learning. Knowledge of results (KR) consists of extrinsic information over and above that provided by the task itself.⁸⁷ During the practice portion of most tasks, increasing any type of feedback appears to improve task performance.⁸⁸ But long-term learning may be improved when KR is provided less often. The relative frequency with which KR is provided in relation to the number of trials is important in learning. Bandwidth KR, in which information is given about trials falling outside a certain range, and a random schedule of feedback appear to be effective for many learning situations in therapy. Delaying KR also improves learning.⁸⁷

Practice Type

The type of practice is important for clients who are learning new skills. A commonly used technique to simplify a task by practicing at a slower speed or practicing a part of a motor task is often not effective. For example, weight shifting is often practiced as a component of gait before walking is initiated. Winstein and colleagues⁸⁹ demonstrated that this part practice did not transfer to gait in a group of clients who had had a stroke. In a study by Man and colleagues,⁹⁰ a complex task was broken down into adaptive training methods (e.g., slower motions) and part-task training (on components of the task). Subjects who practiced the whole task had better performance than either of the other groups. A finding that practicing small components of a task does not make one better at the whole task is not too surprising. Many of us can jump, have good shoulder power, and can throw overhead but cannot, without practice, put this together to play basketball. A minimum basic amount of strength, range of motion (ROM), and interlimb sequencing is necessary to play basketball but is not adequate to play without the actual practice of the sport.

However, practicing other than the whole task may be possible. By use of the same task as that used by Man and colleagues,⁹⁰ Newell and colleagues⁹¹ showed that part-task training was effective when it was conducted in natural subtasks of the whole. These subtasks are part of the whole task but are distinguished by changes in speed or direction. This area of skill acquisition has not been studied adequately to identify subtasks of most common movements. A recent meta-analysis reviews use of part practice and methods of part practice for the most effective motor learning.⁹² Whole practice appears best for tasks low in complexity and high in organization as well as for discrete or serial tasks with high organization. An example might be a golf swing. Part practice appears effective for tasks high in complexity and low in organization, for example, dancing.

Finally, many therapy techniques that improve a client's immediate performance inhibit learning because they are based on the external controls and support provided by the therapist's manipulations, markedly changing the basic task. The types of feedback and the methods by which they are provided are critical to learning new motor skills. For example, when the hip stabilization component of walking is externally provided by the therapist during gait training, the client has no need to develop his or her own hip stabilization patterns, and feedback lacks a basic component of gait. Therefore the manual guidance may give the client a feeling of the movement pattern, but to continue to provide the hands-on control deprives the client of learning the balance and anticipatory components himself or herself.

To review, the conceptual framework for the evaluation and intervention of clients with TBI is based on distributed motor control theory, which states that movement is task or goal oriented and a result of combined systems working together to produce synergistic movement (motor pattern). Synergistic movement has an anticipatory component that is matched with sensory feedback and previous experience to contribute to task refinement through adaptation. Changes in motor behavior may be determined by how “set” the patterns are (dynamic pattern theory). They are influenced by the type of practice, knowledge of

the effectiveness of the results, and how the motor skills are broken down for practice.

EXAMINATION, EVALUATION, PROGNOSIS, DIAGNOSIS, AND INTERVENTION

Terminology and Structure for Client Management

The World Health Organization (WHO), in the International Classification of Functioning, Disability and Health (ICF),⁹³ has developed a common terminology that is used in this chapter. Definitions are as follows (also see Chapter 1 and Figure 30-2):

- *Body functions* are physiological functions of body systems (including psychological functions).
- *Body structures* are anatomical parts of the body such as organs, limbs, and their components.
- *Impairments* are problems in body function or structure such as a significant deviation or loss.
- *Activity* is the execution of a task or action by an individual.
- *Participation* is involvement in a life situation.
- *Activity limitations* are difficulties an individual may have in executing activities.
- *Participation restrictions* are problems an individual may experience in involvement in life situations.
- *Environmental factors* make up the physical, social, and attitudinal environment in which people live and conduct their lives.

The American Physical Therapy Association has published levels of client management leading to optimal outcomes.⁹⁴ The Association's *Guide to Physical Therapist Practice*, which uses examination, evaluation, diagnosis, prognosis, intervention, and outcomes as its basis, will be followed in this chapter. Although this is the terminology used by physical therapists, its application and integration into the profession of occupational therapy should be simultaneously acknowledged. The method used in this chapter for gathering the guide information is based on the Hypothesis-Oriented Algorithm for Clinicians (HOAC II) model.⁹⁵ See [Box 24-7](#) for an overview of this method, and see the text that follows for details of how to perform these items.

Examination

Data are collected from referral information, from the medical record, via observation, and from the client or family interview. A history is taken and should include information regarding the mechanism, GCS score initially, extent and time since onset of injury, client's age, and duration of PTA. This information will be used to help establish a prognosis. Other information about education, family support, and living circumstances will also help with the prognosis as well as with discharge planning. Complications as well as coexisting diseases are reviewed with the client in order to discuss a thorough care plan as well as determine appropriate referrals. Finally, the therapist will develop a list of patient-identified problems (PIPs) and a list of potential problems that could develop secondary to the injury (non-patient-identified problems [NPIPs]).

Examination should lead to an understanding of the underlying causes of the activity or participation limitations and should be the basis of the intervention program. Clients

BOX 24-7 ■ DEVELOPMENT OF INTERVENTION APPROACHES LOOSELY BASED ON HOAC II MODEL⁹⁵

- Collect initial data.
- Have client and family identify client problems with activity and participation limitations.
- Develop an initial set of hypotheses based on a task analysis of identified activity limitations; choose and apply examinations to test those hypotheses.
- Reassess hypotheses in light of examination findings and confirm or deny. Repeat first three steps if denied.
- Develop list of non-client-identified problems, including anticipated problems (such as skin breakdown when sensation is impaired).
- Choose and apply appropriate outcome measures to monitor progress that address the impairments or activity limitations.
- Develop an evaluation and diagnosis identifying why the problems exist or are likely to occur in the future.
- Establish a prognosis, and set goals with time frames for achievement.
- Develop interventions that most effectively ameliorate the problems based on current literature or best practice.
- Reexamine using outcome measures to determine progress.

usually present their problems as activity limitations, for example, "I can no longer walk very far."

Once activity limitations have been determined, a task analysis can be completed by having the client demonstrate the problem—in this case, walking. The therapist will develop a hypothesis as to why the observed deviation from typical performance is present. Tests and measures will be chosen on the basis of the therapist's knowledge of their importance in the task being performed to confirm the hypothesis. For example, in a client who drags his foot in initial swing, the client might lack 45 degrees of full passive knee flexion, but this is not critical in the task of walking. However, being able to dorsiflex the foot at initial swing is important. Therefore testing of both the ability to dorsiflex with the leg in the extended position and the speed at which the client can perform this task would be appropriate. The tests and measures should be chosen on the basis of the hypothesis that the therapist generates from the task analysis. For the components of examination, see [Box 24-8](#).

Evaluation identifies the problems that can be managed by the therapist; serves to "tease" out those factors that influence or restrict the choice of therapeutic approaches; and states which components are most critical for the identified activity limitations. Evaluation provides a qualitative means of determining why a problem is present. It includes considerations of testing, motivation, and psychosocial areas. The evaluation thus determines intervention and goals. The purpose of the evaluation is to determine what prevents the client from performing in a functional, acceptable manner as identified by the client, the therapist, and society.

Diagnosis states the various causes of the problem to determine which are most critical. The therapist has a multilevel task that includes (1) identification of the components

BOX 24-8 ■ COMPONENTS OF EXAMINATION

- I. History: injury, age, PTA, GCS score, job, home environment, educational level, previous injuries, and so on
- II. Client and family data: client and family perception of the limitations, goals, personal factors, socioeconomic factors relating to participation limitations
- III. Other health care team member evaluations
- IV. Screens
 - A. Systems review to emphasize precautions during intervention and to identify any “red flags” that will require referrals.
 1. Circulatory and respiratory
 2. Integumentary
 3. Musculoskeletal
 4. Autonomic nervous system—bowel, bladder
 5. Cognitive
 6. Language
 7. Emotional
- V. Task analyses of client-identified problems
- VI. Formation of hypotheses from the task analyses
- VII. Choose specific tests and measures to confirm the hypotheses; these might include:
 - A. Sensory
 1. Somatosensory
 2. Vestibular
 3. Visual
 4. Hearing
 - B. Integrated, perceptual
 - C. Motor
 1. Muscle strength
 2. Muscle flexibility
 3. Response speed
 4. Tone
 5. Movement speed
 6. Endurance and fatigue
 7. Complex impairments
 - Basic motor patterns available
 - Modification of motor patterns possible
 - Anticipatory and adaptive responses
 - Variability of performance
 - D. Autonomic nervous system
 - E. Cognitive
 - F. Language
 - G. Emotional

GCS, Glasgow Coma Scale; PTA, posttraumatic amnesia.

that compose a complex task or activity, and (2) evaluation of the degree to which a component’s deficit contributes to loss of body function, activity limitation, or participation limitation. Prognosis is used to determine the optimal level of improvement that may be attained based on factors as discussed earlier. Prognosis includes short- and long-term goals that are specific to improved functions along with duration and frequency of intervention to achieve those goals. The interventions are provided by skilled professionals to treat the impairments and activity and participation limitations to achieve optimal outcomes.

Outcomes must be tested and usually are chosen to measure all levels of dysfunction from impairment through participation limitation to determine effectiveness of the intervention strategies and whether or not the client has met the goals. An example of the process is presented in [Box 24-9](#).

Examination of the Client with Brain Injury**Cognitive, Behavioral, and Communication Deficits.**

[Figure 24-1](#) depicts the close association of cognitive, behavioral, and physical functioning soon after injury. The three domains gradually become more distinguishable in later stages of recovery and can be assessed more independently; however, their interrelationships remain exceedingly complex. Cognition includes many aspects of function, including memory, learning, information processing, attention span, motivation, and initiation. Cognitive impairment was the primary contributor to activity limitation in most clients with TBI who scored at moderate to severe levels on the GOS.⁹⁶ Neuropsychologists, speech pathologists, and occupational therapists all perform testing of cognitive function. These tests may include word association, written word fluency, figural fluency, and card-sorting tests. Attention can be tested with the digit span and arithmetic tests on the WAIS⁹⁷ and by serial counting by 7. Information processing is reflected in reaction time tests and digit symbol tests. Choice reaction time is an indicator of information processing and commonly remains below normal in clients with brain injury.⁹⁸ Testing of intellectual functions is often done with the WAIS. However, formal testing of intellectual function can be hampered by inadequate perceptual, visual, and motor performance. Memory can also be tested with the WAIS and with the Galveston Orientation and Amnesia Test.⁹⁹ The Mini-Mental State Exam¹⁰⁰ is a memory screen often used by health care providers to determine whether further testing is indicated. Language and cognitive problems are frequently examined by speech pathologists and/or neuropsychologists using naming tests, aphasia examinations, and tests of auditory comprehension and speed of comprehension. A widely used system of cognitive function at the activities level is based on numerous observations of clients with brain injuries at Rancho Los Amigos Hospital. This has resulted in a descriptive categorization of various stages of “cognitive function,” as shown in [Appendix 24-A](#), with use of the Rancho Los Amigos Levels of Cognitive Functioning Scale.

Examination of Motor Functions

Although most of the following sections describe motor function, motor function is only a small part of the problem of the client with TBI. Social and family problems will likely be the most devastating in the long term. Motivation, attention skills, emotional instability, memory, learning, and social deficits are all cognitive processes that prevent or retard clients’ progress in the therapy program as well as in home and work environments. Working with professionals who specialize in these areas will improve the client’s chances to escape deficits that are permanently handicapping.

Task Analyses and Common Activity Level Impairments after Moderate to Severe Injury. Often the physical therapist begins the examination at the activity limitation level. This usually involves observing those functions

BOX 24-9 ■ CASE EXAMPLE OF EXAMINATION, EVALUATION, PROGNOSIS, INTERVENTION, AND OUTCOME MEASURES FOR A CLIENT WITH TRAUMATIC BRAIN INJURY

EXAMINATION

A client comes to your clinic reporting that he falls several times a week during walking and would like to improve his balance. He is 21 years old and suffered a moderate traumatic brain injury (TBI) 6 weeks ago. He had a Glasgow Coma Scale (GCS) score of 11 initially and 1.5 days of posttraumatic amnesia. He was at ABC Rehabilitation Center for 5 weeks and was discharged home last week. He lives with his parents in a single-story house. He is in his third year of college studying geology.

His systems review demonstrates slight decreased vital capacity of 3.8 L (4.6 L would be normal), but no abnormalities in the musculoskeletal systems or integumentary system. His cognitive functions are within normal limits according to neuropsychological testing, except for memory deficits.

TASK ANALYSIS

You observe this client during walking and note that he has decreased knee flexion in preswing and decreased dorsiflexion throughout swing phase, with the toe intermittently catching on the carpet when you have him speed up his walking. He also has decreased dorsiflexion at initial contact and in terminal stance.

HYPOTHESIS AND HYPOTHESIS TESTING

Because of the decreased dorsiflexion in terminal stance (which is passive), you hypothesize that the decreased dorsiflexion is secondary to gastrocnemius-soleus muscle tightness rather than anterior tibialis weakness. You test the range of motion (ROM) at the ankle, and it is within functional limits. You now develop a second hypothesis that there is increased tone in the gastrocnemius-soleus. On an Ashworth test, the client scores a level 3 for the gastrocnemius-soleus. Because the client does not get adequate plantarflexion at pre-wing (neutral versus 15 degrees for typical adults), you also hypothesize that the client is unable to generate plantarflexion fast enough in preswing to achieve the normal 15 degrees of plantarflexion. Testing by having the client plantar flex rapidly in standing shows that it takes a full 3 seconds to achieve 15 degrees of plantar flexion—much too long to be used in walking.

EVALUATION

The client is experiencing multiple weekly falls secondary to toe drag at initial swing when walking at speeds over 70 m/min. The toe drag comes from decreased dorsiflexion and decreased knee flexion at initial swing because of inadequate plantarflexion. Testing demonstrated both increased gastrocnemius-soleus tone (Ashworth level 3) and decreased ability to generate adequate plantarflexion to achieve the normal 40 degrees of knee flexion during preswing.

PROGNOSIS AND GOALS

The client has a good prognosis. He is early postinjury, is young, and has good family support and a high education level. There is no history of previous TBI. The client started rehabilitation immediately and in a center specialized for people with TBI. His posttraumatic amnesia was short.

Goals

1. The client will achieve 15 degrees of plantarflexion in preswing during walking at 90 m/min within 3 weeks and will be seen 3 × weekly × 3 weeks.
2. The client will not experience any toe drag during swing phase of gait while walking at 90 m/min or faster in 6 weeks. The client will receive 4 × weekly × 30 min body-weight-supported treadmill training (BWSTT) with functional electrical stimulation (FES) to the anterior tibialis muscle to accomplish this.

OUTCOME MEASURES

Gait speed, electromyography (EMG) for onset of contraction of the gastrocnemius-soleus, Rancho Los Amigos observational gait evaluation.²¹²

INTERVENTIONS

BWSTT: Because there is only one study of BWSTT in subjects with acute TBI that did not measure changes in ankle motion or gait speed, the literature for cerebrovascular accident (CVA) was used. This literature shows improved gait speed overground and improved findings on EMG of ankle dorsiflexors in organization of contractions and timing.¹⁸⁶

FES to gastrocnemius-soleus to improve timing and angle of plantarflexion during gait.

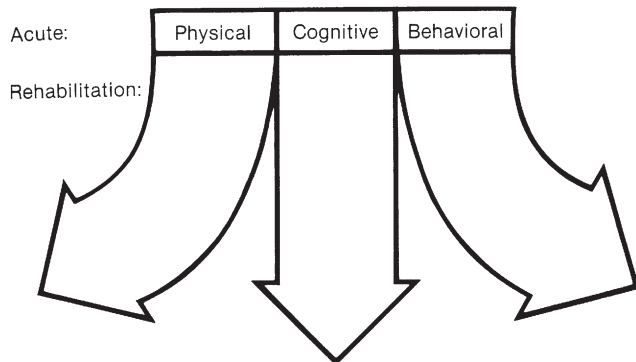

Figure 24-1 ■ Schema representing the close association of cognitive, behavioral, and physical functioning soon after injury. The three domains gradually become more distinguishable in the later stages of recovery.

that the client or family identifies as problems. Activity limitations in clients with TBI range over the entire spectrum of problems depending on the severity of injury. They may include loss of mobility in bed, coming to sit, sitting to standing; loss of household and community ambulation; loss of running, jumping, and kicking skills; poor reach and grasp; loss of throwing and batting skills; loss of activities of daily living (ADLs) such as dressing, toileting, and feeding; and loss of instrumental ADLs such as shopping and driving. The physical or occupational therapist performs a task analysis of the impaired function by comparing the client's performance of the task with typical task performance. For example, the therapist would observe the client performing the sitting-to-standing activity, observing that there is inadequate forward trunk momentum in the preextension phase.¹⁰¹ A reasonable hypothesis may be that the client is fearful of falling forward.

If the problem is loss of balance in the extension phase, a hypothesis may be poor timing of the gastrocnemius firing. Both these hypotheses are based on the task analysis but also on the literature, which defines the importance of trunk momentum to initiate seat-off and timing of gastrocnemius firing during the end of the sitting-to-standing activity to maintain balance.

Examining activity limitations requires the understanding of the performance of the task in healthy individuals of about the same age as the client. Tasks that are described in the literature for typical performance include rolling, rolling to sit, sitting, sitting to standing, standing to sitting, standing balance, walking, hopping, jumping, kicking, running, reach and grasp, throwing, batting, and golfing. Task descriptions are part of therapists' basic educational programs. An example of a task analysis form developed at Regis University, School of Physical Therapy for sitting to standing is shown in Appendix 24-B.

Impairments

Once the task has been analyzed, the impairments leading to poor performance of the task are identified. Breaking motion down to its most basic components may be helpful, but two caveats are necessary. First, improvement in abnormal components may not lead to improvement in activity limitations.

Impairments can be identified and evaluated for their contribution to an activity or participation limitation. Some

critical impairments will have more influences on an activity than will others. For example, in children with cerebral palsy who have gait disabilities, Olney and colleagues¹⁰² demonstrated that poor force output by ankle plantarflexors during the late stance phases of gait was the most important factor in poor gait performance within this population. Another example comes from Perry and colleagues,¹⁰³ who showed that for normal walking velocity to be attained, although cadence and stride length are important, a strength level of 3+/5 is a critical component in the ankle muscles. Deficiencies of timing, strength, or sequencing can contribute to poor hand function, but sensory deficits at the hand level may be the critical impairment related to poor manipulation skills. In addition, impairments in the circulatory, respiratory, integumentary, and musculoskeletal systems can account for activity limitation in the client with TBI (Figure 24-2). Relative contributions of the impairments to the activity limitation or participation limitation are addressed by the therapist's task analyses, hypothesis, subsequent evaluation, and diagnosis,¹⁰⁴ which will determine the focus of the intervention program. Second, treating the individual impairments will not necessarily result in the client learning a skill. Skills result from an organization of many motor functions together and require whole task practice. Conversely, not having a critical component, such as arm strength, may be the one factor preventing a person from learning to perform a skill (e.g., enough force cannot be generated to throw a ball 5 feet in the air to hit a basket).

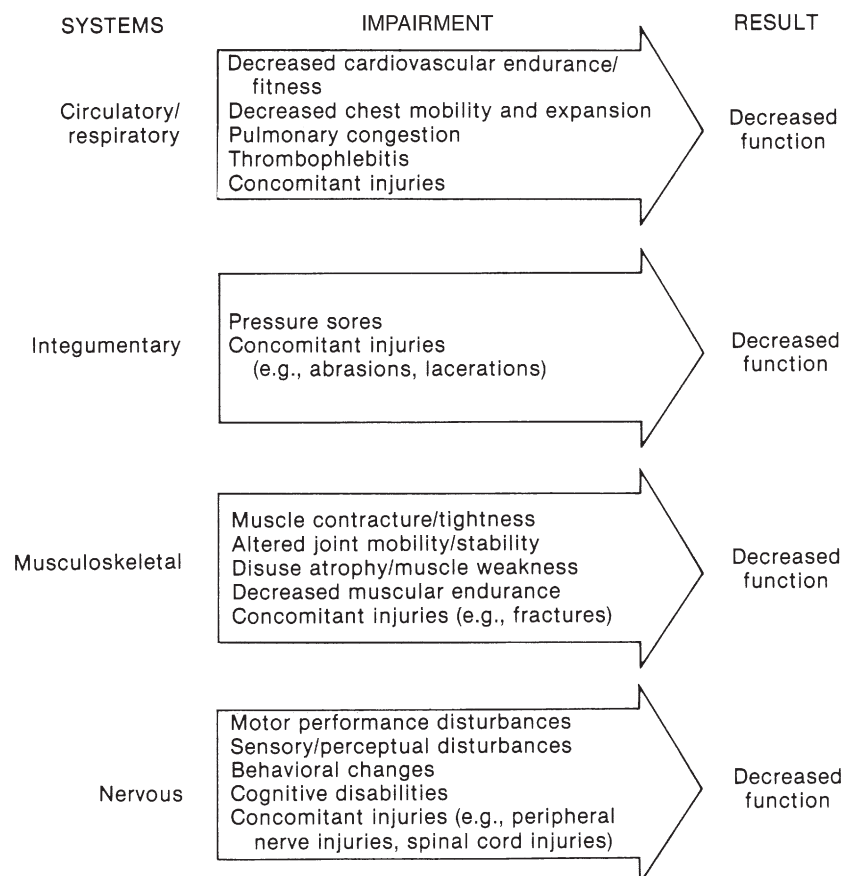

Figure 24-2 ■ Therapists develop intervention strategies to deal with functional deficits that may result from a variety of problems occurring primarily in one or more of the body systems depicted.

Many examinations address the impairment level. These include muscle strength tests, flexibility (ROM) tests, speed of motion, reaction time, sensation, vision, vestibular, tone, and proprioceptive examinations (see Chapter 7).

Impairments that Are Common after Traumatic Brain Injury and Measuring Impairments

Strength or Force Production

Evidence consistently shows that strength and force production are problems in both the upper extremities and lower extremities after TBI. In cases in which strength control or force gradations are significantly impaired at initial admission (about 25% of clients), these problems had generally resolved at a 2-year follow-up, with only 12% of problems remaining in the upper extremities and 7% in the lower extremities.¹⁰⁵

In the case of upper motor neuron lesions, weakness can be a major problem. The number of motor neurons activated and the type of motor neurons and muscle fibers recruited affect force. Motor neurons in the motor cortex can be deficient, leading to disordered and reduced recruitment. Individuals with brain damage show early atrophy and loss of motor units, as well as motor units that fatigue easily.^{106,107} Disuse, cast immobilization, joint dysfunction, improper nutrition, drugs, and aging can cause differential weakness with altered morphological, biochemical, and physiological characteristics within the muscle.¹⁰⁸ EMG studies by numerous investigators^{109,110} suggest that reduced activity alters motor unit properties, discharge frequency, and recruitment patterns. Performance problems are reflected in the inability to generate force in different directions and against different loads as well as in problems sustaining force output.¹¹

Changes in muscle length affect strength. In clients who have had a cerebrovascular accident (CVA), shortened muscles tend to be strong in short ranges and lengthened muscles are strongest in lengthened ranges but weak in shorter positions compared with the strength-length curves of normal muscles.¹¹¹

Strength or force may be examined functionally—for example, by seeing if the client has enough strength to lift the arm overhead, out to the side, and up to the mouth or is able to go from sitting to standing. In some cases, such as those in which the client is unable to perform balance reactions or has been on extended bed rest, testing individual muscles may be important. Traditional manual muscle testing (MMT) with force transducers or strength testing with isokinetic testing¹¹² throughout the range provides good strength information. The level of testing chosen should be consistent with the deficit and the therapist's knowledge of its importance in contributing to the activity limitation.

Flexibility

Flexibility at the muscle and joint level is important. Muscle atrophy occurs rapidly¹⁰⁶ and changes in muscle fiber type and function can be seen as early as 3 days. Viscoelastic properties change with paralysis so that the muscle feels stiffer.^{113,114}

Examinations should determine the contribution of both tone and tissue factors in limiting flexibility. Active and passive motion should be compared because stiffness (not

contracture) often prevents good function. For example, active dorsiflexion is often limited in clients who have full passive ankle ROM because stiffness begins at neutral. The functional result is foot drop or toe catch in the early part of the swing phase of gait because the anterior tibialis muscle cannot generate adequate force production to overcome the stiffness in the gastrocnemius and soleus. This restriction also may limit forward movement of the tibia over the foot during the stance phase of gait, resulting in hip retraction or an apparent balance loss. Knee hyperextension also can result from lack of forward motion of the tibia.

Flexibility measurements are done with goniometers, motion analysis systems, tape measures, inclinometers, photographs, or electronic devices. Taking both passive and active measurements is critical in identifying intervention approaches.

Tone

In the motor learning theories of today, many of the behaviors and resulting motor patterns after brain injury are seen as attempts by the CNS to compensate for loss. For example, spasticity (increased tone) may be the result of an attempt to compensate for the client's inability to increase force. When the amplitude of a contraction cannot be increased because of the injury, the CNS may increase the length of time the muscle fires or may recruit muscles not normally used in a particular pattern of movement; both are characteristics seen in spasticity.

Whatever the cause of increased tone, the therapist can evaluate tone at two levels: is it interfering with function, and, if so, can it be changed? Spasticity is not a single problem.^{107-110,113,115-119} Spasticity can have any or all of the following characteristics:

- Changes in response to stretch
- Decreased ability to produce appropriate force for a specific task
- Increased latency of activation
- Inability to rapidly turn off muscles
- Loss of reciprocal inhibition between spastic muscles and their antagonists
- Changes in the intrinsic properties of the muscle fibers
- Inability to generate enough antagonist power to overcome spastic muscles

Examination begins with identifying whether there is increased or decreased muscle tension at rest. If it is increased, is the tension at the muscle level (stiffness or sarcomere involvement) or the neurological level? Muscle stiffness resulting from tissue changes is common in the client with brain injury. If there is increased tone during movement, EMG may be beneficial to determine the nature of the tone. Is it a problem of co-contraction of agonist and antagonist at a joint? Is it a problem of prolonged contraction? Or is it poor sequencing, either temporally or spatially, of other muscles involved in the movement?

Spatial sequencing of movement involves the contraction of a preset group of muscles. Temporal sequencing involves muscles contracting in a fixed sequence. EMG and video analysis provide additional depth of information regarding the sequence and timing of movement patterns (Figure 24-3). For example, is the normal temporal sequencing in the distal-to-proximal manner present in the upper extremity during a reaching task? In a balance reaction, are the ankle, hip, and

Figure 24-3 ■ Measurement of the sequence of contraction of gastrocnemius and hamstring in forward perturbation with dual-channel electromyographic surface electrodes.

back extensors (spatial sequencing) all contracting in response to a forward perturbation? The most commonly used tool in examination of tone is the Ashworth Scale or Modified Ashworth Scale¹²⁰ (Box 24-10). The Tardieu Scale¹²¹ is similar, but testing is done at three different velocities and may provide a clearer picture of what is caused by tone

BOX 24-10 ■ MODIFIED ASHWORTH SCALE

Grade	Description
0+	No increase in muscle tone
1+	Slight increase in muscle tone, manifested by a catch and release or by minimal resistance at the end of the range of motion (ROM) when the affected part(s) is moved in flexion or extension
1	Slight increase in muscle tone, manifested by a catch, followed by minimal resistance throughout the remainder (less than half) of the ROM
2	More marked increase in muscle tone through most of the ROM, but affected part(s) easily moved
3	Considerable increase in muscle tone, passive movement difficult
4	Affected part(s) rigid in flexion or extension

Reprinted from Bohannon R, Smith M: Interrater reliability of a Modified Ashworth Scale of muscle spasticity. *Phys Ther* 67:207, 1987, with permission of the American Physical Therapy Association.

versus muscle shortening. Testing of deep tendon reflexes identifies problems with stretch reflexes, and surface EMG (sEMG) can determine the presence of co-contraction, prolonged contraction, sequence and timing problems, and increased latencies.

Speed of Motion

Research shows that seemingly different movements may actually be spatially the same (same muscles involved) but may appear different because of pauses within the movements, velocity, or speed.¹²²

Measurements include how quickly a joint can be moved actively. Recording the number of repetitions of a movement in a specific time frame provides an easy clinical measurement. Isokinetic instruments can measure partial- and whole-extremity motion speed. Speed of movement at each joint in a synergistic movement (videotaped or movement analysis systems) can help with analysis of function. Is poor performance the result of speed of movement problems in just one part of the motor pattern or in all parts? Computerized motion analysis techniques can also help examine speed of motion relationships between and among limb segments, which is particularly useful in assessing upper-limb movements such as reaching and grasping activities.

Reaction Time

How fast can the client begin motion? This parameter can be measured by EMG or with other computerized equipment.

Simple reaction time examination gives insight into the time for neurological processing because it is the measurement of time from a stimulus to a response. Rapid reaction times may be critical for many patterns to be effective, but especially for automatic patterns such as balance responses. Simple reaction times appear impaired even long after TBI (moderate to severe),¹²³ although there is conflicting literature in this area.

Testing of reaction times is usually performed with computerized testing with a visual or auditory cue used as a stimulus, then the time to a motor response (usually at the hand or foot) is measured.

Endurance and Fatigue

Fatigue, which is separate from impaired endurance, may result from increased energy requirements resulting from less efficient motor patterns or from more CNS activity. Fatigue is a common complaint after TBI¹²⁴ and is associated with insomnia.¹²⁵ Testing for fatigue is difficult. There are a few paper and pencil tests, including the Chalder fatigue scale.¹²⁶

Muscle endurance refers to the ability of a muscle to produce the same level of contraction over time. The subjective feeling of effort and weakness after fatiguing exercise may be related to the need to recruit more motor units and to increase the mean firing frequency of the motor units to maintain constant force output.¹²⁷ EMG with medium-frequency analysis can test this type of fatigue. Fatigue can also be assessed by measurement of maximal voluntary force, maximal voluntary shortening velocity, or power.¹²⁷ Decreased force production, prolonged time to relaxation of muscle fibers, and recruitment of additional muscles during an activity are characteristic of fatigue.¹²⁸ Although repeated muscle testing can pick up decreased strength in specific

muscles, in most instances overwork fatigue is first noted by an altered pattern of movement of body segments during activity.

Cardiovascular endurance determines how effectively the body can use oxygen and how soon fatigue sets in. This type of endurance can be measured with several bicycle tests^{129,130} and with a treadmill using the Bruce¹³¹ protocol or a branching protocol for clients with less endurance. A simple test is heart rate before and after activity; the less change and the more rapid the return to resting rate, the better the client's fitness level. The 3- and 6-minute walk tests are also reliable and valid for endurance testing.¹³²

Incoordination

Ataxia was one of the most common findings among military personnel who had sustained TBI,¹⁰⁵ with 32% of clients showing ataxia initially and 14% at the 2-year follow-up. There are many subcategories of ataxia, including dysmetria, rebound, diadochokinesia, and intention tremor. Many clinical tests are available. Common tests include having the client touch an index finger to the examiner's finger and back to the client's nose. Running the heel up and down the opposite shin is a test for ataxia in the lower extremity. For a list of coordination tests see Chapter 21.

Sensory Function

Various sensations can be impaired. Problems in the sensory system are often reflected in the motor system, creating distorted movement through faulty information in the feed-forward or feedback processes.

Two broad categories of sensations can be defined on the basis of the type of information: primary sensations and cortical (or integrative) sensations. This arbitrary division is useful functionally but it is not anatomically based. Primary sensations include exteroception and proprioception. The exteroceptors of smell, sight, and hearing are sometimes referred to as *teloreceptors*. Vision, hearing, olfaction, gustation, pain, touch, temperature, position sense, and kinesthesia are commonly checked primary sensations. Sensations cannot be clinically tested definitively without client participation. Further evaluations of sensation are provided in specific systems.

Proprioception, Light Touch, Two-Point Discrimination, and Stereognosis. After TBI, sensory deficits are common. Deficits associated with poor balance included a high number of subjects with discriminative touch deficits (20 of 27 subjects),¹³³ an impairment related to poor upper-extremity function.

Traditional examinations of proprioception include the ability to distinguish motion and motion direction at each joint. Some clients who cannot distinguish direction or movement still function well. They may have proprioceptive function at the unconscious level (e.g., cerebellar) while not perceiving the input at the parietal level (conscious level).

Testing is performed by having the client close his or her eyes; then the therapist places a joint in a specific position (e.g., flexed, extended) and asks the client to copy the position with the uninvolved limb. Asking the client to close the eyes and identify when the therapist passively presents small movements of a joint while the client indicates specific direction of movement can also test proprioception, especially for those with multilimb involvement. Very small joint

movements of about 1 degree are within the discrimination level of typical individuals.

Light touch is tested with a brush for localization and quality of sensation. For more definitive light-touch discrimination, especially on the hands and feet to determine peripheral neuropathies, a monofilament test¹³⁴ can be used. Two-point discrimination can be tested with instruments specifically designed to measure how far apart two separate spots of contact need to be to identify them as distinct. For clients who are thought to be ignoring stimuli on one side, testing at the same time bilaterally is first performed, and then each limb is retested separately. Clients who extinguish stimuli will respond that they feel only one stimulus when both limbs are tested simultaneously but will perceive the stimulus just fine when each limb is tested separately. This is called the *bilateral extinction test*.

Stereognosis. Stereognosis, the ability to identify objects placed in the hand without visual assistance, may be critical to normal hand use. The therapist places multiple objects, such as pens, coins, and safety pins, in the hand and asks the client (eyes are closed) to identify the objects.

Vision and Visual Perception. Vision is critical in recovery of many motor functions because it is responsible for much of the feed-forward or anticipatory control of movement as well as the initial development of a movement pattern. For example, balance can be maintained through the visual system by modifying synergies before surface change occurs. Feedback through the peripheral field through the movement of the visual array on the retina can also trigger balance responses. Campbell¹³³ found problems with visual functions in most clients with mild to moderate TBI; these problems involved poor visual acuity (48%) and problems with vergence (85%), which can cause blurring and doubling of vision, and smooth pursuit (63%), which can cause a "jumping" of the visual image.

Some clients are able to use their hands for grasp and release, in spite of severe somatosensory deficits, when they are able to use vision to guide the motion; therefore many of the standard movement tests should be performed with and without vision.

General visual functions can be screened by the physical or occupational therapist as follows:

1. Tracking is assessed by use of an H pattern of movement of the object being tracked. The examiner observes any nystagmus or refixation saccades. Eye muscle paralysis can be observed during tracking if the client cannot move the eye(s) laterally, up, down, or medially.
2. Focus or accommodation can be checked by observing constriction and dilation of the pupil. Constriction occurs as an object is moved toward the nose, and dilation as the object is moved away from the nose.
3. Binocular vision is controlled through feedback from blurred or doubled vision. This reflex signals whether the eyes and fovea are focused on a single point or target, as the images in both eyes fall on the same retinal points. A "cover test" can screen for binocular vision. The client stares at an object at about 18 inches from the nose. The therapist covers one eye. If there is movement to adjust the remaining uncovered eye back to the object, both retinas may not be focusing on the same point. Observing whether light reflections fall on

exactly the same place on both pupils is useful in evaluating binocular eye focus. Vergence testing can also be an indicator of binocular visual functions.

4. Visual fields can be grossly tested by having the client look forward at a point (observer sits in front of the client to be sure the client remains focused straight ahead [Figure 24-4]). The client indicates when he or she first sees an object coming into the peripheral field from behind, or the “spotter” notes when the client looks toward the object.
5. Vergence is tested by having the client observe an object or pen tip as it is brought from about 20 inches away. The client is told to follow the object with his or her eyes. The object is moved at a moderate speed toward the bridge of the nose, and the client reports when the object becomes blurred or doubles. When typical convergence is present, there will be no blurring or doubling until the object is 2 inches away or closer, and when the object is moved back out, the client will report the object as single within 4 inches.
6. Visual interactions with the vestibular system are assessed through the vestibuloocular reflex (VOR). This reflex maintains a fixed gaze on a target as the head moves. The object should not appear to blur, move, or double during head motion at various speeds.
7. Perceptual tests that evaluate how visual information is used include visual memory tests, cancellation tests, and figure-ground tests.
8. Visual acuity is tested using a Snellen eye chart. Poor acuity can affect balance responses.

Neuro-optometrists and neuro-ophthalmologists are appropriate referrals for clients needing in-depth visual workups, especially when visual perception is involved.

Figure 24-4 ■ Testing of peripheral visual fields from behind the client.

See Chapter 28 for additional information on vision and visual testing.

Vestibular System. The vestibular system monitors the position of the head in space and helps distinguish when the body is moving from when the visual surround is moving. It also provides a vertical reference to gravity to maintain the head upright. Vertigo, dizziness, eye-head incoordination, and postural and balance complications occur as a result of problems in the vestibular-cerebellar systems.

Clients with mild or moderate TBI have a high rate of complaints of dizziness.¹³⁵ In many cases the dizziness is a sign of vestibular dysfunction.¹⁰⁵ Campbell and Parry¹³³ found that 26 of 27 clients with TBI and poor balance also had abnormal VOR testing results. Impairments that can occur with vestibular injury after TBI include verticality and orientation dysfunctions.^{79,116,117,133,136}

The VOR is indicative of vestibular system dysfunction. Vestibular tests can be performed at the screening level to note dizziness with body, head, or eye motions. A practical division includes testing head movement in lying, sitting, and standing positions. Vestibular system evaluation and training¹³⁷ is one such outcome test. Symptoms occurring only with specific head movements can be an indicator of problems in the semicircular canals. Benign paroxysmal positional vertigo (BPPV) is common after brain injury. Dizziness with head tilts might indicate problems in the otolithic system. In-depth evaluation tools may be used when clients are symptomatic, and clients can be referred for electronystagmography, the gold standard for diagnosing unilateral peripheral vestibular dysfunction. See Chapter 22 for additional information on balance and vestibular testing.

Anticipatory Reactions

Anticipatory reactions are dependent on learning. They require combining past information with present information to make motor responses appropriate to internal and external needs. Forces that stabilize limbs or the trunk during movements occur before the firing of the prime mover. The disruption of balance that would occur before moving must be anticipated and counterbalanced before the movement even begins. For example, does the gastrocnemius muscle contract before forward-reaching activities to prevent forward movement of the center of gravity? Does the client shape the hand for picking up objects? Almost all motor functions have an anticipatory component. Use of sEMG can help determine the presence of common anticipatory responses. Visual observation may provide some information about anticipatory responses also. For example, does the client walk smoothly over or around objects, or does he or she need to stop, slow down, or make corrective responses? When reaching or stepping during sitting or standing, does the client fall or lean in the direction the limb moves?

Adaptation

Feedback is used to modify and fine-tune responses. Observation is often used by providing the client with an unexpected perturbation after several expected perturbations. The initial response is usually poor, but as the same perturbation is repeated, the response improves. Other observations can include whether the activity is corrected to meet changing environmental conditions. When not successful at task

performance, does the client use the information to modify or adapt subsequent responses? Is the adaptation appropriate, or does it result in poorer performance?

Activity Level Dysfunction and Testing

Although there are no data on frequency of problems with rolling and rolling to sit in the literature, a recent study of multiple centers that treat clients with acute TBI showed that sitting balance,¹³⁸ sitting to standing,¹³⁹ and losses of standing balance, gait, running, and reaching and grasping have high incidences of impairments at admission.

Sitting Balance

Brown and colleagues¹³⁸ found sitting balance to be impaired in 52% of the clients with TBI at initial examination in their review. Testing includes static sitting without arm support and dynamic sitting with the client reaching in multiple directions.

Standing Balance

Standing balance after TBI is usually affected in mild, moderate, and severe injuries, with 82% of clients showing standing balance problems. Problems include both motor strategy problems and appropriate use and integration of somatosensory, visual, and vestibular information. Newton¹⁴⁰ reported that clients with moderate and severe TBI showed significantly impaired reaction times to perturbation in standing. Although they could grade their responses to the perturbations appropriately, the responses were often asymmetrical.

Balance is tested with feet shoulder width apart, feet together (Romberg), and feet in tandem (sharpened Romberg) with eyes open and eyes closed. A Clinical Test of Sensory Interaction on Balance (CTSIB) test¹⁴¹ is used to test sensory balance components. Perturbations to balance can be used to examine motor components of ankle, hip, and stepping strategies. See Chapter 22.

Gait

People with TBI walk with a significantly slower speed than matched healthy controls. There is a significant difference between groups for cadence, step length, stance time on the affected leg, double support phase, and width of base of support. The most frequently observed biomechanical abnormality is excessive knee flexion at initial foot contact. Other significant gait abnormalities are increased trunk anterior and posterior amplitude of movement, increased anterior pelvic tilt, increased peak pelvic obliquity, reduced peak knee flexion at toe-off, and increased lateral center of mass displacement. Walker¹⁰⁵ found that testing of clients using the tandem gait identified the most frequent physical impairment remaining at a 2-year follow-up in a group of people with TBI. He suggests using tandem gait as one part of the clinical examination for all clients with TBI.

The Barthel Index,¹⁴² FIM,¹⁴³ Tinetti assessment,¹⁴⁴ Gait Assessment Rating Scale,¹⁴⁵ and Motor Assessment Scale¹⁴⁶ also examine different components of gait but more at the activity limitation level. Speed of walking for functional activities such as crossing a street at a stoplight and endurance can be measured by distance and a stopwatch.¹⁴⁷ Endurance can be measured with a 6-minute walk test.¹³²

Reach and Grasp

Numerous problems occur during reaching and grasping. Tests such as the Nine-Hole Peg Test and the Purdue Pegboard Test provide a standardized means of measuring reach and grasp using a timed method. The Motor Assessment Scale has an upper-extremity component that is validated to use alone. The Frenchay Arm Test measures functional use of a dominant hand.

Grip Force. Problems with grip include inability to grade force. Measurements can be done using hand-held dynamometers and asking clients to reproduce specific amounts of force.

Complex Task Level Problems

Although many of the movement problems observed in clients with TBI are at the impairment level, some are at a higher level. Complex task evaluation—evaluation of how movement works as a whole—requires extensive knowledge of abnormal and normal movement. This type of evaluation looks at larger movements involving many joints or even the entire body and may be considered from the point of view of motor control theory as described in the following sections.

Are Basic Motor Patterns Available, Accessible, and Used Appropriately?

Are the three basic components of movement all present? They are as follows¹⁴⁸:

1. Reflex responses that are involuntary, such as the withdrawal reflex.
2. Rhythmic motor patterns, such as walking, that initiate and terminate a sequence of voluntary movements; the movements are relatively stereotypical and almost automatic.
3. Voluntary (volitional) movements that are purposeful, goal directed, complex, and learned. Playing the piano would be an example of this type of movement.

Starting at the reflex level, are reflexes such as swallowing, visual tracking, and smiling intact? Injury at this level may affect basic motor program production and sequencing. Are automatic movement patterns present (e.g., balance synergies, walking, and running)? Are volitional or voluntary movements present?

Are the Basic Motor Patterns Being Selected or Modified to Meet Specific Task Requirements?

Many of these functions are associated with cerebellar functions, which provide tone, timing, coordination, and amplitude of motions. The synergistic system smooths out the motor program and provides adaptability. One of the contributions of synergy use is the ability to limit the degrees of freedom in a movement. Is the client able to use the basic motor patterns in a functional manner? Is the client able to modify and then accomplish activities such as rolling over, coming from sitting to standing, standing, walking, reaching, picking up objects, and ball catching? Is there good interlimb coordination as demonstrated by coordinated two-handed activities, good timing between limbs in walking, and jumping? Does the client appear to have the ability to coordinate motions (decrease the degrees of freedom), or are they limited by too few degrees of freedom? Does the client respond correctly to environmental changes or stimuli such as stepping over or around objects or being able to walk on

different terrain? When motor patterns are used, are they appropriate for the stimulus? For example, is the ankle strategy used for standing on a firm surface and when stopping walking?

Variability of Performance

The plastic nervous system can adapt and change its motor output to meet different requirements. VanSant¹⁴⁹ showed that children and adults vary in the way they stand from supine, even under the same environmental conditions. She states that the most striking observation in nondisabled individuals is this variability of performance. The lack of variability has been suggested as a sign of system damage.⁸⁶ When the client with brain injury is assessed, the therapist should look for variability of performance in basic motor acts. Can the client accomplish the same task in several ways? Can the client adapt to different task demands? As the complex task is being performed, keep in mind that the extent of deficit is important. To what extent is the observed motor behavior involved? Is the behavior totally absent, is it deficient, or are there signs of substitution of function or adaptation?

Following is an example of the examination process. The client complains of difficulty in walking and is experiencing several falls daily. Walking requires several complex elements including extensor strength, postural control, and balance.¹⁵⁰ First, a task analysis is performed, and in this case the therapist would look at the gait pattern, perhaps using the Rancho Los Amigos Observational Gait Analysis to analyze the kinematic aspects of the pattern. The therapist then hypothesizes about specific problems observed during the task (gait) analysis. For example, if the client is dragging his toe in swing and does not have adequate knee flexion in this phase, the therapist might hypothesize that the thigh is advancing too slowly (speed of motion impairment) to promote good knee flexion and that dorsiflexion is limited because of poor anterior tibialis activation (force production problem). Timing the speed of hip flexion and doing MMT might confirm or rule out these hypotheses.

If postural control appears to be the problem, the therapist observes the client in standing, noting that the client leans to the left. The therapist may hypothesize that head-righting reflexes are not intact. This might be tested by leaning the client to the side with eyes closed to determine head-on-body righting. Is the head righted to the body or to gravity (as is normal in adults)? Examination for verticality would include lying, sitting, or standing with the body vertical, both with eyes open where vision can control verticality and with eyes closed to examine somatosensory and vestibular control of posture and verticality. If the walking problem appears to be in the client's balance system, then use of sEMG on the leg muscles will determine whether the client is using balance synergies with a temporal sequence of distal to proximal contraction (ankle strategy) during small perturbations. Does the client use only the appropriate muscles in balance responses (spatial sequence)? Or is the client co-contracting, indicating a temporal or spatial sequencing problem that disrupts the normal motor patterns? Is there efficient movement in the swing leg? Does it move in a straight line, and is foot placement on the floor appropriate (coordinated movement)? Does closing the eyes change the character of the movement? If it does, the client may be

controlling movement by vision without regard to vestibular and somatosensory input. The therapist may hypothesize that sensory influences on balance are impaired and choose to do the CTSIB to confirm this hypothesis. Does the client step over objects placed or rolled in front of him (anticipatory and adaptation)? If not, was it because the client misjudged the height of the object (visual anticipatory responses) or misjudged the distance to move the leg (modification of the locomotion synergy at the amplitude level)? Is movement too disorganized (uncoordinated) to clear the object? The therapist may hypothesize a problem in timing of the leg movements and confirm the hypothesis diagnosis with sEMG.

Prognosis for Improvement by Activity Limitation

In a review⁶³ of long-term problems after moderate or severe TBI, standing balance was most impaired initially (82%) and at 1-year follow-up (24%) compared with other systems. Sitting balance was impaired 52% of the time initially but only 5% at the 1-year follow-up. Strength was more often impaired (about 42% of clients) than coordination (40%) or tone (20%) but showed significant improvement, with less than 20% of clients being impaired in strength and less than 10% in coordination or tone at the 1-year follow-up. Dysphagia was present in 40% of the clients but in only 0.4% at 1 year.

INTERVENTION

Intervention Efficacy

The goals of intervention are to help a client work in the environment to produce movements that are efficient, successful, and to some extent socially acceptable, and to prevent secondary problems from developing. Bach-y-Rita¹⁵¹ and others¹⁵² stated that long-term rehabilitation is key to improved motor control and that recovery can continue to occur as long as the brain is challenged.

The concept that the external environment influences structural neural changes is basic to physical and occupational therapy interventions—that is, activities in which a client participates change brain structure and organization.

Evidence that mammalian brain anatomy and function are modifiable by environmental factors was first irrefutably demonstrated by Wiesel and Hubel,¹⁵³⁻¹⁵⁵ who described the importance of environmental experience on functional development of brain cells in the visual cortex of kittens. These experiments showed that visual experiences determine the synaptic organization of neurons in the visual cortex. Devor and Wall¹⁵⁶ demonstrated this same type of plasticity in other sensory systems.

That intervention makes a difference in recovery after brain injury has been shown in many studies. In studies by Mitchell and colleagues,¹⁵⁷ kittens were deprived of sight by having one eye sutured shut. Recovery of vision occurred in the sutured eye only if the animal was forced to use that eye. Tower¹⁵⁸ demonstrated that when brain lesions caused limb dysfunction, monkeys did not use the involved limb, but if the remaining useful limb was restrained, the monkeys used the original “useless” limb for climbing and other activities. Similarly, Wolf and colleagues¹⁵⁹ and Taub and colleagues¹⁶⁰ showed that function in hemiplegic upper extremities is

improved through use of constraint-induced therapy (CIT) by constraining the uninvolved arm, thus forcing use of the involved arm. Liepert¹⁶¹ demonstrated neuroplastic changes in the motor cortex of clients who had sustained a stroke as the basis for improvement with CIT. Whether this is from learned disuse, as suggested by Taub and colleagues,¹⁶⁰ or by deactivation of silent synapses is unknown.

Jones and colleagues¹⁶² looked at the effects of general versus complex exercise in rats after cortical injury on plasticity by use of a general exercise of walking through a tunnel versus a complex exercise (acrobatics). The researchers monitored recovery by looking at upper-limb coordination tasks and also by the number of new synapses per neuron and the number of multisynapses formed. The rats doing complex exercise showed significantly more multisynaptic formations and better limb coordination. Avoiding excessive use of the intact limb may also prevent impaired recovery of the involved limb, according to a study on rats by Jones and Schallert.¹⁶³

Active participation is also important in motor learning, as Held's¹⁶⁴ experiments demonstrated. Activities that allow practice of the specific task have been proven effective. Walking on a treadmill with partial body-weight support (Figure 24-5) provides practice of the walking pattern and has been widely effective in improving overground gait

Figure 24-5 ■ Client using a partial body-weight system on a treadmill intervention with functional electrical stimulation on the right peroneal nerve to assist with dorsiflexion during the swing phase of gait.

parameters such as speed and improved pattern in a variety of neurological dysfunctions.^{165,166} Whether treadmill walking is as effective as body-weight-supported treadmill training (BWSTT) for clients with TBI has not yet been determined, but there is evidence that this may be the case.¹³⁹

Several authors have suggested that activation of the motor patterns by imagining movement⁸⁴ may be possible. In a study by Porro and colleagues,¹⁶⁷ motor imaging activated the same regions of the brain as motor performance; signal density was 30% as great as in real practice. Mental practice has been effective to improve multiple motor activities in clients with neurological disorders^{168,169} but has not been reported on for clients with TBI.

The neurophysiological mechanisms thought responsible for CNS recovery^{161,170,171} after injury are discussed in earlier chapters.

Because the therapist can identify a deficit during the examination does not mean the deficit can be fixed. The ability to “fix” impairments does not depend solely on the therapist’s skills but includes inherent properties within the client such as the amount of physical damage, cognition, family support, and motivation. Just as critical are external constraints, for example, the availability of treatment devices such as EMG for biofeedback, stimulation devices, pools, and other equipment; travel to and from treatment; availability of qualified providers of care; and financial constraints on intervention.

Based on the evaluation, two levels of intervention are likely to be ongoing. At the impairment level, basic components of performance that are faulty and are contributing to lack of motor performance are addressed. Loss of complex movements, functional activities, and reestablishment of typical motor patterns for rolling, roll to sitting, sitting, sitting to standing, standing balance, gait, running, upper-extremity reach and grasp, and throwing and batting activities will also be part of the rehabilitation targets.

For those clients whose evaluations suggest that recovery of typical function at the body function, impairment level is not probable, substitutions for loss of function such as bracing, wheelchairs, functional electrical stimulation (FES), ambulation devices, environmental changes such as ramps, mobility devices, bath benches, padding for skin care, and reachers provide immediate change and improve the activity limitations almost immediately. The reader must remember that colleagues often use this model to clarify areas needing improvement to reach the goals established by the patients that allow them to participate in the highest quality of life.

With use of the ICF (WHO) model of impairment, activity limitation, and participation restrictions, the therapist determines whether improvement is possible at the level of impairment and then addresses these specific impairments. For example, for a client who is unable to roll over and is both weak and has contractures, strengthening, stretching, and casting may be done. For task-oriented practice, practice of rolling may be used. In the client with a permanent contracture or paralysis, a cloth loop may be provided to allow rolling over by pulling with the arm, a substitution technique at the activity limitation level. This adaptation to rolling allows the patient independence and participation in daily living activities that lead to a quality of life that may not be attained without environmental adaptation.

An example of the ICF intervention model for walking is presented in [Box 24-11](#).

For skill in an activity to be developed, many, many repetitions must be performed. KR and feedback are also important in motor practice.¹⁷² Attention span and motivation factors alone can impede skill acquisition.

Areas of Intervention

Multiple problems may occur after brain injury, most of which are amenable to interventions. A partial list of the most common problems is in [Box 24-12](#).

Motivation, Cognition, and Memory

Multiple cognitive problems remain even after physical problems have resolved for the person with TBI. Fortunately, these problems do appear to improve with intervention. In a study of clients with TBI, Feeney and colleagues¹⁷³ demonstrated an 82% improvement in cognitive, memory, behavioral, and emotional problems in clients with severe problems in the home and community.

The motivational aspect of TBI may be one of the most difficult for the therapist to deal with. Clients' initiation and practice of movement are dependent on the internal

control of the client and not easily dealt with from the external environment.

Working on client goals helps to establish motivation. Client goals that seem unrealistic should not be dismissed as inappropriate. The high school athlete who wants to play basketball next week and currently has no postural control can focus on how he will learn to sit, stand, walk, and run to play ([Figure 24-6](#)). Most clients who go through rehabilitation programs begin to assess their own potential more appropriately once they have worked through part of the program. Many clients and their families believe that the brain heals like any other part of their body and expect full recovery provided a client tries hard enough.¹⁷⁴ Sometimes giving clients time out of therapy to experience everyday life at home and work helps them to determine and readjust goals and skills and to set new priorities. The client who could not understand the point of "silly exercises" comes back asking to learn ADLs. In many cases it is the families who need help understanding their family member's social and behavioral changes.

The neuropsychological evaluation becomes crucial for treatment of clients who have a short attention span and confusion. Early on, techniques to increase attention span will probably include removing distracting stimuli from the client's environment, including auditory, tactile, and visual distractions. But slowly, distracting stimuli need to be reintroduced and attention maintained. (See Chapter 9 for additional information.)

Exercises requiring active involvement in the problem-solving process (e.g., crossword puzzles, study) may help with memory and perceived quality of life.¹⁷⁵ General fitness exercises may also affect cognitive functioning by influencing neurotransmitter functions that slow the decline in dopamine and muscarinic acetylcholinergic receptor density.¹⁷⁶ A higher total number of these receptors is associated with better mental function.

BOX 24-11 ■ ACTIVITY LIMITATION: NOT ABLE TO WALK

IMPAIRMENT: P+ LOWER-EXTREMITY HIP EXTENSOR AND QUADRICEPS STRENGTH

Can improve: Use weights, resistive exercises, antigravity work, stepping up and down steps, functional electrical stimulation (FES), and so on.

Cannot improve (significantly): Address at activity limitation level; use wheelchair, cane, walker, bracing, and so on.

IMPAIRMENT: DISRUPTED SEQUENCE OF MUSCLE CONTRACTION

Can improve: Use exercises to sequence muscles distally to proximally; use electromyographic feedback and so on.

Cannot improve: Use bracing, electrical stimulation for bracing, wheelchair.

BOX 24-12 ■ PROBLEMS AFTER TRAUMATIC BRAIN INJURY

- Impaired affect
- Impaired arousal and attention
- Impaired expressive or receptive communications
- Impaired motor function, including oculomotor and oral motor
- Altered muscle elastic properties
- Impaired respiratory function
- Impaired autonomic nervous system
- Impaired cognition
- Impaired learning
- Impaired sensory integrity and perception
- Impaired adaptive and anticipatory reactions

Figure 24-6 ■ Client with poor balance throwing a basketball to improve anticipatory and perturbation aspects of balance. Motivation for balance practice is high for this client, who loved to play basketball before his injury.

Interventions for Motor and Sensory Impairments

There are few randomized controlled trials to guide interventions for TBI for the physical and occupational therapist. A recent systematic review by Hellweg and Johannes¹⁷⁷ showed the following:

Level A (A to D with A highest, D lowest) evidence for:

- Functional training for sitting to standing, upper-extremity use, and gait (body-weight support or conventional gait training).
- Highly intensive rehabilitation programs leading to improved functional skills (activity level).
- Improving cardiovascular fitness with fitness or aerobic training (but no carryover to activity or participation level).
- Not using overnight splinting in functional positions. No clinical improvements were seen.

Level B evidence for:

- Serial casting to improve passive ROM.

Level C evidence for:

- Serial casting to reduce muscle tone.

Only a limited number of interventions were reviewed, leaving out many interventions such as use of sEMG, mental imaging, and FES.

Some interventions are effective for multiple impairments, for example, FES for improving force control and decreasing fiber type changes. At the impairment level are numerous and well known approaches to intervention. Following is a review of the current basis of some impairment interventions and more nontraditional approaches that may prove beneficial and have some evidence to support their use in clients with neurological diseases, although few studies include people with TBI.

Strength or Force Production. Muscle tension is increased and decreased by the number of motor units firing (spatial summation) and the rate at which they are fired (temporal summation). Literature for changing force production and strength after TBI is poor; however, there is strong evidence in other types of brain injury such as stroke.

FES for recruiting more nerve and motor fibers and changing type I back to type II^{178,179} appears effective. FES applied to the peroneal nerve for improved dorsiflexion in gait also improves force production.¹⁸⁰ sEMG has also been shown effective in changing motor function after neurological injury.^{181,182} It improves force control and is more effective than feedback of angles of movement and traditional treatment in gait retraining.¹⁸³

Traditional strategies have also been effective. Movements that include resistance in eccentric and concentric contractions and movements through varying amplitudes effectively strengthen clients with neurological injury.¹⁸⁴ Using functional tasks for strengthening is often most effective. For example, practicing sitting to standing will help strengthen the hip and knee extensors.

Functionally oriented tasks such as stepping up and down small steps and progressing to larger steps with proximal body-weighting changes force production and require both eccentric and concentric contractions. Changing lever arm length also changes the need for force production; for example, lifting the arm in overhead prehension with the elbow bent, straight, and with weighting during the activity is effective. Picking up and releasing (concentric and eccentric contractions) objects with differing sizes and weight

such as weighted silverware, brushes, or cooking utensils also can improve strength. Throwing weighted balls to different targets can improve force control if done at different speeds. Remember $F = ma$? These tasks also promote more interest and attention.

Improvements in strength are usually speed specific, so use of resistance at different speeds is critical. Body position in space may also be related to differences in force production. Current thought is that the brain uses different spatial maps for movement; therefore use of the extremities and trunk in multiple positions is important to address all different types of patterns of muscle activation. Consideration of how much work is asked of weak muscles is important. Weak muscles sometimes fail to respond well if overworked and can actually get weaker. Treatment in the pool or decreasing the number of repetitions and weight during strengthening may lead to more efficient strengthening and faster recovery.

Flexibility. Loss of sarcomeres and tissue shortening can occur rapidly in muscle and joints when clients are less active and in those with high levels of muscle tone. Flexibility can be addressed with traditional orthopedic techniques, including joint mobilization, stretching, and serial casting. Casting or ankle-foot orthoses may be used to prevent sarcomere loss and promote adaptive changes.¹⁸⁵ To prevent length-tension curves shifting left or right, early attention to maintaining middle length of muscles is probably important. In addition, electrical stimulation^{179,181} is extremely effective in improving flexibility, especially in dorsiflexion, and can substitute for bracing in clients who need assistance for dorsiflexion during gait. For example, a small spot electrode placed over the peroneal nerve at the fibular head and a 2-inch-square electrode medial to the lateral hamstring 2 to 3 inches above the knee works well (Figure 24-7). Wrist flexor tightness has been treated with electrical stimulation with good results. However, electrical stimulation in the unconscious client with increased ICP or one who is agitated is usually contraindicated because noxious stimuli can increase these problems.

Speed of Movement. Speed of movement may be trained with isokinetic equipment, manually during resistive exercises, with proprioceptive neuromuscular facilitation, or with computerized equipment such as force platforms. Having clients vary speed is important with activities. Many gait studies show that activity limitation becomes most apparent when the speed of gait is increased. Walking at slow speeds, less than 50% of the normal gait velocity, also results in disruption in the walking rhythm.¹⁴⁷ BWSTT has shown good carryover in clients with stroke to improve overground walking,¹⁸⁶ especially when working at 1.8 to 2.0 mph.

Reaction Time. Reaction time training can be performed on force platforms with the client sitting or standing. In a pilot study by Winkler,¹⁸⁷ exercise performed while standing on foam pads (10 inches thick and of medium density; Figure 24-8) significantly improved reaction times during weight shifting to a visual stimulus in a group of eight clients with neurological deficits. Work on compliant surfaces may require that the client make faster corrections to avoid falling.

Endurance and Fatigue. Use of repetitions and increasing duration and intensity can improve endurance. BWSTT has been effective in improving cardiovascular

Figure 24-7 ■ Placement of electrical stimulation electrodes for peroneal nerve to attain dorsiflexion for stretching a tight gastrocnemius or for electrical bracing when used with a heel switch.

function in clients with TBI.¹⁸⁸ Upper-extremity ergometry can enhance cardiovascular conditioning in clients who are unable to walk or ride bicycles.

Tone. As previously discussed, problems with tone are caused by a variety of issues. Problems in spatial and temporal sequencing seem better addressed with multiple-channel sEMG (see Figure 24-3). The client can see both the level of muscle recruitment and the sequence in which the muscles function if dual channels are used. Co-contraction can be decreased during functional activities such as gait or reaching by using EMG biofeedback. Activation of muscles omitted in the gait or reaching patterns can be enhanced and the ability to “turn off” muscles with prolonged contractions are also effectively treated by sEMG (see Chapter 33). In clients unable to use EMG biofeedback information to make changes, FES may achieve some of the goals (see Figure 24-7). For example, gait training with use of an electrical stimulator on the dorsiflexor or plantarflexor nerves can achieve more normal activation patterns of the foot while providing some internal feedback information about sequencing and may decrease tone.¹⁸⁰ A heel switch and a unit with separate channel controls and ramp adjustment are necessary. Use of electrical stimulation on the gastrocnemius and hamstrings, with a slight delay of hamstring activation, has been effective in assistance with ankle strategy retraining. The goal is to slowly remove the “artificial” assistance over time. Strengthening exercises may also assist in improving central control of muscles and therefore

Figure 24-8 ■ Foam block to improve speed of motion and reaction time.

improve tone control. Botulism toxin is very effective to reduce spasticity in specific muscles of the upper and lower extremities.

Somatosensory. Incorporating sensory function into movement is critical. Having the client actively involved by differentiating various textures and items is important to recovery.¹⁸⁹ Clients with poor tactile function can perform activities such as manipulation of objects, first in view and then out of view (nuts and bolts of different sizes are useful); using tactile discrimination to pick out objects from other objects (e.g., safety pins in a bowl of rice) is also challenging. The difficulty of the task can be increased by initiating treatment with visual and verbal cues and then removing all cues as the client progresses. Changing the surface of the objects that are manipulated from rough to increasingly smooth and slippery also increases difficulty. Activities can progress from one-handed to two-handed tasks for interlimb coordination. Proprioception at the shoulder and elbow can be enhanced by using a marking pen in the involved hand (a utility cuff may be required for securing) and then having the client practice writing, tracing, and drawing on paper or a blackboard while sitting or standing with eyes open and then closed. sEMG biofeedback can be used to help retrain the feeling of movement by having the client perform a movement based only on the EMG pattern and then reproduce the movement without vision. Lower-extremity sensory retraining can also use targets with and without vision and with shoes on and off. Clients can stand with eyes

closed and practice leaning to a predetermined position while receiving feedback about their success (random or blocked). Tai chi has been shown to improve plantar sensation in clients with plantar sensory losses.¹⁹⁰

Vestibular System. Basic research has resulted in a strong recommendation for vestibular rehabilitation, according to a 2007 Cochrane review.¹⁹¹ Clients with sensory mismatches may require treatment that enhances input from the two normally functioning systems, somatosensation and vision, to adapt or retrain the faulty vestibular system. For example, the client who is dizzy when moving the head may need increased somatosensory input to provide information about the specific body motion that is occurring. The client can perform head motions while supine or sitting with the feet and arms well supported (proprioceptive and tactile input) and eyes open. Progression of treatment occurs by decreasing the additional somatosensory input as symptoms decrease until the client is finally standing and can increase the amount of movement without dizziness or imbalance occurring. Visual cues can be altered by adding movement in the visual surround. This causes the visual system to perceive body motion when there is none and forces the use of the somatosensory and vestibular systems to determine the real motion. Wearing bicycle glasses or taping the medial or lateral aspects of glasses can reduce peripheral visual input, enhancing vestibular and somatosensory input in clients with dizziness caused by visual movement or visual-vestibular conflicts. Provoking imbalance through unexpected perturbation especially of the standing surface helps promote reintegration of the vestibular system. Working on the motor aspect of balance by using soft or inclined surfaces and narrow beams to facilitate hip strategies (see Figures 24-8 and 24-9) and using small perturbations and quick stops to facilitate ankle strategies are important. Typical balance exercises using narrow bases of support in standing and walking can improve the balance problems related to vestibular dysfunction. For clients whose vestibular systems no longer function at all, enhancing visual and proprioceptive information is critical.

Many clients with brain injury who have vertigo have BPPV and will need a canalith repositioning maneuver for effective treatment (see Chapter 22 section on Vestibular Problems for more in-depth discussion of treatment).

Visual System. The visual system can have impairments in the oculomotor areas of tracking, convergence and divergence, the VOR, saccadic motion, and so on. These can be treated with oculomotor exercises, such as looking from a near object to a far object, tracking the movement of the thumb in figure-of-8 patterns, and fixing the eyes on a target during head movement (VOR). Occipital lobe injuries generally result in more perceptual problems—those of making sense of the visual environment. Professionals specializing in these types of problems, such as neuro-optometrists, and occupational therapists usually handle these deficits.

The visual system has separate pathways for movement, color, and form. Therapy can enhance visual input by increasing contrast between objects, such as light objects or print on dark backgrounds. Colors also can assist in easier object identification. Red is a strongly recognized color in deficient systems. Moving visual targets are easier to perceive than stationary ones. Finally, objects with sharp edges and vertical or horizontal lines are easier

Figure 24-9 ■ Providing the appropriate sensory input is critical to stimulating the correct movement synergy or balance response. Although treatment of mechanoreceptive balance problems requires use of flat, firm surfaces, visual and vestibular balance problems are best treated on irregular, compliant, or moving surfaces, such as the multidimensional balance disk shown. The client should not be permitted to hold onto the therapist or to assistive devices because use of the arms changes the balance responses.

to perceive than objects with less distinct or curved lines. (See Chapter 28 for more information on visual problems and treatments.)

Anticipatory Responses. More complex activities such as postural stability require work at the anticipatory response level and at the stability level. Moving the extremities, adding weights to extremities during forward movement, and increasing motion speeds are effective techniques. Pulling and pushing activities require an anticipatory set. More dynamic movement may be practiced with ball activities. Using punching, catching, throwing, and kicking activities with weighted balls and regular balls will change the force and speed involved, requiring the client to adapt responses to the changing environmental demands. Treadmills help clients to adapt their motion to environmental changes and to make anticipatory responses. But remember, treadmills cause sensory conflicts because the somatosensory system and vestibular systems report movement but the visual system reports no forward movement of the head or body as would be normal in walking.

Activity Level Intervention

Activities. In clients in whom the basic body functions are available, basic synergy or skill acquisition should be based on whole-task and natural subtask work. As stated earlier, using subtasks of a whole task improves performance. Identifying natural subtasks is difficult. Winstein¹⁷² suggests that “natural breaks in the resultant velocity profile of a multisegment movement may signify the end of one subunit and may identify natural subtasks of a movement.”

Rolling impairments have been found to be amenable to intervention, showing significant improvements between initial admission and 6 weeks later in clients with severe TBI.¹⁹²

The variability shown in the task performance by nondisabled subjects also may help elucidate subtasks. Assessment of a task, as done by VanSant¹⁴⁹ in her supine-to-standing studies, may provide a model to identify subtasks. In VanSant’s studies, the upper-extremity patterns varied in six ways: push and reach to bilateral push, asymmetrical push, symmetrical push, symmetrical reach, asymmetrical push with thigh push, and push and reach to bilateral push with thigh push. The head and trunk movement patterns varied in five ways: full rotation abdomen down, full rotation abdomen up, partial rotation stomach down, partial rotation stomach up, and partial rotation. The lower-extremity patterns varied in five ways: kneel, jump to squat, half kneel, asymmetrical squat, and symmetrical squat.

A subtask exercise program to teach a client to get up from supine might work as follows: upper-extremity patterns of asymmetrical push with the trunk in partial rotation are practiced until successful; then lower-leg patterns are added; and finally, whole-task training is used. Natural subtask work probably will be more effective if it is performed in the environment in which the pattern is normally used.

When difficulty is encountered in moving from sit to stand, sliding the hips forward and coming to the point of hips-off appears to be a subtask unit and may be practiced. Dependent sit-to-stand is associated with institutionalization.¹⁹³ Sitting to standing practice is outlined in other chapters in detail. Intensive practice of sitting to standing resulted in significant improvements in a group of clients with TBI.¹⁹⁴ Having visual guidance may also help in practice with sitting-to-standing. The shoulder, if tracked visually, will make a reverse C pattern as the client stands up. Having that pattern drawn on a piece of paper and attached to the wall next to the client’s shoulder often helps with achieving the movement more smoothly.

Working on improving balance usually occurs at the impairment level, including use of perturbations for reactive responses and quick arm reaching and leg kicking for anticipatory responses. Following a program of decreasing the base of support during each activity helps improve control of the center of gravity. Sensory components of balance require activities with eyes closed, head turning, or working on compliant surfaces.

Ambulation training requires working in the upright position. A common impairment is a slower swing phase in the more involved leg. This problem is often accompanied by decreases in total knee flexion ROM leading to problems of toe clearance and increased time on the stance leg. To work on this impairment, gait may be broken down into more natural subtasks, for example, working on half a gait cycle

by stepping from the fully extended position (initial swing) to initial contact position. Practicing pulling the thigh forward rapidly and changing speeds of thigh flexion can also be helpful to increase knee flexion.

Whole-task practice of gait in clients with brain injury leads to the question of safety. How does the therapist allow a client who cannot walk without falling to practice walking, in light of research indicating that holding onto or using assistive devices changes the very skill the therapist is trying to teach? If the deficit is in balance, then walking without assistance may be critical to progress. The best the therapist may be able to do is to change the environment. Allowing a client to walk between parallel bars increases the likelihood that the client will catch himself or herself or that the therapist will catch the client during falls. Use of the body-weight support system with full weight bearing and a loosely worn harness provides safety within the clinic. Walking on mats may allow both for an environmental stimulus for soft, uneven surface work and for safer falling. Falling may be critical in relearning ambulation. Little research is available in this area, but in a study by Cintas,¹⁹⁵ children who performed more daring gait activities fell more often (more problem-solving experiences and stronger error signals?) but gained better gait skills. The therapist should work on techniques to reduce injuries from falling and getting up from the floor.

Goal-oriented tasks are mandatory in working with upper-extremity losses, just as with lower-extremity problems. Significant improvements were seen in a group of clients after CVA and TBI using a task-oriented intervention program for the upper extremity.¹⁹⁶ Many clients with minimal function can pick up and carry boxes. Often grip but not release is present. Again, EMG biofeedback is useful in helping develop release.¹⁹⁷ Functional release in clients with grip can be achieved by use of an electrical stimulator on the finger extensors with a hand switch.¹⁹⁸ Some clients respond to continuous low-level stimulation of the finger extensors and can learn to release by relaxing the grip. These activities are practiced while grasping and releasing objects. Feeding can be performed with this technique, as can other ADL tasks such as hair combing, turning on and off light switches, and opening doors. Games including those for the Wii and other interesting activities such as puzzle solving (Figure 24-10) may also be beneficial.

CIT has also proven effective with clients with TBI. They show improvements across a wide number of upper-extremity outcome measures.¹⁹⁹

Reversing tasks for some clients allows them to develop increased control but requires modifying a task or synergy and working muscles both eccentrically and concentrically. For example, slowly lowering a spoon from the mouth may improve lifting the spoon to the mouth by improving motor control of the biceps during eccentric contractions. Wrist weights can be added to improve somatosensory feedback as long as the client does not have ataxia, in which case the wrist weight could increase the imbalance between agonist and antagonist.

Variability. VanSant¹⁴⁹ stated that variability of performance in her study had “something to do with body size, strength and ROM.” Because force production (strength) and ROM may be critical components in variability, work in

Figure 24-10 ■ Games that are challenging for both the mind and the hand provide interesting ways to work on upper-extremity function. This client lacks refined prehension skills in the left hand.

water or with weight to change force production and ROM may also enhance different responses. It is important to build environmental constraints so clients can perform functional movements in alternative ways. Adding environmental changes by having clients stop and start at different points in an activity or changing directions also develops improved responses as well as flexibility. The client is asked to stop without taking another step when he or she comes to a tape line, and to step over objects that are static or moving. The client may have to feed himself or herself while sitting with the involved extremity up against a wall. These techniques provide external influences on motor activities, helping to establish flexibility into responses. Adding objects to the environment to avoid or manipulate and exposing the client to changing environments also develop adaptations and modifications to motor patterns. Obstacle courses promote flexibility in responses. Activities such as tai chi and dancing require refinements in balance and speed of movement. Finally, for clients who are unable to produce movement, guided movement techniques may help with rolling and coming to sit or stand in clients who have lost basic motor patterns.²⁰⁰

Learning, Feedback, and Practice

Learning studies tell us that neuroplasticity underlies both recovery after injury and new learning. Neuroplasticity is facilitated when the activity is goal or task oriented. Novel tasks are better attended and therefore improve learning. Feedback type is critical.

Feedback is essential for learning to occur. According to Winstein,¹⁷² KR research currently suggests a need to reexamine intervention approaches that advocate performance accuracy, strong guidance (manual, tactile, or verbal), frequent and continuous feedback, and avoidance of errors or “abnormal movements.” Mistakes the person makes are a powerful type of feedback called *error signals*. For example, when a person drops a ball thrown to him or her, the brain notes the amount of grip, finger ROM, and so on and

modifies them on the next attempt to improve the outcome. This is called *intrinsic feedback*.

Knowledge of Results

KR feedback is about the outcome of the task. The problem solving is done by the individual. An example of this feedback might be “You stepped into your walker five of 10 steps.”

Knowledge of Performance

Knowledge of performance (KP) relates to the movement pattern used to achieve the goal, for example, “Your knee did not bend on five of the 10 steps.”

KR appears more effective in general than KP.

Frequency of Feedback

Faded feedback (KP and KR) improves learning long term. The KR research findings are consistent with the motor control model that requires the client to be actively involved in problem solving through trial and error and adapting to new environmental situations. The higher-level client needs help to solve his or her own motor problems and thus needs less physical support but expanded environmental experiences. Conversely, the client with minimal motor function or the client who is in an early recovery state may require a great deal of external help with basic components of movement before learning how to access or develop basic motor patterns and skill. Assisting movement is appropriate for the level of this client’s functioning. For example, in training upper-extremity reaching patterns, this client may need trunk support intermittently; then slowly decreasing the support will help develop the balance component necessary for successful reaching. Because feedback is so critical to learning and improving motor performance, especially at the higher levels of functioning, the method of treating highly functioning clients by assisting motion comes into question. Normal movement is unique in that it will change depending on the context in which it is performed and on the task constraints. The client being assisted in ambulation will not be making balance responses if the therapist is providing balance support. The same problems may be inherent in the use of assistive devices such as canes and walkers. For example, Horak and colleagues⁷⁹ showed that using a cane for balance disrupts the normal distal-to-proximal sequence in the lower extremities, and much of the balance responses are transferred to the arm, shoulders, and trunk. Canes also cause a shift in the center of gravity.²⁰¹ The same may be true of many externally guided motions. The therapist must provide the client with opportunities to practice all parts of the complex motor tasks, or the task requirements are not the same. Practice needs to be task specific, and changing environmental and task constraints can build in flexibility of response.

Types of Practice and Their Effects on Learning

Constant Practice. A person practices three different tasks, one at a time, before moving to the next task. This results in better performance during acquisition of the skill.

Random Practice. A person practices the tasks in random order and alternates the practice of tasks. This results in better learning in generalizing and transfer of the skill to other environments and conditions.

Massed Practice. Massed practice consists of sessions in which the amount of rest between trials is less than the length of the practice (Practice > Rest). Although fatigue may occur, learning continues. Do not mistake errors made during acquisition of a skill as the final product.

Distributed Practice. Distributed practice consists of sessions in which the amount of rest between trials is longer than the length of practice (Rest > Practice). It is used for clients with poor endurance and early in rehabilitation.

Substitution

Mobility and prehension are the two most frequent activity limitation losses after brain injury. For clients who will not be able to reestablish walking or prehension skills, functional devices are provided for substitution of the lost skills (e.g., use of a wheelchair for the client who will not be able to walk or use of a feeding cuff for a client who will not develop adequate motor function in the hand for feeding). At this level, the therapist also teaches functional tasks such as sitting transfers, cooking, and self-care with assistive devices and modified techniques.

Summary of Intervention Concepts

In choosing interventions for a client with TBI, both the client's and the family's goals are basic. Once the therapist has examined the activities that the client or family reports are impaired, the therapist determines what potential future problems may also occur. With the problem list established, the therapist begins the task analysis to determine the underlying causes of the activity limitations. Interventions are guided by the literature. There are some global principles that apply to all interventions. Evidence is strong that neuroplasticity underlies the majority of recovery. Interventions that promote neuroplasticity (see Chapter 4) include use of novel situations that are important to the client and also the need for many repetitions. The type of practice and feedback are critical for improvement. Intensity of practice is highly related to outcomes. In general, the more physically involved clients (those with losses of basic motor patterns and with multiple activity limitations or cognitive changes) need more hands-on help from the therapist while trying to develop basic motor programs. Interventions may need to focus at the impairment level, establishing strength, flexibility, timing, and sequencing of movements. Assistive devices such as braces, neck supports, and postural seating systems are often used to substitute for missing components of function. For clients who cannot manage multiple tasks, such as balance, coordination of trunk and limbs, and adaptive and anticipatory reactions, the therapist may choose to work in subtasks. Many less physically involved, functioning clients benefit from high-level functional activities. Square dancing, line dancing, karate, tai chi,²⁰² handball, running, and other sports often promote additional progress in balance, sequencing, and speed of movement. The clever therapist will tease out those components of the activities that best address the deficits in the client and structure enjoyable activities that provide specific training for the deficits in balance, gait, or upper-extremity use. No matter at what level the client is functioning, the teaching of functional skills is critical. More involved clients may learn to roll over and assist with eating and other ADLs by using assistive devices. Modern equipment can enhance all types of function. Computers

communicate for those with severe dysarthria, and power wheelchairs with switches to run lights, television, and so on are available. These devices assist clients in their societal interactions and reduce participation restrictions. Remember, the main purposes of motion are exploration and getting the brain to a place where it can be used!

OUTCOME

Leahy,²⁰³ in a discussion of brain-injured adults, suggested a general categorization of clients for prognosis by a combination of levels of cognitive and physical functioning. Cognition is rated as low, moderate, or high level and physical dysfunction as severely impaired, moderately impaired, or minimally impaired. The therapist may use the GOS and the Rancho Los Amigos Scale of Cognitive Function to determine the categories. This system provides a means of predicting return of functional skills and long-term activity limitation. As Leahy points out, clients with higher-level physical skills and moderate-level or low-level cognition skills often have the most difficult time reintegrating into the family and society. Therefore they may have the higher levels of participation restrictions remaining after rehabilitation because family and co-worker expectations are high on the basis of motor function, but it is the cognitive functions that make a person more successful in society.⁹⁸ These clients need aggressive help in the behavioral and cognitive areas early on. Neuropsychologists and counselors can suggest interventions that help with cognitive functions, especially techniques to deal with memory problems, attention span decreases, and inappropriate behavior. These programs can make a difference. Brotherton and colleagues²⁰⁴ documented long-term social behavior improvement in four severely impaired clients with brain injury who had undergone traditional social skills training programs. Clients with low-level motor skills and higher-level cognitive skills do better because adaptive devices are available for these clients. These devices help substitute for the loss of motor functions. These include head-, mouth-, or hand-controlled electric wheelchairs; computerized communication systems; electric lifts for vans and hand controls for driving; books on tape; and numerous upper- and lower-extremity devices to help with hand control and ADLs. (See Chapter 16 on spinal cord injury for all types of substitution devices.)

Outcome Measures Appropriate for Use with Clients with Brain Injury

Wade²⁰⁵ provides an in-depth presentation of examinations useful as outcome measures for the activity limitation level. Choosing tests and measures validated on clients with TBI is important, but equally important is ensuring that a test is reliable. The Barthel Index¹⁴² is an example of a simple tool for gross measurement of overall activity limitation. It simply asks whether functional skills can be performed within a reasonable time limit. The FIM¹⁴³ is widely used in the United States and incorporates the concepts of the Barthel Index. It has six categories that evaluate independence. Twelve items relating to swallowing, community functions, and cognition (Functional Assessment Measure)²⁰⁶ have been added to the FIM to make it useful for TBI clients. The Disability Rating Scale^{13,207} is also widely used for clients with brain injuries. The High Level Mobility Assessment Tool (HIMAT) was specifically designed to test higher-level

functions and has been shown to be reliable and valid in people with TBI.^{208,209} It is very useful for clients who may be able to jump and run. Upper-extremity movement patterns and function can be examined with use of functional tests such as the Nine-Hole Peg Test,²¹⁰ the Frenchay Arm Test,²¹¹ or the arm portion of the Motor Assessment Scale.¹⁴⁶

These types of indexes should be chosen to address what abilities the client can accomplish. They are not intervention tools. Their purpose is to identify activity limitations and sometimes impairments and to monitor client progress. However, many are not effective in measuring changes in the client with higher-level functioning because they have a ceiling effect. Timed tests tend to have less floor and ceiling effects than other tests. So use of tools such as the Timed Up-and-Go Test (TUG), 3-minute sit-to-stand test, and timed walking tests can be particularly useful as outcome tools.

SUMMARY

The following concepts summarize the theory, research, and intervention concepts presented in this chapter.

1. Intervention is based on the nervous system's ability to learn through environmental influences.
2. The client's goals must be addressed to provide motivation and persistence in exercise and practice.
3. As a starting point, examination (task analysis) and evaluation are done at the activity limitation level.
4. Hypotheses are generated to explain the basic causes of the activity limitations by identifying the impairments that are major contributors.
5. Tests and measures are performed in the examination to confirm the hypotheses.
6. Interventions for prevention of secondary complications such as contractures, skin breakdown, and muscle contractures begin early to prevent loss of function.
7. Neuroplasticity is promoted when the task is novel, is important to the client so that it is well attended, and is repeated.
8. Changing speed of motion and varying the context and environment are necessary for thorough skill reacquisition.
9. Once components of movement are in place, motor pattern development—that is, skill learning—should be stressed through repetition of functional activities.
10. Interventions should be task oriented and performed with the goal of the movement incorporated into the intervention.
11. Practice is necessary in multiple environments and conditions.
12. The client should be allowed to problem solve.
13. Physical assistance by the therapist should be kept to a minimum but used when clients cannot produce movement at all.
14. Variability in performance is normal.
15. sEMG biofeedback, FES, isokinetic methods, and kinematic feedback should be used to modify responses that appear more resistant.
16. Environmental situations that cause changes in responses should be identified and used.
17. Feedback should be provided in well thought-out patterns; random and summary feedback promote learning better than continuous feedback.
18. Substitution devices, assistive devices, and environmental changes should be provided for clients who will not recover from their impairments.
19. Remember that the therapist's uniqueness lies in the ability to perform evaluation and effective intervention.

QUALITY OF LIFE

A life has been saved. The job of the rehabilitation team is to help improve the quality of that life. But what is quality of life? Family members knew the client before injury. The “rehabilitated” client may be dramatically different from their expectation. The rehabilitation team members, who can contrast the client's progress only since the injury, may be quite pleased. Is quality measured by past performance, past potential, present performance, or future potential? Clients themselves may or may not have insight into past, present, or future performance and potential. What is the standard by which quality of life is measured? Is it income, reduction of dependence, contribution to society, or social interaction? Each of these indicators has been used as a standard. Ultimately, the determination of successful rehabilitation relies on the answers to these questions. Jennett and Teasdale⁶ suggest six aspects of living: ADLs, mobility and life organization, social relationships, work or leisure activities, present satisfaction, and future prospects. Most of these factors, although important, cannot be quantitatively measured, and they do not entirely answer the question of what is quality of life. However quality of life is estimated, those who have chosen to help rehabilitate clients with brain injury continue to pursue an ideal of quality for each life that has been saved and may, by doing so, enhance the quality of their own lives.

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 212 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

CASE STUDY 24-1 ■ Mrs. E. K.

EXAMINATION

History

Mrs. E. K. is a 60-year-old woman who sustained a brain injury in a fall 1 year ago. Injury was to the cerebellum and brain stem, resulting in left-sided body involvement and incoordination. Currently she reports falling about two times monthly. She complains of feeling tired constantly and not having enough energy to even accomplish her housework. She lives with her husband and 29-year-old son in a two-story house 1.5 hours from a large western city. Her son is an alcoholic and unable to keep a job. Client goals included being able to sew again and to square dance with her club.

Task Analysis

Gait (with Use of the Observation Gait Analysis Based on the Rancho System)

Mrs. E. K. walks with a normal pattern on the right. She has significantly decreased trunk rotation during right leg swing and a right pelvic drop in left leg stance. On the left during swing phase, hip flexion is limited, and the leg circumducts. The left knee has limited flexion and the foot has excessive plantarflexion. In stance phase on the left, there is limited hip extension during midstance and late stance and flat foot contact at initial contact. The left arm is held tightly against her chest with the elbow in flexion and the forearm in full supination. When the client is asked to put her arm to her side during ambulation, the arm swings uncontrolled in large arcs, actually hitting her in the chest. Speed of walking is slow at 50 m/min. Cadence is 73 steps per minute with a 0.8-m stride length.

Hypothesis 1

Gait

Gait is impaired in kinematics and speed as a result of poor force production in the left hip flexor and dorsiflexors complicated by quadriceps and gastrocnemius hypertonia. Slowed gait is also present because of poor trunk rotation during arm-fixed gait and instability when the arm is not fixed to her chest. Flexibility of tissue in the quadriceps and gastrocnemius-soleus may also contribute to the poor movement patterns, and there may be a disruption of the normal temporal sequencing of muscle firing in stance on the left. Question whether proprioceptive problems may be present because of poor foot placement in stepping. Mrs. E. K. may have anticipatory problems because gait is not compensated during the arm movements.

Hypothesis Testing

Force production: Manual muscle strength (on MMT): 2+/5 left hip flexor and ankle dorsiflexors. Flexibility: ROM testing. Left rectus femoris tight at 100 degrees knee flexion test in prone. The gastrocnemius-soleus is tight at neutral. Tone: Modified Ashworth level 3 in left quadriceps and gastrocnemius-soleus.

Balance testing: no ankle strategy, only combined hip-ankle strategy to all perturbations. There is a proximal-to-distal balance response during small perturbations (EMG).

Proprioception is impaired when Mrs. E. K. is asked to note small changes in flexion and extension of the great toe and ankle within normal limits for knee and hip.

Motor patterns are poor in trunk. There is no trunk rotation during walking, and anticipatory responses are poor as measured by rapid forward reaching resulting in forward

balance loss in standing and no sEMG activation of the gastrocnemius-soleus before deltoid firing.

Evaluation and Diagnosis

Poor walking ability and lack of automatic balance reactions as a result of decreased use of proprioceptive information, decreased strength in the hip flexors and ankle dorsiflexors, tone and limited flexibility in the quadriceps and gastrocnemius, and poor anticipatory responses disrupting balance when the upper extremities are moved rapidly or when the left arm flails.

Sewing (Large 4-Inch Needle with Yarn through 1-Inch Square Holes in Plastic Grid)

Mrs. E. K. hits the hole with the needle averaging one in three attempts. The left hand does not work in a distal-to-proximal manner. The scapula and shoulder initiate the motion and show excessive motion during the reaching phase of the movement. There is minimal braking of the motion as she approaches the target, resulting in overshooting or undershooting of the target. The hand remains excessively supinated throughout the task. Fine motion of the fingers appears within normal limits.

Hypothesis 2—Upper Extremity

Unable to perform sewing task because of poor timing and coordination of the scapula and shoulder muscles producing a sequentially uncoordinated movement pattern. The triphasic velocity pattern of movement is severely disrupted.

Impairments—Tests and Measures

Timing and coordination: sEMG—Poor sequencing and timing of movement of the scapular muscles with hand and wrist motion. Tremor of high frequency in the scapular stabilizers, especially in the external rotators at rest and with movement. There are lower-frequency tremors of larger amplitude in the wrist flexors and extensors during voluntary motion. Co-contraction of the biceps occurs with all shoulder and hand motions.

Adaptation: Modification of motor patterns is poor for upper-extremity reaching. Amplitudes of movement are far too large for tasks but are repeated with each trial without modification.

Evaluation and Diagnosis

Upper extremity is not being used functionally secondary to poor sequencing and timing of muscle firing during activities. Mrs. E. K. is unable to limit the degrees of freedom in the arm during upper-extremity activities. The arm is held in co-contraction during walking and other activities to decrease the instability in balance caused by large movements of the entire arm.

Participation Limitations

Mrs. E. K. has decreased social interaction with friends; she is unable to attend sewing circle and square dance clubs.

Outcome Measures

The TUG was chosen as it measures gait speed and sitting to standing, both problems for this client. Time was 30 seconds. A 15-m timed walk was used for gait speed. Step length was measured on paper using an inked heel during walking. She had 10 degrees hip flexion and lacked 10 degrees to neutral dorsiflexion. Measurements of hip flexion and dorsiflexion angles in midswing were done from videotape stop when the client was even with the camera.

CASE STUDY 24-1 ■ Mrs. E. K.—cont'd**INTERVENTIONS**

Mrs. E. K. was referred to a psychologist, as there appeared to be no other reason for the fatigue on further examination. She was diagnosed with depression. Mrs. E. K.'s physician then prescribed an antidepressant medication.

Because Mrs. E. K. lived 70 miles from the treatment clinic, much of her treatment consisted of a home program. She was seen in the clinic once every 3 weeks for 3 months and then once a month for a year.

The initial home program focused on the basic impairments of reducing quadriceps and gastrocnemius-soleus tightness and increasing hip flexor and dorsiflexor strength in the lower extremity with functional activities such as wearing a 1-lb weight around the foot during walking practice and stepping exercises, tapping a target on the wall with her left knee as many times as possible in 1 min. Exercises included sitting-to-standing repetitions with the knees bent past 100 degrees, keeping the heels on the floor. Mrs. E. K. walked on a treadmill starting at 1.8 miles/hr at home to increase her speed of walking and endurance. She practiced a mental imaging exercise for 20 minutes a day, using sewing as the task. sEMG was used in the clinic to improve scapular-humeral rhythm during functional activities such as drinking from a cup and her sewing task. sEMG was also used to decrease the co-contraction of the biceps during functional use of the arm. At first the sEMG provided continuous feedback with the client observing the screen. After she was able to achieve a particular goal for the session, the visual sEMG was provided only randomly to the client. Practice of activities was for short periods interspersed with different activities. To reestablish some control of amplitude of motion in the left arm, gross movement activities of the hand were done with the elbow stabilized on the support surface and a wrist splint to limit the degrees of freedom—for example, drawing large circles with a pen and pulling long pieces of yarn through some large holes. She also used her left forearm to stabilize paper while writing, finally progressing to using the hand only for stabilization.

The remaining program focused on hand-guided movement activities such as sewing with yarn on a mat with large (1-inch

squares), combing hair, molding clay, playing the organ, and other functional tasks. These activities were first performed with the elbow stabilized and a wrist splint, then with the elbow not stabilized, and finally without the wrist splint.

Lower-extremity work included improving the use of proprioceptive function. Standing exercises with the eyes closed or occluded progressed to stepping activities and finally walking. Ankle strategies were promoted through rapid walking while the client's husband told her to stop abruptly and the client tried not to take a step after being told to stop. She also stood 6 inches from the wall and kept the upper body rigid while she swayed back and forth around the ankle joints. This was progressed to doing the same activity with eyes closed.

sEMG was used in standing to increase the force of contraction of the anterior tibialis.

As the amplitude of arm motion decreased with use, Mrs. E. K. was able to walk with her hands clasped behind her back and worked on trunk rotation coordinated with gait. When this was accomplished, she was able to allow her arm to hang freely at her side and had a natural trunk rotation in walking. Mrs. E. K. practiced line dancing with her husband, using an introduction videotape on line dancing. This activity promoted higher-level balance exercises and provided enjoyment.

OUTCOMES

At discharge, Mrs. E. K. had good motor patterns and improved patterns of motion in the left lower extremity. An articulated ankle-foot orthosis was used for long walks or when she was fatigued. She walked with 90 steps per minute with a 1.2-m stride length. The TUG result was 10 seconds. Tone was a level 2 Ashworth. She performed within normal limits on the CTSIB. Hip flexion improved to 20 degrees in midswing but dorsiflexion still lacked about 5 degrees to neutral.

Upper-extremity testing showed 100% accuracy in putting the needle through the 1-inch squares. She was able to sew and use the left arm for most activities, although a much smaller tremor persisted with volitional movement. She only occasionally (once every 3 months or so) went to the square dancing club. Medication had controlled her depression, and her fatigue was resolved.

CASE STUDY 24-2 ■ C. H.**EXAMINATION****History**

C. H., a 21-year-old woman, was in an automobile accident and sustained a severe brain injury and fractures of the left scapula, left radius, right ankle (fused), and jaw. She developed heterotopic ossification (HO) in the right elbow. C. H. was in a coma for 1 month and a stupor for 2 more months. Her GCS score was 8/15 at 2 hours after the accident. She had 8 days of PTA. Her Rancho Los Amigos Scale of Cognitive Function score was a level V (confused, inappropriate) at 2.5 months. She is now at 5 months postinjury and her Rancho Cognitive Function level is a VII (automatic, appropriate).

Expressive language is minimal with severe expressive aphasia and dysarthria. C. H. appears to understand well, following directions and nodding appropriately to questions. Currently, she has dysarthria and is still very difficult to understand.

Behavior is immature. For example, C. H. continuously hugged and kissed her boyfriend when he was in the room. She was easily frustrated by difficult tasks. At these times she became extremely agitated and scratched herself to the point of bleeding.

Her memory was poor, as noted by her score of 19/30 on the Mini-Mental State Examination.

Continued

CASE STUDY 24-2 ■ C. H.—cont'd

Mobility is by manual wheelchair. C. H. is independent in transfers. She can roll and come to sitting independently, but she needs moderate assistance to come to standing, minimal assistance for standing with feet shoulder width apart, and maximal assistance to walk. She is unable to perform self-care such as personal grooming, hygiene, and dressing or to do household chores. Her chin rests on her chest; however, she lifts her head volitionally when asked to lift.

C. H. was a junior in college majoring in elementary school teaching. She worked part time in a clothing store, where she had to wait on customers, put out stock, and ring up purchases. She lives at home with her mother in a single-story house. Dancing and cooking were her hobbies.

C. H.'s goals include use of the left arm to put on makeup and dance with her boyfriend. Her mother, who is a psychologist, would like her daughter to hold her head upright and have better balance and walking.

Review of Systems

Musculoskeletal system: C. H. had HO in the right elbow; this was surgically removed 1 month ago. ROM is 25 to 110 degrees. Scapular and clavicle fractures are healed.

Left gastrocnemius is restricted in ROM to neutral dorsiflexion. Left shoulder has active flexion to 20 degrees but can hold at 90 degrees. Left elbow ROM is 20 to 135 degrees.

Strength screen demonstrates weakness in the left shoulder rotator, lower trapezius, and deltoid. Strength decreased on third repetition with resistance. There is stretch weakness in the gluteus maximus, which tests 4 in 30 degrees of hip flexion, but 2+ in neutral extension.

Cardiopulmonary system: She demonstrated poor endurance. Preexamination heart rate was 85 beats per minute (bpm) and 130 bpm after 5 minutes of standing balance and upper-extremity exercise. There was a 10-mm Hg increase in blood pressure of 115/65 to 125/72 after 5 minutes of examination. Vital capacity is documented as low normal (3 L).

Integumentary system: Unremarkable. No pressure sores since her injury. Incision healed over right elbow.

Cognitive and behavioral system: C. H. became easily frustrated and on each occasion she scratched her left forearm with her right hand. These episodes lasted 30 seconds or so. C. H. probably needs referral to a psychologist for suggestions for handling these episodes.

Task Analysis

Reach and grasp with left hand: C. H. is right handed. The task was picking up an eyeliner pencil, switching it to her right hand, and applying the eyeliner to the eyes, using the left hand to hold the eyelid taut. Her chin was resting on her chest. There was no anticipatory hand shaping before initiating the reach on the left. Reach component was with forward trunk lean, 20 degrees of left shoulder flexion, and elbow remaining at 90 degrees. She picks up the pencil with inferior lateral pinch and excessive grip force. She was able to switch the pencil to the right hand but able to get her left hand only to clavicle level and so was unable to hold the eyelid for applying the liner.

Complex movements: Motor patterns appear intact except in the cervical area, where the head is not held upright to maintain the eyes level, and the left arm, in which there is a proximal-to-distal pattern of movement.

C. H. is unable to modify the motor patterns in the left elbow, and intralimb joint coordination was poor.

Anticipatory responses were absent in reach and grasp; there was no hand shaping before the reach was initiated, and fingers were held wide open even as she approached the pencil.

Variability of performance: C. H. was able to reach and grasp and bend in many different ways with the right arm and was limited only by elbow ROM. The left arm was maintained in an adducted, internal rotation pattern with the elbow flexed at 90 degrees on the left. She also appeared limited in the degrees of freedom available at the forearm and hand.

Hypotheses: Upper-Extremity and Head Righting Dysfunction

Disuse weakness and limited ROM in the left deltoid and rotator cuff group from immobilization after scapular fracture and prolonged bed rest. Increased tone at the elbow and wrist on the left, causing immobility during reaching. Problems with force production and gradation of force are the result of poor somatosensory function in the left hand. Poor anticipatory control of reach and grasp.

Flexibility loss in the right elbow from postoperative swelling after HO removal.

C. H. is unable to maintain her head in upright on an automatic basis owing to visual and proprioceptive verticality impairment, lack of head-righting reflexes, and overstretch weakness of the neck extensor muscles.

Hypothesis Testing

Strength: MMT—neck extensors: 3–/5. Left arm—not able to actively abduct shoulder but able to actively hold if placed at 90 degrees. Shoulder flexion and external rotation, elbow flexion and extension—3/5 (but range was limited). Wrist extension—2+/5 (half range) and flexion 3+/5.

Force gradation was poor on use of a dynamometer. C. H. could not regulate her force output; she either gripped with full grip or used minimal force when asked to change her grip from minimal, 1 pound per square inch (psi) to 5 psi to 8 psi to 12 psi.

Flexibility: Passive ROM—Left shoulder limited to 100 degrees of flexion and abduction, 45 degrees of external rotation. Right elbow ROM—20 to 90 degrees in flexion and extension and 10 degrees in supination.

Tone: Modified Ashworth—Left arm, 3 in biceps, triceps, and wrist flexors, 2 in the finger flexors, otherwise 0 or 1 throughout. The tone was of a co-contraction nature at the elbow. There was poor spatial sequencing throughout the limb as tested during forward reach on sEMG.

Sensory and perception: Proprioception was impaired for the left hand; movement was perceived but direction was not consistent. Stereognosis—identified four of 10 objects placed in the left hand.

Visual-perceptual: C. H. complained of diplopia and identified a pen as vertical when in a left 10-degree tilt.

Task Analysis

Standing Balance

C. H. stood in quiet standing, feet shoulder width apart. There was hip flexion of 20 degrees with forward trunk lean. More weight was on the right leg than left. Shoulders were rotated 20 degrees to the left, and she had a 15-degree upper-trunk left

CASE STUDY 24-2 ■ C. H.—cont'd

lean. Her chin was resting on her chest. Standing is with increased sway in the fore-aft direction and no loss of balance in 30 seconds; sway increased moderately with eyes closed. Feet-together stance caused loss of balance in 15 seconds and in 10 seconds with eyes closed. When asked to reach rapidly forward, she fell forward and needed maximal assistance to recover her balance. Responses to small perturbations were with flexion at the hips and knees, and she continued to flex at the hips and knees with larger perturbations, again requiring assistance to recover her balance. When asked to take a step with the right foot in response to a perturbation, C. H. did not shift the weight to the left and required maximum assistance for balance recovery.

Hypotheses: Standing Balance

Forward lean is secondary to poor vertical perception (seen with lack of head righting with and without vision) from visual, proprioceptive, and vestibular dysfunction. There is overuse fatigue of hip extensors for maintaining continuous contraction whenever C. H. is upright. Trunk rotation secondary to increased left side tone in trunk, upper extremity (scapular retraction), and lower extremity. Balance losses were secondary to lack of anticipatory responses when reaching forward and for weight shift before right-foot stepping. The losses of balance with perturbation were secondary to a lack of stepping strategy and exclusive use of a mixed strategy for all standing conditions. Weakness of the gastrocnemius resulted in the early use of the hip strategy. Reaction times increased in response to perturbations, also contributing to imbalance.

Hypothesis Testing

Strength: MMT: 3/5 strength in left leg except 2+/5 in the left hip extensor and gastrocnemius.

Tone: Modified Ashworth 3 in the left quadriceps and gastrocnemius. The left lumbar extensors have above-normal tone and often elicited an extensor spasm during forward bending.

Muscle endurance: Poor in trunk and lower-extremity muscles; there was a reduction in amount of resistance tolerated after approximately five repetitions with isolated muscle testing of the quadriceps, hip extensors, back extensors, and cervical extensor muscles.

Sensory and perceptual systems: Proprioception was decreased (needs larger movement for accuracy) in the left ankle, knee, and hip.

Visual testing: C. H. had a left hemianopsia. No nystagmus was present. (Vision and vestibular systems are also addressed under the activity limitation.) Left tilt off vertical 15 degrees in standing with eyes open and with eyes closed.

Vestibular testing: C. H. complained of double vision and objects “jumping” with moderate and fast head motion with trying to maintain eye fixation on a pen tip. C. H. had increased sway during this test (in sitting). Unable to maintain balance for CTSIB testing.

Verticality: Unable to hold head up consistently; no head righting reflexes to tilts. Did not right lower body to floor in standing. No change with eyes closed.

Balance synergies to large and small perturbations: sEMG—appeared intact, in the right lower extremity, but ankle strategy is absent in the left. Small perturbations at the chest to balance are responded to with synergies showing a proximal-to-distal

firing beginning in the trunk flexors and extensors. Amplitude of muscle contraction at the gastrocnemii was small even for large perturbations, less than 25% of her maximal contraction.

Gastrocnemius reaction times were 400 ms to perturbation on sEMG.

Anticipatory responses were generally absent in the left lower extremity and trunk during stepping. C. H. fell to the right each time she tried to raise her right leg. There was no anticipatory shift of weight to the left. sEMG showed no left gastrocnemius firing before rapid forward reaching.

Attention span was about 2 minutes during therapy.

EVALUATION AND DIAGNOSIS

Poor force control, timing and sequencing, lack of wrist and finger proprioception, co-contraction of the biceps and triceps, and poor anticipatory hand shaping during reach and grasp resulted in nonuse of the left hand. Contributing to the lack of use of the hand was poor strength in the scapular stabilizers after a scapular fracture that was immobilized and prolonged bed rest from decreased consciousness for 3 months. Lack of adequate elbow ROM from HO and postoperative swing in the right elbow prevented independent grooming, personal hygiene such as teeth brushing, and applying makeup when combined with deficits in the left hand.

C. H. appears unable to stand or walk without moderate to maximum assistance because of a lack of appropriate balance synergies in response to perturbations, lack of anticipatory responses to movements of her center of gravity, and impaired perception of vertical. Poor left gastrocnemius strength contributes to lack of an ankle strategy. Standing posture is with a forward lean owing to poor perception of vertical. The forward lean has in turn overstressed the back and hip extensors, and perhaps the gastrocnemius, which is consistent with disuse weakness from prolonged bed rest during the time when C. H. was in a coma and stupor and overuse weakness secondary to chronic forward lean position.

C. H. has problems perceiving the vertical position in sitting and standing because of visual, vestibular, and proprioceptive impairments.

Head righting is absent owing to loss of visual and proprioceptive head righting as well as overstretch weakness of the cervical extensors.

She has poor muscular endurance from prolonged bed rest.

Participation Limitations

Immature behavior and inappropriate anger and self-destructive responses resulting in loss of friends. Inability to balance and reach and grasp with the left hand restricts her from performing her job in a clothing store.

Outcome Measurement Tools

FIM score 79/126. Gait requires maximum assistance of 1. Romberg 15/30 seconds, Nine-Hole Peg Test 1 minute, Frenchay = 1/5.

Prognosis

Long-term goals: In 4 months, C. H. will be independent in all self-care activities and ADLs using the left hand as an assist. C. H. will be able to participate in activities with appropriate emotional responses (no episodes of scratching herself) and will have independent standing balance with and without perturbation using appropriate strategies.

Continued

CASE STUDY 24-2 ■ C. H.—cont'd

Short-term goals: Improved force production and timing of left gastrocnemius using FES daily for 15 minutes on a home exercise program and EMG biofeedback 3 × weekly for 2 weeks in clinic.

Improved force gradation for grasp so C. H. can grasp and release a paper cup filled with water and not deform the cup or spill the water in 2 weeks.

The prognosis for meeting the goals was good because C. H. is young, has a supportive family (sister and mother), and showed more focal lesions on MRI. The literature shows that problems of force production, flexibility, and ambulation modification in clients with brain injury have shown good modification. Decreasing the overall frustration level by working on achievable short-term goals and doing behavior modification should result in more appropriate emotional responses and improve her compliance.

INTERVENTIONS

Initial goals included addressing those impairments that did not allow higher levels of functioning. These were improvements in neck and hip strength and overstretch; gastrocnemius strength and flexibility; visual skills, particularly in tracking of objects into the left visual field; and awareness of vertical.

The head was the first focus. FES was applied to the posterior cervical muscles (5:1 duty cycle and frequency at 35 pps) for strengthening and upright head position. A sterno-occipital-mandibular immobilization support (SOMI) was worn intermittently to prevent further stretch weakness; later the SOMI was changed to a Philadelphia collar. Visual focus on a door frame was used to encourage visual control of head and body position for improved alignment. Complex neck activities to encourage basic synergy use and modification included seated activities in which C. H. wore a “hat” with a flat top from which she tried to prevent an object from falling off (first flat stable objects and later more rounded objects). This exercise was performed first on a firm, flat-seated surface and progressed to sitting on an exercise ball. The ball promoted automatic neck muscle motor patterns in which the body moves and the head is kept upright and still. To make the activity at the automatic level, C. H. did side-to-side leans while sitting on the ball, looking in a mirror to monitor head verticality and then doing the activity without the mirror.

Upper extremities: Traditional basic left upper-extremity strengthening exercises included the use of Thera-Band. Functional activities that required scapular use such as emptying the dishwasher with the left hand were assigned homework. Bilateral hand use was allowed early on. After C. H. could accomplish this, then only left hand use was allowed; a 1-lb wrist weight was added, which was gradually increased to 3 lb.

Electrical stimulation twice a day for 15 minutes to the right triceps and biceps gained 20 degrees of extension and 100 degrees of flexion. In the clinic, C. H. worked on picking up and manipulating objects of different sizes and shapes, throwing balls at targets, and doing two-handed carrying with a laundry basket and quick release of the basket. She sorted different-sized objects by retrieving them from a bucket which also contained marble-sized balls with her vision occluded to force the development of stereognosis.

C. H. enjoyed cooking, so tasks were given that used elbow extension, such as rolling out cookie dough. Exercises such as

washing the dishes with hands in soapy water for proprioceptive feedback and practice of slip grip for enhancement of feedback through the fingertips were used. Setting the table with the left hand helped establish better functional use (plastic dishes).

Doing two-handed activities facilitated complex functions in manipulation with the left arm. C. H. hooked a small rug. When able, she began trying two-handed typing. Two of the most motivating activities were applying makeup and inserting contact lenses.

Visual treatment used exercises that required visual fixation at different points in space and at different distances using letters and objects, while moving the head left and right with the goal of seeing only one image. These exercises advanced to include moving objects and head moving with a fixed object and progressed to both the object and head moving while a single image was maintained. Finally, full body movement with eyes fixed on a moving object was accomplished. Vergence exercises were worked on, first using a ball with an “X” marked on it on a string, swinging the ball toward and away from her. She did five swings at a time and wrote down how many times the X stayed single. The ball was swung side to side, and C. H. had to point at it with her finger for left visual field loss.

Standing balance exercises focused on developing anticipatory responses. Exercises early on used a Gymnastik Ball, as well as wrist-weighted reaching exercises. Different weight balls were thrown and returned to C. H. She also worked on kicking a ball to a goal with the right foot. First the kick was very slow, and then the ball was made smaller and the kick faster. Kicking with the left leg was with eyes closed to promote increased proprioception. Exercises to promote ankle strategy such as swaying around the ankles were practiced to increase gastrocnemius control and timing.

After C. H. was able to stand and weight shift without support, small-angle, slow random tilts on a tilt board were used to promote both vertical upright and vestibular responses for balance. To promote vertical trunk control as well as anticipatory responses, C. H. practiced taking a full step forward on each foot. C. H. had a penlight attached by Velcro to a belt she wore on her waist. The goal was to keep the light, aimed at a wall target in front of her, from moving more than 2 inches side to side. This was also facilitated by moving the parallel bars extremely close together (about 1 inch from each hip) and asking C. H. not to touch the bars with either hip as she practiced stepping.

Tone was addressed with exercises to promote less co-contraction and distal-to-proximal sequencing in both the left leg and left arm. sEMG with a two-channel setup on the triceps and biceps and wrist flexors and wrist extensors was used with a faded schedule of feedback to teach decreased co-contraction during activities such as reaching and lifting.

C. H. used a NordicTrack machine for general cardiovascular fitness work. The gliding motion with toe loops allowed her to keep her feet near the ground when moving forward, and the arm work encouraged free movement of the trunk in rotation and hip extension without having to flex the hips through large ranges, that is, work her hip extensors in the shortened range to avoid overstretch positions.

CASE STUDY 24-2 ■ C. H.—cont'd

The goal C. H. had when first starting therapy was “to dance with my boyfriend.” To encourage functional use of postural and balance motor patterns, dancing was used. She started first with slow dancing with her boyfriend. Gradually she was able to dance to faster music without being held, by using trunk and arm motion and a sidestepping motion. Finally, forward-backward movements and turning and bending were added. In addition, C. H. agreed to model in the brain injury association fashion show in 6 months, which provided motivation to walk independently.

Home exercises were not popular with C. H. A behavioral modification program was established so that she was given control to stop activities that were too stressful for her. She participated in a volunteer program on a farm feeding and watering animals two or three times a week on a fixed schedule to establish personal responsibility and provide a positive learning environment. A program of rewards and withholding of rewards was established to extinguish self-destructive behavior. Verbal feedback was provided when immature behavior was exhibited.

C. H. kept a diary of duties and accomplishments to help with memory and reinforce successes.

Motor learning was enhanced by using a program of blocked feedback to start, with only three trials before

feedback was given. The number of trials increased to about 10, and then she progressed to random feedback, as C. H. was able to tolerate higher frustration levels. She began doing her own self-assessment of her performance after about 2 months of therapy for each of her activities.

OUTCOMES

C. H. reached the goals of independent standing both quiet and perturbed in about 6 weeks. She had vertical upright trunk and head posture but still needed the collar support intermittently for the neck. The left arm had good assistive and gross independent use. Tone in the left arm and left quadriceps was at a level 2 (Modified Ashworth Scale) at 6 weeks; however, the trunk tone was still interfering with standing posture and left side rotation remained, although at only about 50% of the initial rotation. C. H. was independent in all grooming and all but the most difficult of ADLs. The FIM score was 110/126, TUG 13 seconds, Frenchay 5/5, and Nine-Hole Peg Test 18 seconds. C. H. had no episodes of scratching herself and much higher tolerance for more difficult tasks. She continued to have some immature behaviors, but the work at the farm helped her to assess her own deficits better. She made friends, had a strong social life, and participated in the fashion show as a fundraiser activity for the Brain Injury Foundation.

APPENDIX 24-A ■ Patient Information**Family Guide to the Rancho Levels of Cognitive Functioning**

Cognition refers to a person’s thinking and memory skills. Cognitive skills include paying attention, being aware of one’s surroundings, organizing, planning, following through on decisions, solving problems, using judgment, reasoning, and being aware of problems. Memory skills include the ability to remember things before and after the brain injury. Because of the damage caused by a brain injury, some or all of these skills will be changed.

The Rancho Levels of Cognitive Functioning is an evaluation tool used by the rehabilitation team. The eight levels describe the patterns or stages of recovery typically seen after a brain injury. This helps the team understand and focus on the person’s abilities and design an appropriate treatment program. Each person will progress at his or her own rate, depending on the severity of the brain damage, the location of the injury in the brain, and the length of time since the brain injury. Some individuals will pass through each of the eight levels, whereas others may progress to a certain level and fail to change to the next higher level. It is important to remember that each person is an individual and there are many factors that need to be considered when assigning a level of cognition. There are a range of abilities within each of the levels, and your family member may exhibit some or all of the behaviors listed below.

Cognitive Level I**No Response**

A person at this level will:

- not respond to sounds, sights, touch, or movement.

Cognitive Level II**Generalized Response**

A person at this level will:

- begin to respond to sounds, sights, touch, or movement.
- respond slowly, inconsistently, or after a delay.
- responds in the same way to what he hears, sees, or feels. Responses may include chewing, sweating, breathing faster, moaning, moving, and/or developing increased blood pressure.

Cognitive Level III**Localized Response**

A person at this level will:

- be awake on and off during the day.
- make more movements than before.
- react more specifically to what he or she sees, hears, or feels. For example, he or she may turn toward a sound, withdraw from pain, and attempt to watch a person move around the room.
- react slowly and inconsistently.
- begin to recognize family and friends.
- follow some simple directions such as “Look at me” or “Squeeze my hand.”
- begin to respond inconsistently to simple questions with “yes” and “no” head nod or shakes.

What family and friends can do at Cognitive Levels I, II, and III:

- Explain to the individual what you are about to do. For example, “I’m going to move your leg.”
- Talk in a normal tone of voice.
- Keep comments and questions short and simple. For example, instead of “Can you turn your head toward me?” say, “Look at me.”

Continued

APPENDIX 24-A ■ Patient Information—cont'd

- Tell the person who you are, where he or she is, why he or she is in the hospital, and what day it is.
- Limit the number of visitors to two or three people at a time.
- Keep the room calm and quiet.
- Bring in favorite belongings and pictures of family members and close friends.
- Allow the person extra time to respond, but don't expect responses to be correct. Sometimes the person may not respond at all.
- Give the person rest periods. He or she will tire easily.
- Engage the person in familiar activities, such as listening to favorite music, talking about the family and friends, reading out loud to the individual, watching TV, combing his or her hair, putting on lotion.
- The person may understand parts of what you are saying. Therefore be careful what you say in front of the individual.

Cognitive Level IV

Confused and Agitated

A person at this level may:

- be very confused and frightened.
- not understand what he or she feels or what is happening around him or her.
- overreact to what is seen, heard, or felt by hitting, screaming, using abusive language, or thrashing about. This is because of the confusion.
- be restrained to prevent injury.
- be highly focused on basic needs—that is, eating, relieving pain, going back to bed, going to the bathroom, or going home.
- may not understand that people are trying to help.
- not pay attention or be able to concentrate for a few seconds.
- have difficulty following directions.
- recognize family and friends some of the time.
- with help, be able to do simple routine activities such as feeding himself or herself, dressing, or talking.

What family and friends can do at Cognitive Level IV:

- Tell the person where he or she is and reassure the person that he or she is safe.
- Bring in family pictures and personal items from home, to make the individual feel more comfortable.
- Allow the person as much movement as is safe.
- Take the person for rides in the wheelchair, with permission from nursing.
- Experiment to find familiar activities that are calming to him or her, such as listening to music or eating.
- Do not force the person to do things. Instead, listen to what he or she wants to do and follow this lead, within safety limits.
- Because the person often becomes distracted, restless, or agitated, you may need to give breaks and change activities frequently.
- Keep the room quiet and calm. For example, turn off the TV and radio, don't talk too much, and use a calm voice.
- Limit the number of visitors to two or three people at a time.

Cognitive Level V

Confused and Inappropriate

A person at this level may:

- be able to pay attention for only a few minutes.
- be confused and have difficulty making sense of things outside himself or herself.
- not know the date, where he or she is, or why he or she is in the hospital.

- not be able to start or complete everyday activities, such as brushing the teeth, even when physically able. Step-by-step instructions may be needed.
- become overloaded and restless when tired or when there are too many people around.
- have a very poor memory (the person will remember past events from before the accident better than the daily routine or information the individual has been told since the injury).
- try to fill in gaps in memory by making things up (confabulation).
- get stuck on an idea or activity (perseveration) and need help switching to the next part of the activity.
- focus on basic needs such as eating, relieving pain, going back to bed, going to the bathroom, or going home.

What family and friends can do at Cognitive Level V:

- Repeat things as needed. Don't assume that the person will remember what you say.
- Tell the individual the day, date, name and location of the hospital, and why he or she is in the hospital when you first arrive and before you leave.
- Keep comments and questions short and simple.
- Help the person organize and get started on an activity.
- Bring in family pictures and personal items from home.
- Limit the number of visitors to two or three at a time.
- Give frequent rest periods when he or she has problems paying attention.

Cognitive Level VI

Confused and Appropriate

A person at this level may:

- be somewhat confused because of memory and thinking problems; he or she will remember the main points from a conversation but forget and confuse the details. For example, the person may remember having had visitors in the morning but forget what they talked about.
- follow a schedule with some assistance but becomes confused by changes in the routine.
- know the month and year, unless there is a severe memory problem.
- pay attention for about 30 minutes but has trouble concentrating when it is noisy or when the activity involves many steps. For example, at an intersection, the person may be unable to step off the curb, watch for cars, watch the traffic light, walk, and talk at the same time.
- brush teeth, get dressed, feed himself or herself, and so on, with help.
- know when he or she needs to use the bathroom.
- do or say things too fast, without thinking first.
- know that he or she is hospitalized because of an injury but will not understand all of the problems he or she is having.
- be more aware of physical problems than thinking problems.
- associate his or her problems with being in the hospital and think that he or she will be fine once at home.

What family and friends can do at Cognitive Level VI:

- You will need to repeat things. Discuss things that have happened during the day to help the individual improve his or her memory.
- The person may need help starting and continuing activities.
- Encourage the individual to participate in all therapies. He or she will not fully understand the extent of the problems and the benefits of therapy.

APPENDIX 24-A ■ Patient Information—cont'd

Cognitive Level VII

Automatic and Appropriate

A person at this level may:

- follow a set schedule.
- be able to do routine self-care without help, if physically able. For example, he or she can dress or feed himself independently.
- have problems in new situations and may become frustrated or act without thinking first.
- have problems planning, starting, and following through with activities.
- have trouble paying attention in distracting or stressful situations—for example, family gatherings, work, school, church, or sports events.
- not realize how the thinking and memory problems may affect future plans and goals.
- Therefore the person may expect to return to the previous lifestyle or work.
- continue to need supervision because of decreased safety awareness and judgment. He or she still does not fully understand the impact of the physical or thinking problems.
- think more slowly in stressful situations.
- be inflexible or rigid and may seem stubborn. However, these behaviors are related to the brain injury.
- be able to talk about doing something but will have problems actually doing it.

Cognitive Level VIII

Purposeful and Appropriate

A person at this level may:

- realize that he or she has a problem in thinking and memory.
- begin to compensate for the problems.
- be more flexible and less rigid in thinking—for example, the person may be able to come up with several solutions to a problem.
- be ready for driving or job training evaluation.
- be able to learn new things at a slower rate.
- still become overloaded with difficult, stressful, or emergency situations.
- show poor judgment in new situations and may require assistance.
- need some guidance to make decisions.
- have thinking problems that may not be noticeable to people who did not know the person before the injury.

What family and friends can do at Cognitive Levels VII and VIII:

- Treat the person as an adult by providing guidance and assistance in decision making. His or her opinions should be respected.
- Talk with the individual as an adult. There is no need to try to use simple words or sentences.
- Be careful when joking or using slang, because the individual may misunderstand the meaning. Also, be careful about teasing.
- Help the individual in familiar activities so he or she can see some of the problems in thinking, problem solving, and memory. Talk to the person about these problems without criticizing. Reassure him or her that the problems are because of the brain injury.
- Strongly encourage the individual to continue with therapy to increase thinking, memory, and physical abilities. He or she may feel completely normal. However, he or she is still making progress and may possibly benefit from continued treatment.

- Be sure to check with the physician on the individual's restrictions concerning driving, working, and other activities. Do not just rely on the individual for information, because he or she may feel ready to go back to the previous lifestyle.
- Discourage the individual from drinking or using drugs, because of medical complications.
- Encourage the individual to use note taking as a way to help with the remaining memory problems.
- Encourage the person to carry out self-care as independently as possible.
- Discuss what kinds of situations make the person angry and what he or she can do in these situations.
- Talk with the person about his or her feelings.
- Learning to live with a brain injury can be difficult, and it may take a long time for the individual and family to adjust. The social worker and/or psychologist will provide the family and friends with information regarding counseling, resources, and/or support organizations.

Level IX—Purposeful, Appropriate: Stand-by Assistance on Request

- Independently shifts back and forth between tasks and completes them accurately for at least 2 consecutive hours.
- Uses assistive memory devices to recall daily schedule, make “to do” lists, and record critical information for later use with assistance when requested.
- Initiates and carries out steps to complete familiar personal, household, work, and leisure tasks independently and unfamiliar personal, household, work, and leisure tasks with assistance when requested.
- Is aware of and acknowledges impairments and disabilities when they interfere with task completion and takes appropriate corrective action but requires standby assistance to anticipate a problem before it occurs and take action to avoid it.
- Is able to think about consequences of decisions or actions with assistance when requested.
- Accurately estimates abilities but requires standby assistance to adjust to task demands.
- Acknowledges others' needs and feelings and responds appropriately with standby assistance.
- Depression may continue.
- May be easily irritable.
- May have low frustration tolerance.
- Able to self-monitor appropriateness of social interaction with standby assistance.

Level X—Purposeful, Appropriate: Modified Independent

- Able to handle multiple tasks simultaneously in all environments but may require periodic breaks.
- Able to independently procure, create, and maintain own assistive memory devices.
- Independently initiates and carries out steps to complete familiar and unfamiliar personal, household, community, work, and leisure tasks but may require more than usual amount of time and/or compensatory strategies to complete them.
- Anticipates impact of impairments and disabilities on ability to complete daily living tasks and takes action to avoid problems before they occur but may require more than usual amount of time and/or compensatory strategies.
- Able to independently think about consequences of decisions or actions but may require more than usual amount of time and/or

Continued

APPENDIX 24-A ■ Patient Information—cont'd

- compensatory strategies to select the appropriate decision or action.
- Accurately estimates abilities and independently adjusts to task demands.
 - Able to recognize the needs and feelings of others and automatically respond in appropriate manner.

Copyright 1990, Los Amigos Research and Educational Institute (LAREI).

- Periodic periods of depression may occur.
- Irritability and low frustration tolerance when sick, fatigued, and/or under emotional stress. Social interaction behavior is consistently appropriate.

APPENDIX 24-B ■ Sit-to-Stand Task Analysis

DESCRIBE START POSITION		CHECK BOX FOR PATTERN FOR EACH PHASE OF THE TRANSITIONAL MOVEMENT				SUMMARIZE MOVEMENT PATTERN AND HYPOTHESIZE BODY STRUCTURE IMPAIRMENTS TO EXPLAIN DEVIATIONS FROM EXPECTED PATTERN
DESCRIBE END POSITION		FLEXION MOMENTUM	MOMENTUM TRANSFER	EXTENSION	STABILIZATION	
Critical Events (circle if observed)		Feet 10 cm back Momentum generation	Continued LE flexion	LE and trunk extension	Ankle strategy	
UE	UEs push on chair UEs reach forward					
Trunk	Insufficient speed Insufficient flexion Insufficient extension					
LE	Insufficient ankle dorsiflexion Insufficient knee flexion Insufficient tibial translation Insufficient hip extension Insufficient knee extension Unstable					

LE, Lower extremity; UE, upper extremity.

CHAPTER 25 Brain Tumors

CORRIE J. STAYNER, PT, MS, RACHEL M. LOPEZ, PT, MPT, NCS,
and KARLA M. TUZZOLINO, PT, NCS

KEY TERMS

astrocytoma
biopsy
chemotherapy
Gamma Knife
glioblastoma multiforme
hospice care
Karnofsky performance status scale
meningioma
metastatic
radiation therapy
ventriculostomy

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify the categories of primary brain tumors.
2. Recognize and interpret signs and symptoms of primary brain tumors specific to tumor location.
3. Recognize current diagnostic tests used to detect brain tumors.
4. Identify the types of medical and surgical management for brain tumors and how that management will affect functional movement.
5. Describe the side effects associated with the treatment of brain tumors and recognize their impact on therapeutic intervention.
6. Discuss the multiple considerations necessary to plan and execute an intervention program for the client with a brain tumor.
7. Recognize the emotional and psychosocial impact of the disease process on the client, the client's support system, and the interdisciplinary team.

AN OVERVIEW OF BRAIN TUMORS

The rehabilitation clinician serves many different populations, including clients with brain tumors. Despite the prognosis for limited survival associated with primary brain tumors, these individuals have shown progress in the rehabilitation setting similar to that noted in clients with diagnoses of stroke or traumatic brain injury.¹⁻³ Advances in medical and surgical treatment for clients with cancer have resulted in improved survival rates and longer life expectancy. However, individuals are often faced with progressive impairments resulting from the disease process.² These impairments may be physical or cognitive, or both, and require an interdisciplinary team approach to best facilitate the individual's participation in a meaningful lifestyle. In addition, clinicians must recognize the psychological and emotional needs of the individual given this diagnosis and be sensitive and flexible in accommodating the patient's feelings. Improved quality of life, especially the opportunity to return home, remains the ultimate goal of the rehabilitation process.

The clinical presentation of clients with brain tumors mimics that of persons with other central nervous system (CNS) conditions. The location of the tumor or vascular accident determines the impairments the client will exhibit. However, in the brain tumor client the burdensome effects of standard medical intervention and the aggressive nature of the disease course itself provide obstacles to therapeutic intervention. The client's probability of eventual body structure and function deterioration provides a challenge to the clinician attempting to formulate realistic goals and plan for future needs. Therefore a thorough knowledge of the tumor's natural history, the complications and side effects of treatment, and the neurological impairment the

client exhibits will assist the clinician in best developing a comprehensive, individualized plan of care.

Incidence and Etiology

The incidence of adult brain tumors is on the rise in the United States, with an estimated 62,930 new cases of primary benign or malignant brain and CNS tumors for 2010. The statistics for children include 4030 new cases for the same 12-month period, of which 2880 will occur in children younger than 15 years of age.^{4,5}

The exact cause of the increase in incidence of brain tumors is not known. Studies suggest that the increase is the result of more tumors being diagnosed with improved tumor imaging, rather than an actual increase in the occurrence of malignant brain tumors.^{6,7}

In the United States, brain tumors typically occur in two distinct categories of patients: (1) children aged 0 to 15 years and (2) adults in the fifth to seventh decades of life. In adults, white Americans have a higher incidence than black Americans, and in both pediatric and adult populations males are more frequently affected than females.^{8,9} In children, a primary brain tumor is now the most common cause of solid tumor cancer death in the 0- to 15-year-old age group and the second overall cancer after leukemia.⁵

The frequently occurring meningioma, typically benign, accounts for 33.8% of all primary brain tumors. Glioblastoma multiforme, a malignant tumor, accounts for 17.1% of adult primary tumors (Figure 25-1).⁵ The largest percentage of childhood tumors (17%) are located in the frontal, temporal, parietal, and occipital lobes of the brain, followed by 16% in the cerebellum and 11% in the brain stem.⁵

The etiology of brain tumors remains unclear. Theories suggest that heredity is a contributing factor, but studies

Figure 25-1 ■ Distribution of all primary brain and central nervous system tumors by histology. (From Central Brain Tumor Registry of the United States (CBTRUS): 2010 Statistical report: primary brain and central nervous system tumors diagnosed in the United States, 2004-2006, Hinsdale, Ill, 2010, CBTRUS.)

show familial incidence can be explained by a common toxic or infectious exposure.^{10,11} Research indicates an association, but not a causal relationship, linking brain tumors to certain chemicals and materials (petrochemicals, organic solvents, rubber). These materials are frequently found in specific occupations, such as farming and manufacturing. Electromagnetic field exposure is associated with an increased incidence of brain tumor.¹² Ionizing radiation, used therapeutically in high doses to treat tumors, was found to have a causal relationship to the development of a second brain tumor.¹³

Continued investigation into possible causal relationships with potential risk factors is essential if the incidence and mortality rate associated with brain tumors are to decrease.

Classification of Tumors

The World Health Organization (WHO) first published a universal classification system for CNS tumors in 1979. This system classifies tumors according to their microscopic characteristics and has been accepted as the universal method for the classification of brain tumors.^{14,15}

Primary Brain Tumors

Primary tumors originate in the CNS, whereas metastatic or secondary tumors spread to the CNS from systemic cancer sites outside the brain. Characteristics of the most common brain tumors are discussed in the following paragraphs, with information provided regarding age at onset, location, medical treatment, and prognosis.

Gliomas are primary tumors that arise from supportive tissues of the brain and are frequently located in the cerebral hemispheres. These tumors may also occur in the brain stem, optic nerve, and spinal cord. In children, the cerebellum is a primary location for gliomas.^{13,16} Gliomas have four primary categories and are classified by their predominant cellular components: astrocytomas and oligodendrogliomas

originate from glial cells, ependymomas from ependymal cells, and medulloblastomas from primitive cells.¹⁷

Astrocytomas are derived from astrocytes, which are star-shaped glial cells, and are the most common primary brain tumor in adults and children.¹⁸ Astrocytomas vary in morphology and biological behavior, from those that are diffuse and infiltrate surrounding brain structures, to those that are circumscribed with a decreased likelihood of progression. Astrocytomas are typically found in the cerebrum, originating in the frontal lobe in adults, and in the cerebellum in children. In adults the primary age at onset is typically in the third to fifth decades of life.^{7,14}

Astrocytomas are further classified into four grades: pilocytic, well-differentiated, relatively benign low-grade tumors most common in childhood and young adults (grade I); diffuse, well differentiated, low-grade tumors (grade II); anaplastic, high-grade tumors (grade III); and glioblastoma multiforme, high-grade (grade IV). The higher the grade, the poorer the prognosis.⁷

Low-grade tumors (grade II) grow slowly and are typically subtotally resected through surgery when accessible, whereas grade I tumors occur primarily in children and are typically cured with complete surgical resection. As a result of incomplete resections, recurrence is common.⁷ As these tumors recur, their form and structure often change to that of an anaplastic astrocytoma or glioblastoma.¹⁷ Anaplastic, midgrade (grade III) tumors grow rapidly, typically carry malignant cell traits, and routinely progress toward glioblastoma multiforme tumors.¹⁴

Astrocytomas are typically treated with surgery, radiation therapy, and chemotherapy, depending on the grade, location of the tumor, age of the patient, and Karnofsky performance scale score (Table 25-1).^{7,16,19} Pilocytic astrocytomas carry a 5-year survival rate of 94%; however, patients with grade III astrocytomas have a 5-year survival rate of only 27%.⁵

Glioblastoma multiforme is the distinct name given to the highly malignant grade IV astrocytoma. These tumors grow rapidly, invade nearby tissue, and contain highly malignant cells. Glioblastomas are predominantly located in the deep white matter of the cerebral hemispheres but may be found in the brain stem, cerebellum, or spinal cord. Fifty percent of these tumors are bilateral or occupy more than one lobe of a hemisphere.^{7,14,16} Glioblastomas account for 17% of all primary brain tumors. They are most common in older adults and uncommon in children, with males having a 1.6:1 incidence rate over females.⁵ The medical prognosis is poor for persons with glioblastoma: less than 33% survive more than 1 year and less than 5% survive 5 years.⁵ The most important prognostic variables are age, tumor histology, and postoperative score on the Karnofsky performance status scale. These tumors are treated by surgical resection, radiation therapy, stereotactic radiosurgery, and chemotherapy.⁷

Oligodendrogliomas are slow-growing but progressive tumors that typically develop over a period of several years, with 50% involving multiple lobes. Fifty percent of these tumors occur in the frontal lobe, 42% in the temporal lobe, and 32% in the parietal lobe. Many clients have seizures as the only clinical manifestation of the tumor.^{14,20,21} Oligodendrogliomas typically appear in the fourth to sixth decades of life, and the ratio of affected males to females is 2:1.²² The prognosis with oligodendrogliomas varies considerably and

TABLE 25-1 ■ KARNOFSKY PERFORMANCE STATUS SCALE

CONDITION	PERFORMANCE STATUS (%)	COMMENTS
A. Able to carry on normal activity and to work; no special care is needed	100	Normal; no complaints; no evidence of disease
	90	Able to carry on normal activity; minor signs or symptoms of disease
	80	Normal activity with effort; some signs or symptoms of disease
B. Unable to work; able to live at home, care for most personal needs; a varying degree of assistance is needed	70	Care of self; unable to carry on normal activity or to do active work
	60	Requires occasional assistance but is able to care for most of personal needs
	50	Requires considerable assistance and frequent medical care
C. Unable to care for self; requires equivalent of institutional or hospital care; disease may be progressing rapidly	40	Disabled; requires special care and assistance
	30	Severely disabled; hospitalization is indicated, although death not imminent
	20	Very sick; hospitalization necessary; active supportive treatment necessary
	10	Moribund; fatal processes progressing rapidly
	0	Dead

Adapted from Karnofsky DA, Burchenal JH: The clinical evaluation of chemotherapeutic agents in cancer. In Macleod C, editor: *Evaluation of chemotherapeutic agents*, New York, 1949, Columbia University Press.

is dependent on age at diagnosis and tumor grade. Positive prognostic indicators have been age at onset of less than 40 years and a tumor grade of I or II. These patients have a 5-year survival rate of 79% and 10-year survival rate of 64%.⁵ The 5-year survival rate decreases to 47% with anaplastic oligodendroglioma.⁵ Treatment is dependent on symptoms and ranges from observation and seizure control with anticonvulsant drugs to surgical resection followed by radiation and chemotherapy.^{7,17,20} Negative prognostic indicators include age at onset over 40 years, hemiparesis, and cognitive changes.²³

Ependymomas and *ependymoblastomas* are tumors arising from ependymal cells, cells that line the ventricles of the brain and central canal of the spinal cord.^{16,17} These cells have glial and epithelial characteristics. The tumors grow into the ventricle or adjacent brain tissue. The most common site is the fourth ventricle (70% originate here); they occur less frequently in lateral and third ventricles.²² For supratentorial tumors, the age at onset is evenly distributed across the life span, whereas tumors originating in the fourth ventricle more frequently occur in childhood.²² Ependymomas are primarily treated with surgical resection followed by radiation therapy, but chemotherapy is also used.^{7,16,17,22} These tumors frequently recur, and prognosis is dependent on the success of resection, with a 5-year survival rate approaching 82%.⁵

Medulloblastomas are malignant embryonal tumors thought to arise from primitive neuroectodermal cells, specifically pluripotential stem cells that have been prevented from maturing to their normal growth-arrested state. The exact cell of origin, however, is still unknown.²² These

tumors are typically located in the posterior fossa, originating laterally in the cerebellar hemispheres in young adults and in the vermis in children.¹⁴ Medulloblastomas typically grow into the fourth ventricle, blocking cerebrospinal fluid (CSF) flow, causing hydrocephalus and increased intracranial pressure (ICP).⁷ These tumors primarily occur in children, accounting for 20% of childhood (0 to 19 years) brain tumors, with the most common age of onset being 4 to 8 years old; they are more prevalent in males than females.²² An overall 5-year survival rate of 61% has been noted among adults and children; the most common treatment is surgery followed by radiation and chemotherapy.^{5,14,22}

Meningiomas are slow-growing tumors that primarily originate from cells located in the dura mater or arachnoid membrane and account for 33% of reported brain tumors.^{5,18,22} Frequently these tumors are found incidentally during imaging studies or at autopsy.²⁴ Approximately 25% of patients are symptomatic when diagnosed.^{18,24,25} Meningiomas are classified by their cytoarchitecture and genetic origin into four categories: (1) meningothelial or syncytial, (2) fibroblastic, (3) angioblastic variants, and (4) malignant.²² The incidence increases with age, and they occur in females at a 2:1 ratio over males.^{3,5,26,27} Resectable tumors are primarily treated by surgery, and recurring tumors are treated with surgery, radiation therapy, or stereotactic radiosurgery.¹⁷ Patients with nonmalignant meningiomas have a 5-year survival rate of 70% versus a 5-year survival rate of 55% with malignant meningiomas.^{5,28}

Pituitary adenomas are benign epithelial tumors originating from the adenohypophysis of the pituitary gland and frequently encroach on the optic chiasm.^{14,17,22} These tumors

are characterized by hypersecretion or hyposecretion of hormones.^{7,16} Age at onset spans all ages, but pituitary adenomas are rare before puberty.⁷ The female-to-male ratio of incidence is 3:1.⁵ These tumors are primarily treated by surgical resection and drug therapy.^{7,16,17} Prognosis is related to size and tumor cell type, with a 5-year survival rate of 70%.⁵

Schwannomas are encapsulated tumors composed of neoplastic Schwann cells that can arise on any cranial or spinal nerve.^{16,17} The eighth cranial nerve is the cranial nerve usually involved, and a schwannoma here is called an *acoustic neuroma*.¹⁴ Acoustic neuromas produce otological, focal or generalized neurological impairments, depending on the location of the tumor. These tumors are typically located in the internal auditory canal but may extend into the cerebellopontine angle.^{7,22} These tumors are frequently treated by surgical resection, but stereotactic radiosurgery is increasing in popularity as an alternative method of treatment.^{16,29,30} The prognosis for patients with these tumors is good, yet complications can result from treatment, including facial paralysis, deafness, and equilibrium impairments. Resulting activity limitations after surgery vary depending on the size and location of the tumor. Currently these tumors rarely result in death, and with the increasing use of noninvasive procedures the eighth cranial nerve is more frequently being preserved.³⁰

Primary CNS lymphoma represents only 1% of intracranial tumors, although the incidence has significantly increased in the last two decades. This increase may be a result of its frequency in individuals with acquired immunodeficiency syndrome (AIDS) and other immunosuppressed states. Surprisingly, there is an increased frequency in immunocompetent persons; however, no evidence-based explanation has been found. These lymphomas have a slightly higher incidence in men and peak in the fifth through seventh decades of life, or in the third and fourth decades in individuals with AIDS. The tumor cells are similar in histology to systemic non-Hodgkin lymphoma cells, but it is uncertain how this tumor arises, as the CNS lacks lymphatic tissue.^{22,31} The tumor may be solitary or multifocal, forming a poorly defined mass that may be difficult to distinguish from an astrocytoma.²² Although CSF cytology may be diagnostic, stereotactic brain biopsy is often needed for definitive diagnosis.³¹ Primary brain lymphomas may arise in the cerebrum, cerebellum, or brain stem; however, 60% occur in the cerebral hemisphere. More frequently, presenting symptoms are behavioral and personality changes, confusion, dizziness, and focal cerebral signs rather than headache and other signs of increased ICP.²² Surgical resection is typically ineffective because of the deep location of these tumors. Cranial irradiation and corticosteroids frequently yield a partial or complete response; however, the tumor recurs in 90% of these individuals.²² A more recent favorable treatment includes the administration of intravenous methotrexate and leucovorin over 2- to 3-week intervals with corticosteroids to control neurologic symptoms.²² CNS lymphoma carries a poor prognosis, with only 27% of patients surviving longer than 5 years.⁵

Secondary Brain Tumors: Metastatic Brain Tumors

Metastatic brain tumors originate from malignancies outside of the CNS and spread to the brain, typically through the arterial circulation.^{7,22} Approximately 25% of individuals

with systemic cancer develop metastatic brain tumors, approximately 80% in cerebral hemispheres and 20% in the posterior fossa.^{22,31,32} One third of brain metastases originate in the lung, followed by the breast, skin, gastrointestinal tract, and kidneys in order of frequency. The frontal lobe is the most common site for metastatic disease from these systemic sources. Common clinical manifestations of metastatic brain tumors are similar to those of gliomas, including seizures, headache, focal weakness, mental and behavioral limitations, ataxia, aphasia, and signs of increased ICP.²²

Treatment for these tumors is tailored to the individual and dependent on the management of the systemic disease, the accessibility of the lesion, and the number of lesions.^{32,33} Current treatment regimens use combinations of corticosteroids, brain irradiation, surgical intervention, and chemotherapy.²² The prognosis varies, with positive prognostic indicators including the Karnofsky performance scale score of 70 or greater, age 60 years or younger, remission or resolution of the primary cancer, and metastases located in the brain only.^{32,33} The average survival with treatment is approximately 6 months but varies widely and is affected by the extent of other systemic metastases. With some radiosensitive tumors, survival increases to 15% to 30% for 1 year and 5% to 10% for 2 years.²²

Signs and Symptoms

The clinical manifestation of a brain tumor can range from a decreased speed in comprehension or a minor personality change to progressive hemiparesis or seizure, depending on the type and site of the tumor. Patients with brain tumors typically have headaches, seizures, nonspecific cognitive or personality changes, or focal neurological signs.^{22,34} The presenting sign in some may be a general sign, a specific neurological symptom, or a combination of both.

General Signs and Symptoms

General signs and symptoms of the presence of a brain tumor include headache, seizures, altered mental status, and papilledema. *Headache* is the presenting symptom in 30% of cases and develops during the course of the disease in 70% of cases. These headaches are generally dull, intermittent, and nonspecific and are usually on the same side as the tumor. They are often difficult to distinguish from migraine or cluster headaches. It is important to identify the specific nature of the headaches, because certain features often indicate the presence of a brain tumor. These features include the following:

1. The headache that interrupts sleep or is worse on waking and improves throughout the day
2. The headache that is elicited by postural changes, coughing, or exercise
3. The headache of recent onset that is more severe or of a different type than usual
4. The new onset of headache in a previously asymptomatic person
5. The headache associated with nausea and vomiting, papilledema, or focal neurological signs^{1,7}

The mechanism of the headache is not clearly understood but may be related to local swelling, distortion of blood vessels, direct invasion of the meninges, and increased ICP. When the tumor has grown to a volume large enough to cause compression and displacement of the brain, the onset

and severity of the headache seem to correlate with changes in ICP.³⁵ With increased ICP, a bifrontal or bioccipital headache is present regardless of the tumor location.^{22,36}

Seizure activity is the presenting symptom in one third of cases and is present in 50% to 70% of cases at some stage of the disease.^{13,34} Approximately 10% to 20% of adults with new-onset seizure activity have brain tumors. Seizures are usually focal but may become generalized and cause loss of consciousness.³⁷ Frontal lobe gliomas produce seizures in 59% of all cases. The percentages of patients exhibiting seizures from gliomas in other lobes are as follows: parietal, 42%; temporal, 35%; and occipital, 33%.³⁴

Altered mental status is the initial symptom in 15% to 20% of individuals with brain tumors and is frequently present at the time of diagnosis. Mental status changes can range from subtle changes in concentration, memory, affect, personality, initiative, and abstract reasoning to severe cognitive problems and confusion.³⁴ Subtle changes may be incorrectly attributed to worry, anxiety, or depression.²² Changes in mentation are common with frontal lobe tumors and in the presence of elevated ICP. Increased ICP causes drowsiness and decreased level of consciousness, which can progress to stupor or coma if treatment is not initiated.³⁴

The incidence of *papilledema*, swelling of the optic nerve, is less frequent today because brain tumors are being diagnosed earlier with the use of sensitive imaging techniques. Papilledema is associated with symptoms of transient visual loss, especially with positional changes, and reflects evidence

of increased intracranial hemorrhage transmitted through the optic nerve sheath. It is more common in children and with slow-growing tumors and posterior fossa tumors.³⁴ Other, less common symptoms are vomiting and frank positional vertigo, usually accompanying tumors found in the posterior fossa.²²

Specific Signs and Symptoms

Certain clinical features are related to functional areas of the brain and thus have a specific localizing value in medically diagnosing a brain tumor.³⁴ Therefore it is essential that clinicians be familiar with the lobes of the brain and their distinct functions to effectively manage the impairments resulting from the tumor (Figure 25-2). These symptoms may vary among individuals and result in activity limitations that range from mild to severe.³⁵

The *frontal lobe* is responsible for motor functioning, initiation of action, and interpretation of emotion, including motor speech, motor praxis, attention, cognition, emotions, intelligence, judgment, motivation, and memory.^{38,39} Therefore frontal lobe tumors may result in movement disorders such as hemiparesis, seizures, aphasia, and gait difficulties. Initially the tumor may be clinically silent. As the tumor grows, however, there may be personality changes, including disinhibition, irritability, impaired judgment, and lack of initiation.³⁴ Bifrontal disease usually associated with infiltrative gliomas and primary CNS lymphomas may cause bilateral hemiplegia; spastic bulbar

Figure 25-2 ■ Correlation between clinical symptoms and anatomical location of the tumor. (Used with permission from Barrow Neurological Institute.)

palsy; severe cognitive impairment; emotional lability; dementia; and prominent primitive grasp, suck, and snout reflexes.³⁵

The *parietal lobe* processes complex sensory and perceptual information related to somesthetic sensation, spatial relations, body schema, and praxis. General symptoms of a parietal lobe tumor include contralateral sensory loss and hemiparesis, homonymous visual deficits or neglect, agnosias, apraxias, and visual-spatial disorders. If the dominant parietal lobe is involved, aphasia and seizures may be present. With nondominant parietal lobe involvement, contralateral neglect and decreased awareness of impairments can commonly be found.^{26,34,36}

The *occipital lobe* is the primary processing area of visual information. Therefore lesions of the occipital lobe often result in dysfunction of eye movement and homonymous hemianopsia. If the parieto-occipital junction is involved, visual agnosia and agraphia are often present. Although less common, visual seizures may be present, characterized by lights, colors, and formed geometric patterns.^{33,34,36} Bilateral occipital tumors may cause cortical blindness.³⁵

The *temporal lobe* is responsible for auditory and limbic processing. Anterior temporal lobe lesions may be clinically silent until they have become quite large, resulting in seizures. If the lateral hemispheres are involved, auditory and perceptual changes may occur. When the medial aspects of the lobe are involved, changes in cognitive integration, long-term memory, learning, and emotions may be seen. When the dominant temporal lobe is involved, aphasia may be present. Anomia, agraphia, acalculia, and Wernicke aphasia, characterized by fluent, nonsensical speech, are specific to left temporal lobe lesions.^{33,34,36} In comparison with bifrontal tumors, bitemporal tumor involvement is rare and causes memory deficits and possible dementia.³⁵

The *cerebellum* is responsible for coordination and equilibrium.²⁶ (Refer to Chapters 21 and 22A.) The most common symptoms of cerebellar tumors in adults include headache, nausea and vomiting in 40% of cases, and ataxia in 25% of cases. Lesions of the midline cause truncal and gait ataxia, and lesions of the hemispheres cause unilateral appendicular ataxia, most commonly seen in the upper extremities. Lesions of either hemisphere may cause ipsilateral dysmetria, dysdiadochokinesia, and intention tremor. If the tumor involves the cerebellopontine angle, hearing loss, headache, ataxia, dizziness, tinnitus, and facial palsy may occur. If the tumor invades the meninges at the foramen magnum or increased ICP causes cerebellar tonsil herniation, nuchal rigidity and head tilt away from the lesion may be seen. Abnormal posturing of the head is observed in children but not adults.³⁵ Because the cerebellum is located in an extremely confined space, even minimal increases in pressure can cause death from cerebellar tonsil herniation.^{7,34,35,40}

The *brain stem*, which communicates information to and from the cerebral cortex via fiber tracts, controls basic life functions. The reticular formation specifically controls consciousness and attention. Even small changes in tumors invading or compressing the brain stem can lead to death or devastating signs and symptoms. Symptoms of a brain stem tumor have an insidious onset and may include gait disturbances, diplopia, focal weakness, headache, vomiting, facial numbness and weakness, and personality changes.⁷ If the

dorsal midbrain is involved, Parinaud syndrome, characterized by loss of upward gaze, pupillary areflexia to light, and loss of convergence, may be seen. If the reticular system of the pons and medulla is involved, symptoms of apnea, hypoventilation or hyperventilation, orthostatic hypotension, or syncope may occur.^{7,40}

The *pituitary gland* is an endocrine gland that secretes hormones that regulate many bodily processes. Pituitary tumors are typically large and affect pituitary function by compressing its structure or hypersecreting hormones. An enlarging tumor causes a loss of pituitary function and decreases hormone secretion, resulting in pituitary disorders specific to the type of hormone involved (e.g., Cushing disease, hypothyroidism, Addison disease, diabetes). As the tumor enlarges it may invade or compress nearby structures. Lateral extension involving the third and fourth cranial nerves causes diplopia; fifth cranial nerve involvement causes ipsilateral facial numbness; and internal carotid artery occlusion causes cerebral infarction. Upward extension is more common and may compress the optic chiasm, hypothalamus, or third ventricle. Downward extension may compress the sphenoid sinus, typically without clinical signs.⁷

Medical Diagnosis of Disease or Pathology

Advances in research and imaging technology have greatly improved brain tumor medical diagnosis. When a physician suspects a brain tumor, many specialized tests may be used to gather clinical, radiological, pathological, and laboratory information to confirm the diagnosis.^{31,34}

Clinical Diagnosis

A clinical diagnosis consists of information the physician gathers during a comprehensive evaluation. First, a thorough medical history, including the specific nature of signs and symptoms, must be obtained. A neurological examination is then performed to test reflexes and assess visual, cognitive, sensory, and motor function.⁴⁰ If the presence of a brain tumor is suspected after the neurological examination, the next diagnostic step, tumor imaging, is warranted.²²

Radiological Diagnosis

The modern era of CNS imaging began with the introduction of computed tomography (CT) in 1973 and with magnetic resonance imaging (MRI) in 1979.⁷ The availability of sensitive imaging allows for earlier tumor detection and has revolutionized the diagnosis and management of brain tumors.^{34,41} Tumor imaging has continued to develop and can be classified into three categories: static, dynamic, and computer integration imaging. Each type of scan shows different features and function of the brain; therefore several scans may be needed for an accurate diagnosis.¹⁶

Static Imaging. Static neurological imaging includes CT and MRI, which are noninvasive techniques that provide accurate anatomical and functional analysis of intracranial structures.³⁴ CT uses ionizing radiation, thin bands of x-rays, to produce images of slices of brain tissue.³¹ It was the first brain imaging technique to allow determination of tumor size. Contrast enhancement helps to identify isodense tumor from surrounding parenchyma, hypodense lesions in edematous areas, and optimal sites for tumor biopsy.^{7,34} After surgical intervention, CT can be used to

confirm the proper tissue biopsy site and determine the success of tumor resection. Although MRI has become the preferred method, CT scanning offers lower cost, a shorter scanning time, and a more sensitive method to detect calcification and bony involvement.²²

Magnetic Resonance Imaging. MRI is the initial diagnostic imaging procedure of choice. MRI uses magnetic fields rather than ionizing radiation and is superior to CT scanning in detecting and localizing brain tumors, as well as evaluating edema, hydrocephalus, or hemorrhage.^{22,34,35} CT scans can miss structural lesions, especially posterior fossa tumors and low-grade gliomas.³⁷ MRI is a more sensitive imaging modality than CT for identifying lesions and margin abnormalities by providing greater anatomical detail with thin slices and multiplanar images. With MRI, different signal intensities differentiate between normal brain and tumor. Contrast enhancement with gadolinium sharpens the definition of a lesion.^{7,22,36} Under certain conditions, MRI enhanced with gadolinium can distinguish between tumor and edema. However, not all high-grade astrocytomas enhance with gadolinium, and MRI signals may imitate imaging abnormalities seen in low-grade astrocytomas or nonmalignant conditions. MRI also cannot accurately predict tumor type or grade of malignancy, for which surgical biopsy is necessary.^{7,34}

Dynamic Imaging. Dynamic functional imaging includes positron emission tomography (PET), single-photon emission CT (SPECT), magnetic resonance spectroscopy (MRS), and functional MRI. PET is a noninvasive technique using a cyclotron and specific isotopes to obtain dynamic information about the metabolism and physiology of the brain tumor and the surrounding brain tissue. PET scans using radioactive markers to measure glucose metabolism can be useful in determining the grade of primary brain tumors and in differentiating tumor regrowth from radiation necrosis.^{9,36,42} PET can also be helpful in studying the metabolic effects of chemotherapy, radiation therapy, and steroids on the tumor.³⁴ However, PET is expensive and less reliable in patients treated heavily with chemotherapy and radiation therapy.^{7,22}

Single-Photon Emission Computed Tomography. SPECT is a functional imaging technique evolved from PET and uses isotopes without cyclotron to assess cerebral blood flow and determine tumor location.^{7,22,34} SPECT is used to identify high- and low-grade tumors and to differentiate between tumor recurrence and radiation necrosis.^{7,34} SPECT is used preoperatively with static imaging to localize the highest metabolic area within tumor for biopsy. Although SPECT is a less sensitive method of obtaining physiological information on brain tumors, it is more readily available and less expensive.⁷

Magnetic Resonance Spectroscopy. MRS is a noninvasive technique used in conjunction with static MRI to measure the metabolism of brain tumors.⁷ MRS has been proved to differentiate successfully normal brain from malignant tumor and recurrent tumor from radiation necrosis. It also has been used to document early treatment response and provide information regarding histological grade of astrocytomas.^{43,44} In the future, MRS targeting may enhance the diagnostic yield of brain biopsy and possibly be a noninvasive alternative to surgical biopsy.^{43,45} Magnetic resonance angiography (MRA) generates images of blood vessels without dye or ionizing radiation to

evaluate the blood flow and position of vessels leading to the brain tumor.³¹

Functional Magnetic Resonance Imaging. Functional MRI uses a conventional MRI scanner fitted with echo planar technology to map cerebral blood flow at the capillary level. Its intended purpose is to provide information regarding the diffusion of contrast into tumor, resulting in better resolution of tumor and edema.⁷ Functional MRI can also be used to identify the motor, sensory, and language areas of the brain or the functional eloquent cortex.^{16,46}

Modern computer technology allows for the two- and three-dimensional reconstruction of identical planes in cranial space by combining tumor images from different modalities, including CT, MRI, PET, and SPECT. *Computed integration imaging* involves the simultaneous display of images from different techniques in a single imaging system that is transposed to a reference stereotactic frame. This development has resulted in significant advances in stereotactic biopsy, interstitial radiotherapy, and laser-guided stereotactic resection.⁷ By improving targeting and visualization of tissues, stereotaxis provides a safer, more accurate method of tissue acquisition and biopsy. A correct tissue diagnosis can be made in 95% of cases with this technique.⁴⁷ (Refer to Chapter 37 for additional discussion on all types of imaging and visual examples.)

Biopsy

Surgical biopsy is performed to obtain tumor tissue as part of tumor resection or as a separate diagnostic procedure.¹³ Stereotactic biopsy is a computer-directed needle biopsy. When guided by advanced imaging tools, stereotactic biopsy yields the lowest surgical morbidity and highest degree of diagnostic information. This technique is frequently used with deep-seated tumors in functionally important or inaccessible areas of the brain in order to preserve function.⁴⁸

Laboratory Diagnosis

Laboratory testing is often used to further assess focal deficits during the diagnosis and management of brain tumors. Perimetry is the measurement of visual fields used when evaluating tumors near the optic chiasm. Electroencephalography (EEG) is used to monitor brain activity and detect seizures but has limited value during screening because EEG findings are often normal in clients with brain tumors.³⁴ Lumbar puncture is used to analyze CSF, which is useful in the diagnosis and detection of dissemination of certain brain tumors. However, lumbar puncture is risky in patients with increased ICP and should be avoided in those cases.^{22,34,36} Audiometry and vestibular testing are useful for diagnosing tumors in the cerebellopontine angle. Endocrine testing is used to examine endocrine abnormalities with tumors in the pituitary gland and hypothalamus.³⁴

Medical and Surgical Management

After diagnosis of a brain tumor has been confirmed, specific treatment must be selected. The ultimate goals of tumor management are to improve quality of life and extend survival, by preserving or improving body function and structures.⁴⁹ These goals are accomplished by removing or decreasing the size of the tumor. Treatment techniques are determined by histological type, location, grade, and size of tumor; age at onset; and medical history of the patient.^{7,17,49}

Four types of treatment are discussed: (1) traditional surgery, (2) chemotherapy, (3) radiation therapy, and (4) stereotactic radiosurgery.

Traditional Surgery

The primary goal of traditional surgery is maximal tumor resection with the least amount of damage to neural or supporting structures.⁷ Gross total resection is associated with longer survival rates and decreased neurological impairment.³⁷ Benign tumors, if accessible, are resected completely, whereas malignant tumors are typically partially resected secondary to location or size of the tumor.^{7,49} The purposes of surgery in the management of brain tumors include the following:

1. Biopsy to establish a diagnosis
2. Partial resection to decrease the tumor mass to be treated by other methods
3. Complete resection of the tumor
4. Provision of access for adjuvant treatment techniques¹⁶

Biopsies are performed through open, needle, and stereotactic needle techniques. Open biopsies involve exposure of the tumor followed by removal of a sample through surgical excision. Needle biopsies involve insertion of a needle into the tumor through a hole in the skull and the excision of the tissue sample drawn through the needle. Stereotactic needle biopsies use computers and MRI or CT scanning equipment to assist in directing the needle into the tumor. This type of biopsy is useful for deep-seated or multiple brain lesions.^{7,16}

Partial and complete resections are accomplished through craniotomy. Craniotomy involves removal of a portion of the skull and separation of the dura mater to expose the tumor. Stereotactic craniotomy uses technology to create computed three-dimensional pictures of the brain to guide the neurosurgeon during the procedure. CT scanning and MRI scanners are used to provide an evaluation of the tumor resection during the procedure.^{7,50} Awake craniotomy allows for intraoperative brain mapping that helps to identify and protect functional cortex and in recent years has become an alternative surgical treatment for most supratentorial tumors.⁴⁶

Preoperative Management. Before surgery, clients are evaluated for general surgical risks and the possibility of tumors in additional locations. Unless medically contraindicated, steroids are administered before surgery if brain edema is present or if extensive manipulation will be occurring during surgery. Anticonvulsant medications are also administered preoperatively to prevent seizures during or after surgery.^{7,49}

Intraoperative Management. During surgery, precautions are taken to prevent an increase in edema or ICP. Mannitol, a vasodilator to decrease ICP, is used to shrink the surrounding brain tissue, thus providing easier access to the tumor. Steroid use is continued and antibiotics are administered to prevent infection. Hyperventilation, with a CO₂ level of 25 mEq/L, is also used to reduce ICP.^{7,49}

Postoperative Management. Patients are observed in an intensive care unit for at least 24 hours for possible intracranial bleeding or seizures. Blood pressure is monitored continuously. After surgery, patients are at risk for developing deep vein thrombosis or pulmonary embolism secondary to decreased muscle activity, but because these patients are at

risk for intracranial bleeding, anticoagulants cannot be given.⁵¹ Therefore compression stockings are used prophylactically in an attempt to prevent deep vein thrombosis. Steroids are tapered after surgery over 5 to 10 days. Anticonvulsant medications are continued after surgery, with the length of time dependent on the presence of seizure activity before and after surgery.^{7,49} The primary limitations of traditional surgery include the following:

1. Medical complications such as hematoma, hydrocephalus, infection, and infarction from the surgical procedure
2. Complications resulting from general anesthesia
3. Increased cost of the hospital stay and surgical procedure^{30,33,49}

Chemotherapy

Chemotherapy is another treatment frequently used to manage brain tumors. It can be used independently or as an adjuvant to surgery or radiation. Chemotherapeutic drugs are not effective on all types of tumors. Some tumors are known to be resistant to certain drugs, and therefore other treatments are more successful in treating these tumors. Drugs can be given in combination to target all cell types present within the tumor. Because different drugs have different modes of action and side effects, combined drug therapy often proves to be one of the most effective treatments.⁵² Chemotherapy can be administered in a number of different ways. Most agents are given intravenously through a peripheral intravenous line or through a catheter such as a peripherally inserted central catheter (PICC) or Groshong catheter. Other drugs are placed directly into the tumor bed or are given intramuscularly, orally, or by means of an implanted device.

Chemotherapy drugs impede cellular replication of the tumor cells, interfering with their ability to copy deoxyribonucleic acid (DNA) and reproduce. Once the replicating capability of the tumor cell has been disrupted, the cell dies. In this way the tumor is prevented from growing and is destroyed at the cellular level.⁵²

Methotrexate is a highly toxic drug and is usually paired with an antidote drug, leucovorin, to reverse the side effects on normal cells.⁵³ Typically methotrexate is used to treat cancer outside of the CNS; however, it is the major chemotherapy drug used to treat CNS lymphoma.²² Methotrexate has been found to produce a high degree of neurotoxicity when used in combination with radiation therapy.⁵⁴

Neurotoxic to surrounding tissue, methotrexate and ara-C are drugs able to be introduced directly into the CSF through an intraventricular Ommaya reservoir.³⁵ The reservoir, implanted under the scalp, is filled by use of a syringe, and the medication is then circulated through the ventricles to the brain.⁵² The drugs are typically given in a clinic setting by a registered nurse certified in chemotherapy administration. A patient's chemotherapy schedule varies depending on the drug given. An on-off cycle is used to allow the patient to recover from the toxic effects of the drug.

One of the challenges in delivering cytotoxic drugs to the brain is the blood-brain barrier (BBB). The BBB is the brain's natural protective barrier against transmission of foreign substances from the blood into the brain.⁵² One class of drugs that does penetrate the BBB is the *nitrosoureas*. These include BCNU (carmustine) and CCNU

(lomustine), which are lipid soluble and cell cycle specific. These drugs are given in high doses and typically used to treat glioblastoma multiforme and anaplastic astrocytoma; however, often these high-grade tumors invade and destroy the BBB.

BCNU can also be administered in the form of wafers placed by the neurosurgeon directly into the brain tumor. An initial study for recurrent malignant gliomas found that patients' tumors responded to the treatment.⁵⁵ This report was followed by an up-front study for glioblastoma multiforme.⁵⁶ U.S. Food and Drug Administration (FDA) approval for these wafers (Gliadel) followed.

Temozolomide is an orally available chemotherapeutic agent introduced in the 1990s for the treatment of malignant gliomas.⁵⁷ Initial results in treating recurrent anaplastic astrocytoma⁵⁸ and glioblastoma⁵⁹ were so successful that the drug was approved for the treatment of recurrent brain tumors by the FDA. For recurrent tumors the drug is administered orally 5 days per month. Temozolomide was then tested for the up-front treatment of glioblastoma. This occurred in a multicenter study in which the drug was given daily as part of the initial treatment with radiation therapy, followed by five doses per month for maintenance treatment.⁶⁰ Survival increased substantially with this regimen, and as a result the FDA approved the use of temozolomide as part of first-line treatment of glioblastoma. Temozolomide is also used to treat anaplastic gliomas.

Another major breakthrough in chemotherapy of brain tumors was the finding that the antiangiogenesis monoclonal antibody Avastin (bevacizumab) improved the progression-free survival and the tumor images on MRIs of patients with glioblastoma.⁶¹⁻⁶³ The drug targets vascular endothelial growth factor (VEGF) and is administered intravenously. It has recently been approved by the FDA for the treatment of recurrent glioblastoma multiforme. It is usually administered with another chemotherapy agent, for example, irinotecan.

Radiation Therapy

Radiation therapy can be used alone or in conjunction with surgery or chemotherapy to treat malignant brain tumors. It is typically chosen as a treatment option for tumors that are too large or inaccessible for surgical resection and to eradicate residual neoplastic cells after a surgical debulking.

Radiotherapy consists of the delivery of high-powered photons, with energies in a much greater range than that of standard x-rays, as an external beam directly at the tumor site. The external beam is transmitted to the tumor through a linear accelerator or a cobalt machine that uses cobalt isotopes as the radiation source. External beam radiation is the most widely used form of radiation treatment.⁷

Conventional radiation therapy as described previously is fractionated into small doses delivered over a period of time.¹⁶ Often, if a large fraction is to be delivered, the dose is divided and given more than once per day; this is called hyperfractionation. Hyperfractionated radiation therapy is believed to increase the efficacy and decrease the long-term side effects of radiation. More studies need to be completed to know its exact benefits.

Conformal radiation is the use of high-dose external beam radiation, produced by a linear accelerator, to precisely

match or “conform” to the tumor shape. One such method of conformal radiation delivery is the Peacock system. This method attempts to deliver a uniform amount of radiation to the tumor and minimize irradiation of healthy brain tissue.¹⁶

Radiosurgery involves relatively high-dose hypofractionated radiation beams directed at small tumor areas through the use of computer imaging.¹⁶ This type of treatment includes the Gamma Knife, linear accelerators, and the cyberknife, which are discussed later.

The radiation oncologist determines the dosage, frequency, and method of radiation delivery depending on tumor type, location, growth rate, and other medical issues for each client. A typical course of radiation therapy will last 6 weeks. Clients are irradiated for just 1 to 5 minutes, 5 days a week. The radiation is intended to kill the malignant cells and preserve healthy cells, but certain rapidly growing cells, those in skin tissue and mucosa, are killed as well. The side effects experienced by those undergoing treatment are a result of this destruction of healthy cells.

Radiation therapy has considerable limitations and disadvantages. There is an accepted maximum lifetime dosage of radiation that the brain and body can tolerate. As doses come close to this limit, the risk of radiation necrosis increases. Because the brains of young children are particularly vulnerable to radiation, other therapies, such as chemotherapy, are used until the developing brain is more tolerant of radiation. Metastatic lesions have invaded multiple organs or body systems, and a more systemic treatment such as chemotherapy is most effective for this type of brain cancer.¹⁶

Stereotactic Radiosurgery

Stereotactic radiosurgery is defined as delivery of a high dose of ionizing radiation, in a single fraction, to a small, precisely defined volume of tissue.^{7,33,49,64} The high-energy accelerators involved with stereotactic radiosurgery improve the physical effect of radiation by allowing energy to travel more precisely in a straight line and penetrate deeper before dissipating.⁶⁴ The goal of stereotactic radiosurgery is to arrest tumor growth.⁶⁵ This technique has been shown to be most beneficial for treating centrally located lesions less than 3 cm in size and for patients with increased surgical risk factors.^{33,64} Advantages of stereotactic radiosurgery are as follows:

1. Is a noninvasive procedure using local anesthesia and sedation to place the stereotactic frame
2. Avoids risks of general anesthesia and immediate post-operative risks such as bleeding, CSF leak, and infection
3. Lowers treatment cost and shortens hospital stays^{7,30,64,66}

Stereotactic radiosurgery is used to treat benign and malignant tumors, vascular malformations, and functional disorders.^{49,64} The primary modes of administration for stereotactic radiosurgery include the Gamma Knife, linear accelerators, and the cyberknife.^{7,17,49}

The *Gamma Knife* was first introduced in Sweden in 1968 and is now used worldwide at 65 sites (Figure 25-3). The Gamma Knife uses 201 discrete sources of cobalt 60, which are focused precisely to one point in three-dimensional space within the cranium.^{33,49,64,67} The Gamma Knife is typically used for deeply embedded small tumors that require precise delivery of radiation.³³

Figure 25-3 ■ The Leksell Gamma Knife.

MRI, CT scanning, or angiography is used to identify the exact location of the lesion to be treated after the stereotactic frame is placed on the client's head. The stereotactic frame is then fixed to the machine and attached to a collimator helmet containing 201 holes for the radiation to pass through. The patient is then locked into position. The prescribed dose is given over 20 minutes to 2 hours. After treatment the frame is removed; the client is observed and is frequently discharged after 24 hours. Return to previous activity typically occurs within a few days.^{30,33,49,67}

With the Gamma Knife, the full dose of radiation is received only at the point where the 201 beams intersect, thereby giving only a minimal dose to uninvolved tissue when targeted accurately. Side effects are rare, but headache and nausea may occur.⁷ The primary limitations of the Gamma Knife are the limited brain volume that can be treated with one dose and the cost of the Gamma Knife machine.^{7,49}

Linear accelerators used for conventional radiation can be modified for stereotactic radiosurgery. The brain lesion to be targeted is stereotactically placed in the center of the arc of rotation of the machine. A single, highly focused beam of radiation is delivered over multiple sweeps around the brain lesion. Linear accelerators can be used to treat larger tumors with precise shape while maintaining uniform dose. Because linear accelerators are used for conventional radiation, a quality check for beam accuracy is imperative before the machine is used for stereotactic radiosurgery.^{7,49}

The *cyberknife* uses a compact linear accelerator mounted on a robotic arm, with the robotic arm moving around the linear accelerator to multiple precalculated positions (Figure 25-4). At each position the accelerator fires a beam of radiation at the tumor or lesion. A high cumulative dose of radiation is achieved at the tumor or lesion because of the convergence of the beams. This dose is typically strong enough to destroy the abnormal cells while minimizing the damaging effects of radiation to healthy surrounding tissue. The cyberknife differs from other stereotactic radiosurgery because a linear accelerator is combined with an image guidance system. The robotic arm allows the cyberknife to target difficult-to-reach areas of the body, as well as adjust quickly for changes in target location during treatment.

Figure 25-4 ■ The cyberknife.

Several research studies have reported on the use of stereotactic radiosurgery, including the Gamma Knife and linear accelerators, and compared this modality with microsurgery; however, studies involving the cyberknife are limited. In patients with brain metastases, the Gamma Knife is typically indicated for small lesions that are centrally located. Surgical resection is indicated for superficial lesions greater than 3 cm in diameter, when a significant mass effect of the tumor exists, or if edema is present in the cranium.³³ The Gamma Knife has been shown to achieve tumor control rates as high as those for surgery and whole-body radiation therapy combined and to halt or reverse neurological progression in 78% of patients treated.^{68,69}

Microsurgical resection has shown a 90% cure rate for acoustic neuromas less than 3 cm in size. Stereotactic radiosurgery avoids the risk of an open procedure, but the tumor is controlled rather than removed. Thus far, a 92% tumor control rate has been noted, but the patients in this study have not had a 10-year follow-up.^{29,30}

Research exists for both low- and high-grade gliomas, but large, controlled studies are few. With low-grade tumors, small studies have shown increased survival after stereotactic radiosurgery, but these studies are uncontrolled and limited by the small number of participants.⁶⁶ For high-grade tumors, recent studies have found median survival rates ranging from 9.5 to 17 months with use of stereotactic radiosurgery.^{39,70-72} For recurrent malignant gliomas, survival after fractionated and nonfractionated stereotactic radiosurgery has been shown to be 8 to 11 months.^{51,73-75} The addition of radiosurgery to surgery and radiation therapy produced only modest improvement when compared with surgery and radiation therapy alone.⁶⁶

The preferred treatment for *meningiomas* is surgical resection, if complete resection is possible. When surgery is not an option and the tumor is less than 3 cm in size or 5 mm away from the optic nerve, stereotactic radiosurgery is indicated.^{27,76,77} Four-year survival rates of 91% in benign meningiomas and 21.5% in malignant meningiomas have been demonstrated after use of the Gamma Knife.^{27,76} In a survey taken 5 to 10 years after radiosurgery, 96% of patients believed radiosurgery had provided a satisfactory outcome.⁷⁶

REHABILITATION

Overview

Rehabilitation is a key component in the management of the client with a brain tumor. With advances in technology and treatment intervention, survival rates of people with cancer have improved. Consequently, people are living longer with physical impairments resulting from the disease or its treatment, necessitating interdisciplinary therapeutic intervention.² Rehabilitating the body function and structural impairments complicates the medical and psychological issues typically associated with cancer diagnosis.¹⁹ By preventing complications, maximizing function, and providing support, rehabilitation specialists ultimately improve the client's quality of life.¹⁹ Research has shown that the functional outcomes and discharge to home for individuals with brain tumors are comparable to those of individuals with stroke or traumatic brain injury.⁷⁸ The most effective rehabilitation plan is flexible, to allow for increasing impairment, and sensitive, to accommodate the highly emotional impact that accompanies the diagnosis of a primary brain tumor. The tumor's invasion is marked by complaints of pain and growing activity limitations. These functional consequences of the disease process are the target of the rehabilitation team. In addition to the side effects of therapeutic intervention, functional progress may be affected by cerebral edema, hydrocephalus, tumor regrowth, infection, and radiation necrosis. Compared with clients with other diagnoses, clients with brain tumors have a higher rate of unplanned transfers back to acute care, primarily because of infection.⁷⁹

The management of a client with a brain tumor is different from that of other CNS disorders, despite a similar clinical presentation. To establish an appropriate plan of care, the clinician must understand the nature of the specific tumor, consider the client's fluctuating neurological status, and prepare for the likelihood of progressive decline. The preferred approach is holistic, addressing quality of life issues such as physical, psychosocial, and emotional needs, incorporated into the systems model of motor control. Factors defining quality of life are unique to each individual, and therefore clinicians should identify and use these factors to construct a meaningful treatment program.⁸⁰ Individuals with advanced cancer who participated in exercise therapy have reported increased physical functioning, improved quality of life, and decreased fatigue.⁷⁸

Evaluation, clinical analysis, intervention, discharge planning, and psychosocial issues specific to the management of the client with a brain tumor are discussed in the following sections.

Evaluation

The evaluation process must include a comprehensive examination and assessment of all systems in order to establish an appropriate impairment diagnosis, problem list, prognosis, and plan of care. Before a neurological assessment is performed, a thorough review of the client's medical history and an understanding of the medical diagnosis are necessary. The client's occupation, support system, personal goals, and role in the family are important psychosocial factors that should be identified in the evaluation. These factors, along with a thorough functional and neurological examination, assist the clinician through the diagnostic process. This process includes

identification of clinical problems, establishment of realistic and appropriate goals, selection of the most effective intervention, and discharge planning.

Although the neurological examination yields important information regarding strength, reflexes, sensation, vision, and cognition, it is important not to rely solely on its findings to determine an appropriate intervention. Because multiple systems interact to produce normal movement, it is difficult to examine isolated systems and apply the findings accurately to movement patterns. Therefore clinicians are encouraged to examine all systems through functional tasks to understand how the impaired neurological, musculoskeletal, and cognitive systems are affecting the client's movement. During the evaluation process the clinician notes systems that are functioning normally, identifies abnormal components of movement, and determines appropriate interventions to optimize motor recovery.³⁸ The progressive nature of the disease necessitates ongoing evaluation followed by accommodating intervention.

Goal Setting

The functional impairments and objective neurological findings provide the clinician with valuable information to assess prognosis, establish goals, and determine a treatment plan. Despite the progressive nature of the disease, treatment goals should maximize the potential for function, introduce effective, task-oriented movement strategies, and offer multiple movement options.³⁸

To set realistic and client-oriented goals, it is important for the clinician to envision where the patient will be at discharge based on present level of function, prognosis, and disease course, while considering client and caregiver personal goals. Appropriate goals range from comprehensive caregiver training to independent mobility with transition back to a work environment. Goals need to challenge the client to attain an optimal level of function but must also allow for fluctuations in potential resulting from the disease process. Clients who have the potential to return to work may require additional intervention from neuropsychology, vocational rehabilitation, or a multidisciplinary day program, depending on the nature of the job and the deficits.

Because the rehabilitation potential for clients with brain tumors varies greatly, it is imperative that the client, family members, rehabilitation team, and third-party payers understand and agree with the purpose of the client's rehabilitation program. Pathways can be extremely instrumental in clarifying rehabilitation goals and identifying the caregiver's role on discharge (Table 25-2). If a client has a poor prognosis, the rehabilitation team can successfully train family members and order equipment within 1 week if the family understands the goals and the need to be present during treatment sessions. The pathway serves as a guideline assisting the rehabilitation team in achieving the client's goals in an effective and efficient manner.

Functional Assessment

Historically persons with primary malignant brain tumors have not been considered rehabilitation candidates because of the progressive nature of their disease. Physicians, health care providers, and third-party payers have questioned the efficacy of rehabilitation in this population because of poor

TABLE 25-2 ■ BRAIN TUMOR CLINICAL PATHWAY: 1-WEEK STAY

	DAY 1	DAY 2	DAY 3	DAYS 4-5	DAYS 6-7
Nursing	Medical and functional assessment Establish LOS with MD Initiate care plan with caregivers	Provide education regarding sequelae of diagnosis and treatment Facilitate team meeting Collaborate with CM	Provide nutritional and dietary education prn Train caregiver with tube feedings prn	Skin care B&B training Home safety Address medical questions	Provide info regarding medications (i.e., pain and antiepileptics) Review side effects of radiation and chemotherapy Refer to palliative care or hospice prn
Physicians	Provide education and handouts to patient and family regarding diagnosis, prognosis, and treatment plan	Prescribe medications to minimize side effects (e.g., seizure, pain) and maximize rehabilitation potential	Maintain open communication between oncologist and rehabilitation physician		Recommend follow-up appointments and treatment
Physical Therapy	Functional evaluation Assess family support Schedule home evaluation prn	Provide education and handouts for caregiver body mechanics, physical therapy positioning, and mobility techniques Determine and order equipment	Continue mobility training—different types and surfaces Educate regarding safety precautions and energy conservation	Caregivers return demonstrate competency with mobility techniques Home evaluation completed	Patient discharged if caregivers competent in all necessary mobility techniques and equipment obtained
Occupational Therapy	Functional evaluation Discuss home environment Schedule home evaluation prn	Provide education and handouts for caregiver body mechanics, extremity management, and ADLs techniques Determine adaptive equipment needs and place order	Continue training Train caregivers in visual-perceptual needs	Caregivers return demonstrate competency with ADL techniques Home evaluation completed	Patient discharged if caregivers competent in all necessary ADL and mobility techniques and equipment obtained
Speech and Language Therapy	Bedside swallow evaluation performed Diet recommended MBS and FEES scheduled prn	MBS and FEES completed prn Provide education and handouts regarding precautions and strategies for safe swallowing, appropriate diet Signs of aspiration	Initiate cog/com evaluation Monitor diet Continue caregiver training for swallowing	Complete cog/com evaluation Provide family with ideas to modify environment to improve cog/com function Educate caregiver regarding signs of functional decline	Continue to monitor diet Continue caregiver education regarding swallowing, safety and judgment, and cog/com function
Therapeutic Recreation	Evaluate patient's leisure interests		Leisure skill building with holistic approach	Review community resources	Discharge
Neuropsychology Case Management and Social Services	If indicated Initiate assessment	Complete assessment Inform physical therapy and caregiver of team recommendations and LOS	Order DME	Arrange for continued therapies prn	Review discharge plans and recommendations with patient and caregivers

prognoses and limited survival rates. However, advances in medical diagnosis and intervention are resulting in longer survival of people with multiple limitations that require rehabilitation. Functional assessment scales provide objective evidence that rehabilitation is effective and worthwhile for these clients.^{3,78,81}

The functional assessment is a critical component in the development of the treatment intervention. It provides a method of analyzing deficits, compiling a problem list, developing a treatment plan, and measuring functional outcomes. The Functional Independence Measure (FIM) is a functional assessment tool used to measure degree of disability, regardless of underlying pathology, and burden of care to demonstrate functional outcomes of rehabilitation and assist clinicians with discharge planning.⁵¹

Functional outcome scales such as the FIM provide a means of documenting the client's response to therapy intervention for clinicians, physicians, and third-party payers in the rehabilitation setting. Research using FIM data demonstrates efficacy for inpatient rehabilitation of brain tumor clients similar to that noted in those with traumatic brain injury or stroke when matched by age, sex, and functional status on admission.^{1,3,29,81}

Physicians use specific functional evaluation scales to measure the success of treatment. The Karnofsky performance scale, which rates patients' functional performance, is the tool most widely used in clinical research and treatment decisions (see [Table 25-1](#)).¹⁹ The client receives a score from 0 to 100 based on independence or level of assistance required for normal activity. The scale is used in research to evaluate an individual's physical response to treatment.^{19,51,82,83}

Side Effects and Considerations

Through advances in chemotherapy and radiation therapy, the ability to reduce tumor mass has greatly improved. Unfortunately, despite the often favorable long-term results of these treatments, the immediate effects create physical and psychological challenges for the client and clinician. Clients who are being treated aggressively during the rehabilitation phase will probably experience a decline in neurological or hematological status. These declines often limit the individual's tolerance for treatment intervention and increase client and caregiver feelings of depression and hopelessness. Clinicians have the opportunity to provide more than physical restorative services and should offer psychosocial support when possible to enhance successful rehabilitation.⁸⁴

The side effects and special considerations that arise with this population range from physical to cognitive to psychosocial and emotional. The following paragraphs relate the spectrum of complications and side effects the client may experience when undergoing medical treatment, and the impact these may have on therapeutic intervention.

Not everyone undergoing chemotherapy or radiation treatment will experience physical side effects; however, the possibilities include hair loss, fatigue, nausea, skin burns or irritation, difficulty eating or digesting food, anorexia, and dry, sore mouth.^{53,85} The side effects are caused by the toxic effects the drugs have on healthy, rapidly dividing cells, including bone marrow cells, cells lining the mucosa, and hair cells.^{52,85}

The toxic effect chemotherapy has on bone marrow impairs the client's ability to produce red and white blood cells and platelets.^{5,52} The client may develop anemia, infection, or hemorrhage as a result of depressed hematological values.

The lining of the mouth, esophagus, and intestines may become inflamed and irritated and interfere with the ability to eat or digest food. The client may experience nausea, vomiting, diarrhea, or constipation, any of which will impair mobility and energy for daily activities.¹⁷

Hair loss is a common side effect of brain radiation and chemotherapy. This requires an especially difficult adjustment for most people because it causes a drastic change in appearance.^{16,52}

Clinicians involved in the management of clients who are currently receiving radiation therapy or chemotherapy need to be mindful of these side effects when developing a plan of intervention. Fatigue, low blood count, and gastrointestinal complaints may limit a client's ability to fully participate in the planned therapy session or may call for a modification in activity or environment. Moreover, the clinician must use these factors to determine if the client's health or safety would be jeopardized by therapeutic intervention at any particular time. In addition, the clinician must be flexible to determine the optimal time when intervention is most effective and does not interfere with medications or meals.

Together with the physical side effects mentioned previously, many clients with brain tumors have changes in cognition or personality as a result of the tumor's location. A patient with a frontal lobe tumor who was previously quiet and withdrawn may, over time, become loud and disinhibited as a result of tumor growth. Tumors that invade the speech-language area cause communication and comprehension difficulties that create challenges for the client and clinician. The client who has a left parietal tumor may be aphasic and not respond to verbal commands. In this case, the clinician must engage in alternate means of communication or provide therapeutic facilitation with tactile cues. An observant, critical analysis of the client's physical deficits and impaired communication, comprehension, and feedback mechanisms is essential to select an effective, client-specific intervention plan.

Because of the emotionally charged nature of the disease process, psychosocial and emotional issues frequently arise. Clinicians should be sensitive to fluctuations in temperament and mood that the diagnosis itself and subsequent treatment strategies create. Clinicians can offer psychosocial support and direct the client and family to resources that may give direction and guidance during difficult transitions.

Intervention

The ultimate goal of rehabilitation is to achieve maximum restoration of function, within the limits imposed by the disease, in the client's preferred environment. The clinician must recognize that the physical, cognitive, and emotional status of these individuals is inconsistent and changing as a result of the disease process or medical intervention. Treatment plans must be flexible to effectively manage fluctuations in the client's presentation. A comprehensive rehabilitation plan is individualized to accommodate progressive changes in functional mobility and provides problem-solving experiences to prepare the client and caregiver for

these situations. The rehabilitation process typically begins in the intensive care unit and continues in the inpatient, outpatient, and home health settings.

In the intensive care unit, communication with nursing staff regarding the client's present medical status and an understanding of ICP, hemodynamic values, and monitoring devices are crucial to determining tolerance for therapy intervention (Figure 25-5). For a ventriculostomy, a catheter is placed in the third ventricle to drain CSF and to monitor ICP. Mobilizing a patient with a ventriculostomy is possible, but nursing staff must close the drain before any positional change and should inform the clinician of appropriate treatment measures. A client's dependence on these monitoring devices does not prevent therapeutic intervention, but the critical status of these individuals must be considered. The monitoring equipment provides constant feedback that assists the clinician in assessing the client's tolerance to activity and his or her ability to proceed with treatment.

As the client becomes more medically stable, the clinician upgrades mobility and prepares the client for the next stage of rehabilitation. Despite clients' decreased medical acuity in the rehabilitation setting, clinicians must continually reassess functional and neurological status and alert physicians to any changes. Clinicians spend many hours with clients during their rehabilitation stay. This daily interaction gives the clinician the opportunity to connect with the client on a personal level and observe her or him in many settings. Intuitive therapists are often the first to notice physical, cognitive, and emotional changes. Communication to the physician of significant changes is imperative for appropriate follow-up procedures and referrals to provide optimal care.

In the inpatient rehabilitation setting, treatment focuses on optimizing functional capabilities to prepare the client and family for discharge. Integrating the client's personal goals and interests into therapeutic intervention invests the client and family in the rehabilitation process. The incorporation of these quality-of-life issues encourages the pursuit of a meaningful lifestyle on discharge. If clinicians believe the client's goals are unrealistic, gentle redirection is helpful to channel energy toward achievable goals. Goals for

inpatient rehabilitation range from returning the client to an independent lifestyle to training family members to be caregivers in the home environment.

The restoration of previous functional movement patterns is desired. The literature reports increasing evidence that the CNS has dynamic properties, including neural regeneration and collateral sprouting, which supports the concept of plasticity. Plasticity allows intact neural centers to recognize and assume functions of areas of the brain impaired or destroyed by the lesion or its medical management.⁸⁶ The treatment focus may need to turn to compensatory strategies if the potential for motor recovery and learning is lacking. Once compensatory patterns are established, it is not clearly known whether recovery of normal movement will be achieved.⁸⁶ Compensatory techniques may be beneficial in increasing safety and efficiency with mobility and activities of daily living, or in providing more independence for the client.⁵¹ Increasing independence can assist in improving quality of life for the client and may permit return to work or participation in previous recreational activity.⁵¹ For example, an avid golfer with right-sided hemiparesis and impaired standing balance can modify his clubs and return to the game at the wheelchair level.

The rehabilitation program should prepare the client and caregivers for an efficient transition from the structured care setting to the home. Using motor learning principles (refer to Chapter 4) to teach functional mobility will best produce transfer of learning from a constant environment to an unpredictable home environment. Repetitious practice of specific parts of a skill in fixed surroundings, with physical and verbal guidance throughout the movement and frequent feedback during and after completion of the task, are beneficial in teaching acquisition of a specific movement or activity.⁸⁷⁻⁸⁹ Practicing the whole activity in a variable context, with irregular feedback and decreased physical and verbal guidance, expedites learning.⁸⁹⁻⁹¹

Learning results in the ability to execute a task in any setting. Community outings and home passes naturally provide an environment that facilitates learning. The clinician can measure retention and transfer of learning by the client's performance in the community or at home. This information should be used to adjust the treatment plan and make

Figure 25-5 ■ A patient after a partial tumor resection. Labels indicate the equipment commonly seen in the neurological intensive care unit.

recommendations for environmental modifications that minimize physical and cognitive demands on the client. A client whose individual treatment focus is transfers gains confidence when able to transfer from a wheelchair to a table chair in a crowded restaurant.

An interdisciplinary team approach is used for community reentry to provide a meaningful experience for the client. Recreational therapists play an integral part in identifying the individual's interests, reintegrating the client into the community, and modifying leisure activities to meet physical abilities. Activities addressed in daily therapy sessions are practiced in the community, and feedback is provided to the appropriate clinician as well as the client. Initial reentry into the community can be intimidating to the client and may cause changes in the client's behavior that will affect mobility performance. Therefore it is necessary for the clinician to be sensitive and recognize the issues the client may be experiencing.

For caregiver training and education to be successful, a good rapport must be established among clinician, client, and the family members or caregivers. Caregiver training includes mobility training and education regarding the effect the tumor may have on the client's present and future mobility. Instruction should be given based on present level of function, but the probability of progressive decline should not be overlooked. An intuitive clinician should offer effective techniques and problem-solving to address potential obstacles created by the disease process. For example, when performing transfer training, the clinician may demonstrate a stand-pivot transfer but may also suggest a squat-pivot transfer if physical or cognitive changes mandate increased assistance by the caregiver.

Discharge Planning

Discharge planning is initiated early, continues throughout the rehabilitation process, and must allow for changes in the client's functional status. On discharge from the rehabilitation setting, the client will make the transition to one of the following settings: home, skilled nursing facility, or hospice. The transition to home is typically preferred by the client, caregiver, and interdisciplinary rehabilitation team. If the client cannot be physically or medically managed at home, then placement in a skilled nursing facility may be necessary. The client may choose hospice care when medical treatment is no longer providing control of the tumor and the physical demands of the client are not manageable by the caregivers. The case manager contacts insurance providers to determine coverage and, after conferring with the interdisciplinary team, gives the client and family information regarding discharge options.

Clinic and caregiver training and education constitute an integral part of discharge planning. Before discharge, the client and caregiver should be instructed in functional mobility and activities of daily living, informed of equipment needs and vendor resources, and provided with community resources for support and education. During individual training, the clinician is able to provide feedback to the caregiver and client to facilitate an easier transition to home. Documentation of caregiver education and training should be included in the progress and discharge notes. A sample form for interdisciplinary documentation of education is provided in [Figure 25-6](#).

Equipment necessary to assist the client and family with mobility and activities of daily living is recommended by the appropriate clinician. When equipment is ordered, fluctuations in the client's present status, as well as the probable progressive decline in function, are considered. If the client is functioning without equipment at discharge, resources such as equipment vendors or local charitable organizations for future equipment needs should be provided.

Information about local community and national resources specific to brain tumors also should be provided before discharge. These resources can be found on the Internet, in the local phone book, or through communication with previous patients or other health care professionals familiar with these organizations. Support groups provide the caregiver and the client with an opportunity to share experiences and information, prevent isolation, foster hope, allow the client and caregiver to discover coping skills, and offer emotional support.⁹² A study conducted to describe experiences and needs of clients with brain tumors found that "attendance and participation in a support group empowers people to seek the most out of life following a brain tumor diagnosis."⁹² (Refer to Chapter 6 for additional information regarding support groups.) National organizations can provide educational information and support to clients ([Box 25-1](#)). These organizations can help the client find local resources unfamiliar to the clinician.

Hospice Care

A time may come when traditional tumor treatment is ineffective and local control is no longer expected. Patient and family must make a decision regarding the living environment and type of care desired. One option available is hospice care. In the United States, the hospice movement in health care has evolved to include specific standards, licensure requirements, and certification. Providing physical, emotional, and psychosocial support to patients and their families in their final days is the intent of hospice care.⁹³ Hospice recognizes the impact terminal illness has on a patient's family system, and the demands, both physical and emotional, it places on the caregiver.⁹⁴ The use of hospice implies a holistic approach that allows families the opportunity to be directly involved in the patient's care and encourages the expression of grief, love, support, and acceptance.

Inpatient hospice facilities provide continuous nursing care in a structured, supervised environment. Hospice services in these facilities offer ongoing pastoral counseling and emotional support to patient and family. However, if patient and family prefer, hospice care can be provided in the patient's home, with home health aides and nursing staff giving limited physical care or providing respite care.

Typically, mobility and caregiver training for the hospice patient are addressed by a therapist earlier in the patient's disease process. However, positioning, range of motion, and pain relief are important to the patient's continued comfort throughout the course of the disease and in any setting.

PSYCHOSOCIAL CARE

With many clients living extended lives with brain tumors, it is important to measure the efficacy of treatment not only in terms of functional outcome, but also in terms of its effect

BRAIN TUMOR TEACHING GOALS

ADULT BRAIN TUMOR

* Please note: For the brain tumor patient who is able to completely or partially use his or her extremities and cognitive abilities, the emphasis on rehab is to maximize the patient's own ability to be independent. It is also to educate and teach the family or care giver appropriate care and safe assistance with the patient and his or her equipment. Efforts will be directed to facilitate the patient's return to home and to resume work (if able) in his or her community in the most efficient and practical manner possible for the patient and the family.

on quality of life. Quality of life is the individual's subjective sense of well-being as a whole and has been studied closely in the treatment of clients with brain tumor.⁸³ *Health-related quality of life* (HRQOL) refers to an individual's overall quality of life—physical, emotional, spiritual, and intellectual functioning. HRQOL has become an important secondary end point for treatment and clinical studies of individuals with gliomas and metastatic brain tumors. Recently, several self-reporting instruments to measure HRQOL specific for individuals with brain tumors have been developed.⁹⁵ Some additional tools used clinically include the Functional Living Index, the Karnofsky performance scale, the Index of Independence in Activity of Daily Living, the State-Trait Anxiety Inventory, and the Self-Rating Depression Scale.⁹⁶ The World Health Organization (WHO) has developed two additional scales to measure quality of life used in all types of medical as well as movement diagnoses that might lead to a decrease in perceived quality of life.^{97,98} For further discussion and general information refer to the WHO website.⁹⁹

The development of a strong supportive relationship with client and caregivers is key to successful rehabilitation. This process begins with respecting the client's unique experience and involves continually evaluating and addressing his or her changing psychosocial needs.⁸⁶ Many individuals with brain tumors experience higher levels of anxiety and depression as well as feelings of a loss of independence, loss of self, and loss of relationships.¹⁰⁰ The clinician must feel invested, demonstrate good communication skills, and exhibit self-confidence in discussing sensitive issues for a caring relationship to develop. By active listening, the clinician can identify the client's true concerns and feelings and assist the client and family in coping with cancer. The clinician's consistent interaction with the client can foster a supportive and safe environment in

which emotional and spiritual feelings can be shared. Once a trusting relationship has been established, the clinician's empathy can help decrease common feelings of isolation and helplessness and support the client through the different stages of the disease.⁸⁶

Hope is a key psychosocial need of the individual with cancer. It is an important coping strategy that can help clients with brain tumors face an uncertain and often fearful future. Hope gives the client something to look forward to each day. Clinicians can create a hopeful environment by encouraging clients to share their expectations, identify realistic short-term goals, and acknowledge hopes, even if they are unrealistic. It is important to recognize that hope must be balanced with reality and honest disclosure regarding diagnosis and prognosis.^{86,101}

Psychological and social problems are not identified in 80% of physically ill persons, possibly owing to clinicians' personal behaviors or beliefs. Clinicians may find it easier to focus on the physical aspect of care to avoid becoming emotional or experiencing the client's distress. Persons with cancer often experience feelings of powerlessness and isolation, which may be increased by distancing behaviors demonstrated by clinicians. Before offering support to clients, clinicians need to examine their own thoughts, feelings, and past experiences with death and dying. This awareness may prevent the clinician from internalizing the client's grief, from protecting the client and family members from the pain of grieving, and from allowing personal values to adversely influence their psychosocial support.¹⁰¹ By recognizing that psychosocial care involves holistic healing, clinicians will be able to develop the best environment for interventions to improve multiple aspects of the client's quality of life.¹⁰¹

SUMMARY

It is important for the clinician involved in the treatment of a client with a brain tumor to anticipate the activity limitations that will develop as a result of the medical intervention or the tumor itself. These limitations provide the foundation for treatment planning and goal setting. Improved quality of life is the goal of the rehabilitation process. This means restoring the client to maximal functional capacity with the least amount of assistance from others. Regardless of the client's life expectancy, the rehabilitation process should enable the client to pursue a productive and meaningful life. **Case Study 25-1** is an example of the complexity of the problems faced by an individual with a CNS tumor. These problems include both the medical condition and the functional activity limitations caused by the tumor and/or the medical management.

CASE STUDY 25-1 ■ MEDICAL DIAGNOSIS: LOW-GRADE ASTROCYTOMA

Mrs. S. is a 46-year-old woman diagnosed 9 years ago with a low-grade astrocytoma in the right posterior frontal lobe. Before this diagnosis, she had a 4-year history of seizures. She underwent a partial resection of a microcystic pilocytic astrocytoma. Postoperative medical management focused on controlling seizure activity. Radiation therapy and chemotherapy were not provided. Physically, she had resultant left foot weakness and minor seizures characterized by tingling numbness and tremors in the left foot. She was able to continue to work, but a career change was necessary owing to cognitive changes, including the inability to perform fast calculations, impaired memory, and decreased recall.

Three years later, imaging studies revealed tumor enlargement and Mrs. S. underwent Peacock radiation therapy. She remained independent for an additional 2 years. Mrs. S. then developed left facial weakness, progressive left hemiparesis, and hyperreflexia on the left side; 2 weeks later, MRI scans revealed a lesion in the right midcerebral hemisphere below the original tumor site. A stereotactic biopsy confirmed a diagnosis of glioblastoma multiforme. She then underwent a gross total tumor resection, received Gamma Knife radiosurgery, and was subsequently treated with chemotherapy.

Mrs. S. was admitted to the neurological rehabilitation unit for comprehensive rehabilitation. During the examination, it was noted that her speech was fluent and she tended to be hyperverbal, distractible, and perseverative. Manual muscle testing revealed functional strength in the right hemibody and $\frac{1}{2}$ strength in the left hemibody except for hip flexion of $\frac{2}{5}$. Decreased sensation to light touch and proprioception in the left hemibody were noted. Because of the location of the lesion, Mrs. S. experienced left seventh cranial nerve involvement, left homonymous hemianopsia, severe left-sided neglect, and right gaze preference. These visual-perceptual deficits greatly impaired her mobility. She was able to attend to the left side with maximal cues, but carryover was not observed.

Functionally, Mrs. S. required moderate assistance to assume sitting on the edge of the bed, where she demonstrated fair sitting balance. Owing to poor standing balance, she required maximal assistance to stand and pivot to her wheelchair. In standing, her head was rotated to the right and flexed, her pelvis was rotated to the right, her hips were flexed, her left knee was buckled, and her left foot was inverted. She was able to ambulate 15 feet in the parallel bars with maximal assistance to address these postural impairments and to advance the left leg. She was able to propel her wheelchair with her right arm and leg with much assistance and encouragement.

Mrs. S. refuses to use a wheelchair at home because her goal is to walk. She is married with three children and lives in a single-story house. Her husband works full-time, necessitating independent and safe mobility to return home. Mrs. S. and her family demonstrate poor understanding of her prognosis and express unrealistic goals. They frequently refer to her previous return to independence after her first resection and expect a similar outcome this time.

The clinician, in consideration of the client's goal to walk, incorporated standing, pre-gait, and gait training into treatment sessions. However, Mrs. S. was encouraged to propel her wheelchair as a means of independent mobility on the rehab unit. A knee-ankle-foot orthosis (KAFO) was fabricated to provide stability in the left leg and assist in her goal of walking again.

Two weeks into her rehabilitation program, Mrs. S. began to demonstrate increased lethargy, decreased ability to participate in treatments, and increased weakness. She required more assistance with mobility. The clinician modified the treatment intervention to an appropriate yet challenging level. Sitting balance and transfers became the focus rather than standing balance and gait. The therapy team notified the physician of these changes and the client was transferred to acute care. She underwent additional surgery to drain a cyst and remove necrotic tissue within the tumor.

On her return to rehabilitation Mrs. S. became more alert and able to participate in therapy sessions. She and her family expressed hope that this surgery would cure the tumor. The clinician expressed encouragement but gently reminded the client and family members that although the drainage of the cyst may have allowed for functional improvements, the tumor was still present. The client's strength continued to improve and functional gains were observed. In gait, her left leg became able to stabilize during the stance phase; however, an Ace bandage was necessary to control foot drop. The client was able to ambulate household distances with minimal assistance.

The interdisciplinary team provided the client and family with the appropriate resources to choose a facility where Mrs. S. could continue her therapy and the family could easily visit. They also were provided with referrals regarding support groups and hospice care if needed in the future. At the time of discharge, Mrs. S. was delighted with her ability to walk but was disappointed that her left arm remained flaccid and that she was not returning home. The client and family continued to search for hope daily, but left with a better understanding of the poor prognosis.

KEY TERMS

brain abscess
encephalitis
functional activities
hypertonicity
hypotonicity
intervention goals
meningitis
postural control

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify and comprehend the terminology for classifying different types of inflammatory and infectious disorders within the brain.
2. Discuss the range of neurological sequelae that occur.
3. Discuss the components of the comprehensive evaluation process and their interrelationships.
4. Structure the examination process to gather the information required to generate an appropriate plan of care.
5. Discuss the general goals of the intervention process.
6. Plan the interventions to meet the needs of the client.

The diversity of neurological sequelae that may occur after an inflammatory disorder in the brain (brain abscess, encephalitis, or meningitis) provides a range of challenges to the rehabilitation team. The therapist must identify the problems underlying the individual's movement dysfunctions without the template of the cluster of "typical" problems available with some other neurological diagnoses. Each client presents a combination of problems that is unique to that client and that requires the creative design of an intervention program. The following discussion of the therapeutic management of individuals recovering from an inflammatory disorder in the brain focuses on the process of designing an intervention plan to address the specific dysfunctions of the individual client. Because the management of the clinical problems is built on an understanding of the underlying pathological condition and because therapists may not be as familiar with these disease processes, an overview of the inflammatory disorders of the brain is presented.

OVERVIEW OF INFLAMMATORY DISORDERS IN THE BRAIN

Categorization of Inflammatory Disorders

Inflammatory disorders of the brain can be categorized based on the anatomical location of the inflammatory process and the cause of the infection, as follows:

- A. Brain abscess
- B. Meningitis (leptomeningitis)
 1. Bacterial meningitis
 2. Aseptic meningitis (viral)
- C. Encephalitis
 1. Acute viral
 2. Parainfectious encephalomyelitis
 3. Acute toxic encephalopathy
 4. Progressive viral encephalitis
 5. "Slow virus" encephalitis

In most individuals, the defense mechanisms of the central nervous system (CNS) provide protection from infecting organisms. Compromises of the protective barriers can result in CNS infections as complications of common infections. The response of the CNS to the infection depends on several factors, including the type of organism, its route of entry, the CNS location of the infection, and the immunological competence of the individual. CNS infections occur with greater frequency and severity in individuals who are very young or elderly, immunodeficient, or antibody deficient.

The inflammatory process may be a localized, circumscribed collection of pus; may involve primarily the leptomeninges; may involve the brain substance; or may involve both the meninges and the brain substance. The infecting agents may be bacteria, viruses, prions, fungi, protozoa, or parasites. The most common agents producing meningitis are bacterial; the most common agents producing encephalitis are viral. However, bacterial encephalitis and viral meningitis also are disease entities. The following overview of the inflammatory processes within the brain is organized based on the anatomical location of the infection. More comprehensive discussions based on specific infecting organisms can be found in the references at the end of the chapter.¹ The site of the infection will determine the signs and symptoms of the CNS infections, whereas the infecting organism determines the prognosis, including the time course and severity of the problems.²

Brain Abscess

Brain abscesses occur when microorganisms reach brain tissue from a penetrating wound to the brain, by extension of local infection such as sinusitis or otitis, or by hematogenous spread from a distant site of infection. The route of infection influences the CNS region involved. The extension of a local infection tends to produce a solitary brain abscess

in an adjacent lobe. Multiple abscesses may originate from the spread of microorganisms through the blood. The introduction of microorganisms by a penetrating trauma may result in an abscess soon after the trauma or several years later. As with the disorders presented in the subsequent discussions, circumstances that result in a compromised immune system (chronic corticosteroid or other immunosuppressive drug administration, administration of cytotoxic chemotherapeutic agents, or human immunodeficiency virus [HIV] infection) may predispose the individual to develop opportunistic infections.

The site and size of the abscess influence the initial symptoms. Evidence of increased intracranial pressure, a focal neurological deficit, and fever are described as the classic presenting triad.³ However, the classic triad occurs in less than 50% of patients.⁴ Most individuals experience an alteration of consciousness. In 47% of the cases, the frontal, parietal, or temporal lobe is involved.^{4,5} Medical management of the abscess typically consists of antibiotic therapy (depending on the infecting agent and size and site of the abscess) and, often, surgical aspiration or excision. Bharucha and colleagues³ describe neurological sequelae in 25% to 50% of the survivors, with 30% to 50% having persistent seizures, 15% to 30% having hemiparesis, and 10% to 20% having disorders of speech or language.

Meningitis

Meningitis (synonymous with leptomeningitis) denotes an infection spread through the cerebrospinal fluid (CSF) with the inflammatory process involving the pia and arachnoid maters, the subarachnoid space, and the adjacent superficial tissues of the brain and spinal cord. Pachymeningitis denotes an inflammatory process involving the dura mater. Meningitis can be caused by a wide variety of organisms, some of which cross the blood-brain barrier and the blood-CSF barrier. The CSF also can become contaminated by a wound that penetrates the meninges as a result of trauma or a medical procedure, such as implantation of a ventriculoperitoneal (VP) shunt. Once the organism compromises the blood-brain and blood-CSF barriers, the CSF provides an ideal medium for growth. All the body's typical major defense systems are essentially absent in the normal CSF. The blood-brain barrier may impede the clearance of infecting organisms by leukocytes and interfere with the entry of pharmacological agents from the blood. The infecting organism is disseminated throughout the subarachnoid space as the contaminated CSF bathes the brain. Entry into the ventricles occurs either from the choroid plexuses or by reflux through the exit foramen of the fourth ventricle. The spread of the organism through the CSF circulation accounts for the differences in the variety and extent of the neurological sequelae that can result from meningitis.

Bacterial Meningitis

Clinical Problems. The diagnostic categorization of meningitis depends on the infecting agent (e.g., *Haemophilus influenzae* meningitis, *Streptococcus pneumoniae* meningitis, and viral meningitis) and on the acute or chronic nature of the meningitis (acute, subacute, or chronic meningitis). The term *acute bacterial meningitis* denotes infections caused by aerobic bacteria (both gram-positive and gram-negative).^{5,6} The most common infecting organism producing acute bacterial meningitis varies according to the age

of the population. During the neonatal period and in the older adult, infections by gram-negative enterobacilli, especially *Escherichia coli*, and group B streptococci occur most frequently. Typical causative agents in children include *H. influenzae*, *Neisseria meningitidis*, and *S. pneumoniae*.⁷ *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* are the most common causes of community-acquired meningitis.^{5,7,8} Individuals with a condition such as sickle cell anemia, alcoholism, or diabetes mellitus and individuals who are immunosuppressed are at increased risk.^{1,9} Meningococci have been implicated in meningitis that strikes young children most often but can also infect adolescents and young adults. Freshman who live in dormitories are almost four times more likely to get meningitis than other college students.

An example of an organism that uses a typical systemic route of bacterial infection is the *H. influenzae* organism—a member of the normal flora of the nose and throat. During an upper respiratory tract infection, the organism may gain entry to the blood. The route of transmission of the organism from the blood to the CSF is not well established.

The circulation of CSF spreads the infecting organism through the ventricular system and the subarachnoid spaces (Figure 26-1). The pia and arachnoid maters become acutely inflamed, and as part of the inflammatory response, a purulent exudate forms in the subarachnoid space. The exudate may undergo organization, resulting in an obstruction of the foramen of Monro, the aqueduct of Sylvius, or the exit foramen of the fourth ventricle. The supracortical subarachnoid spaces proximal to the arachnoid villi may be obliterated, resulting in a noncommunicating or obstructive hydrocephalus caused by the accumulation of CSF. As the CSF accumulates, the intracranial pressure rises. The increased intracranial pressure produces venous obstruction, precipitating a further increase in the intracranial pressure. The rise in the CSF pressure compromises the cerebral blood flow, which activates reflex mechanisms to counteract the decreased cerebral blood flow by raising the systemic blood pressure. An increased systemic blood pressure accompanies increased CSF pressure.

The mechanism producing the headaches that accompany increased intracranial pressure may be the stretching of the meninges and pain fibers associated with blood vessels. Vomiting may occur as a result of stimulation of the medullary emetic centers. Papilledema may occur as intracranial pressure increases.

Other routes of bacterial infection may involve a local spread as the result of an infection of the middle ear or mastoid air cells. Meningitis may occur as a complication of a skull fracture, which exposes CNS tissue to the external environment or to the nasal cavity. Fractures of the cribriform plate of the ethmoid bone producing CSF rhinorrhea provide another route for infection. Meningitis may be a further complication to the clinical problems of a traumatic head injury.

Clinical features of acute bacterial meningitis include fever, severe headache, altered consciousness, convulsions (particularly in children), and nuchal rigidity. Nuchal rigidity is indicative of an irritative lesion of the subarachnoid space. Signs of meningeal irritation are painful cervical flexion, the Kernig sign, the Brudzinski sign, and the jolt sign.¹⁰ Cervical flexion is painful because it stretches the inflamed meninges, nerve roots, and spinal cord. The pain triggers a

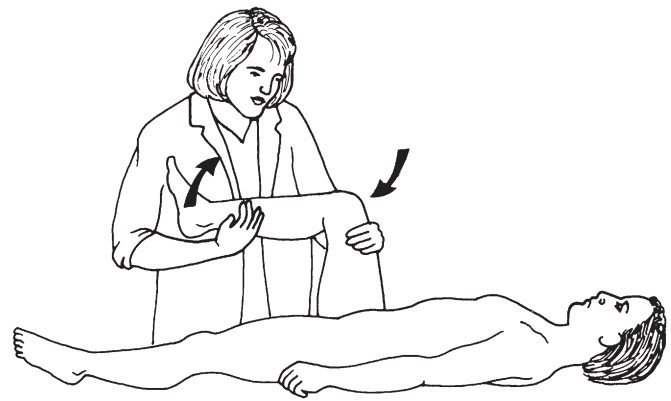

Figure 26-1 ■ The meninges, showing the layers of the dura, arachnoid, and pia mater and their relationship to the subarachnoid space and brain tissue.

reflex spasm of the neck extensors to splint the area against further cervical flexion; however, cervical rotation and extension movements remain relatively free.

The *Kernig sign* refers to a test performed with the client supine in which the thigh is flexed on the abdomen and the knee extended (Figure 26-2, A). Complaints of lumbar or posterior thigh pain indicate a positive test result.¹⁰ This movement pulls on the sciatic nerve, which pulls on the covering of the spinal cord, causing pain in the presence of meningeal irritation. The same results are achieved with passive hip flexion with the knee remaining in extension. This is the same procedure described by Hoppenfeld¹¹ as the straight leg raising test for determining pathology of the sciatic nerve or tightness of the hamstrings. Passive hip flexion with knee extension can be painful because of meningeal irritation, spinal root impingement, sciatic nerve irritation, or hamstring tightness. The *Brudzinski sign* refers to the flexion of the hips and knees elicited when cervical flexion is performed¹⁰ (see Figure 26-2, B). These signs will not be present in the deeply comatose client who has decreased muscle tone and absence of muscle reflexes. The signs may also be absent in the infant or elderly patient. Finally, the jolt test, which has the patient turn his or her head from side to side quickly (two to three rotations per second), has a positive result if the maneuver worsens the patient's headache.¹⁰

The diagnosis of bacterial meningitis can be established based on blood cultures and a sample of CSF obtained by a lumbar puncture. CSF pressure is consistently elevated. The CSF sample in bacterial meningitis typically reveals an increased protein count and a decreased glucose level.

The type and severity of the sequelae of acute bacterial meningitis relate directly to the area affected, the extent of CNS infection, the age and general health of the individual, the level of consciousness at the initiation of pharmacological therapy, and the pathological agent involved. Some of the common CNS complications include subdural effusions, altered levels of consciousness, seizures, involvement of the cranial nerves, and increased intracranial pressure.

A

B

Figure 26-2 ■ A, Kernig sign. B, Brudzinski sign.

Medical Management. Medical management of bacterial meningitis consists of the initiation of the antimicrobial regimen appropriate to the infecting organism and procedures to manage the signs and symptoms of meningitis that have been described in the preceding paragraphs. Medical intervention strategies in both these areas change with the development of new pharmacological agents. Thus, medical

management can change within short periods. The reader is encouraged to always review recent literature for additional information on current aspects of the medical management of the client with meningitis.

Prevention. Vaccination has significantly decreased the incidence of meningitis from *H. influenzae* type B in young children and infants. College freshmen who live in dormitories are four times more likely than other college students to develop meningococcus meningitis, and there is now a vaccine that has shown promise in reducing the outbreak rate.

Potential Neurological Sequelae. Even with optimal antimicrobial therapy, bacterial meningitis continues to have a finite mortality rate, which varies with the infecting organism, age of the individual, and time lapse to initiation of treatment, and has the potential for marked neurological morbidity. Neurological sequelae occur in 20% to 50% of the cases.^{1,9} Bacterial meningitis is considered a medical emergency; delays in initiation of antibacterial therapy increase the risk of complications and permanent neurological dysfunction.^{1,9}

Reports of the long-term outcome of individuals with bacterial meningitis indicate that up to 20% have long-term neurological sequelae.^{1,5} The sequelae may be the result of the acute infectious pathological condition or subacute or chronic pathological changes. The acute infectious pathological condition could result in sequelae such as inflammatory or vascular involvement of the cranial nerves or thrombosis of the meningeal veins. Cranial nerve palsies, especially sensorineural hearing loss, are common complications. The risk of an acute ischemic stroke is greatest during the first 5 days.⁹ Weeks to months after treatment, subacute or chronic pathological changes may develop, such as communicating hydrocephalus, which manifests as difficulties with gait, mental status changes, and incontinence.^{10,12} Approximately 5% of the survivors will have weakness and spasticity.⁶ Focal cerebral signs that may occur either early or late in the course of bacterial meningitis include hemiparesis, ataxia, seizures, cranial nerve palsies, and gaze preference.^{1,13} Cognitive slowness has been found in 27% of clients after pneumococcal meningitis, even with good recovery as documented by a Glasgow Outcome Scale score of 5.¹⁴

Damage to the cerebral cortex can result in numerous expressions of dysfunction. Motor system dysfunction may be the observable expression of the damage within the CNS, but the location of the damage may include sensory and processing areas, as well as those areas typically categorized as belonging to the motor system. Perceptual deficits or regression in cognitive skills may present residual problems. Cranial nerve involvement is most frequently expressed as dysfunction of the eighth cranial nerve complex and produces auditory and vestibular deficits.

Aseptic Meningitis. Aseptic meningitis refers to a nonpurulent inflammatory process confined to the meninges and choroid plexus, usually caused by contamination of the CSF with a viral agent, although other agents can trigger the reactions. The symptoms are similar to those of acute bacterial meningitis but typically are less severe. The individual may be irritable and lethargic and complain of a headache, but cerebral function remains normal unless unusual complications occur.^{5,15} Aseptic meningitis of a viral origin usually causes a benign and relatively short course of illness.^{16,17}

A variety of neurotropic viruses can produce aseptic (viral) meningitis. The enteroviruses (echoviruses and the Coxsackie viruses), herpesviruses, and HIV are the most common causes.^{5,7,18} The primary nonviral causes of aseptic meningitis are Lyme *Borrelia* and *Leptospira*.¹⁹ The diagnosis of this type of aseptic meningitis may be established by isolation of the infecting agent within the CSF or by other techniques. The glucose level of the CSF in bacterial meningitis is usually depressed; however, the glucose level in viral meningitis is normal.²

Treatment of aseptic meningitis consists of management of symptoms. The condition does not typically produce residual neurological sequelae, and full recovery is anticipated within a few days to a few weeks.

Encephalitis

Clinical Problems. *Encephalitis* refers to a group of diseases characterized by inflammation of the parenchyma of the brain and its surrounding meninges. Although a variety of agents can produce encephalitis, the term usually denotes a viral invasion of the cells of the brain and spinal cord.

Different cell populations within the CNS vary in their susceptibility to infection by a specific virus. (For example, the viruses responsible for poliomyelitis have a selective affinity for the motor neurons of the brain stem and spinal cord. Viruses such as Coxsackie viruses and echoviruses typically infect meningeal cells to cause the benign viral meningitis discussed in the previous section.) In acute encephalitis, neurons that are vulnerable to the specific virus are invaded and undergo lysis. Viral encephalitis causes a syndrome of elevated temperature, headache, nuchal rigidity, vomiting, and general malaise (symptoms of aseptic or viral meningitis), with the addition of evidence of more extensive cerebral damage such as coma, cranial nerve palsy, hemiplegia, involuntary movements, or ataxia. The difficulty in differentiating between acute viral meningitis and acute viral encephalitis is reflected in the use of the term *meningoencephalitis* in some cases.

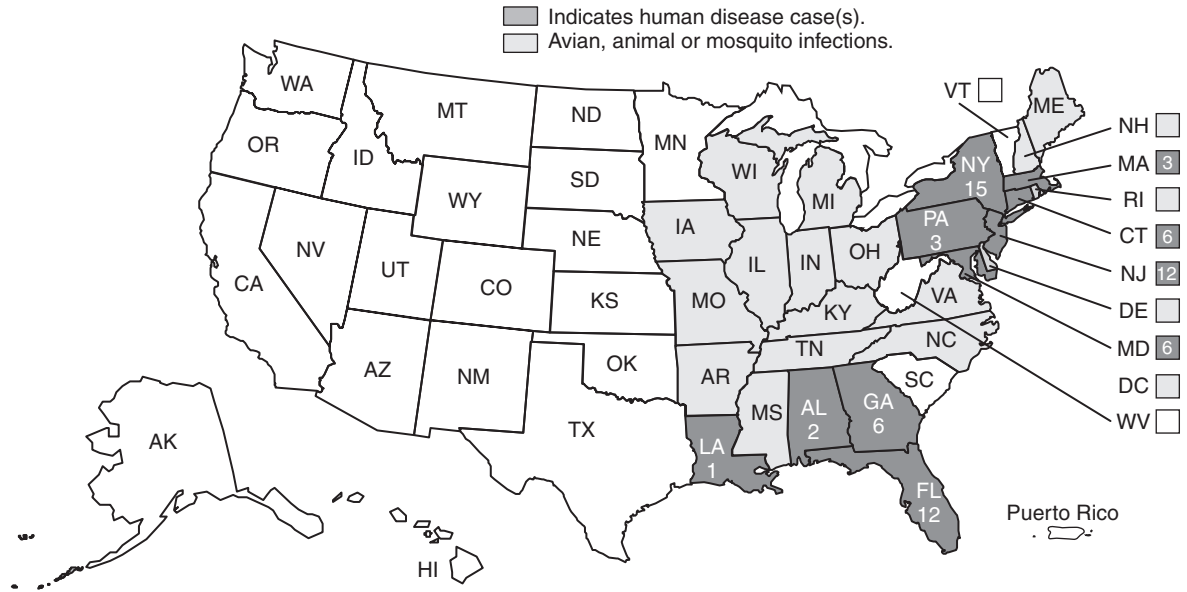

The pathological condition includes destruction or damage to neurons and glial cells resulting from invasion of the cells by the virus, the presence of intranuclear inclusion bodies, edema, and inflammation of the brain and spinal cord. Perivascular cuffing by polymorphonuclear leukocytes and lymphocytes may occur, as well as angiitis of small blood vessels. Widespread destruction of the white matter by the inflammatory process and by thrombosis of the perforating vessels can occur. Increased intracranial pressure, which can result from the cerebral edema and vascular damage, presents the potential for a transtentorial herniation. The likelihood of residual impairment of neurological functions depends on the infecting viral agent. Patients with mumps meningoencephalitis have an excellent prognosis, whereas 55% of the individuals with herpes simplex encephalitis treated with acyclovir have some neurological sequelae.⁶ Because of the slow recovery of injured brain tissue, even in patients who recover completely, return to normal function may take months.²⁰

Plum and Posner²¹ discuss viral encephalitis in terms of five pathological syndromes. Acute viral encephalitis is a primary or exclusively CNS infection. An example would be herpes simplex encephalitis, in which the virus shows a partiality for the gray matter of the temporal lobe, insula,

cingulate gyrus, and inferior frontal lobe. Other examples are the mosquito-borne viruses, such as the St. Louis encephalitis, California virus encephalitis, and most recently the West Nile virus (WNV). From 1999 to 2005 in the United States, the incidence of infection from the WNV has increased from 62 cases to 3000 cases.²² Currently all states have some level of WNV activity, and only four states are without human cases (Figure 26-3). The majority (80%) of

people infected by the WNV will be asymptomatic; of the remaining people infected, less than 1% will develop severe illness.²³ Risk of neuroinvasive disease from WNV is 40%; neuroinvasive disease involves meningitis, encephalitis, or poliomyelitis, with wide variety in clinical presentation (Figure 26-4).²⁴ Parainfectious encephalomyelitis is associated with viral infections such as measles, mumps, or varicella. Acute toxic encephalopathy denotes encephalitis that

occurs during the course of a systemic infection with a common virus. The clinical symptoms are produced by the cerebral edema in acute toxic encephalopathy, which results in increased intracranial pressure and the risk of transtentorial herniation. Reye syndrome is an example. Global neurological signs, such as hemiplegia and aphasia, are usually present, rather than focal signs. The clinical symptoms of the previous three syndromes may be similar. Specific diagnosis may be established only by biopsy or autopsy.

Progressive viral infections occur from common viruses invading susceptible individuals, such as those who are immunosuppressed or during the perinatal to early childhood period. Slow, progressive destruction of the CNS occurs, as in subacute sclerosing panencephalitis. The final category of encephalitis syndromes consists of “slow virus” infections by unconventional agents (the prion diseases) that produce progressive dementing diseases such as Creutzfeldt-Jakob disease and kuru.²⁵

Medical Management. The medical management of virally induced encephalitis has been, and with many infecting agents remains, primarily symptomatic. In some cases, intensive, aggressive care is necessary to sustain life. Pharmacological interventions are available to treat some viral infections, such as herpes encephalitis. The probability of neurological sequelae differs according to the infecting agent. Aggressive management of increased intracranial pressure is required because persistently elevated intracranial pressure is associated with poor outcome.^{1,26} Further information concerning the clinical features, medical management, and potential for neurological sequelae of a specific type of encephalitis should be sought in the literature based on the infecting agent.

Clinical Picture of the Individual with Inflammatory Disorders of the Brain

An individual within the acute phase of meningitis or encephalitis or with residual neurologic dysfunction from these disorders may demonstrate signs and symptoms similar to those of generalized brain trauma, tumor disorder, or other identified abnormal neurological state. The variability in the

clinical picture is reflected in the inclusion of the category “infectious diseases that affect the central nervous system” in the *Guide to Physical Therapist Practice*.²⁷ Practice patterns for physical therapists that apply to this population include the following:

- 5C: Impaired Motor Function and Sensory Integrity Associated with Nonprogressive Disorders of the Central Nervous System—Congenital Origin or Acquired in Infancy or Childhood
- 5D: Impaired Motor Function and Sensory Integrity Associated with Nonprogressive Disorders of the Central Nervous System—Acquired in Adolescence or Adulthood
- 5I: Impaired Arousal, Range of Motion, and Motor Control Associated with Coma, Near Coma, or Vegetative State
- 5A: Primary Prevention/Risk Reduction for Loss of Balance and Falling

Although these patterns have been identified within the physical therapy practice patterns, the concepts and selection of evaluation and intervention procedures are just as applicable for occupational therapists and other individuals working on movement dysfunction. In the acute phase the inflammatory process may result in impairments in arousal and attention that range from nonresponsiveness to agitation. The degree of agitation may range from mild to severe, depending on both the client’s unique CNS characteristics and the degree of inflammation. The agitated state may be the result of alterations in the processing of sensory input, with the consequence of inappropriate or augmented responses to sensory input. The client may respond to a normal level of sound as though it were an unbearably loud noise. Low levels of artificial light may be perceived as extremely bright.

Perceptual and cognitive impairments may be present, resulting in a variety of functional limitations and disabilities. Clients may have distortions in their perception of events as well as memory problems. As their memory returns, accuracy of time and events may be distorted, leading to frustration and anxiety for both the client and those family members and friends who are interacting within the environment.

In addition to alterations in mentation, the individual may demonstrate impaired affect, such as a hypersensitivity or exaggerated emotional responses to seemingly normal interactions. For example, when upset about dropping a spoon on the floor, a client may throw the tray across the table. When another individual was told his girlfriend would be a little late for her afternoon visit, the client became extremely upset and stated his intent to kill himself because his girlfriend did not love him anymore.

Because of the variety of pathological problems after acute inflammation, the client may have residual problems manifested as generalized or focal brain damage. The specifics of these impairments cannot be described as a typical clinical picture because they are extremely dependent on the individual client. These variations require the therapist to conduct a thorough examination and evaluation process to develop an appropriate individualized intervention program. Although content from the *Guide to Physical Therapist Practice* has been incorporated into the discussion of the examination, evaluation, and intervention processes, the model presented provides a structure that can accommodate the specific disciplinary expertise of both occupational and physical therapists.

EXAMINATION AND EVALUATION PROCESS

Just as the medical intervention with clients who have an inflammatory disorder of the CNS is, to a large extent, symptomatic, so is the intervention by therapists. Designing an individualized intervention program based on the client's problems requires a comprehensive initial and ongoing evaluation to define the impairments, functional limitations, and disabilities and to note changes in them. Although the discussion of examination procedures is separated from the discussion of intervention strategies, it must be recognized that the separation is artificial and does not reflect the image of practice. The evaluation process should be considered in relationship to both the long-term assessment of the individual's changes and the short-term within-session and between-session variations. For example, documentation of the level of consciousness of a client on day one of intervention will provide a starting point for calculation of the distance spanned at the time of discharge. Perhaps more critical to the final outcome is determination of the level of consciousness before, during, and after a particular intervention technique to determine its impact on the individual's level of arousal and ability to interact with the environment. The evaluation process is a constant activity intertwined with intervention. The observations and data from the process are periodically recorded to establish the course of the disease process and the success of the therapeutic management of the client.

Observation of Current Functional Status

The examination process should be conceptualized as a decision-making tree that requires the therapist to determine actively which components are to be included in a detailed examination and which can be eliminated or deferred. The first step in this process is the observation of the client's current functional status. If the client is comatose and nonmobile, the focus of the initial session might be an assessment of the stability of physiological functions, level of consciousness, responses to sensory input, and joint mobility.

If the client is an outpatient with motor control deficits, the initial session might focus on defining motor abilities and components contributing to movement dysfunctions with a more superficial assessment of physiological functions and level of consciousness. The therapist must be alert to indications of the need for a more detailed evaluation of perceptual and cognitive function (e.g., the client cannot follow two-step commands, indicating the need to assess cognitive skills).

Some of the components discussed in this process may be examination skills that are more typically possessed by other professions (e.g., assessment of emotional or psychological status). The inclusion of these items is not meant to suggest that the therapist must complete the formal testing. The items are included to indicate factors that will affect goal setting for the client and that will have an impact on the intervention strategy. Although the therapist may not be the health care team member who has primary responsibility for evaluation of these areas, he or she should recognize these areas as potential contributors to movement dysfunctions.

Observation of the current functional status of the client provides the therapist with an initial overview of his assets and deficits. This provides the framework into which the pieces of information from the evaluation of specific aspects of function can be fit. The therapist must not allow assumptions made during the initial observation to bias later observations. The therapist might note that the client is able to roll from the supine to the side-lying position to interact with visitors in the room. When the same activity is not repeated on the mat table in the treatment area, the therapist, knowing the client has the motor skill to roll, might conclude that he is uncooperative or apraxic or has perceptual deficits. The therapist may have failed to consider that the difference between the two situations is the type of support surface or the presence or absence of side rails, which may have enabled the client to roll in bed by pulling over to the side-lying position. It is characteristic of human observation skills that we tend to "see" what we expect to see. The therapist must attempt to observe behaviors and note potential explanations for deviations from normal without biasing the results of the subsequent observations.

The following discussion of the specific considerations within the examination process does not necessarily represent the temporal sequence to be used during the data collection process. As different items are discussed, suggestions for potential combinations of items will be made. The sequence of the process is best determined by the interaction of therapist and client. [Figure 26-5](#) outlines the components that should be considered during the evaluation process and provides a synopsis of the following discussion.

The general philosophy in the evaluation of the client with neurological deficits as a result of brain inflammation is a whole-part-whole approach. General observations of the client's performance provide an overall description of the client's abilities while indicating deficits in his or her performance. The cause(s) of the deficits (impairments) are explored to provide the pieces of data defining her or his performance. These pieces of data then are arranged within the framework provided by the general observation to define the whole of the client's assets and deficits. As the whole picture is established (with the realization that it will be constantly adjusted), the process of goal setting is initiated.

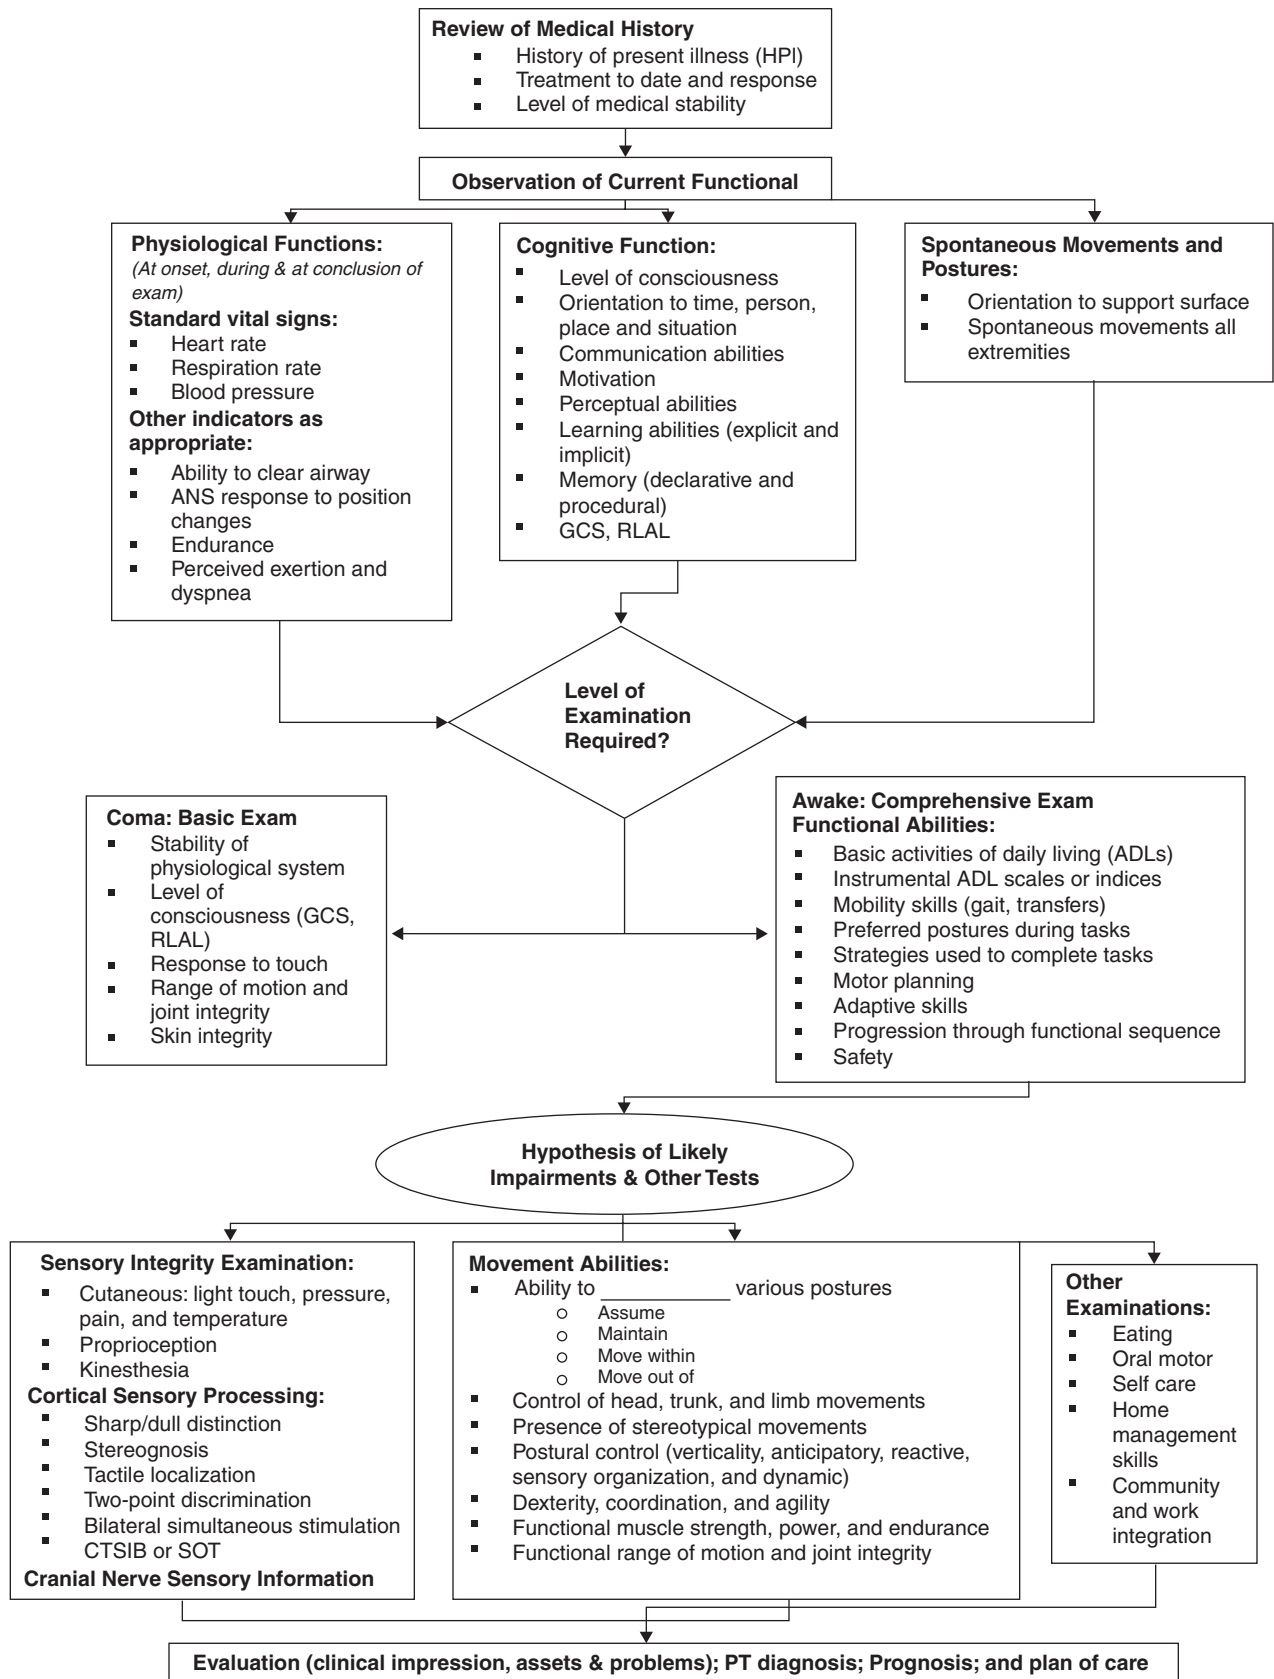

Figure 26-5 ■ Flow chart of the evaluation process.

These goals need to consider the patient's and family's desires. The process presented for refining evaluation data into an intervention plan is applicable whether the client's neurological dysfunction is the result of a bacterial or viral infection, cerebrovascular accident, trauma, or other factors.

Evaluation of Physiological Responses to Therapeutic Activities

It is assumed that the therapist enters the initial interaction with a client after reviewing the available background information. This may provide the therapist with information on the baseline status of the client's vital physiological functions. Any control problems in these areas should be particularly noted. Until the therapist determines that the vital functions, such as rate of respiration, heart rate, and blood pressure, vary appropriately with the demands of the intervention process, these factors should be monitored. The monitoring process should include consideration of the baseline rate, rate during exercise, and time to return to baseline. The pattern of respiration and changes in that pattern also should be noted.

Other tests and measures of the status of ventilation, respiration, and circulation may be indicated in specific individuals. Individuals with limited mobility or motor control of the trunk or those with cranial nerve dysfunctions may demonstrate difficulty with functions such as moving secretions out of the airways. Inactivity during a prolonged recovery period may result in cardiovascular adaptations that compromise endurance and contribute to increases in the perceived exertion during activities.

Autonomic nervous system dysfunctions may be expressed as inappropriate accommodations to positional changes, such as orthostatic hypotension. Clients with depressed levels of consciousness may display temperature regulation dysfunctions. One mechanism for assessing the client's ability to maintain a homeostatic temperature is to review the nursing notes. The events surrounding any periods of diaphoresis should be examined. If no causative factors have been identified, then interventions that involve thermal agents as discussed elsewhere in this text should be used judiciously.

Evaluation of Cognitive Status

Because the evaluation process encompasses the stages of recovery from the critical acute phase through discharge from therapy, a range of aspects are included under the evaluation of cognitive status. As indicated previously, the observation of current functional status will direct the therapist toward the appropriate component tests and measures.

Acute bacterial meningitis and various forms of viral encephalitis may result in changes in the client's level of consciousness. *Consciousness* is a state of awareness of one's self and one's environment.²¹ *Coma* can be defined as a state in which one does not open the eyes, obey commands, or utter recognizable words.²⁸ The individual does not respond to external stimuli or to internal needs. The term *vegetative state* is sometimes used to indicate the status of individuals who open their eyes and display a sleep-wake cycle but who do not obey commands or utter recognizable words. DeMeyer²⁹ presents a succinct description of the neuroanatomy of consciousness and the neurological examination of the unconscious patient. Plum and Posner²¹ also provide extensive information in this area.

Several scales have been developed to provide objective guidelines to assess alterations in the state of consciousness. The Glasgow Coma Scale²⁸ assesses three independent items: eye opening, motor performance, and verbal performance. The scale yields a figure from 3 (lowest) to 15 (highest) that can be used to indicate changes in the individual's state of consciousness. The evaluation format is simple, and the scale demonstrates both interrater and intrarater reliability. Refer to Box 24-4 for the specific scale. The Rancho Los Amigos scale assesses level of consciousness and behavior.²⁸ The therapist can use assessment tools such as the Glasgow Coma Scale and the companion Glasgow Outcome Scale to determine if the intervention program has resulted in any recordable changes in the client's level of consciousness. Ideally, the client with decreased levels of consciousness will be monitored at consistent intervals to determine changes in status. Any carryover or delayed effects of the intervention could then be noted. The record of the client's level of consciousness might also display a pattern of peak awareness at a particular point in the day. Scheduling an intervention session during the client's peak awareness time may maximize the benefit of the therapy.

Performed in conjunction with the assessment of the client's state of consciousness is the determination of the individual's orientation to person, time, place, and situation. Because the individual's level of orientation (documented as oriented times 4) is frequently recorded by multiple members of the rehabilitation team, the information in the medical chart may provide insights into fluctuations over the course of a day or a week.

Gross assessment of the individual's ability to communicate, both the expressive and receptive aspects of the process, is an important component of the examination. If a dysfunction is present in the client's ability to communicate, the client should be evaluated by an individual with expertise in this area so that strategies for dealing with the communication deficit can be developed. Evaluation of the movement abilities of the client with communication deficits requires creative planning on the part of the therapist but usually can be accomplished if generalized movement tasks are used. With the client who cannot comprehend a verbal command to roll, the therapist should use an alternate form of communication, such as manual cueing or guidance. The therapist could structure the situation to elicit the desired behavior by activities such as placing the client in an uncomfortable position or positioning a desired object so that it can be reached only by rolling.

As the therapist progresses through the examination and intervention process, ongoing data collection should be occurring on factors that influence the motivation of the individual. Individuals with damage to certain areas within the frontal lobe will have difficulty with committing to long-term projects and may not be motivated to work during a therapy session by an explanation detailing the relationship of the current activity to the larger goal of returning home. In these situations, the therapist must create appropriate immediate rewards, such as a 2-minute rest break after completion of a specific movement task.

Deficits in cognition may be evident as problems in the area of explicit (declarative) or implicit (procedural) learning. Explicit learning is used in the acquisition of knowledge that

is consciously recalled. This is information that can be verbalized in declarative sentences, such as the sequential listing of the steps in a movement sequence. Implicit or procedural learning is used in the process of acquiring movement sequences that are performed automatically without conscious attention to the performance. Procedural learning occurs through repetitions of the movement task (refer to Chapter 4). Because explicit and implicit learning use different neuroanatomical circuits, implicit learning can occur in individuals with deficits in the components underlying explicit learning (awareness, attention, higher-order cognitive processes) (refer to Chapter 5 for additional information regarding implicit and explicit learning).

The emotional and psychological aspects of the client and the higher-order cognitive and retention skills of the client should be evaluated informally by the therapist, with referral to appropriate professionals if dysfunction in these areas is suspected. A coordinated team approach is necessary for clients with emotional and psychological, cognitive, perceptual, or communication problems or a combination of these problems. A consistent strategy used by all team members eliminates the necessity on the part of the client of trying to cope with different approaches by different people in an area in which she or he already has a deficit. The impact of cognitive deficits on the process of learning motor skills is further discussed in the next section on movement assessment. The assessment of the impact of perceptual dysfunctions is incorporated within the evaluation of sensory channels.

Examination of Functional Abilities

As indicated in the introduction to the evaluation of clients with inflammatory and infectious disorders of the brain, the examination process is not compartmentalized. As the therapist is examining the movement abilities of the individual through the format described in the previous section, he or she is also collecting information on the functional abilities of the individual. The components underlying the movement abilities of the client can be examined within the framework of the basic or instrumental activities of daily living (ADLs), depending on the functional level of the person. The treatment setting and documentation requirements within that setting will determine whether the data on basic ADL and instrumental ADL skills are recorded with use of a formal scale or index or are gathered through an individualized process.

The introduction of specific tasks provides the therapist with the opportunity to observe the preferred posture used to accomplish the different tasks. The therapist should construct situations that require the individual to respond to unexpected occurrences to provide some insight into the person's ability to adapt to the unexpected. Throughout the process of examining a patient's movement abilities and functional abilities, the therapist is assessing the individual's awareness of safety considerations and judgment in attempting tasks.

The presence of motor planning dysfunctions can be noted as the client attempts a movement sequence or a functional task. The therapist may have to cue the client physically to initiate the sequence, which then flows smoothly. The therapist may observe that the client has the correct components to a movement sequence, but that the sequence

of the components is incorrect. Or the client may demonstrate the ability to produce a movement sequence under one set of conditions but not another. Indications of these types of motor planning problems can be observed during the initial interactions with the client. Similarly, the therapist also should be aware of indications of problems with dexterity, coordination, and agility, as well as with signs of cerebellar dysfunctions.

Another aspect of the evaluation process that can be integrated in the observations of movement abilities is identification of perceptual deficits. Aspects of the client's motor performance can provide indications for detailed perceptual testing to classify the deficits. This testing should be conducted by the health care team member qualified in the area of perceptual testing. During the general evaluation procedures, the therapist can screen the client for signs of perceptual deficits. Clients' abilities to cross their midlines with their upper extremities can be demonstrated in movement sequences, such as moving from the supine to the side-sitting to the sitting position (Figure 26-6). The quality of the integration of information from the two sides of the body can be indicated by the symmetry or asymmetry of posture in positions that should be symmetrical. The therapist may suspect that the client has a deficit in body awareness or body image by the poor quality of movement patterns that are within the motor capability of the individual. Spontaneous comments by the client as to how he or she feels when moving ("my leg feels so heavy") also add to the therapist's assessment of the client's body image. Problems with verticality can be seen with the client who lists to one side when in an upright posture. When the therapist corrects the list to a vertical posture, clients may express that they now feel that they are leaning to one side. Individuals who cannot appropriately relate their positions to the position of objects in their environments may have a figure-ground deficit or a problem with the concept of their position in space. When approaching stairs, these clients may fail to step up or may attempt to step up too soon. These examples should provide an indication of the observations that can indicate the need for detailed perceptual testing.

The preceding aspects of evaluation of movement abilities focused on facets of motor performance. Within this process the therapist should intertwine an appraisal of the individual's ability to learn motor tasks (or elements of the task). The therapist attempts to determine whether the client can maintain a change in the ability to perform a movement throughout a therapy session and into the next session. The client's ability to capture and integrate changes into the movement repertoire is fundamental to the success of the intervention program. The program can focus on the learning of movement sequences and the generalization of these sequences to movements within other contexts. Individuals with lowered levels of consciousness (typically Rancho Los Amigos Levels I to III) will be unable to learn or have difficulty learning and generalizing new motor skills. Therapy sessions may be more successful if the focus remains on the performance of motor tasks that were previously "overlearned" and automatic. Although the therapist may be able to manually guide the individual in coming to sit on the edge of the bed, until the individual demonstrates a higher level of processing, it may be unrealistic to expect that he or she will consistently reposition the legs without cueing before

Figure 26-6 ■ Movement sequence from the supine to side-sitting to sitting positions. **A**, Supine position. **B**, Handling to side lying. **C**, Handling toward side sitting; arm positions are important. **D**, Side sitting; note propping patterns with arms. **E**, Handling to symmetrical sitting.

attempting the movement sequence. From looking at the “whole” of function, the therapist needs to determine the impairments that require further examination.

Evaluation of Sensory Channel Integrity and Processing

The examination process must include an assessment of the channels for sensory input. Knowledge gained in the assessment of the sensory systems will be used in the program-planning process to select the intervention strategies that have the highest probability of success. Although movements can be performed (and in some cases even learned) in

the absence of typical sensory feedback, the presence of altered sensory function creates more challenges for both the client/learner and the therapist/teacher. The therapist assesses both the client’s ability to perceive the sensory stimulus and the appropriateness of the response to the stimulus. Therefore it is important to determine if the sensory modality is intact, impaired, or absent, and if it is impaired, whether it hyperresponsive, hyporesponsive, or inconsistent. In addition, variations in the interpretation of sensory input may occur in some clients. Gentle tactile contact may be perceived by the person as a noxious input. Some individuals will have difficulty processing and discriminating information

with high levels of one type of sensory input (e.g., the noisy clinic area) or with multiple simultaneous inputs (e.g., talking to the therapist while walking down a hallway with people moving toward the individual).

The therapist should develop a systematic approach to the initial cursory screen of the sensory systems. Deficits identified in the initial examination will provide structure for scheduling more comprehensive evaluation of deficits in specific systems. The therapist must also monitor changes in the status of physiological vital functions during sensory input, especially if the client has a history of instability of heart rate, blood pressure, or rate of respiration.

Based on the information from the screen, the therapist will organize the components of the more detailed examination. Components to be considered include the integrity of the peripheral sensory circuits, the cortical level processing of the sensory information, the integrity of the cranial nerve sensory circuits, and the processing of multichannel input.

Cutaneous input has several aspects that must be assessed. Some of the inflammatory diseases of the brain may result in cutaneous distributions in which sensation is absent or diminished. These areas should be routinely evaluated for changes in distribution of level of sensation. Tests of light touch, pressure, and pain can be used if the client can communicate reliably. In most cases, inclusion of assessment of differentiation of hot and cold will not add appreciably to the information needed for treatment planning unless thermal modalities are a consideration.

A gross assessment of the intactness of the touch system can be made in the noncommunicative client by introducing a mildly aversive (not painful) stimulus, such as a light scratch, while monitoring the client for changes in facial expression, posture, or tonus. The possibility of a spinal-level reflex response should be kept in mind when interpreting the results of such a gross assessment.

Assessment of the client's response to proprioceptive input is incorporated within the assessment of the client's movement abilities and is intertwined with the intervention process because a variety of intervention techniques are based on proprioceptive input. Evaluation of the proprioceptive channels can be conducted through assessment of the client's static position sense and dynamic kinesthesia. These tests allow the therapist to make inferences concerning the client's cognitive abilities to interpret proprioceptive information. Inherent in the successful completion of these tests is the necessity for the client to be able to understand directions and to be able to communicate data to the therapist. Because information input, processing, and output are involved in these tests, failure to comply with the test instructions cannot be definitively attributed to dysfunction of the proprioceptive system. The therapist also should consider information obtained from watching the client move before drawing a conclusion concerning the intactness of the proprioceptive channels. Some of the factors to consider include disregard of an extremity and variations in quality of performance between visually directed and non-visually directed movements. Although tests of position sense and kinesthetics provide one aspect of the evaluation of the proprioceptive system, the therapist also must be involved constantly in assessing the client's response to the intervention techniques that are part of the treatment plan. This again illustrates the intermingling of assessment and intervention.

Intervention places a demand for movement on the client. As the movement occurs, the therapist assesses the quality of the movement. If the quality is not appropriate, the therapist initiates intervention to improve the quality. If the technique does not produce the desired result, a second technique can be tried and the cyclical process continues.

In addition to determining the integrity of the peripheral sensory pathways and recognition of the input, it is important to assess the individual's ability to process more complex presentations of cutaneous input. Difficulties in the cortical-level processing of cutaneous stimuli are identified through tests of sharp and dull discrimination, stereognosis, tactile localization, texture recognition, two-point discrimination, and bilateral simultaneous stimulation.

Central processing and integration of sensory information as it affects postural control can be examined using the Clinical Test of Sensory Integration and Balance (CTSIB)³⁰ or with computerized dynamic posturography using the Sensory Organization Test (SOT). With both tests, the effectiveness of using vision or somatosensory or vestibular sensation at the appropriate time (sensory weighting) and changing from one sensory system to the other is examined.

Assessment of the integrity of the cranial nerve sensory channels is typically incorporated within the standard cranial nerve examination. Review of the physician's notes may provide sufficient information; however, the therapist may need to complete more specific tests before considering certain intervention techniques. Of specific note are vision and vestibular screening, both of which are discussed in detail elsewhere in this text. Simple visual system tests, such as identification of field deficits, assessment of tracking abilities, and a gross evaluation of visual acuity, can be performed quickly.

The complex functions of the vestibular system can be assessed through a variety of avenues such as the Ayres Post-Rotatory Nystagmus Test,^{31,32} the SOT, and tests of the vestibular ocular reflex (head-thrust test, head-shaking test, and test of dynamic visual acuity [DVA]), and are discussed in detail elsewhere in this text. It is important to examine the vestibular influence in both postural control and gaze stability. The integrity of the connections underlying a vestibularly induced nystagmus response is assessed by physicians through the caloric test (warm and cold water or air introduced into the ear channel to induce nystagmus). The effect of rapid linear accelerations and decelerations can be evaluated as potential activating mechanisms increasing the level of consciousness or level of muscle activity. An example is the Dynamic Gait Index, a functional test that incorporates changes in speed and head movements during walking.³³ Slow, rhythmical reversals of linear movements may have a calming effect on the client's behavior or level of muscle activation. Linear movements in all planes and diagonals should be explored.

During the evaluation of the client as well as during intervention with the client, the therapist must be aware of the potential to bombard him or her with sensory input and overload his or her ability to respond discriminatively to it. If the therapist detects that the client has difficulty in responding appropriately to sensory input, as with a client in a lowered state of consciousness or an agitated state, or demonstrating tactile defensiveness, sensory input should be used selectively during the initial examination or intervention

sessions. If multiple sensory inputs are used, the positive or negative effects cannot be attributed to a specific input or necessarily to the series of inputs. Evaluation as well as intervention with sensory inputs should proceed in a controlled fashion. Inclusion of additional sensory modalities in the intervention plan should occur systematically.

The individual's response to multichannel sensory conflict input is typically assessed as a component of higher-level balance assessment and locomotor abilities. A more thorough discussion of sensory assessment is discussed elsewhere in the text. The therapist should apply these concepts during the evaluation of all motor tasks. Consider the following example: a client who relies on visual input to supplement vestibular and somatosensory information is performing the task of sitting on the edge of the mat table. She remains relatively steady until someone walks directly toward her from across the clinic. This change in the environmental context of the performance requires her to assess whether she is moving toward the individual or the individual is moving toward her. Without reliable vestibular and somatosensory check points, the client may activate a postural response to the incorrect assessment. As this example demonstrates, the evaluation of the sensory channels is intertwined with the evaluation of the person's movement abilities.

Examination of Movement Abilities

The initial assessment of the individual's movement abilities is conducted by observing as she or he moves through a sequence of functional postures. The therapist determines the functional postures to be examined for a specific client, ranging from bed mobility activities (assessment of movement in prone and supine positions) through upright ambulation. The medical status of the individual, the extent of involvement, the intervention setting, and the age of the individual are considerations in determining the appropriate functional postures to be examined. The therapist gathers information on the movement abilities of the client as he or she moves into, within, and out of the position.

The assessment focuses on both the quantity and quality of motor performance. The quantitative aspect of the movement assessment involves the number of different functional postures the individual can use. The quality of the movement abilities is assessed within the posture as well as in the process of moving between postures. For example, the therapist should assess the quality of the head, trunk, and extremity control demonstrated throughout the movement sequences. The use of stereotypical movement patterns should be noted because their presence may limit the adaptability of movements required to accomplish functional tasks. Other items relating to the client's movement abilities are assessed during this process.

Indications of abnormal ranges of movement of all joints can be obtained. The range may show a limitation of movement or an indication of joint instability. Once the gross deviations are identified, these joints can be examined to determine the source of the problem: joint capsular, ligamentous, bony, skin, or muscular and fascial dysfunction. Conducting the gross assessment of range while the client is moving eliminates the time spent in performing a joint-by-joint goniometric evaluation of articulations with normal excursions.

As the individual is moving (either independently or with the therapist assisting), an assessment of the distribution and fluctuations in muscle activity can be made and will provide information on functional muscle strength, power, and endurance. The timing, accuracy, and sequencing of muscle activation within the movement should be noted. The therapist can identify the postures that will be the most conducive to optimal motor performances and those that should be avoided. As the client is moving through various postures, the function of specific musculature can be examined. Muscle groups should be examined with regard to their ability to function in both stability (distal segment fixed) and mobility (distal segment free) situations. Because numerous demands are being placed on each muscle group, therapists can assess the ability to perform isometric and isotonic (concentric and eccentric) contractions. Each different posture introduces a new set of variables; therefore the performance of a muscle group must be reexamined as each new movement pattern is performed.

The therapist can identify postural control in a variety of functional positions. Within each posture, the therapist must examine the control the client displays over the posture. Because the assessment takes place as part of a dynamic sequence, the therapist can assess the client's ability to assume the posture. If the posture cannot be achieved independently, the therapist assesses the factors interfering with achieving the position, the type of assistance necessary to facilitate assumption of the posture, and the effect of the various intervention techniques used to assist the client in achieving the position. Once the client is in the posture, her or his ability to maintain the posture is examined. Factors that interfere with the performance are noted. The client's ability to move within the posture is identified. Movement demands placed on the client should include aspects of both static and dynamic equilibrium. Static balance in the sitting position (such as on the side of the bed) could be demonstrated by the individual matching the strength of a force attempting to displace him backward and maintaining the position when the force is suddenly released.

The presence of dynamic balance of the upper torso in the sitting position could be demonstrated by the individual reacting to a quick sideways displacement force administered to the shoulder by activating the trunk lateral flexors to compensate for the displacement. Equally important is the individual's ability to demonstrate appropriate equilibrium responses to self-imposed perturbations. The absence of anticipatory control in standing could be demonstrated by having the client do the rapid arm raise test with a 5-lb weight and noticing reactive stepping instead of doing a posterior weight shift in anticipation of the destabilizing force.

The final stage in examining the individual's movement abilities explores the individual's ability to move out of the posture. The client should have the ability to move out of the posture to a lower-level posture and to a higher-level posture before mastery of the posture is considered to have been achieved.

Many aspects of the client's performance are analyzed simultaneously. When the therapist assists the client in moving to a new posture, an analysis of the influence of facilitation and inhibition techniques is being conducted. The individual's response to these handling techniques cues the therapist in

projecting the client's response to an intervention program. The therapist is constantly monitoring the client for changes in physiological functions or changes in the level of consciousness. Anything that results in expressions of pain by the client should be noted. Intervention programs should be a learning experience for clients. If they are attending to pain, they cannot attend to learning. The factor(s) producing the pain should be identified and measures instituted to eliminate the factor(s). If the factors producing the pain cannot be resolved, the intervention program should be designed to avoid triggering the pain.

In addition to looking at postural control in a variety of postures, it is also important to determine the type of postural control dysfunction, such as vertical orientation to the surface or to gravity as the situation dictates, anticipatory postural control, reactive postural control, sensory organization for postural control, and dynamic balance for gait.

PROGNOSING AND GOAL SETTING

Ideally, the process of establishing the prognosis and setting the goals for a client is a coordinated effort that involves all members of the health care team, including the client (if feasible) and family. If the therapist is not functioning in a setting where involvement of many disciplines is viable, the therapist can progress through the goal-setting process in the context of his or her role in the client's care.

Having collected data from the examination process, the first steps are to establish two lists: one dealing with specific problems (impairments, functional limitations, and disabilities) the client is encountering and the second dealing with her or his assets. Formulating an asset list focuses on the positive data elicited from the evaluation process and is critical for prognosing outcomes. Items on the asset list could be observations, such as the client being able to assume the position of sitting on the side of the bed with setup assistance only, improved head control in this posture being facilitated by approximation, and controlled weight shifting being elicited by alternated tapping. The asset list provides a reference defining the postures and intervention techniques that are effective. This reference is used to develop the intervention goals and plan. Formulating and recording a problem list and an asset list can be completed relatively quickly as one gains familiarity with the process. Whereas novice therapists will benefit from generating a written asset list, experienced clinicians may formulate a mental asset list while completing the written evaluation format required by the facility. Just as the evaluation process is ongoing, so are the steps involved in goal setting. The asset and problem lists are redefined as the client's status changes.

After assets and problems have been identified, the next step is to establish the expected outcomes from this episode of care. This is considered the prognosis. These outcome statements represent the general objectives toward which the intervention process is oriented. They identify the end point of the intervention process and are the exit criteria for terminating the episode of care.

The *Guide to Physical Therapist Practice* views outcomes in relationship to "minimization of functional limitations, optimization of health status, prevention of disability, and optimization of patient/client satisfaction," whereas goals "relate to the remediation (to the extent possible) of

impairments."²⁷ The breadth of acceptance of these definitions with the neurorehabilitation professions remains to be determined. These definitions at least give professionals a place to start communicating with consistency. The International Classification of Functioning, Disability and Health (ICF) model of the World Health Organization provides similar definitions, with the focus being client centered.

Measurable, interim objectives should be established in relation to the outcome statements. To determine if the objective has been achieved, the objective should be measurable—either in terms of producing a numerical indicator of performance, such as time span, number of repetitions, distance covered, or accuracy of performance, or in terms of a precise description of the target motor behavior. The appropriate objective indicator must be carefully selected. Performing a movement more quickly may indicate that the individual is performing it with more normal control and therefore greater ease of movement, or it may indicate that the individual has become more skilled in using an abnormal pattern based on inappropriate muscle activation. If it is not appropriate to formulate the objective in terms of a numerical indicator, the objective can be formulated in terms of an observable behavior. The therapist can precisely describe body segment movements based on the component method of movement analysis presented by VanSant.³⁴ For example, the task of coming to standing from supine can be described in terms of the upper-extremity component, axial component, and lower-extremity component.³⁵ Formulation of an appropriate short-term objective could specify use of the upper extremities in a push-and-reach pattern during the task of coming to standing from supine. The interim objectives should be constructed so that observing the client's behavior will allow the therapist to state whether the criteria of the short-term objective were achieved. Table 26-1 gives an example of some components of short-term objectives leading to mastery of functional activities in sitting.

The outcome statements define the client's destination. The interim objectives define the mileposts. The therapist then uses the asset list to design the intervention program, which is the vehicle to get the client to his or her destination. From the asset list, the therapist knows the intervention techniques that have the highest probability of success. Adopting this process simplifies the task of outlining the strategy for intervention.

As the therapist considers the appropriate outcomes and goals for the client, a decision must be made as to whether the format of the intervention will focus on a "training" approach or a "motor learning" approach. During the assessment process, if the therapist concludes that the individual's level of cognitive function precludes the development of insight into movement errors (both the detection and correction of an incorrect performance) or the ability to retain the insight over time, then the therapist should delineate the outcomes and intervention plan to accommodate this limitation. The "training" approach requires more structure and repetition of activities within that structure. If it is more appropriate to design the intervention plan according to motor learning considerations, the therapist must consider the appropriate schedule and environmental context for the practice, the type and schedule for the feedback provided,

TABLE 26-1 ■ EXAMPLES OF SHORT-TERM OBJECTIVES RELATING TO MASTERY OF FUNCTIONAL ACTIVITIES IN SITTING*

	CONDITION VARIABLES†	ACTIVITY	CRITERIA
1. When sitting on a mat	a. Using the upper extremities for support	The client will maintain the posture	For _____ seconds
2. When sitting on the edge of a mat table	b. Using one upper extremity for support		
	c. Without using the upper extremities for support		
3. When sitting in a chair	d. With the therapist displacing the position of the: pelvis shoulders head lower extremities	The client will make postural adjustments of the head and trunk	Appropriate to the degree of displacement
	e. Leaning forward and returning to erect sitting	The client will bring the right foot to the left knee (as if to put on a shoe)	

*Outcome: The client will master functional activities in sitting. Short-term objective: Select one phrase from each column.

†Therapist needs to consider all aspects of each variable (i.e., 1—a, b, c, d, e; 2—a, b, c, d, e; 3—a, b, c, d, e).

and techniques to promote the generalization of the learning beyond the specific practice session.

General Goals for the Intervention Process

Whereas the goal-setting process described earlier results in specification of the outcomes, goals, and objectives for a specific client, the general goals for the intervention process can be delineated to guide the process. As described in the overview of inflammatory disorders at the beginning of this chapter, the extent of the neurological sequelae may range from a single discrete problem to a devastating clinical picture composed of compromised functions in multiple areas. The goals for the intervention process address the problem areas that (1) jeopardize the efficiency and effectiveness of functional activities and (2) are the primary or secondary results of compromised neurological function. The listing of goals does not directly include consideration of secondary problems (such as decreases in joint range of motion [ROM], cardiovascular fitness, and endurance). The therapist should integrate these considerations in the overall assessment of the components of the movement problems.

The following goals are written as outcomes of the intervention process and not as goals for a specific client. Because of the broad nature of the goals, other professions also will contribute to the attainment of the goals. The goals of the therapeutic intervention program for clients with inflammatory CNS disorders are as follows:

Goal 1: Postural control is optimized as demonstrated by the ability to maintain a position against gravity and the ability to automatically adjust before and continuously during movement.

Goal 2: Selective, voluntary movement patterns within functional activities are optimized.

Goal 3: Performance of functional activities is enhanced.

Goal 4: Integration of sensory information is fostered.

Goal 5: Cognitive status and psychosocial responses are optimized.

Each of these goals is discussed in conjunction with the general therapeutic intervention procedures that can be used to achieve the goal.

GENERAL THERAPEUTIC INTERVENTION PROCEDURES IN RELATION TO INTERVENTION GOALS

■ *Postural control is optimized as demonstrated by the ability to maintain a position against gravity and the ability to adjust automatically before and continuously during movement.*

Because it is assumed that functional abilities are built on the base of the ability to control postures, the intervention goal of promoting optimal postural control underlies the ability to make selective, voluntary movement patterns (goal 2) and the performance of functional activities (goal 3). Optimization of a postural set includes the concepts of decreasing muscle activity that is too high to allow performance of movement sequences, augmenting activation that is too low to support the accomplishment of a movement sequence, and fostering proper timing of the postural responses. Intervention techniques to achieve this goal demand that the therapist constantly monitor the client's performance so that appropriate interventions are added when needed and continued only as long as they are needed.

Optimal postural control is defined by two elements. The client should have the ability to maintain a vertical orientation with regard to gravity and should be able to maintain balance in the presence of both internal and external perturbations. Automatic adjustments in the postural set should occur in anticipation of and continuously during movements (internal perturbations). Both elements should be performed with minimal physical or cognitive effort on the part of the client. Horak describes five components of normal postural control, including vertical orientation; anticipatory, reactive, sensory organization; and dynamic postural control for gait.³⁶ By looking at the subsets of postural control, interventions can be designed to specifically match the impairment (Table 26-2).

Verticality, or maintaining an upright posture, first requires the client to recognize the desired alignment. Augmenting internal feedback mechanisms with the use of mirrors, force plates, or scales or even using a flashlight attached to the client that shines on a target when he or she is vertical

TABLE 26-2 ■ INTERVENTIONS FOR POSTURAL CONTROL PROBLEMS

POSTURAL CONTROL PROBLEM	POSSIBLE INTERVENTIONS
Malalignment and verticality problems	<p>Augment sensory feedback:</p> <ul style="list-style-type: none"> ■ Mirror ■ Static force plate ■ Flashlight on target ■ Videotape ■ Align without vision and check (knowledge of results) ■ Stepping with eyes closed
Limits of stability perception problems	<p>Computerized feedback of actual versus possible</p> <p>Weight shifting exercise with feedback and targets (somatosensory, visual, both)</p> <p>Surface orientation exercises (static, ankle sway, hip strategies)</p>
Anticipatory control problems	<p>Hold on and slow down (lessen the need for anticipatory control—substitution)</p> <p>Mental rehearsal (weight shift, then move)</p> <p>Practice limb movements where balance must be controlled (start slow and get faster)</p> <ul style="list-style-type: none"> ■ Interactions with the environment with a static base of support, such as reaching up in a cupboard, opening a door, opening a drawer, lifting a suitcase, lifting a bag of groceries, wearing a backpack ■ Interactions with the environment with a dynamic base of support (stepping up a step, kicking a ball, stepping over an object, stepping around an object, changing the pitch of the surface—inclines) <p>Practice rapid limb movements where balance must be controlled (opening a door, opening a drawer, lifting a briefcase, lifting a bag of groceries, lifting a suitcase, wearing a backpack).</p> <p>Practice order:</p> <ul style="list-style-type: none"> ■ Practice the anticipatory postural adjustment ■ Practice the focal action while supported ■ Combine the anticipatory postural adjustment with the focal action unsupported (slow to fast) ■ Practice varying similar tasks (predictable to unpredictable) <p>Example: After the patient is doing better on a lifting task involving one object, he or she can work to be successful with several objects of different weights; first cognitively solve what must change for achievement of success in lifting one object versus another; then much repetition of alternating one object versus another; and eventually, work with a variety of objects in a varied pattern.</p>
Reactive postural control problems	<p>Work to regain balance strategies (ankle, hip, and stepping)</p> <p>Remediate any biomechanical issues that affect use of balance strategies</p> <p>Begin with self-perturbation and progress to reacting to external perturbations</p> <p>Need to learn to match the magnitude and direction of perturbation</p> <p>Physioballs, T-stools, tilt boards, reaching, weight shifting</p>
Sensory integration problems	<p>If client is overreliant on vision, be sure to help patient with another strategy before you take vision away</p> <p>Surface orientation exercises (tuning into somatosensory feedback)</p> <ul style="list-style-type: none"> ■ Textured surface ■ Textured surface + visual tracking ■ Textured surface with vision occluded <p>Enhancing use of vestibular system:</p> <ul style="list-style-type: none"> ■ Compliant surface with stationary visual target ■ Compliant surface + visual tracking ■ Compliant surface with moving visual background ■ Changing surface + head turns ■ Changing surface + head turns + moving visual background ■ Obstacle course with varying sensory demands
Dynamic balance problems in gait	<p>Alter the sensory contexts (e.g., resisted walking)</p> <p>Walking and reading signs right and left</p> <p>Carrying objects and looking at items carried</p> <p>Walking with quick stops (predictable distances and reactive)</p> <p>Practice falling without injury and getting up; practice slips and trips</p> <p>Walking and negotiating obstacles (around and over)</p> <ul style="list-style-type: none"> ■ Practice both around and over obstacles ■ Larger steps, standing on one foot, changing directions ■ Practice stopping quickly with feet in target ■ Practice shorter steps, on a slippery surface; braiding <p>Gesturing while walking</p>

can be effective. Manual skills such as positioning the client and using approximation to reinforce the position can be added to the treatment. Progression of intervention strategies can be done by having the client maintain the posture and then begin to manipulate objects with the extremities. Research suggests that the CNS is organized around tasks and not movement patterns. So, as the client is learning to maintain vertical and move in and out of the position, designing a task will likely give a better outcome. For example, Paul developed encephalitis, which left him with residual deficits in verticality. The simple task of keeping a book balanced on his head while sitting or walking gave him the type of feedback he needed without constant cues to “stand up straight” being the focus. Further progression involves teaching the client to move to his limits of stability and find vertical again.

Anticipatory postural control involves the postural preset, which positions the trunk to allow skilled use of the extremities without loss of balance. It requires the client to recognize the situation and the likely destabilizing force that will result, and posturally preset so destabilizing will not occur. The process requires memory and the ability to recognize the critical environmental and task cues. Interventions focus on practicing both the postural adjustment and the focal action before the two components are combined. Table 26-2 also has suggested interventions for reactive, sensory integrative, and dynamic balance in gait problems. Postural control is affected as well by biomechanical constraints, such as tonal abnormalities.

The client’s ability to demonstrate optimal postural control may be restricted by the presence of hypertonicity or hypotonicity in various muscle groups. These states may be relatively static or may fluctuate with the demands of a particular situation. Inappropriately high levels of muscle activity may be present in a stereotypical muscle distribution in the extremities, whereas the activity of the trunk musculature may be too low to support an antigravity posture. The therapist must design the interventions creatively to meet the shifting responses of the demands of a particular activity.

Being cognizant that spasticity is a reaction to initial peripheral instability, the therapist must select treatment that deals with the fact that as spasticity is modified, weakness or hypotonicity may be present. Inappropriately high levels of activity in a muscle group or groups may limit the client’s ability to demonstrate optimal postural control (and optimal selective movements as addressed in the second goal). The therapist can select intervention techniques that are mediated through any of the sensory channels functional for that client. The choice of which channel or combination of channels to use for the input is based on the therapist’s initial and continuing evaluation of the client’s response to specific types of sensory input.

The therapist must address the hypertonicity influencing postural control as a generalized problem before demanding selective voluntary activation of specific muscle groups. Vestibular input that is slow and rhythmical may promote a generalized relaxation of skeletal muscle activity. In some clients, the trunk remains “stiff” in movement sequences in which a segmental response between the upper and lower trunk should occur. Repetitions of rhythmical movements in side lying in which the therapist gently and progressively stretches the client’s pelvis in one direction around the body axis while moving the shoulder girdle in the opposite direction and

then reverses the movement may effectively alter the biomechanical and neurological contributions to the stiffness (Figure 26-7).

For some clients, changing the dynamics of a spastic extremity may permit the emergence of more optimal levels of postural control. The appropriately designed ankle-foot orthosis (AFO) may alter the individual’s need to rigidly control the position of the pelvis to remain upright. Use of a soft webbing thumb loop to alter the resting position of the first metacarpal may change the overactivity of musculature throughout the upper extremity and allow appropriate adjustment of the shoulder girdle as part of postural responses.

If the client is sufficiently alert that attending to and understanding directions is a possibility, the therapist should direct the person to focus on the effects of the movement responses rather than focusing attention on the movement of the body.³⁷ As the person begins to appreciate the consequences of what is transpiring, he or she should be asked to assist in maintaining the changes that promote the more skillful movement response. Unless otherwise indicated by the client’s status, interventions must actively involve the individual in the process of planning, initiating, completing, and evaluating the movement. Although the therapist may manipulate the environment (internal and external) in which the response is made, the client must be an active participant for learning to occur.

Although some clients will demonstrate a pattern of generalized overactivity of the postural muscles of the trunk, many will have difficulty generating sufficient activity in the appropriate groups to sustain a posture or to permit movement in the posture. With generalized hypotonia, temporary improvement in postural responses may occur by providing vestibular input that is characterized by rapid and irregular changes. The labyrinths should be stimulated by quick stops and starts with changes in direction. The program should include the introduction of movements in all planes. Approximation can be effective in developing appropriate postural activity from a state of either hypertonicity or hypotonicity. Empirically, it seems that more force is applied to increase than to decrease the postural response. Approximation appears to elicit a response in all the muscles surrounding a joint in preparation for responding to the demands on the erect posture or the demands of weight bearing. Approximation lends itself to combination with other proprioceptive techniques, such as quick stretch or tapping. Although the changes

Figure 26-7 ■ Counterrotation of shoulder girdle backward (retraction) and the pelvis forward. Hand placement of therapist is important so that shoulder and hip movements can occur freely.

evoked by these techniques may be of short duration, the alterations can evoke movement components that would not otherwise occur and thereby provide the opportunity for the individual to learn from the movement. As the therapist applies various techniques in an attempt to elicit a specific response, the therapist must evaluate the desired response in relationship to the environmental context. If the client is sitting on the edge of a mat table, the activity of the trunk musculature will vary depending on whether the feet are flat on the floor, the client is engaged in an activity, the client is leaning on one arm for support, or the client is resting between activities. The client who slouches in sitting when fatigued, bored, or overwhelmed by the sensory input may present a different clinical picture when the appropriate factors are altered.

■ *Selective, voluntary movement patterns within functional activities are optimized.*

The concept of the influence of the environment on the quality of a movement response, discussed in relation to the first goal of the intervention process, is also incorporated in the second goal. High-quality, selective, voluntary movement patterns are sought within the framework of functional activities, rather than as isolated and abstract movements. Optimization of the selective movement patterns may require a decrease in the stereotypical linkages of certain muscle

groups, an increase in the ability to selectively activate certain muscle groups, the development of the ability to execute the movement in different postures, or a number of other variations.

Performance of functional activities requires that the individual have the capability of performing both mobility and stability patterns with the extremities. Mobility patterns are open kinetic chain movements in which the distal segment is free. These patterns are necessary for placing the extremities (e.g., swing phase of gait or reaching for a doorknob).

Clients who exhibit stereotypical posturing of the upper extremity with a restricted repertoire of available movement patterns require intervention to change the initial position of the extremity before movements are attempted. The influence of the spasticity that interferes with the repositioning of the extremity can be reduced by applying approximation through the long axis of the extremity. Preferably, the therapist's manual contacts for the application of the approximation force are on the weight-bearing surfaces of the hand. If the flexed position of the wrist prohibits application of the force to the heel of the palm, the approximation can be applied gradually through the fist. As the resistance to passive movement diminishes, the wrist can be moved toward the neutral position so that the therapist can apply the approximation through the heel of the palm (Figure 26-8).

Figure 26-8 ■ Facilitating opening of the hand. **A**, Fisted hand; stretch to the extensors and approximation through hand, wrist, and elbow is applied. **B**, Approximation is continued; some resistance to the extensors may be applied. **C**, Approximation is applied to thenar eminence to further facilitate extensor tone. **D**, Full extension is achieved; approximation is maintained.

The therapist is moving the extremity toward an alternative resting position so that a new movement sequence can be attempted. It is important to use an intervention technique, such as approximation, to reduce the level of spasticity before passive movement is attempted so that a more appropriate position can be assumed without inappropriately stretching the spastic muscles.

The client is asked to assist the therapist with the movement, with the person being cued to do so with a minimum of effort. Too often, clients attempt to make a selective movement through a massive effort and overactivation of the muscle groups, which compounds the underlying spasticity. Clients should be encouraged to make easy, effortless movements—those they are instructed to perform with reduced effort so that they can relearn selective activation of motor units rather than mass firing patterns. Working “harder” often creates additional impairments versus increasing normal functional movement responses. It is critical that the movements requested relate to a functional activity or skill. Research suggests that skilled movements require attention and therefore motivation. Shaping the activity to both interest the client and afford some level of success is important.³³

Electrical stimulation can be used as an adjunct to facilitate performance of a particular component of a mobility pattern. The wrist extension component of the proprioceptive neuromuscular facilitation (PNF) pattern of flexion, abduction, and external rotation can be reinforced by using a portable electrical stimulation unit with adjustable surge duration. The electrical stimulation elicits the correct movement so that the client could learn from the feel of the correct pattern. Adjusting the practice schedule so that the pattern is performed with and without the electrical stimulation support of the movement avoids the potential problem of reliance on the device to produce the movement. Electromyographic biofeedback can be a useful adjunct to achieve activation of specific muscle groups or to guide the client’s attempts to reduce the level of activity of a muscle group.

Mobility patterns in the upper extremity have as their foundation the freedom of the scapula to adjust appropriately to the position of the humerus. The mobility of the scapula can be addressed through techniques that result in a general decrease in muscle activity and diagonal movement patterns of the scapula. The scapular stabilizers, such as the rhomboids, trapezius, and serratus anterior, must be capable of allowing appropriate adjustment of the scapula, as well as providing the fixation base on which humeral elevation can occur.

In stability patterns, the distal segment of the extremity is fixed (closed kinetic chain). These patterns are used in the weight-bearing components of the functional activities, such as the stance phase of gait or creeping. The components of the stability patterns are enhanced by proprioceptive input, such as approximation. During the performance of both stability and mobility patterns, the therapist should control the situation so that the client learns the appropriate movement patterns and not those imposed on top of inappropriate muscle activation.

Performance of movement patterns should progress toward an ability to easily reverse the direction of the movement. This can be promoted by incorporating rhythmical movements within a posture or between postures as early as possible in the intervention sequence. The end point at which the reversal is

required should vary. In preparation for mastering the movements required to move from supine to sitting on the edge of the mat table, the client might be asked to move from the supine position to side sitting and back to supine; then the client could move from the supine position to side lying propped on one elbow (the halfway point in the overall movement), then reverse to supine. Incorporating reversal of movement patterns within the intervention program prepares the client to deal with situations that mandate unexpected adjustments in the movement sequence.

Clients who demonstrate problems with the sequencing of movements, such as those with motor dyspraxia, frequently perform better if the movement is performed at a speed that is close to normal. Clients who had normal movement sequences before the brain infection seem to be able to trigger better movement responses at normal speeds than at slower speeds. The slower movement speeds appear to disrupt the typical flow of the movement. In working with clients with sequencing problems, all team members should provide the same, consistent sensory cues to elicit a movement pattern. For example, the therapist may establish a coupling of the verbal cue “roll” with a quick stretch to the ankle dorsiflexors to elicit a rolling pattern. These same cues can be used by other team members to assist the client in changing positions in bed or in performing dressing activities. The consistency of cues may elicit a consistent response from the client. Once the pattern is well established, the intervention program can be designed to reduce the cues progressing toward the ability of the client to perform the activity in response to the demands of the situation rather than to externally imposed cues.

The flow of a movement pattern may be disrupted by problems categorized as incoordination. The origin of the coordination problems could be dysfunction of the visual-perceptual system (see Chapter 28) or vestibular system (see Chapter 22), dyspraxia (see Chapter 14), or dysfunction caused by cerebellar damage (see Chapter 21). If possible, the factors involved in producing a lack of coordination should be identified.

■ *Performance of functional activities is enhanced.*

As the client develops more appropriate postural control and the ability to perform selective movement patterns within functional activities, she or he is developing the basis to perform increasingly challenging functional activities. The movement patterns (and the postural control that underlies them) provide the building blocks for mastering an expanding variety of activities.

As the therapist designs the expansion of activities within the intervention program, the demands of each new functional activity and posture must be scrutinized. The client’s ability to meet these demands was examined in the evaluation process. The intervention strategy must focus on the quality of the client’s ability to assume a posture, maintain the posture, move within the posture (static and dynamic equilibrium responses to both self-generated and external perturbations), and move out of the posture. The therapist will change the sequence of this progression of activities to meet the needs of the client. The client may achieve independence in maintaining a posture while still requiring assistance in assuming the posture.

This progression should be grounded within the context of functionally relevant activities. Unless the individual has

difficulty tolerating change, activities should be practiced within different environments to enhance generalization of learning. The creative therapist can design a variety of functionally relevant activities that require similar movement components.

With infants, the therapist may choose to use the developmental sequence as a general model for the functional activities progression. Progression through the developmental sequence should be viewed as a dynamic process so that the intervention incorporates movement both within and between postures. For individuals through the remainder of the life span, the focus should be on the age-appropriate functional activities essential to the individual's daily life, such as bed mobility, sitting to standing, standing to sitting, ambulation, reaching, and manipulation.

Examples of handling techniques that can be adapted to enhance the individual's progression through the sequence of functional activities can be found in the works of Bobath,³⁸ Carr and Shepherd,^{39,40} Duncan and Badke,⁴¹ Levitt,⁴² Ryerson and Levitt,⁴³ Sullivan and Markos,⁴⁴ and Voss and colleagues,⁴⁵ as well as throughout this book. These authors can provide the therapist with ideas for ways to enhance the client's performance within a specific activity.

■ *Integration of sensory information is fostered.*

At the same time that the therapist addresses the previous intervention goals, the goal of fostering integration of sensory input must be considered. Unless the therapist has advanced knowledge of sensory integration theories, this goal may be secondary rather than primary; nevertheless, it cannot be ignored.

The potential for an exaggerated and inappropriate response to sensory input was discussed as part of the clinical picture. Before the therapist expects the client to exhibit adaptive behavior to the potential bombardment of input from combinations of cutaneous, proprioceptive, auditory, and visual input, the therapist must assess the client's ability to respond to multisensory inputs. The ability to respond adaptively progresses from a response to a single sensory system input, to a response to the input in the presence of multiple system input, and then to an adaptive response based on inputs from two or more sources. The therapist must be sure that adding more sensory inputs augments an adaptive response rather than detracting from it. The client may respond to handling techniques that provide proprioceptive and cutaneous cues but may demonstrate a deterioration of performance when auditory input is added. When verbal cues are added, the therapist should follow the philosophy that verbal commands should be concise, sparse, and appropriately timed.⁴⁵

All sensory inputs should evoke the correct response on the part of the client, rather than cause her or him to sift through the jumble of inputs to recognize the appropriate inputs to which a response should be made. At the highest level the client will demonstrate cross-modal learning in which input from one sensory system will evoke a response based on input previously obtained through a different system. Recognition of a comb by touch is based on the precept of "combness" usually obtained initially by visual input. If the therapist recognizes the hierarchy in the process of integrating sensory input, intervention situations that require too high a level of performance from the client can be avoided. The client who can respond adaptively to input from only

one source would not be expected to perform in a crowded treatment area that presents extraneous visual and auditory input. The therapist will also recognize the need to include in the intervention plan situations that involve the controlled introduction of sensory inputs so that the client progresses toward the ability to deal with multiple inputs. Carr and Shepherd⁴⁰ discuss some general principles that can be used during the training of motor tasks in the presence of somatosensory and perceptual-cognitive impairments.

Dysfunctions in perceptual integration are addressed as the client moves through functional sequence activities. Although these movement activities would not provide the total program for an individual with a specific perceptual integration dysfunction, goals in this area can be addressed if the therapist is aware of indications of dysfunctions. The therapist must critically observe the performance of a movement sequence to identify substitute actions to compensate for problems such as inability to cross the midline. The therapist must then attempt to redesign the demands of the situation to elicit the desired behavior. The client who moves from the supine to the side sitting to the long sitting positions without the upper extremities crossing the midline could be required to side sit to the left and transfer objects with the right hand from the left side of the body to the right side (Figure 26-9).

Figure 26-9 ■ Child crossing midline of body when transferring objects from left to right. **A**, Beginning act on contralateral side. **B**, Ending sequence by crossing midline and placing objects on ipsilateral side.

The therapist must determine whether the client is truly crossing the midline or rotating the midline of the body to continue to avoid crossing it.

Therapists may be most aware of disturbances in the client's ability to integrate sensory information into an appropriate response when this dysfunction disrupts balance. The ability to maintain and move in upright postures requires successful processing of information from the sensory triad of postural control: the visual, vestibular, and somatosensory systems. When one component is missing, unreliable, or discrepant with the other two, the person is at risk for loss of balance. During the ongoing evaluation process, the therapist gathers information on the integrity of each system and any evidence of central processing difficulties. Incorporated within the practice of activities to develop postural control, to promote selective movements with functional activities, and to develop mastery of increasingly difficult functional activities is the simultaneous practice of integrating sensory information so that a successful response can be generated.

Clients who are performing at higher levels can be challenged to maintain balance when one element of the sensory triad is missing (e.g., vision occluded) or altered (e.g., sitting, standing, or walking on a soft, compliant surface). Successful maintenance of balance outside the protective environment of the therapy clinic requires the ability to switch the primary information source to any one of the three systems. Walking in the dark requires the person to rely on vestibular and somatosensory input. Standing on a moving bus looking out a window requires resolution of the conflict between visual input (the external world is moving), vestibular input (you are moving), and somatosensory input (you are stationary). Movement experiences within the therapy program should foster practice of this sensory integration process (see [Table 26-2](#)).

■ *Cognitive status and psychosocial responses are optimized.*

In addition to attending to the factors directly related to motor performance, the therapist also must attend to the client's psychosocial and cognitive responses. Although the therapist does not have primary responsibility in this area, a goal of the intervention process should be to enhance the individual's psychosocial and cognitive responses.

Particularly in the agitated state that may be a component of the response to the inflammatory process, the client may demonstrate exaggerated and inappropriate emotional responses to events. Dealing with these emotional fluctuations can become a major determinant in goal attainment in the other areas. Maintaining a positive, nonthreatening interaction allows the client to use the therapist as a reference for judging the appropriateness of emotional responses.

If the client's state of agitation is interfering with the intervention program, the therapist may alter the program to include techniques that have a calming effect. For example, the individual can be wrapped in a cotton sheet blanket and rocked in a slow, rhythmical, repetitive manner to decrease agitation. Auditory and visual input should be controlled to avoid overloading sensory processing mechanisms.

Earlier in this text the psychosocial adjustment that occurs in the process of recovering from a neurological disability was discussed. The therapist must be aware of how the client's regression in affective and cognitive domains

affects the intervention process. The therapist should seek assistance from the health care team members responsible for intervention in these areas to deal with the client constructively. The therapist must remember that both the family members and the client are in the process of adjusting to the client's changed and, it is hoped, changing status. Family members may be an asset or a liability to the client's recovery process. During the therapist's interactions with the family members in activities such as instructions in the client's home program, the therapist should be prepared to deal with expressions of the individual's difficulty in adjusting to the situation. The therapist also should be prepared to assist family members in identifying appropriate sources to help them deal with their problems.

Changes in mentation, perception of events, and memory losses present challenges to both the client and the therapist. Repetition in the recounting of past events may help reorder past knowledge. Use of brief verbal or visual cues may assist the client in recalling safety instructions or the components of the exercise program. The therapist should try to generate a nonstressful environment when working on these deficits so that attention and recall are not overshadowed by emotional pressure. As the therapist works with the client on an intervention program, situations arise that require problem solving to determine a way to accomplish a task. If the task is to accomplish an independent transfer from a wheelchair into a bathtub, decisions must be made concerning the sequence of movements. Therapists can approach this situation in two ways. They can instruct clients step by step in what to do, or they can involve clients to the extent possible in the process of deciding what to do. If the therapist instructs the client step by step, the client may master the task but may not be able to perform it under different conditions. If the therapist involves the client in the decision-making process, the client may be learning not only how to accomplish the specific task, but also how to accomplish the task under varied conditions. The intervention process should lead to the ability to respond to the demands of a situation, and involvement of clients in the problem-solving process helps prepare them for independence. The therapist must structure the client's role in decision making to the level of the client's ability to participate so that the experience is not frustrating. Although the client's participation may initially increase the time required to complete a task, it promotes skills that may lead more quickly to independence of function.

INTERACTION WITH OTHER PROFESSIONALS

The therapist needs to design an intervention program that is articulated with that of other members of the health care team. The recovery process of the client should be facilitated by a care plan in which each team member reinforces the goals of the other team members. The care of the person must be a collaborative effort. Each client deserves an intervention process that considers him or her as a whole person, not as a set of fragmented problems.

SUMMARY

This chapter has presented a brief discussion of the pathology and medical management of various inflammatory processes that affect the brain. The process of assessment, the role of

assessment in designing an intervention program, the goals of the intervention process, and the means to meet those goals were presented to assist the reader in more effective management of clients with these diagnoses.

Although the problem-solving process presented in this chapter for assessment, prognosis, goal identification, and treatment planning is not limited to clients with inflammatory supraspinal disorders, its application in the presence of typical neurological sequelae has been described. When dealing with inflammatory disorders of the brain, the variability of neurological sequelae is examined based on the anatomical location of the inflammatory process and the cause of the infection.

Although the neurological disorders discussed in this chapter are life-threatening, many clients recover and return to their previous lifestyles. Clients will vary within the spectrum of minimal to severe involvement and from specific to generalized CNS dysfunction and will demonstrate little to full recovery after the acute distress. Prognosis for recovery depends on the type of infecting organism and the extent of involvement. The therapist must remain flexible and willing to adjust every aspect of therapeutic intervention to meet the specific needs of each client. Yet the therapist must also remember that learning requires active participation on the part of the client.

CASE STUDY 26-1

A 74-year-old client with cryptococcal (*Cryptococcus gattii*) meningitis was seen in the outpatient setting 1½ years after onset with residual complaints of constant dizziness, imbalance, and need for assistance with mobility tasks.

HISTORY OF PRESENT ILLNESS

Client manifested dementia and overt meningitis 1½ years prior. He was treated with liposomal amphotericin B + 5FC for 3 weeks and then put on fluconazole. He was transferred to a skilled nursing facility with dementia and need for significant assistance for all ADLs. His cognition and functional status continued to diminish over the next 3 months, when it was determined he had hydrocephalus, and a VP shunt was placed. This resulted in significant improvement in mentation and function, and he was discharged home with home care 3 months later.

PAST MEDICAL HISTORY

The past medical history included profound bilateral sensorineural hearing loss postmeningitis, chronic obstructive

pulmonary disease (COPD), and possible Parkinson-like symptoms.

SUMMARY OF KEY FINDINGS

The client was alert and oriented to person, place, time, and reason for referral. He had some short-term memory loss. He lived with his wife in a single-story home. He was walking with a two-wheeled walker with standby assistance as his primary mode of mobility. He had difficulty with steadiness during transfers and when turning. He complained of constant dizziness, which he described as a sense of movement and at times spins. All movements worsened the symptoms, and being still decreased the symptoms.

Vision screen was normal, but he complained of increased dizziness with eye movement. Vestibular ocular testing findings were abnormal; client had a positive head-thrust test result bilaterally, and abnormal DVA with head movements at 2 Hz. Light touch and proprioception were intact for both legs. The accompanying table presents a summary of objective findings.

	FTSST	Strength	Berg	SOT	Ambulation	DVA (2 Hz)
Initial	18.73 s	LE 5/5 except hip extensor 4/5 and PF 2/5 bilaterally	38/56	28% (fell 9/18 trials—all sway referenced support)	Two-wheeled walker with SBA	20/200
1 month	15.12 s	Not tested	55/56	Not tested	Two-wheeled walker independent	20/125
2 months	Not tested	LE 5/5 except PF 4/5	Not tested	39% (fell 6/18 trials—conditions 5 and 6) Use of vision significantly improved from 0% to 55%	Single-point cane	20/80 horz
3 months	15 s	Not tested	55/56	Not tested	Single-point cane	20/63–2* at 2 Hz (horz); 20/80 (vert)
4 months	12.1	LE 5/5 with PF 4/5	Not tested	56% (fell 4/18 trials – first 2 attempts conditions 5 and 6)	No device on level surfaces, cane on uneven surfaces	20/50
5 months	51 s	Hip abductor 4/5 and ankle PF 2+/5	34/56	Fell conditions 3 and 4 of M-CTSIB in <5 s	Two-wheeled walker	20/100
10 months	16.9 s	LE 5/5 except PF only 2+/5	52/56	Only falls condition 4 of M-CTSIB	Single-point cane all surfaces	20/125

* The patient read the line with two errors.

DVA, Dynamic visual acuity test; FTSST, five-times-sit-to-stand test; LE, lower extremity; horz, horizontal; M-CTSIB, Modified Clinical Test of Sensory Interaction and Balance; PF, plantarflexors; SBA, standby assist; SOT, Sensory Organization Test; vert, vertical.

CASE STUDY 26-1—cont'd

PHYSICAL THERAPY MOVEMENT DIAGNOSIS

The client had an increased risk of falls, with significant balance impairment and gaze instability consistent with mixed peripheral (bilateral hypofunction) and central vestibular dysfunction postmeningitis (Physical Therapy Practice Patterns 5D and 5A). He also had lower extremity weakness and reduced vertical orientation. His strengths included supportive family and excellent motivation.

GOALS

1. Client will be able to ambulate independently in his home without assistive device (4 months).
2. Client will improve gaze stability to 20/80 with head movements at 2 Hz in either direction (4 months).
3. Client will be independent and safe to negotiate a flight of stairs with rail (2 months).
4. Client will be able to maintain standing with eyes open on foam surface >30 seconds (2 months).

INTERVENTIONS

The client lived 2 hours from the clinic, so many of the interventions were through progressive home exercises. Client was seen one or two times each month, and the program consisted

of balance retraining, gaze stability exercises (vestibuloocular reflex [VOR] retraining beginning in sitting, plain background), lower-extremity strengthening, endurance activities, and gait training. Given the patient's hearing loss and memory deficits, teaching included demonstration, written instructions, and instruction of the client's wife. The client progressed steadily the first 4 months, then he began not feeling well. He complained of increased nausea and trouble eating and had a slow decline in mentation. At the 5-month visit, the client's condition had declined significantly, and after discussion with the client's physician, he underwent a series of tests which concluded that the patient was having intermittent shunt malfunction. After the shunt revision, the client did improve as noted at the 10-month follow-up visit.

KEY TAKE HOME POINTS

1. It is not unusual to have both cranial nerve and CNS involvement with meningitis.
2. Remember to monitor for signs of shunt malfunction, and the importance of educating the client and family members.
3. Use standardized objective measures in case management.

Acknowledgment

I would like to thank Dr. Rebecca Porter, PhD, PT, for her contributions to the first four editions of this book. She not only has made a significant contribution through her publications and this chapter in the book but also is an inspiration to many of us within the profession of Physical Therapy.

Reference

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies

this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 45 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Define the basic terminology and discuss the prevalence of cognitive disturbances seen in older persons.
2. Describe normative changes in brain function with normal aging and their relevance to the diagnoses of delirium and dementias.
3. Discuss how symptoms are altered with normal aging (specifically related to the Arndt-Schultz principle, law of initial values, and habitual biorhythms) for an individual.
4. Describe normal sensory changes with aging and how they alter a person's overall ability to adapt to stress.
5. Describe how, and for what type of patient, to use the Mini-Mental State Examination as a part of the physical or occupational therapy examination.
6. Describe common sensory changes with dementia and implications for adapting physical or occupational therapy evaluation and intervention.
7. Discuss common changes in learning styles with aging and implications for adapting physical or occupational therapy intervention to enhance patients' ability to perform at their highest functional level.
8. Describe how environmental design and ergonomics can enhance patient performance in activities of daily living and instrumental activities of daily living.
9. Describe a strategy to evaluate a patient's emotional capacity to participate in a learning task and its clinical relevance to both occupational and physical therapy outcomes.
10. Describe criteria for delirium and reversible dementia and sample strategies for modifying evaluation and treatment procedures.
11. Discuss symptoms and disease progression in irreversible dementia.
12. Discuss the therapist's role on the treatment team in educating key caregivers and support personnel and sample training strategies.
13. Discuss treatment skills that are helpful in working with persons who have irreversible dementia.
14. Describe research activities and new findings that affect physical evaluation and treatment of the patient with dementia or delirium.

THE STARTING POINT WITH OLDER PERSONS IN PHYSICAL OR OCCUPATIONAL THERAPY

Older persons can adapt to new physical problems. It is critical to use the processes of habilitation and rehabilitation to train caregivers (family, friends, or staff) to bring out the best functional performance in the older person. The health care staff, caregivers, family, and friends relating to the older person in a time of crisis need to prioritize creating a sense of safety, acceptance, and support based on the patients' preferences and habits. The specifics in this process include the following:

1. Evaluate, document, and make available to the hands-on caregivers what the patient "likes"—his or her preferences and habits for all activities of daily living

(ADLs) and instrumental activities of daily living (IADLs).

2. Train caregivers to create a care plan for daily living and nursing that builds in the patients' preferences to support his or her personal identity and self-image.
3. Create specific physical therapy or occupational therapy functional goals that build on and reinforce patient preferences with regard to mobility, eating, bathing, grooming, dressing, socialization, and so on. (Note: If caregivers change, training needs to be added and new goals may need to be developed because not all caregivers have the same capacity to relate to the patient.)
4. Train caregivers with the older person to use specific neurofacilitation strategies to: (a) enhance breathing, (b) increase bed mobility, (c) improve balance in sitting

and standing, (d) perform active range of motion (AROM) and active assisted range of motion (AAROM) for ADLs and IADLs, (e) achieve skeletal weight shift for ADLs and IADLs, (f) encourage head, neck, and spine to upright postural response during ADLs and IADLs, and (g) encourage walking and stair climbing safely and as able.

5. Screen for signs of reversible cognitive losses.
6. Provide adaptations and training for performance of ADLs when chronic cognitive problems exist.
7. Train caregivers and the older person in ways to adapt the ADLs and IADLs to maximize ability.

PARADIGM FOR AGING, THE BRAIN, AND LEARNING

Life involves ongoing learning. The brain and human nervous system have at least 3×10^{10} parts. As Feldenkrais stated, "This is large enough for its balanced functions to obey the law of large systems. The health of such a system can be measured by the shock (stimuli) it can take without compromising the continuation of its processes."¹ Adaptability and health can be measured by the number of stimuli or amount of shock people can tolerate without their usual way of life being compromised. Aging is a process that requires ongoing adaptation to and compensation for the losses that are imposed on human beings from the *outside* world and the internal physiological changes that occur with the passage of time, physical activities, emotional state, fatigue, digestive and elimination processes, and habitual rest-activity cycle. If a person's health is altered by illness or trauma, then he or she goes through an adaptive process. If too many changes happen too quickly, the brain is not able to create a functional adaptive response, and the individual must alter or simplify her or his life processes or face negative mental or physiological reactions. The literature demonstrates that regression periods and illness seem to be linked.²⁻⁵ As human beings explore coping with unfamiliar experiences, they require more nurturing, rest, and physical contact that is perceived as empowering.

Human beings progress to adulthood through the millions of perceptions and choices that are recorded and responded to through the developmental years. Human beings are not born with the brain and nervous system having the skills of an adult. In infancy the brain begins to learn during interactions with the environment. The kinesthetic and sensory connections provide data about the internal and external environments. Through this interactive learning process each human being (with a nondifferentiated nervous system) discovers new differentiations and thus new strategies for relating to the world. With advancing age there is a gradual decrease in the acuity of the kinesthetic and sensory information received. These changes can affect interactive learning for the older adult.⁶⁻⁸ Active participation has a positive impact on recall and learning,⁹ predictable events support recall,¹⁰ and ordered events are easier to recall. Differentiation for human beings does not happen uniformly.^{11,12} As a person grows, the result of this lack of uniformity is that some adults prefer to relate to the world visually, others aurally, and still others by touch or kinesthetically. In other words, people specialize with their sensory processing and at the same time

become more vulnerable to issues of sensory adaptation and selection.¹³

The adult phase of brain and central nervous system development will, for most people, involve a gradual narrowing of the focus in the development of new skills as well as increased repetition of certain activities. The tendency is to have activity narrow more and more to the activities in which a person excels or feels comfortable. Intuitive or practical people continue to pursue self-knowledge and explore ways to maximize their talents. By accident or through mentoring, these people discover that lifelong learning is the gift of life itself. Ongoing and ever-increasing self-awareness allows for enhanced adaptability at any age.

What if rehabilitation after illness or trauma invited a guided examination of self-awareness and habitual strategies as the basis for inventing new functional adaptive strategies? The Feldenkrais Method is one model for neurological facilitation and enhancement of human learning and adaptability that is built on the concept of starting from the current habits of action of the person.^{1,14,15} The Feldenkrais Method also uses several other basic learning strategies that make this approach helpful for the older patient: going slowly, simplifying the movement or stimuli, proceeding from the perception of the patient, learning to detect and respond to the smallest possible input, and increasing the awareness and use of the skeleton and the support it gives. Feldenkrais noted what a person automatically did during a crisis, such as a fall. He noted the automatic human response and then built in a self-defense response that took advantage of the innate reflex.¹⁶ The result is that exploratory learning is easy for the patient because it builds on the automatic response with which the person is already familiar. The goal is to invent physical therapy interventions that encourage patient participation and that feel safe and useful to the patient.

In this chapter the paradigm for aging and lifelong learning presumes the following:

1. The brain and central nervous system are viewed as the master system and the controller of the other human systems (e.g., digestive, cardiovascular, muscular, hormonal).
2. Capacity exists for ongoing learning (self-awareness), self-regulation, and adaptability through the life span.
3. The whole (human being) is greater than the sum of its parts.
4. Language shapes reality and the experience and perceptions of life.
5. Enjoying a comfortable and easy pace for new learning is beneficial. Being able to learn new skills is important for adaptability and for lifelong well-being.
6. The mind and body are not separate.
7. Personal variations in learning style and preferences for relating can be used to maximize adaptation throughout life.
8. The activation of the limbic system for "fight or flight" is normal, and the ability to release the limbic activation and find the resting state when the crisis (real or imagined) is over becomes a critical skill for adapting as people grow older.¹⁷
9. Creation of environments that encourage safe exploration of new ideas and ways of self-expression can generate lifelong human growth and development.

FRAMEWORK FOR CLINICAL PROBLEM SOLVING

Therapists working with patients with cognitive impairments need to have received adequate advanced training in assessment of communication skills and neurological functioning as well as gerontology so they can work with maximal efficacy and enjoy the clinical interactions with each patient. In 37 BC the Roman poet Virgil wrote, “Age carries all things, even the mind, away.”¹⁸ Nearly 400 years ago, Shakespeare described the last stage of human life as “second childishness and mere oblivion, sans teeth, sans eyes, sans taste, sans everything.”¹⁹ This pessimistic view of the fate of the elderly persists among health care workers today despite the fact that significant cognitive deficits affect only 6.1% to 12.3% of the elderly (people older than age 65 years) in the United States.^{20,21}

The clinician should not assume that an older person has impaired cognitive functioning. Perhaps the most crucial concept for clinical problem solving is that the clinician must not assume that the current abilities reflect the true capacity of the person. When a patient is observed to have altered brain function, description of the extent and type of the distortion of intellectual capacity and determination of the time of onset (sudden or gradual) are necessary to enable a diagnosis and the provision of appropriate and effective treatment and care. The capacity to learn is a possibility, although the process of learning may be altered or different from that of unaffected older adults.²²⁻²⁵ When age, illness, or medications create a temporary or permanent change in cognitive abilities, all functional training requires alteration to meet the unique cognitive abilities of the patient at the moment. For example, the son of a patient who needed physical and occupational therapy showed staff how to communicate with his mother so she did not get scared. The therapist walked slowly into the room and greeted the patient by touching her softly on the cheek with the back of her hand. The patient looked up and smiled. The therapist smiled back and stroked the patient softly on the top of her head. The patient smiled again. The therapist knelt down so that she was eye to eye with the patient sitting in the wheelchair. She took the patient’s hand in her own hand and with her other hand slowly stroked the back of the patient’s hand. The patient smiled again. The therapy session had begun. For this patient, words were actually confusing so they were avoided.²⁶ The need for tactile nurturing input stays and persists as people age.²⁷ Nurturing tactile input done at a pace that is pleasant for the patient can actually support a positive clinical outcome.²⁸

Definition of Terms

Intellectual impairment falls into three categories: mental retardation, delirium, and dementia. A definition of terms is necessary to ensure that all personnel use the same framework for clinical problem solving.

1. *Mental retardation*: A person with mental retardation (also called *developmental disability*) has had some degree of intellectual impairment all her or his life. A person with mental retardation also can develop delirium or dementia. Delirium or dementia differs from mental retardation in that a change from the baseline level of functioning has occurred in that person.
2. *Delirium*: A person with delirium usually shows a change both in intellectual function and in level of

consciousness.^{29,30} The patient may be perplexed, disoriented, fearful, forgetful, or all of these. The patient is often less alert than normal and may be sleepy or obtunded; however, many patients with delirium are hypervigilant and may be extremely agitated and suspicious. Delirium frequently occurs in the presence of a concurrent dementia. Early identification of the symptoms and formal medical assessment and treatment are critical to ensure the return of a normal level of alertness and intellectual function and to prevent the development of secondary functional impairments and possible dementia.³¹

3. *Dementia*: Dementia is the impairment of some or all aspects of intellectual functioning in a person who is fully alert. Some diseases that can cause dementia are treatable, and if treated early and aggressively, the patient’s deterioration of intellectual function may be either reversed or halted. Dementia usually involves cognitive impairment affecting memory and orientation and at least one of the following^{32,33}:
 - Abstract thinking. This is a common loss and involves an altered ability to relate to anything other than tangible reality. In dementia or Alzheimer disease (AD), this skill is predictably missing in most cases. This is exacerbated by fear and anxiety.
 - Judgment and problem solving. This capacity decreases in the first stage of AD and is missing by the second stage.³⁴⁻³⁶
 - Language. Use of language for communication becomes altered in the second stage of AD, and by the third stage little verbal or no verbal communication is possible.³⁷
 - Personality. A complex of all the attributes—behavioral, temperamental, emotional, and mental—that characterize a unique individual. A person makes choices that, whether remembered or not, make up his or her personality. Human beings live through these choices, which become filters for all future life experiences, and they believe that they are the truth. Caregivers and therapists must be aware of how the world is perceived by the patient. The staff must respect patients and their beliefs and work to minimize confrontation and agitation despite a person’s beliefs, prejudices, and biases.
4. *Alzheimer disease*: This is not synonymous with dementia but rather is one of the many causes of dementia. The term should be used only as a diagnosis when a complete clinical evaluation has been performed, a diagnosis of dementia has been made, and all other possible causes of the dementia have been ruled out. Definitive diagnosis of this disease is not possible until an autopsy or brain biopsy has been performed. Although multiple putative causes of the disease have been proposed, the cause and pathogenesis are unknown. No curative treatment for AD is currently available. Some drugs appear to slow the process of cognitive deterioration in some patients, and patients and their families can be helped through rehabilitation to cope better with the vicissitudes of the disease (see Chapters 6 and 36). Psychiatric problems may be present before old age or may develop as a result of dementia and need to be assessed

and treated along with the dementia. Depression, for example, can mimic dementia.

Epidemiology

Currently 5.3 million Americans are estimated to have AD. One in eight people over the age of 65 has AD.³³ Researchers estimate that by 2050 13.2 million Americans will have AD if current trends continue and no cures are found.³⁸ Half the people aged 85 years and older will have some form of dementia (9.5 million in 2050).³⁹ Disorders causing cognitive deficits are expected to continue to be a growing public health problem for at least the next 50 years. The projected statistics, assuming no cures or effective means of preventing the common causes of dementia are discovered, are that by 2040 five times more individuals with dementia will be in society as today (7.4 million Americans). This increase is partially the result of the increased life expectancy of Americans.⁴⁰ The most rapid population growth in this country is in the oldest age group, hence the increase in the prevalence of severe dementia. The prevalence of dementia rises from approximately 3% at ages 65 to 74 years to 18.7% at ages 75 to 84 years and to 47% of those older than 85 years.³⁹ The increasing number of persons older than age 85 years will be paralleled by an increase in the incidence of dementia.

More than 70 conditions are known to cause dementia.³³ Secondary behavioral problems in the patient with dementia can be interpreted as a response to somatic, psychological, or existential stress. Because memory impairments, impairments of abstract thinking or judgment, or global cognitive impairments in an elderly person may be symptoms of acute physical illness, the patient's physical, emotional, social, and cognitive status and physical, social, and caregiver environment need to be systematically evaluated.³³

Gradual or sudden changes in intellectual capacity or memory function are not a normal part of the aging process. Any change, whether it develops slowly over time or happens suddenly, should be diagnosed, and when possible the underlying cause(s) of the delirium or dementia should be treated. Even if the cause of the dementia is untreatable, teaching the patient and significant others strategies to make the patient's ADLs and IADLs easier to manage is always possible (see sample home program).

Physical and occupational therapists are an important part of the comprehensive evaluation, treatment, and caregiver training for patients with delirium or dementia. All treatment planning should occur as a part of a team effort in which the patient, the family or significant others, the physician, nurses, social worker, physical therapist, and occupational therapist collaborate so that a consistent treatment plan and orientation are followed. Inclusion of the day-to-day caregivers is crucial for all training because they most need to know and use the adaptations for the patient's personal style of communication and how to facilitate functional movement for ADLs and IADLs.

PHYSIOLOGY OF AGING: RELEVANCE FOR SYMPTOMATOLOGY AND DIAGNOSIS OF DELIRIUM AND DEMENTIAS

The Normal Brain

The brain of a normal person at age 80 years shows several significant anatomical, physiological, and neurochemical changes when compared with the brain of a younger person.

Brain weight decreases with advancing age.⁴¹ For example, the mean brain weight for women aged 21 to 40 years is 1260 g, whereas for women older than 80 years it is 1061 g.⁴² Dickstein and colleagues⁴³ and Cabeza and colleagues⁴⁴ have noted that although the brain loses thousands of cells daily, the areas of the brain involved in language, memory, and cognition are relatively spared from significant loss of neurons. Normal age-related changes vary from person to person in degree and severity and can include the following:

- Disturbance in ability to register, retain, and recall certain recent experiences
- Slowed rate of learning new material²⁴
- Slowed motor performance on tasks that require speed^{24,45}
- Difficulties with fine motor coordination and balance⁴⁶⁻⁵²

A motivated, upbeat elderly person who is not undergoing emotional stress will show few negative changes in intellectual capacity and may actually demonstrate an increase in intellectual functioning over time.^{19,53-55}

Because many of the variables that need to be considered as part of the clinical evaluation of the rehabilitation potential of the person with dementia are affected by both aging and disease, therapists working with the aged patient should be aware of these variables. The therapist explores ways to compensate for these changes; as a result, the patient will have a greater possibility of achieving her or his potential for self-care and contentment.

A slowing of the natural pace of movement is commonly noted in people older than 80 years. This slowdown is manifested in the brain as a slowing of resting electroencephalogram (EEG) rhythms. At age 60 years, the mean frequency of the occipital rhythm is 10.3 Hz; at age 80 years, the mean frequency is 8.7 Hz. The average change in EEG frequency is approximately 1 cps per decade during these years.⁵⁶ The speed of nerve conduction in the elderly can be 10% to 15% slower than in younger persons.⁵⁷⁻⁵⁹ Because of these physiological changes, if the process and structure of evaluation and care of the healthy older person emphasize speed of execution or timed activities, older adults will appear less capable than they really are. The therapist may need more time when working with persons older than 70 years than is generally required with the younger adult.

For a person's brain to function effectively, it requires a delicate synchronization of a large number of variables. To maximize intellectual function, the brain must have the following:

- No genetic defects
- A constant supply of nutrients, neurotransmitters, and other neurochemicals from a personally suitable diet
- Functional daily elimination
- An unailing supply of oxygen (implying appropriate blood count, collateral circulation, normal respiratory exchange and ruling out sleep apnea)
- Adequate cardiac output
- Fluid, rhythmic breathing that adapts to needed changes in posture and exertion of the activity
- Normal blood biochemistry, especially fluid and electrolytes; adequate fluid intake is critical, and dehydration can contribute to altered brain function
- Normal hepatic and renal function
- Freedom from noxious stimuli such as trauma, infection (including periodontal and gum disease), or toxins (including medications)

- Optimal levels of sensory stimulation and emotional stimulation balance
- Optimal levels of intellectual stimulation
- Adequate rest and sleep

The brain is the most physiologically active organ in the body. The brain represents only 2% of the total body weight, yet it consumes up to 20% of the oxygen and 65% of the glucose available in the circulation in the entire body.¹⁸ The minimal cardiovascular output required to deliver this is 0.75 L/min, which is equal to 20% of the total circulation (also dependent on body size). Because of the high level of nutrient use by the brain, it is one of the organs of the body most likely to be affected by any acute change in homeostasis. The homeostasis of the elderly brain is more vulnerable to disruption because of the normal age-related changes already discussed, as well as the increased permeability of the blood-brain barrier and increased sensitivity of neurons to the effects of outside agents such as drugs,⁶⁰ junk food, allergies, and food sensitivities.

Arndt-Schultz Principle

The Arndt-Schultz principle summarizes the differences between the abilities of the younger brain and the aged brain to discriminate or respond to stimuli⁶¹:

1. The elderly require a higher level or a longer period of stimulation before the threshold for initial physiological response is reached. A related safety issue is that heat takes longer to be perceived, so the elderly are more likely to get a severe burn.
2. The physiological response in the aged is rarely as large, as visible, or as consistent as noted in younger people. In response to a heat pack, for example, the elderly skin may not turn bright red in response—the skin may turn white instead. When fever is present, they may not feel warm to the touch but instead may be very tired or clumsy.
3. The only similarity between the responses of the young and the elderly to stimuli is that once the threshold has been reached, then more stimuli result in an increase in response.
4. On average, the range of safe therapeutic stimulation is narrower for the elderly than for the young.

The implication of the Arndt-Schultz principle for clinical problem solving is that the level of a stimulus (e.g., heat, cold, sound, light, or emotional input) needs to be adjusted to compensate for the altered physiology of the aging patient. Optimal balance of the levels of sensory stimulation and emotional stimulation that is therapeutic for a young person may not be therapeutic for the older person. The stimulus may be too low so it does not reach the threshold for generating a physiological response, or it may go beyond the safe therapeutic range for the older adult and become harmful. Therefore when an elderly patient does not respond to treatment or presents an unusual physical response, the clinician needs to ascertain whether the strength of the stimulus is too strong or too weak and if modification of the stimulus is necessary because of factors associated with the aging process or the patient's cognitive deficits (he or she may be unable to accurately report the response because of a cognitive deficit). The older person with mild or moderate confusion needs small, slow clinical input and precise monitoring of the general response (heart rate, blood pressure, respiration) as

well as local response. (*Clinical consideration—Use pulse oxygen meter to monitor exercise response on evaluation.*) This is especially true for persons who are hearing impaired. Because the patient may not hear what is being spoken, the therapist may assume that the patient does not have the capability to comprehend what is being said. Never assume that a person does not comprehend when she or he may simply be unable to hear what is being spoken.

Law of Initial Values

The law of initial values is both a physiological and a psychological principle stating that with a given intensity of stimulation, the degree of change produced tends to be greater when the initial value of that variable is low at the onset of stimulation. In other words, the higher the initial level of functioning, the smaller the change that can be produced.^{62,63} The law of initial values, when defined and applied to younger persons, presumes that homeostasis is a stable and consistent process. When the law is used to describe physiological and psychological responses in older persons, it cannot be presumed that homeostasis for any variable is predictable or consistent from one person to the next, or even within a 24-hour period for the same individual. For example, an older person with mild dementia may eat only sweets if left without companionship at a meal. As a result, after the meal the individual may feel unsteady and afraid to walk back to the room. (*Clinical consideration—Check blood sugar for all diabetics on evaluation before exertion.*) In the young, defining the average times of peak activity for most physiological processes as well as for intellectual capacity is possible. In the clinical assessment of the older persons, defining the peak times of day for awareness and intellectual capacity for each individual is necessary. For example, some patients are best able to participate in learning a new skill in the early morning, and some only in the late afternoon.

Biorhythms

The brain has a biological clock that controls all physiological functions in a precise temporal course, whether daily (e.g., secretion of some hormones), monthly (e.g., menstruation), or during a certain period of the life cycle (e.g., ability to become pregnant).^{2,64,65} Before evaluating a geriatric patient with dementia or disturbance of intellectual functioning, assessment of the patient's premorbid biorhythm is helpful. What was her or his daily schedule of activities before the medical crisis? The assessment or time study can map such things as rest periods, activities and level of exertion, sleep or rest periods, mental stimulation, emotional stimulation, eating, and elimination cycles across a 24-hour period. The patient assessment must allow for and assess the current and past variability of individual biorhythms. These biorhythms should be clearly documented and their stability evaluated and maintained as much as possible (critical if the patient will be going back to the family). For example, if a woman has worked for 40 years as a night nurse, being primarily active from 11 PM to 7 AM, she will most likely be alert and best able to participate in a rehabilitation program during those hours. In most cases the patient should be allowed to choose the best time for treatment. For patients whose dementia is too severe for them to make this determination, the staff, by monitoring the patient's behavior, can

choose a time for treatment when the person is most alert. For the elderly, and particularly for those who have dementia, the time of assessment and treatment must be documented to maximize the person's rehabilitation potential.^{66,67}

Sensory Changes with Aging

Aging can also be defined in terms of adaptation. Aging is the progressive and usually irreversible diminution, with the passage of time, of the ability of a person or body part to perform efficiently or adapt to changes in the environment. The consequence of the process is manifested as decreased capacity for function and for withstanding stresses.⁶⁸ Because the rehabilitation evaluation identifies functional problems, therapists should examine the possibility that sensory losses or disturbances (e.g., vision, hearing, touch, taste, smell, proprioception, temperature, and kinesthesia) are contributing to the functional impairments.⁶¹ A partial or total loss of one or more of the normal sensory inputs can result in disturbance of an individual's mental status.

The more sudden the loss of a sense, the more difficult is the adaptation to the sensory disability. This is especially true for elderly persons because several mild sensory changes related to normal aging are already taxing their capacity to adapt. Adaptation to a sensory loss in one modality is typically accomplished through increased use of the other senses. For example, a young blind patient can adapt by using hearing and kinesthesia and usually learns to function well in spite of the loss of visual input. The older the patient is when blinded, however, the more difficulty she or he will have in making this adaptive crossover to other senses. At some time in any person's life, adaptive crossover from one sense to another becomes exceedingly difficult, if not impossible. Thus psychopathological or behavioral changes may occur if a sensory impairment develops.⁶⁹ This situation becomes more likely if the disruption is caused by a central nervous system deficit with multiple and abrupt simultaneous sensory input loss, such as might occur from a stroke.

The poliomyelitis epidemics of the early 1950s demonstrated the relationship between sensory input and abnormal behavior. Patients with poliomyelitis who were placed in tank-type respirators developed intermittent disruptions in mental state, including hallucinations, delusions, and dream-like experiences while awake. The patients were deprived of normative input to the senses (kinesthesia and proprioception) and had severely restricted vision and hearing because of the nature of the construction of and the noise that emanated from the respirator. Solomon and Shackson⁷⁰ and Solomon⁷¹ called this problem "sensory deprivation psychosis," but this clinical situation may include cognitive changes in addition to psychotic symptoms. This type of problem often occurs today after a hip fracture when, to control the pain, a patient is given a medication that has the side effect of disrupting orientation to time and place. Until other medication can be tried to control the pain, the patient is described as "out of his or her mind," especially at night. The patient may try to remove all clothing or call out to people for help, often a mother or father. The psychosis stops when the medication is removed. Recovery is also enhanced when consistent nurturing is provided. Note: Other common triggers can be the requirement to stay in one position (e.g., sleep on the back after surgery) or the need to have a spacer between the knees after surgery.

Sensory changes associated with normal aging can lead to the same degree of loss or distortion of significant sensory input as previously described.⁷²⁻⁷⁴ A bilateral loss of vision may lead to agitation and disorientation. Elderly people with hearing impairments often have grave difficulty relating to the world. Elderly persons who become deaf commonly experience some episodes of paranoid behavior.⁶⁹ The problems for hearing-impaired elderly persons are often exacerbated by health care professionals who do not know how to place a hearing aid in a patient's ear, replace a battery, adjust the volume on the aid, remove excess ear wax from the aid, identify the need to trim ear hair, or consider the possibility of a malfunctioning aid. Finally, sensory impairments may become exacerbated by surgical or medical interventions.

Certain medications, as well as some diseases, can also distort kinesthesia or retard the activity and movement of the patient.⁶⁰ Movement is significant in the maintenance of an efficient nervous system. Anything that denies a person the ability to perform physical movement (e.g., drugs, restraints, traction, passive motion machine, positional props, or architectural designs not adapted to the elderly) hastens and increases the difficulty of adapting to functional limitations. The patient loses her or his freedom to move and may feel trapped and helpless. This can trigger memories of other trauma or violent experiences that involved feeling helpless or victimized. Movement is necessary for accurate sensation.^{14,75} It has been demonstrated that if movement of the eyes does not occur properly, vision becomes ineffective. The same is true to a lesser degree for hearing. If movement does not occur in the course of the hearing process, hearing can become distorted and misrepresented at the central level.

New research on brain function in the elderly points to the following ideas for clinical consideration and possible modifications to enhance functional performance:

1. Evaluate the capacity to demonstrate the visual search response. This eye response is a tool to verify that the patient is relaxed and ready for new learning. A clinical example would be to have the person rest supine (with props for comfort as needed under the head, wrists, knees, ankles) and then begin a very slow passive rolling of the head 1 to 4 degrees per second to one direction and observe the eye response. The eyes of a relaxed person will naturally follow objects in the visual field in a functional tracking response as the head is rolled. The skill of visual search is altered (i.e., eyes dart around in a rapid visual search process or rest passively and do not move actively in the direction of the rolling of the head) when limbic activation or actual brain damage is present (90% discrimination).^{13,76,77} When the visual search is compromised, the Feldenkrais Method or other neurofacilitation techniques can be used to normalize the resting pattern of the neck and chest and invite the enhanced functional response for eye-head righting. Therapeutic exercise and neurofacilitation to encourage eye participation and other eye-body coordination training strategies have resulted in good functional improvements for persons with AD.⁷⁸
2. Evaluate the capacity to use symbols. Assess the capacity to use signage in the building; does the patient comprehend and demonstrate comprehension by performance?

For example, when an arrow points left, does the patient turn left?

3. Evaluate the capacity to perform complex motor skills (e.g., consistent step-by-step sequence). Even if the skill is not mastered, does the patient show improvement in the speed of a repetition task or increased emotional ease and willingness to participate even if verbal or physical cuing is still needed? Even if the patient cannot perform one motor skill, she or he may still show normal capacity to learn another motor skill.
4. If anxiety is present, try to alleviate it because anxiety interferes with integration of sensory learning (e.g., try a hot pack to the belly area for 5 to 10 minutes to promote relaxation).

Cognitive Changes in Normal Aging

The idea that cognitive decline is a necessary part of aging is a myth. This belief has been debunked by research on crystallized and fluid intelligence.^{79,80} Crystallized and fluid intelligence are components of general intelligence. Crystallized intelligence involves the ability to perceive relationships, engage in formal reasoning, and understand intellectual and cultural heritage. Crystallized intelligence can be affected by the environment and the attitude of the individual.⁸¹ Crystallized intelligence can increase with self-directed learning and education as long as a person is alive. The measurement of crystallized intelligence is usually in the form of culture-specific items such as number facility, verbal comprehension, and general information.

Fluid intelligence, what has been called “native mental ability,” is the product of the brain’s information processing system. It includes attention and memory capacity and the speed of information processing used in thinking and acting.⁸² It is not closely associated with acculturation. It is generally considered to be independent of instruction or environment and depends more on the genetic endowment of the individual.⁹ The items used to test fluid intelligence include memory span, inductive reasoning, and figural relationships, all of which are presumed to be unresponsive to training. Because fluid intelligence involves those intellectual functions most affected by changes in neurophysiological status, it has been generally assumed to decline with age. Several studies have shown this to be untrue; one study noted that during middle age, scores on tests for fluid intelligence are similar to scores in midadolescence.^{53,83} These changes, however, are primarily associated with processing speed and working memory and executive function.^{12,84}

Recent studies that have looked at the effects of cognitive changes in activities have shown that older people perform activities at a slower rate and use different areas of the brain in the process compared with younger people. Those additional areas of the brain used have mostly to do with monitoring and processing the ongoing activity.^{13,85} Activities are therefore performed more in a feedback rather than a feed-forward manner, which also requires more time. So, if older adults are given time to complete tasks, they usually do well.

Botwinick³⁵ described the classic pattern of changes in intelligence with aging. In the adult portion of the life span, verbal abilities decline little, if at all, whereas psychomotor abilities decline earlier and to a greater extent (greater decline if the individual is not engaged in regular physical activity). The period between ages 55 and 70 years is a transition time,

and some decreases in performance are noted on many cognitive tests. A substantial decline on laboratory tests of cognitive function is generally limited to those older than 75 years.⁴⁰ In these latter years, however, the decline in fluid intelligence is offset by the growth in crystallized intelligence for most people unless dementia is present. Although changes may be demonstrated in the laboratory, they may not be significant in the “real world,” and the elderly may be as capable as the young of participating in rehabilitation training. For elderly people to benefit maximally, however, they must control the pace of training because the tasks that are the most difficult for older adults are those that are fast paced, unusual, and complex.⁸⁶ All physical and occupational therapy treatments with older patients need to be structured to encourage the patient to set his or her own pace. The goal is to have a pace that allows ease of breathing and a comfortable, functional upright posture so that the person can enjoy the experience. Interventions should be predictable and progress by adding one new concept at a time.

“Terminal drop” is another type of cognitive change that differs from those that occur in normal aging and in those with dementia. This involves a decline in IQ scores in persons within the year before their death. This change in intellectual function is thought to result from some predeath changes in brain physiology. Research studies that show drastic decreases in intellectual function with advanced age may have a large percentage of subjects who were near death as a part of the sample.⁸⁷ Subjects who did not experience this terminal drop would then appear similar to those in studies on normal elderly persons.

Stress and Intellectual Capacity

Selye⁵⁵ defined stress as the nonspecific response of the body to any demand made on it. All human beings require a certain amount of stress to live and function effectively. When a stressor (stimulus) is applied, the body predictably goes through the three stages of response called the *general adaptation syndrome* (GAS). The first response is a general alarm reaction, a “fight-or-flight” response that mobilizes all senses in an effort to make a judgment about the response needed. The older person is at a disadvantage because collecting and processing accurate sensory data are decreased with normal aging owing to short-term memory loss. This will manifest in a patient asking the same question repeatedly during a crisis. The sensory memory in an older person lasts less than 1 second.²⁴ The next stage involves judgment and the selective adaptation to the stressor. A decision is made regarding which action is needed, and all other bodily activities return to homeostasis. The older person is slower to search and retrieve the information from storage. If the stimulus continues and goes beyond the therapeutic or functional level, then the body system or part will gradually experience physiological exhaustion. A person in physiological exhaustion is likely to manifest abnormal responses to any new stimulus. Paradoxical reactions are unusual physiological or psychological responses to stimuli (e.g., an erythematous response when an ice pack is applied or a patient becoming more agitated after receiving a sedative).

When a person is under perceived stress (whether real or imagined), a predictable set of cognitive changes can occur. These cognitive functional changes can include preoccupation; forgetfulness; disorientation; confusion; low tolerance

to ambiguity; errors in judgment in relation to work, distance, grammar, or mathematics; misidentification of people; inability to concentrate, solve problems, or plan; inattention to details or instructions; reduced creativity, fantasy, and perceptual field size; decreased initiative; decreased interest in usual activities, the future, or people; and irritability, impatience, anger, withdrawal, suspicion, depression, and crying. Differentiating whether the patient is having a stress reaction or has dementia is critical. If the changes occur with a sudden onset, they are probably related to a medical or pharmaceutical problem and may be reversible.

With aging, the brain undergoes physiological changes that make the older person less physiologically efficient in her or his response to stressors. The general alarm reaction is poorly mobilized and takes longer to become activated (Arndt-Schultz principle). The stage of resistance should yield a series of responses that allows the body to economize in its response to stress. In persons of all ages who receive too many different stimuli and in the elderly who experience normal levels of stimuli, the body becomes less efficient at turning off the general alarm response and replacing it with more appropriate and limited responses. When a person is overwhelmed by this type or level of stress, the individual may demonstrate mild global or specific cognitive impairments, especially mild short-term memory loss.⁸⁸

The historical clinical data become the only means of establishing a diagnosis because no tests are currently available to distinguish acute dementia from emotional exhaustion. In cases of domestic violence that have been kept secret for years, this can be a difficult problem. For example, a 90-year-old man had beaten his wife a few times early in their marriage. They later came to an agreement and their marriage had continued with only verbal abuse and no physical abuse. As he approached 85 years of age, however, he again began to get violent and would shove her during arguments. At one point she fell, broke her hip, and ended up in a nursing home for 8 weeks. Another time he was bringing her to therapy and on the way he became angry and let go of the wheelchair, and it ran into a wall. The wife chose to do nothing and say nothing. The only sign was that she always cried in physical therapy when she started to relax. The client eventually confided to the physical therapist and was referred to a crisis counselor to determine how to proceed. She saw the counselor weekly for more than 4 years. Another incident happened in which the wife was hurt and protective services were called. The patient refused to press charges and returned to the home, stopped all counseling, withdrew in embarrassment, and within several weeks became confused. The husband placed her in a nursing home and she was given the diagnosis of dementia and placed on haloperidol (Haldol). No other therapeutic services were offered. Access to one-on-one counseling and family therapy is critical. What if support had been offered? Could this situation have turned out differently? If the person had been 36 years old, a psychiatric evaluation would likely have been made and treatment could have reversed the confusion that masked the severe depression.

The assessment of an elderly person, with or without dementia, must include a determination of the type, number, and severity of the patient's current stressors. Positive life events (e.g., marriage or the birth of a grandchild) are also stressful life events. Scores that rate stressful life events can

identify patients who are at greatest risk of physiological and emotional exhaustion.⁸⁹ Developed in the 1970s, the Holmes-Rahe Social Readjustment Rating Scale is still a commonly used life stress evaluation tool (see www.stresstips.com).⁹⁰ Elderly patients, with their numerous psychosocial problems and chronic and acute illnesses, are likely candidates for physiological and emotional exhaustion and the development of psychopathology. Thus the environment and process of rehabilitation care need to be modified to counteract the effect of stress on the intellectual capacity of the older patient. Any action that modifies stress so that a deterioration of intellectual function is stopped or reversed is an efficient and cost-effective part of the total rehabilitation effort.

STRATEGIES FOR ASSESSING, PREVENTING, AND MINIMIZING DISTORTIONS IN INFORMATION PROCESSING

Each person acts on the available data perceived at a specific moment. This stimulus-response cycle has four major steps; each step contains a possibility for distortion or error. When a person is presented with a stimulus, the brain processes all the data (physiological, psychological, sociological, and environmental) collected and then integrates it with data from past experience. Based on this process, a response is elicited, which is then followed by the behavior appropriate for this response.

At the outset of the process of patient assessment, *it is important to identify whether the patient communicates best with verbal, written, or a combination of both strategies.* With an overview of the patient's cognitive capacity, the rehabilitation staff may be able to modify the process of evaluation to maximize the patient's performance (e.g., several 15-minute interactions spread over the 8-hour workday instead of an hour without rest; performing the assessment in the presence of a regular caregiver the patient trusts). A basic assessment of the patient's functional abilities (ADLs and IADLs) at a given moment to allow a comparison of cognitive capacity at other times in the 24-hour cycle provides the clinician a specific description of what aspects of intellectual function appear to be impaired and pinpoints those aspects of intellectual functioning that are still intact. Based on this approach, the rehabilitation evaluation can proceed in a language (perhaps the native language of childhood) and at a pace that are comfortable for the patient and at the time of day when the patient is most alert.

Mini-Mental State Examination and Other Cognitive Scales

The Mini-Mental State Examination (MMSE) was developed as a result of a study noting that 80% of cognitive disorders among elderly people were not detected by the general practitioner.^{20,91} It appears to be the most predictable test but is only helpful if all caregivers can monitor the cognitive state of the older patient. All caregivers must be part of the team effort to get a real 24-hour picture of the cognitive capacities of the patient. Although training is improving in this area, most professionals on the rehabilitation team (physicians, nurses,^{92,93} physical therapists⁹⁴ and social workers⁹⁵) are likely to have had only minimal specialty training in gerontology and the unique symptoms and needs of the elderly.

The MMSE provides a screening test for identifying unrecognized cognitive disorders in the elderly (Figure 27-1).^{21,96,97} The MMSE assesses only cognition and does not examine other aspects of the traditional mental status examination such as mood, delusions, or hallucinations. The test can identify whether the patient is oriented; remembers (short term); and can read, write, calculate, and see and reproduce in drawing the relation of one object or figure to another. The examination is used to screen for cognitive dysfunctions, much as a measurement of blood pressure or blood sugar is used to screen for significant medical disorders. The MMSE also may be used in a serial fashion to quantify changes in a patient's cognitive status over time. This examination can be used as a springboard for planning how to carry out the traditional rehabilitation evaluation of a patient who has some intellectual dysfunction.^{98,99}

The MMSE has been standardized for elderly persons living in the community. The scores on this test correlate significantly with the Wechsler Adult Intelligence Scale and the Wechsler Memory Test. The MMSE is reported to have a high test-retest reliability for both normal and psychiatric sample populations with $r = 0.89$ or greater. It has been found that when a cutoff score of 24 is used for the detection of dementia, the MMSE had a sensitivity of 87.6% and a specificity of 81.6%.⁹⁶ Several studies have noted that interviews with informants are highly consistent with elderly persons' scores on the MMSE.¹⁰⁰

The examination takes only a few minutes to administer, is scored immediately, and can be administered by any member of the rehabilitation team. The entire examination grades cognitive performance on a scale from 0 to 30. A score of 24 or less usually indicates some degree of cognitive dysfunction,

MINI-MENTAL STATE EXAMINATION

<i>Maximum score</i>	<i>Score</i>	
		ORIENTATION
5	()	What is the (year) (season) (date) (day) (month)?
5	()	Where are we: (state) (county) (town) (hospital) (floor)?
3	()	REGISTRATION
		<i>Name 3 objects: 1 second to say each. Then ask the client all 3 after you have said them.</i>
		<i>Give 1 point for each correct answer. Then repeat them until the client learns all 3. Count trials and record.</i>
		TRIALS
5	()	<i>Attention and calculation</i>
		<i>Serial 7's. 1 point for each correct. Stop after 5 answers. Alternatively spell "world" backwards.</i>
3	()	<i>Recall</i>
		<i>Ask for 3 objects repeated above. Give 1 point for each correct.</i>
9	()	<i>Language</i>
		<i>Name a pencil and watch. (2 points)</i>
		<i>Repeat the following "No ifs, ands, or buts." (1 point)</i>
		<i>Follow a 3-stage command: "Take a paper in your right hand, fold it in half, and put it on the floor." (3 points)</i>
		<i>Read and obey the following: "Close your eyes." (1 point)</i>
		<i>Write a sentence. (1 point)</i>
		<i>Copy design. (1 point)</i>

but some patients with dementia may score above 24 and some with depression or delirium may score significantly below 24. A low score on this examination can mean that the patient probably has dementia, delirium, mental retardation, amnesic syndrome, or aphasia. A low score on the MMSE can indicate the areas of specific cognitive impairment and gives the rehabilitation team data about how to best communicate with the patient. MMSE scores are also correlated with educational level, with scores dropping 10% to 20% for people with an eighth-grade education or less if older than 70 years.¹⁰¹ A shortened version of the MMSE has been developed that uses only 12 of the 20 original variables. Although the original study suggested that the shortened version of the MMSE is equally as effective as the full MMSE in identifying elderly patients with cognitive deficits, more recent studies have questioned these findings. Another test recently developed to screen for cognitive deficits is the Mini-Cog. It is reported to have higher sensitivity and accuracy of classification because it is not biased by language or educational level.¹⁰²

Older persons may show changes in mental abilities immediately after surgery, after hypoxia (low oxygenation), with delayed care after a fall, or after hitting the head during a fall or other trauma. The Glasgow Coma Scale and the Rancho Los Amigos Cognitive Scale can be used in many ways to assess the cognitive status of an individual, especially if brain injury results from an impact to the head or severe whiplash, for example. First, the extra testing helps staff choose which patients can live safely and compatibly in the same unit. The Rancho Los Amigos Scale can help identify the need to segregate the patients who are prone to screaming incomprehensible words over and over. The coma state may be temporary as a result of medication, anxiety, or anesthesia. Test scores may be used to create a patient group that allows calm and functional use of the shared living space. Another purpose in using these additional tests is to create small groups where patients at level 4 (confused, agitated, alert, active, aggressive or bizarre behaviors, nonpurposeful motor movement, short attention span, inappropriate verbalization) are segregated from those at level 5 (agitated by too much stimulation, require continual redirection) to allow level 5 clients to live and function to their full capacity and allow level 4 patients to have room to move and express. A level 4 patient may become upset and cry on a unit that has mostly level 5 and a few level 3 (inconsistent response to commands, turns toward or away from sound) patients. The biggest factor is to use the test scores to target activities and recreation to a specific cognitive level so that satisfaction and social comfort are possible.

Sensory and Perceptual Changes with Dementia

Patients with dementia may have specific problems that inhibit the integration of sensory input. Aphasias and disruption of association pathways may inhibit the patient's ability to integrate accurately perceived sensory information in a meaningful way. Bassi and colleagues¹⁰³ and Fozard¹⁰⁴ have demonstrated that patients with AD, multiinfarct dementia,¹⁰⁵ and alcoholic dementia may demonstrate disturbances in visual acuity, depth perception, color differentiation, and differentiation of figure from ground when compared with normal age-matched control subjects and normal younger subjects.

An assessment of specific sensory systems is necessary when a person demonstrates cognitive losses. The challenge in rehabilitation is to design a process and environment of care so that compensation and modification maximize the ability of the elderly patient with sensory deficits to adapt to most life situations. The example of visual deficits is a case in point. One of every two blind persons in the United States is older than 65 years (see www.afb.org/ and click on AFB senior site).¹⁰⁶ Techniques of environmental adaptation and special measures to organize care to help elderly blind people have allowed many of them to live independently in the community.¹⁰⁷ However, many elderly people with visual impairments are not blind. Some of the structural changes that result in mild to moderate deficits of vision include yellowing; uneven growth, striation, and thickening of the lens; increasing weakness of the muscles controlling the eye; alteration in the perception of color (especially fine distinctions in tone and brightness); and slower adaptation to light.¹⁰⁴ Modifications of the environment can include adequate effective lighting (including adequate intensity and controlling of reflection), dark and clear large-print, low-vision aids (e.g., magnifying glass), verbal orientation and escort by persons accompanying patients in a new environment, consistent furniture placement, explanation when changes occur, clear hallways, a systematic storage system for clothes and toilet articles, and the use of consistent contrasting colors to identify doors, windows, baseboards, and corners.^{77,92,104,108}

Older Adult Learning Styles and Communication

Learning occurs throughout life.⁸⁶ In physical and occupational therapy, habilitation occurs when the client learns new skills, and rehabilitation occurs when the person relearns old adaptive skills. As with intelligence, the learning process does not change abruptly when an individual reaches old age, but differences in performance have been reported. One challenge for rehabilitation therapy is to find ways to improve the efficiency of learning by the older person.

Botwinick³⁵ has noted that learning and performance are not the same. Poor performance on a learning task may mean that insufficient learning has occurred, that learning has not transferred to a new environment or task, or that the performance does not accurately reflect the extent of learning achieved.⁹ The key variables that affect a person's ability to participate in a learning task can include intelligence, learning skills acquired over the years, and flexibility of learning style. Noncognitive factors also can have a strong bearing on an individual's performance. The noncognitive factors include visual and auditory acuity, health status, motivation to learn, level of anxiety, the speed at which stimuli and learning are paced, and the meaningfulness to the individual of the items or tasks to be learned. Research has shown that learning styles change over the life span and that people learn better when instructional approaches are matched to their learning style.²⁵ Therefore a rehabilitation assessment needs to include a review of the preferred learning style of the patient. This is particularly important before discharging a patient from a rehabilitation program. The rationale is that a lack of progress may not reflect the patient's lack of capacity for rehabilitation, but rather may reflect a dissonance between the patient's learning style and

skills with the presentation of materials in the treatment program (e.g., verbal input has not been adapted to match the level or pace of comprehension of a person who may have a strong preference for visual learning and slower pace).

Interference

Interference can make the learning process less efficient in two major ways.¹⁰⁹ First, interference can result from a conflict between present knowledge and the new knowledge to be learned. Second, if the task to be learned has two or more components, secondary components may interfere with the learning of the primary components. This is particularly true if secondary components overlap in time or use the same sensory modality.⁸² The elderly have special difficulties if they must concentrate on intake, attention, and retrieval processes at the same time. Therefore the process and therapeutic environment of rehabilitation for the elderly patient must not be disturbed by background noise, other stimuli in the environment, or anxiety. When learning a new task, the elderly patient may require a quiet room with no stimuli other than that offered by the therapist. The need to rid the environment of distractions is particularly important when working with an elderly patient with dementia because this patient will have greater difficulty filtering out irrelevant sensory inputs compared with elderly patients without dementia.

Pacing

The pacing of therapeutic intervention is a significant variable in helping an elderly person learn. Elderly persons (with or without dementia) perform best if they are given as much time as they need and when learning is self-paced.³⁵ The major drawback of a fast pace (as perceived by the patient) is that the elderly person generally chooses not to participate rather than risk making a mistake. A lack of response by the patient is often interpreted as apathy, poor motivation, or “confusion.”¹¹⁰ Patient participation is increased when extra time to complete a rehabilitation task is offered. After the individual assessment, group work (where concepts can be presented, reviewed, and examined at leisure) also can be used to reduce the psychological pressure of faster paced one-on-one learning. The details of therapy must be planned carefully, including how questions are asked (this involves asking clear and precise questions in nonmedical language) and, most important, setting aside enough treatment time so the patient can respond at a manageable pace.

Organization

If data are organized in the brain as part of the learning process, the retrieval of these data becomes easier. Older persons are less likely than members of other age groups to organize data spontaneously to facilitate learning and later retrieval (memory) of that learning.³⁷ Elderly people who are highly verbal show fewer weaknesses in the ability to organize stimuli. Elderly persons with poor verbal skills show significant improvement in data retrieval when strategies for organization of data are provided by others (e.g., the therapist). Older learners have difficulty following content because they cannot anticipate what will be taught and do not see the “whole picture” of what is being presented.¹¹¹

This is an example of how organization may influence the learning process.

Organizing therapy by beginning with an overview in outline form of the entire lesson is helpful. This presents the patient with a conceptual map of the upcoming experience. The use of purposeful organizing also can help bridge the gap between what the older person knows and the new information or task to be learned. The use of neurolinguistic programming (NLP) is especially effective with elderly patients and patients with cognitive deficits because it builds consciously—through language, kinesthesia, and visual input—a picture of a new concept from a known and familiar frame of reference.¹¹¹

Inefficient learning, and at times an inability to learn, occurs in the older adult if material is presented in one way and the older person is expected to apply it in some other way. Instructions need to be provided in the format and context in which they are to be used. If possible, one piece of new data should be presented at a time. A conscious transition needs to be made by the therapist from the patient’s current frame of reference to the understanding of the new data, and the pace needs to be set by the patient.

Several other strategies exist for maximizing the efficiency of older adult learners based on awareness of normal age-related changes. Some of the more frequently used techniques are summarized in [Box 27-1](#).

Communication

Therapists can begin by inquiring into what the reality of the patient looks like. The first goal should be to communicate with words, gestures, positioning, and so on so that stimuli

BOX 27-1 ■ TECHNIQUES FOR MAXIMIZING THE EFFICIENCY OF OLDER ADULT LEARNERS

1. Use mediators; the association of word, story, mnemonics, or visual inputs can help the person remember.
2. Choose learning activities that are meaningful for the client.
3. Use concrete examples to make learning easier.
4. Provide a supportive learning environment to prevent stress, which can interfere with efficient learning.
5. Use supportive or neutral feedback and avoid feedback that is presented in a challenging tone.
6. Reward all responses but reward correct responses more than incorrect responses. This can encourage elderly persons to decrease the number of errors by omission, which are often interpreted as apathy or lack of cooperation.
7. Use combinations of auditory and visual input to facilitate the learning process. This is effective only if the data presented are similar because variation between the two kinds of messages can result in interference and a decrease in the efficiency of learning.
8. Active learning is more effective. A patient who moves the involved body part while receiving verbal and visual input is likely to better master the new skill.
9. Design the learning situation so that successful completion of the task is likely. Older people are more likely to focus on errors, which increases anxiety and lowers self-esteem. Worst of all, with all the energy focused on the error, there is a strong chance of repeating the error.

bring out functional responses in the patient. All people have an ongoing internal dialogue. As a healthy adult, the therapist chooses to notice his or her own dialogue, hear the content, and then pursue the goals and commitments that enhance interaction with the patient.

The interaction with the patient needs to be grounded in the present moment. The power for action lies in the present moment. The patient will bring his or her authentic self to the conversation or the interaction. The therapist needs to be sensitive to the entire communication—what is said and what is withheld. The patient with cognitive problems may not understand the content, but many patients still have the ability to sense and respond to the therapist's affective state at the moment. When beginning communication, be clear of all previous concerns and bring no extra or extraneous emotions into the interaction. Caregivers and therapists bring into the conversation the power of intention to create a therapeutic interaction and the choice to stay on task. Patients bring their own sets of concerns at any particular moment. Knowing something about the patient's concerns helps the process.

Therapists and caregivers need to be self-aware. What is the therapist's favorite strategy for communication? What is the therapist's favorite sentence structure? Our habitual forms of presentation need to be assessed with regard to whether they are effective, because the patient needs to be the focus of attention. Honoring the communication habits of the patient is necessary if effective communication is to occur with a person with cognitive deficits. If the therapist chooses to speak to the patient as if there were no cognitive deficits, consistent results will not occur and the patient may be upset or agitated. The patient could be approached as if he or she were a person from another culture that has its unique customs, norms, and ways of communication. The patient-therapist interaction becomes an inquiry in which success is measured by the achievement of functional outcomes that are needed and wanted (e.g., the patient transferring into bed and feeling safe).

Now the question becomes what is the specific process of interaction with which the patient appears to be most comfortable and feels safe? Every patient is different, and it may depend on the time of day or whether the patient is tired or feeling threatened. Persons commonly respond best to one particular style of communication and are predictably upset or agitated by another style. If a patient wants to joke around and be playful, this should be a cue to staff that this is a workable style of communication. Another patient smiles whenever the tone of the conversation is soft, nurturing, and tender, and if staff is willing, this is where ease of relating can occur. Other patients relate best to rules and need predictable structures and boundaries. They love to know what is coming next. Still another category is people who can relate and communicate when definite admiration and respect are built into the conversation or when patient and therapist can agree to disagree. Each patient with cognitive problems needs to have caregivers develop a chart of what works to create a sense of relatedness and ease in communication. A challenge here for caregivers is that the patient's abilities can change; guidelines for communication when new caregivers are introduced to the patient can also be helpful. Someone who is familiar and enjoys interacting with the patient should introduce new staff to the patient.

For persons with cognitive disturbances, familiarity and rituals are keys to ease of adaptability. The basis for rituals is well-organized documentation to which all caregivers have access and contribute on an ongoing basis. This information needs to be filtered and organized so that each shift can see what is working for the patient today. Even a non-verbal patient can relate effectively to bathing if a ritual exists regarding dressing and undressing (e.g., the socks always come off first). Mace and Rabins⁹⁹ spelled out the details of the importance of caregivers being aware of the power of familiarity and rituals. Mintzer and colleagues¹¹² reinforced the same idea in their research on the effectiveness of alternative care environments for agitated patients with dementia. Another detail that requires staff or caregiver attention, evaluation, and adaptation in daily care is *ideational apraxia*. LeClerc and Wells¹¹³ described this as "a condition in which an individual is unable to plan movement related to an object because he or she has lost the perception of the object's purpose." This is especially important in relation to feeding, dressing, toileting, and bathing. The authors described a tool that can help caregivers assess ideational apraxia and problem-solving compensations to prevent unnecessary agitation or disability and take actions to preserve existing abilities. Savelkoul and colleagues¹¹⁴ emphasized the importance of effective communication between staff and patients and the importance of routines for patient care to maximize functional behaviors for institutionalized elderly living in residential homes. Another key point noted was that staff corrected and tested residents too often, which can create agitation and anxiety. This appeared to be related to lack of training and information on the part of the staff about the dementia and cognitive status of patients as well as a lack of support from other staff.

As a patient goes through gradual deterioration of cognitive status, as is common in AD, staff, family, and caregivers must be trained in nonverbal, positional, and manual cues and emotional communication techniques. Many patients come to a place in their lives with dementia when words are a source of confusion. Other strategies to communicate should then be used. Sign language is initially a possible tool until the associative functions begin to disappear. Accurate assessment needs to create adaptations in communication. It may be necessary to use hand-guided communication, in which the patient is led through a task or parts of a task to get his or her cooperation. At this stage of communication, ease and trust are the most important goals. It may take 5 minutes of tenderly holding a patient's hand before the patient is ready to walk to the dining room or bathroom. This requires much patience on the part of caregivers. Positional communication can be used as well as simple touch. As patients begin to feel safe with their state of being, they will relax and choose to participate. At times patients have unique needs, such as only wanting to be cared for by a female caregiver or a male caregiver. Honoring patient needs is critical because the cognitively impaired may not be able to learn or adapt to the demands of the staff member because of previous trauma (assault or incest, real or imagined).

As a way to summarize the considerations about communication with a person with cognitive impairment, therapists may find it useful to examine their own intentions from moment to moment. "What is my goal in this interaction?"

“Who am I being at this moment?” The task may be important and the “doing” of it may be critical. For the patient with cognitive disturbance, therapists must provide life-enhancing stimuli on the basis of the patient’s perceptions. If in the zeal to “do,” the patient is accidentally scared, intimidated, or bullied, the damage may not be able to be undone. The cognitively impaired patient presents a unique challenge if a threat has been created, because reestablishing their trust is often difficult. Often the patient may be afraid of the therapist and simply needs the therapist to leave the room for some time. The saving grace for many patients is that their short-term memory is poor so they may not remember the incident tomorrow. The problem with agitation occurs when other cognitively impaired clients in the area also get upset.

The solution to the crisis moment, when a breakdown in communication has occurred, is to redirect communication and the focus of the present moment effectively. For example, a staff member could purposely bump into a chair and knock it over, drop a cup of water or a book, start to sing, whistle loudly, or clap his or her hands. At that moment a distraction is created. If the distraction works, then the patient’s attention is pulled away from his or her old thought and focused to a new topic. At that moment the staff needs to be intentional. The new focus needs to offer comfort or nurturing or a predictable sense of well-being (e.g., helping to clean up, eating some food, looking at a picture of a favorite thing, holding a favorite item, touching a favorite comfort object, hugging).

The research findings and techniques previously discussed describe many of the aspects of the Feldenkrais approach to learning.^{1,14} The Feldenkrais Method has been applied to the needs of elderly persons with good results. The principle that learning needs to be pleasurable is especially applicable to elderly clients (with or without dementia) because they are often under more stress and have fewer supportive resources to cope with a crisis. Despite changes in learning style, the older person (with or without dementia) can be helped to learn more efficiently through well-planned instruction. The use of techniques to increase learning efficiency in the elderly has been demonstrated to decrease the stress that at times may result in emotional or cognitive overload and abnormal cognitive reactions.

Ann¹⁵ notes that because habits and procedural memory (behaviors learned by doing) are two of the last areas of the brain affected by AD and dementia, individuals with these diseases can often walk around after they are no longer able to be aware of their surroundings, consistently communicate, or reason. The Feldenkrais Method taps into an individual’s habits, producing positive and lasting results through the capacity of the individual to still use procedural learning (even though she or he is not able to describe verbally or be consciously aware of the learning that is achieved). One example of how the Feldenkrais Method taps into procedural memory follows. Lee, a man of age 92 years with advanced dementia, was able to achieve changes in his behaviors, even though he was worked with while he was sleeping, which changed his behavior while he was awake. Because of Lee’s constant walking and potentially combative behavior, working with him initially was difficult. When he was asked to sit or lie down, he complained loudly and told the therapist to get away. Instead, the therapist worked

with him during his frequent naps. He walked bent over with his feet and legs turned out and a wide stance. He held both arms close to his sides, with his elbows bent and no arm swing. He was unable to move isolated areas of his torso; he therefore did not turn his head to look at something next to him. Instead, he turned his whole body. Lee would decide to sit down without looking to see if a chair was behind him, partially because he did not have safety awareness and partially because he did not have the capability to rotate his body. Immediately after waking up or finishing a meal, he would start to walk. As a result of these limitations and actions, Lee was constantly falling. Lee needed to learn how to differentiate the movement pattern of turning his head separate from his trunk. Lee had a pattern that was “un”differentiated in which he moved his head and trunk as a single unit; he had no choice to do anything else. Through gentle movements while Lee was lying on his back or side, the first several sessions involved exploring passive movement of his pelvis and spine. The focus was to explore with Lee his capacity to move in diagonal patterns and to create a kinesthetic relationship between his right shoulder and his left hip and vice versa, the sensation of elongating his spine and learning to twist his torso. He began to demonstrate the capacity to breathe by allowing his chest to expand in the lower rib area. The passive movement explorations involved exploring upper torso rotation, including head turning, shoulder blade differentiation, and the ability to move the shoulder blades independently of his ribs, and connecting movements of the ribs and chest to flow with the movements of the upper spine. After the third session, Lee stopped falling while walking. Although he still exhibited rigid movements and difficulty moving his arms away from his body, he shifted weight a little more easily and demonstrated minimal trunk rotation for walking in both directions. Lee did not fall for several months until he stopped walking because of a sore on the ball of one foot. Lee gradually discovered how to allow the therapist to work with him and the protest stopped. This ability to learn to allow the therapist to sit next to him and touch him is an example of learning through use of emotional memory, another type of memory that seems to work in conjunction with procedural learning. Both procedural and emotional memory are preserved long after other memories are lost. Even without cognitive recognition, emotional memory capabilities in persons with AD allow them to communicate and establish trust with another human being and learn new functional ways to balance in gravity.

Another example is Dina, an 83-year-old with advanced AD, Parkinson disease, depression, and cataracts. The Feldenkrais sessions with her demonstrated the power of focusing the communication and interaction on keeping the activities pleasant and working within the comfort zone of the patient. The chief problem was that the patient had swollen knees and had not been able to straighten her knees past 90 degrees for the previous 2 years. Dina had received traditional physical therapy in which the intervention included attempting to straighten the knees by placing a weight on top of them. Dina cried during this treatment and reported pain. She could not propel her own wheelchair, and it took two staff members to transfer her to and from her wheelchair. Her reaction to their attempt to transfer her was to lift her legs off the floor and give them her entire weight. She

did not rest her feet on the floor, even in sitting. Dina had difficulty lying in all positions. When on her back, her lower body twisted to the side. She stayed where she was placed and in the position she was placed in. Dina was unable to specifically point to a body part and say it hurt her. The focus of the first session was to explore how to help her rest more comfortably. The first efforts were to try to enhance mobility in her ribs and spine. After the first session, she was able to rest more fully on one side. After the second session she was able to rest more fully on both shoulder blades and on her pelvis evenly. After the fourth session, Dina began wheeling herself in the wheelchair with her feet, and staff reported that later in the day they saw her stand up from the wheelchair for about 1 minute by herself. None of the sessions had involved direct work with her legs, and the progress in her ability to participate in her life points to the fact that movement deficits are not always the root of problems. The capacity to feel safe and allow touch and other physical and social communication can create improvements in the ability to live in gravity and assist caregivers with the chores of life. The Feldenkrais Method is an example of effective, functional communication, manual therapy, and neurological rehabilitation that enhances daily living skills in people with AD and other dementias.^{1,14,115}

ENVIRONMENTAL CONSIDERATIONS

Hypothermia

The temperature of the living environment must be carefully controlled because aged clients may not perceive that the environment is cold and may not experience shivering. Accidental hypothermia can develop in an older person even at temperatures of 60° F (15.5° C) to 65° F (18.3° C). Accidental hypothermia is a drop in the core body temperature to less than 95° F (35° C). Patients at risk for hypothermia are presented in [Box 27-2](#).

The symptoms of hypothermia may include a bloated face, pale and waxy or pinkish skin color, trembling on one side of the body without shivering, irregular and slowed heartbeat, slurred speech, shallow and slow breathing, low blood pressure, drowsiness, and symptoms of delirium. The two principles of treatment of hypothermia are that the person will stay chilled unless the body temperature

is slowly increased and that he or she should be evaluated by a physician, regardless of the apparent severity of the hypothermia.^{9,116}

If a person continues to be at risk for hypothermia, specific measures can be taken to prevent subsequent distortions of cognitive status. First, the room temperature should be set to at least 70° F (21° C). Second, the person should wear adequate clothing; this may include long underwear and an undershirt. Adequate nutrition also may be a factor in preventing hypothermia.

Patients and their caregivers may attempt to save money by lowering room temperatures and thus inadvertently cause hypothermia. To prevent accidental hypothermia in institutions with central air conditioning, special accommodations for the elderly, such as a special wing of the building or individual temperature controls in the rooms, are required.¹¹⁶

Transplantation Shock

Some elderly persons seem to function well in a familiar environment but become severely disoriented and unable to perform ADLs if taken out of their own homes. As a general rule, these persons have mild symptoms of dementia that are not readily apparent when they remain in a structured, familiar, stable environment and maintain a consistent daily routine. When faced with the need to adapt to a new environment and bombarded with multiple unfamiliar sensory stimuli, however, their limited brain capacity is unable to make sense out of the large volume of new stimuli. If a patient was oriented before admission to an institution and then becomes disoriented, the patient's cognitive functioning will likely return to its baseline level of functioning on return to the familiar environment. Therefore all moves by a patient from one hospital room to another or from one institution to another, and all changes in a treatment regimen, need to be carefully planned. If a change is anticipated, the patient should be involved in the decision making. If the change is a permanent move, the patient needs to have a chance for one or two trial visits before the actual move. The patient needs to be informed of all changes well in advance, and this information needs to be given repeatedly to the patient with dementia. The precautions mentioned can help the patient relocate without creating transplantation shock and the negative cognitive and emotional changes.

BOX 27-2 ■ PATIENTS AT HIGH RISK FOR HYPOTHERMIA

- Persons older than 65 years
- Persons showing no signs of shivering or pale skin in response to cold
- Persons taking medications containing a phenothiazine (to treat psychosis or nausea)
- Persons with disorders of the hormone system, especially hypothyroidism
- Persons with head injuries, strokes, Alzheimer disease or other dementia, Parkinson disease, or other neurological conditions
- Persons with severe arthritis
- Persons with arteriosclerotic peripheral vascular disease, chronic ulceration, or amputation

EMOTIONAL CAPACITY TO PARTICIPATE IN A LEARNING TASK

Many elderly persons who come for physical therapy are in a state of emotional overload, as evidenced by disorientation, depression, anger, or a withdrawn and apparently uncooperative attitude. A person who is at or near the point of emotional overload needs to be evaluated regarding his or her ability to be involved in learning tasks that require active participation. If the patient is in emotional overload, forms of therapeutic intervention that temporarily allow the patient to be a passive recipient of therapeutic intervention can be used. Various types of therapeutic interventions, including massage, connective tissue massage, heat, breathing exercises, relaxation exercises, and *Feldenkrais Functional Integration*, can promote a relaxation response, lower the anxiety level, reinforce self-pacing of activity, and thereby prepare the patient to participate in more physically

active types of therapeutic exercise.¹¹⁷ If asked directly, most patients will state whether they feel able to participate actively.^{1,14,115}

If for any reason the patient is not able or willing to state his or her feelings, evaluating the patient's ability to participate is still possible. If the therapist can get a patient's cooperation, the following movements can be attempted and then evaluated. (These active movements should be used only if active diseases involving the eyes are not present and no pain occurs during the movements.) The therapist asks the patient to do the following:

1. Close your eyes.
2. Close your eyes and keep them closed for 30 seconds, then for 1 minute.
3. Close your eyes; move only the eyes to the right and left slowly (slow movements with control is the goal).
4. Close your eyes; move your eyes diagonally: right and up, left and down, left and up, right and down.

If a patient is unable to perform these movements, feels they require too much effort, or experiences discomfort, a high level of tension is usually present. Another option is to create a screening of ease of movement and capacity for following increasingly complex directions using the mouth and tongue or movements involving the hands and face. When the patient is extremely tense, treatment should begin by using passive therapeutic procedures. If a person can comfortably execute the movements, she or he (i.e., the central nervous system and the body) is likely to be able to receive and integrate new data and act with ease. When the specific therapeutic intervention requires active participation by the patient, psychomotor readiness to participate can be explored using these kinds of screening activities.

Distortions in intellectual and emotional capacity to receive input, integrate input, and then act on the input affect a person's ability to participate in a learning task. This section has described the most common sources of distortion in information processing that are external to the patient and therefore under the direct control of the rehabilitation team. The rehabilitation team may choose to acknowledge the common age-related changes and common sources of stress response in the elderly and then design a learning process and environment of care that maximize the elderly patient's potential.

DELIRIUM AND REVERSIBLE DEMENTIA: EVALUATION AND TREATMENT

This section focuses on the patient's internal environment (physiological, psychological, spiritual, and pathological) and presumes that all unnecessary external environmental stressors have been removed. Delirium and dementia have been previously defined. Delirium can manifest suddenly or over a period of hours or days. Delirium may occasionally be chronic, but this is relatively infrequent. Dementia, whether reversible or irreversible, usually has a much longer time of onset, although an acute onset can occur.

The establishment of the diagnosis of the underlying cause of dementia or delirium is the key to effective care. Although the diagnostic process is primarily at the level of pathology, the therapist can obtain information, as part of a team evaluation, that will help establish the underlying

diagnosis. Historical information needs to be obtained regarding the following:

- The amount of time that has elapsed since the onset of symptoms
- The progression or lack of progression of symptoms
- Associated functional impairments and associated medical signs and symptoms
- Use of prescription drugs, over-the-counter medications, home remedies, illegal drugs, alcohol, caffeine, and nicotine
- Exposure to toxins at work or during recreation

Even in a patient with cognitive disturbances, this information can frequently be obtained and corroborated by obtaining a history from significant others.

The causes of delirium and reversible dementia are many. In the elderly person, however, certain causes are more common than others (Box 27-3). Alcohol and drugs (prescribed, over-the-counter, or illegal medications and home remedies) are prime offenders (see Chapter 36). The delirium may be the result of intoxication, side effects, or withdrawal syndromes.⁷⁰ Benzodiazepines are among the most commonly prescribed offenders; even a low dose (2 mg) may cause demonstrable cognitive changes.⁵⁴ Other common drugs that cause delirium or reversible dementia are alcohol, oral narcotics, psychotropic medications, steroids, antineoplastic drugs, digoxin, anesthetic agents, antiparkinsonian drugs, and antihistamines. However, all drugs have the potential to cause significant cognitive problems in the elderly.¹¹⁸ These symptoms often resolve with discontinuation of the offending agent or treatment of the withdrawal syndrome. For some patients a medication holiday of longer than 24 hours may be needed before a positive change in cognition can be noted.⁶⁷

At times, the symptoms may be clearly correlated with the pharmacokinetic profiles of the medications taken by the client. The dose or frequency of administration of medications can be a contributing factor to a delirious state.¹¹⁹ Every member of the rehabilitation team needs to document the patient's ability to participate in learning tasks and the time of the assessment because timing of medication administration can affect functional performance. The rehabilitation team needs the input of a clinical pharmacologist who can help the team focus on concepts such as biological half-life, clearance, bioavailability of drugs, and the time course of drug concentration in plasma as a function of dose and frequency.

Several medical diseases are likely to cause symptoms of delirium or reversible dementia, which will also reverse with treatment of the underlying disease. Urinary tract infections, more common in women, are the cause of delirium in 28%¹²⁰ of elderly patients. Fecal impaction is another common cause of acute cognitive change in elderly persons. Others are distended bladder caused by prostate enlargement or drug-induced urinary retention, dehydration, malnutrition, cardiovascular disorders,¹¹⁶ metabolic disturbances (particularly undiagnosed diabetes mellitus),¹⁸ endocrine diseases, renal diseases, hematological diseases, pneumonia or bronchitis,¹¹⁶ and vitamin B₁₂ deficiency.

Transient (and usually mild) cognitive deficits may be the result of a cerebrovascular accident (CVA). The cognitive deficits after a CVA are often reversible, although they may last for several months after the stroke. The rehabilitation

Intoxication
Toxicity
Side effects
Withdrawal

CARDIOVASCULAR OR PULMONARY CONDITIONS

Congestive heart failure
Cardiac arrhythmia
Hypertensive crisis
Hypoxia
Chronic obstructive pulmonary disease

METABOLIC OR ENDOCRINE CONDITIONS

Electrolyte disturbance (especially hyponatremia)
Hypercalcemia
Dehydration
Overhydration
Renal failure
Hypoglycemia
Diabetic ketoacidosis
Hypothyroidism
Hyperthyroidism
Malnutrition
Vitamin B₁₂ or folate deficiency
Hepatic failure
Wernicke-Korsakoff syndrome
Cushing syndrome

INFECTION

Urinary tract infection
Pneumonia or acute bronchitis

Tuberculosis
Other acute infections

NEUROLOGICAL CONDITIONS

Stroke
Head trauma
Mass lesion (e.g., tumor, hematoma)
Seizure

PHARMACOLOGICAL CAUSES

Benzodiazepines
Barbiturates and other sedative-hypnotics
Antidepressants
Neuroleptics
Antihistamines
Anticholinergics
Cardiac glycosides
Steroids
Antineoplastic drugs
Narcotics
Antiarrhythmics
Antihypertensives

MISCELLANEOUS CAUSES

Sensory deprivation
Sensory overstimulation
Acute or chronic pain
Constipation or fecal impaction
Urinary retention

team needs to evaluate and regularly reevaluate the patient's cognitive capacity and build a program of care around current abilities. A program of therapeutic intervention that allows the older person to work in a self-paced program for 1 to 3 months can yield good therapeutic results and also prevent unnecessary secondary deconditioning until part or all of the patient's cognitive capacity returns.¹²¹

Depression is commonly misdiagnosed as dementia in the elderly.^{116,122} For many years depression was thought to be a form of "pseudodementia" or false dementia.¹²³ Depression can result in mild and subtle cognitive changes affecting immediate recall, attention, and the ability to perform basic ADLs. Some reports noted that as many as 31% of those thought to have dementia have depression instead.¹²⁴ However, recent research has clarified the close relationship between structural changes in the elderly brain and the onset of depression, thus bringing the concept of pseudodementia, or depression as a reversible dementia, into disrepute.^{125,126} Depression is a treatable disorder, and many patients with cognitive impairments show some improvement in their cognitive functioning if the depression is treated; however, the underlying cognitive problem does not resolve with treatment of the depression.¹²⁷

Because the presence of depression can interfere with the progress of rehabilitation through cognitive deficits or its effects on motivation, this disorder needs to be diagnosed early

and accurately. The Geriatric Depression Scale, a 30-item yes-no questionnaire, screens for this disorder.¹²⁸ No arbitrary cutoff score signifies depression in this test, and most individuals with a score of 15 or higher have this disorder. The higher the score, the more likely that the patient has depression and the severity of the depression is greater.

Depression after a stroke can produce a reversible decline in cognitive performance.¹²⁹ Depression after a stroke is more likely to occur in patients with left hemisphere lesions and as the site of the lesion moves toward the frontal pole.⁹ The relation between site of lesion and depression also has been noted on neuropsychological testing.⁸⁷

The treatment of major depression generally involves pharmacotherapy, psychotherapy, and environmental manipulation, which can require support from the entire rehabilitation team.¹³⁰ In the treatment of a patient with depression, therapeutic techniques can promote a relaxation response, enhance upright posture, decrease anxiety level (massage, heat, or Feldenkrais Functional Integration), and help bring the patient to the point at which aerobic training is possible, which is known to have a beneficial effect. All aerobic training for the elderly needs to begin with a stress test, modified as necessary to determine the patient's exercise target heart rate. The modification most commonly required is use of the upper extremities to achieve the training effect, because lower-extremity function may be limited, or use of major ADLs

involving the upper extremities as the stress test or training program.

The causes of delirium and reversible dementia are usually treatable, and if diagnosis and care are provided in a timely fashion, the patient can likely regain full command of his or her cognitive processes. When this does not happen, the patient probably had mild, irreversible dementia that remained hidden until the onset of an acute problem that uncovered the poor cognitive functioning. The length of time in an institution (hospital or nursing home) needs to be kept as short as possible to avoid learned dependency and learned helplessness,¹³⁰ which make a return to full cognitive functioning and independent living difficult.¹²²

Therapy for elderly persons with delirium or reversible dementia consists of treating the underlying causes of the cognitive changes. A close working relationship among all members of the rehabilitation team, including a geriatric psychiatric consultant, is necessary. Even before the cause of the disorder is elucidated, the patient should receive the same emotional and physical support as any patient with an irreversible dementia. The therapist must adapt all activities to the extent and types of cognitive losses that are present. The patient needs to feel secure, live in an environment that has as few changes as possible, and have a consistent and stable schedule for activities.

IRREVERSIBLE DEMENTIA

The course of irreversible dementia is unique for each patient. The variation in clinical course occurs based on the cause of the underlying disease and superimposed biological and psychosocial factors, including medications, concurrent illness (including delirium), the nature of the social support system, and the patient's premorbid personality structure. The causes of irreversible dementia are summarized in [Box 27-4](#).

Regardless of the cause of the dementia, the clinical course of these disorders has several commonalities.⁸³ Most of these diseases are progressive. Symptoms may be subtle early in the course of the illness, and the onset of disease is usually noted by the person with the disorder, family members, friends, or colleagues at work rather than by a physician. The signs of impairment of mental ability are typically memory loss, poor judgment, or incompetence at work. The patient can often succeed at hiding his or her symptoms for a while. The social consequences of the cognitive impairment usually bring the patient to the attention of health care professionals. In addition, the patient with dementia can manifest a variety of psychiatric symptoms, including mood disturbance, agitation, violent behavior, socially inappropriate behavior, delusions, hallucinations, catastrophic reactions, and perseveration.^{99,131} The pattern of onset and the types of psychiatric symptoms are often directly related to the underlying pathological condition.

When a physician is finally consulted, the diagnostic process can begin. When a complete diagnostic evaluation—including history, physical examination, neurological examination, neuropsychological testing, and laboratory testing ([Box 27-5](#))—is performed, an accurate diagnosis can be made in approximately 90% of patients, although experienced geriatric psychiatrists can make an accurate diagnosis in more than 95% of patients.¹³²

BOX 27-4 ■ COMMON CAUSES OF IRREVERSIBLE DEMENTIA

DEGENERATIVE CAUSES

- Alzheimer disease
- Parkinson disease
- Huntington disease
- Pick disease
- Fahr disease
- Multiple sclerosis

INFECTIOUS CAUSES

- Neurosyphilis (general paresis)
- Tuberculosis
- Acquired immunodeficiency syndrome (AIDS)
- Creutzfeldt-Jakob disease

VASCULAR CAUSES

- Multiinfarct dementia
- Stroke
- Binswanger dementia
- Anoxia
- Arteriovenous malformation

OTHER CAUSES

- Normal-pressure hydrocephalus
- Mixed dementia
- Alcoholic dementia
- Toxins
- Head trauma
- Mass lesions

BOX 27-5 ■ LABORATORY EVALUATION FOR DELIRIUM AND DEMENTIA

- Complete blood count
- Thyroid function tests
- Vitamin B₁₂ or folate levels
- Urinalysis
- Blood levels of drugs patient is taking
- Urine drug screen
- Electrocardiogram
- Magnetic resonance imaging scan of head (computed tomographic scan if magnetic resonance imaging is contraindicated)
- Automated chemistries (including electrolytes, glucose, renal function, hepatic function, protein and albumin, cholesterol, and triglycerides)
- Blood alcohol level
- Human immunodeficiency virus (HIV) titer
- Chest radiograph

Once the diagnostic process is completed, treatment can be started. Medications can assist in reversing underlying causes in only a small percentage of cases; patients in whom drug therapy is successful usually have potentially reversible dementia that has gone untreated and now have permanent sequelae of the disorder. Medications may be able only to slow the process of an irreversible disorder (e.g., tacrine for AD) or prevent further deterioration (e.g., aspirin for

multiinfarct dementia). Psychotropic drugs may reverse depression or the behavioral symptoms associated with dementia.^{124,130,133} Medical management also involves the prevention and treatment of other medical conditions and side effects of the new interventions as they are added.

Medical management of irreversible dementia focuses on maximizing the patient's remaining functions and roles, rehabilitating some lost functions, and providing family education and support.⁹⁹ Training caregivers to adapt to the patient (e.g., modifications for getting the patient out of bed, bathing), simplifying the individual's living space, and referring relatives to family support services are some of the issues to be addressed.¹³⁴

Alzheimer Disease

The treatment of irreversible dementia is a long-term process. Recent studies have found that the average duration of illness from first onset of symptoms to death is 8.1 years for AD, 6.7 years for multiinfarct dementia,¹³⁵ and 5.6 years for Pick disease.¹²⁴ Medical and nursing care can extend the life expectancy of patients with dementia for up to 20 years or more.

In 1907, Alois Alzheimer³⁴ described the case and the neuropathology of a 54-year-old woman who developed morbid jealousy, which was followed by loss of memory, inability to read and understand, and death 4.5 years after onset of the illness. Since then, it has been noted that 50% of patients with dementia have AD.¹⁰¹ In making the diagnosis of AD, all other causes of cognitive dysfunction must be ruled out. The disease can occur at any age, but the onset of the disease is almost always after age 65 years. The prevalence of the disease gradually increases to a rate of 20% in persons older than 85 years.³³

AD can be clinically staged. The use of staging enables the family and health care team to plan ahead for the individual's needs. Staging helps the family prepare longitudinally for the process of interacting with the patient. It allows the treatment team to plan for appropriate levels of services as the individual's abilities decline. Finally, it allows the health care team to quantify change in functional and cognitive abilities over time, which helps assess the effectiveness of the patient's treatment plan and establish evidence-based practice. The use of staging requires an accurate description of the patient's behavior (without the use of jargon) as well as an assessment of the patient's mental state.

Traditionally the symptoms of AD have been thought to progress in three stages.

Stage 1 lasts from 2 to 4 years and involves loss of functional skills or orientation, memory loss, and lack of spontaneity. The patient is often aware of the losses and is, in many cases, able to cover up the cognitive losses by talking around the issues. During this stage the patient and family may need to deal with the issue of giving up a job, hobbies, or other types of meaningful activity because of the patient's inability to carry them out safely and independently. The patient begins to lose the ability to handle money and a personal budget, drive a car safely, and tell time. The family or significant others may have to come to terms with the question of whether the patient can live alone. Depression is common during this stage of the disorder.¹³⁰

Stage 2 is characterized by progressive memory loss and the presence of a variety of neurological symptoms. Aphasias, apraxias, wandering, repetitive movements and stereotypical

behavior, increased or decreased appetite, constant movement, and a peculiar wide-based gait can manifest. Psychotic symptoms (especially paranoid delusions and hallucinations), agitation, violent behaviors, and uncontrollable screaming are common symptoms during this stage of the disorder.

In stage 3 the patient develops vegetative symptoms. The patient may become mute, stop eating, and become incontinent of bowel and bladder. Muscle twitches or jerks, spasms of the diaphragm, and an inability to walk generally occur. The patient may develop seizures, and emotional responsiveness, if present, is at a primitive level. Eventually the patient dies from the disease.

The MMSE also may be used as a staging tool. Scores of 26 or more are generally associated with minimal, if any, dementia; scores of 21 to 25 are associated with mild dementia, scores of 15 to 20 with moderate dementia, scores of 10 to 14 with severe dementia, and scores of 9 or less with profound dementia. The severity of most other symptoms correlates well with the MMSE score.

There is wide agreement now on a seven-stage scale to describe the progression of Alzheimer's (see www.alz.org/alzheimers_disease_stages_of_alzheimers.asp). This scale is probably the most accurate staging system for AD and correlates more closely with the progression of different sets of symptoms through the course of the disease.

The Barthel Index

The Barthel Index (Table 27-1) is a profile scale that rates 10 self-care, continence, and mobility criteria.¹³⁶ The specific rating guidelines used in scoring are presented in Appendix 27-A. The advantage of the Barthel Index is its simplicity and usefulness in evaluating patients before, during, and after treatment. It is functionally oriented and may be best used when accompanied by a clinical evaluation.⁸⁷ The scale allows documentation of functional changes over time. It is useful when discussing with families the need for help for the patient who cannot manage self-care (ADLs and/or IADLs). Work continues to develop more effective and reliable scales for assessing function and status in people with AD.¹³⁷

STRATEGIES FOR TREATMENT AND CARE

Most elderly people with decreased cognitive abilities live with family or friends and not in institutions. Because of this, the rehabilitation team needs to include the caregivers and the patient as much as possible in treatment planning. The goal of rehabilitation is to ensure that the patient remains safe, independent, and able to perform ADLs and IADLs for as long as is reasonable. The planning to reach these goals is best done within the context of the patient's social support system.

The rehabilitation process begins while the diagnostic workup is still in progress. At this stage of treatment, the rehabilitation plan includes basic training for the patient in performing and adapting the ADLs. It also includes caregiver training and support for significant others so they can make needed environmental modifications to ensure the safety of the patient with dementia.

Once the diagnosis is established, treatment planning for long-term care at home or in an institution must be carefully made. No matter where the patient will be living, involvement of the caregivers and significant others is essential to maximizing functional outcomes. The emotional, physical, and

TABLE 27-1 ■ BARTHEL INDEX

	WITH HELP	INDEPENDENT
1. Feeding (score as “with help” if food needs to be cut)	5	10
2. Moving from wheelchair to bed and return (including sitting up in bed)	5-10*	15
3. Personal toilet (wash face, comb hair, shave, clean teeth)	0*	5
4. Getting on and off toilet (handling clothes, wipe, flush)	5	10
5. Bathing self	0*	5
6. Walking on level surface (or if unable to walk, propel wheelchair)	10	15
7. Ascending and descending stairs	5	10
8. Dressing (includes tying shoes, fastening fasteners)	5	10
9. Controlling bowels	5	10
10. Controlling bladder	5	10

Modified from Mahoney FI, Barthel DW: Functional evaluation: the Barthel index, *Md State Med J* 14:61, 1965.

A patient scoring 100 is continent, feeds himself or herself, dresses, gets up and out of bed and chairs, bathes himself or herself, walks at least a block, and can ascend and descend stairs. This does not mean that he or she is able to live alone. The patient may not be able to cook, keep house, and meet the public but is able to get along without attendant care.

*A score of 0 is given in the activity when the patient cannot meet the criteria as defined (see [Appendix 27-A](#)).

financial resources of the patient and family or significant others who will be the caretakers must be ascertained. A review of the caretakers' willingness to perform basic tasks or make visits, their willingness to learn and teach the necessary skills, and the realistic need for respites must be determined.¹³⁸ Family training and orientation manuals that deal with all the details of caring for a person with dementia are available (see www.alz.org/living_with_alzheimers.asp).⁹⁹ The same detailed orientation is needed for institutional staff who care for elderly patients with dementia. The structure and process of care can help patients be maximally active in their self-care and prevent unnecessary anxiety and catastrophic reactions.

Supporting Families and Caregivers with Their Own Sense of Loss, Frustration, and Helplessness

Family, significant others, and caregivers go through their own coping and adaptive process as the patient experiences gradual or sudden cognitive disturbances.¹³⁹ These people have a history with the patient and have expectations about what the relationship and communication should be. As cognitive disturbance occurs, they experience a series of losses because the patient is no longer able to respond and interact as he or she has in the past. With progressive cognitive decline, family and friends experience ongoing losses because the patient is continually changing and less able to relate. For many patients with cognitive disturbances, at the final stage all communication disappears and the family is left with only nonverbal communication or no communication at all. Staff who work with a patient over a period of time also face their own personal reactions of loss, unfulfilled expectations, and a continual need to reassess how to relate effectively to the patient. The responsibility for creating a positive relationship falls on the people who are interacting with the patient. The family and caregivers themselves need training and ongoing support in learning how to nurture and maintain an ongoing relationship with the patient. This requires that caregivers and family members be aware that they are in a healing process as they relate to the loss of the relationship that previously existed.

Epstein: Stages of Healing for Caregivers

Epstein¹⁴⁰ provides a workable description of the stages of healing that occur when major trauma or loss occurs. Epstein defines *healing* as “putting right our wrong relation to our body, to other people and . . . to our own complicated minds, with their emotions and instincts at war with one another and not properly understood and accepted by what we call ‘I’ or ‘me.’ The process is one of reorganization, reintegration of things which have come apart.”¹⁴⁰ When a patient experiences cognitive changes, the first stage of response by those who care for or love this person is suffering. Chaos exists during this traumatic time. For example, the patient suddenly cannot understand simple directions on how to operate the new electric cart and insists on getting the old one back. The family is upset and arguments ensue. The family and patient together eventually get a medical workup and they are told that “Mom has some type of degenerative cognitive problem.” They all experience a profound sense that “something is wrong.” The response to helplessness for most human beings is to resist. The lesson of this stage is acceptance. When acceptance is present, then detachment from the emotions is possible. With acceptance present, adaptation and compensation for losses are possible. In the example noted, this would mean that the family would return the new electric cart and have the old (familiar) model refurbished. The family would get training from the therapist in exactly what skills of interaction Mom does not have so that they can work to avoid creating situations in which she feels “stupid and helpless.” When a cognitive loss is truly present, training in skills only creates frustration in the patient that may lead to anger and rage. The staff and family need to be trained to understand the exact nature of the losses and provide appropriate compensations in their oral communication and how they relate to the patient.

Stage 2 has been alluded to as a part of stage 1. Therapists, the family, and caregivers search for second opinions, see other types of physicians, and try alternative treatments to gain power over the sense of helplessness. The polarities and rhythms of this process define this stage. All persons involved, even the patient, eventually begin to note that the emotions of

the interactions may actually be making things worse. Acceptance that no magic solution is available begins. Everyone involved looks with interest at the proposition, “What can I do to make *this* life—*this* person—cope more effectively and have a reasonable quality of life (regardless of my opinion about what cognitive loss means to me personally)?” The lesson at this stage is another level of acceptance.

The third stage invites an examination of the ways in which people are “stuck in a perspective.” When overwhelming stimuli occur, people commonly resort to their favorite strategy from childhood. For some people the favorite strategy is to withdraw, for others it may be to eat to create a distraction, and for others it may be anger. The emotional and mental options created to adapt to a difficult situation are as varied as the human race itself. Human beings dwell in the desire to know why or how to fix something. The lesson of this stage is, again, another level of acceptance and insight about how involved individuals contribute to the problem by reactions at the moment.

Stage 4 begins the process of “reclaiming power.” This is the stage at which people realize that the “script” (their internal dialogue) from the last three stages is not workable or even desirable. The anger is recognized and it brings an awareness that this reaction is not helping. Recognition begins that resisting is also not working because the condition of the patient is not affected in a positive way by the emotional reaction on the part of the caregiver(s). The truth of the matter is that the first four stages of healing often cause family and caregivers to be part of the problem and not part of the solution. The problem is how to support the patient to heal and adapt to the cognitive changes, whether temporary or permanent. Family and caregivers need to bring their healing process to their own support system, which needs to be separate from the patient. When caregivers attempt to share their frustration, suffering, sadness, or anger with the patient, the patient is usually upset because she or he cannot comprehend what the details of the issue really are. The patient knows only that people are upset. This will cause the patient to be further upset and agitated. The stages of healing in staff and family must be recognized and services created or referral to support groups made so the patient can interact with people who are able to adapt to his or her needs and not cause further upset.

Stage 5 is called “merging with the illusion” and represents the first step in being able to “relate to the facts in a powerful way” rather than resisting or trying to manipulate them. It is the step at which family and caregivers begin to integrate the facts into their view of the world. The adult son may say, “I hate the fact that my mom cannot live alone; it makes me feel so helpless [or frustrated or angry or upset or inadequate].” Many health care providers get upset when cognitive losses occur in their loved ones. The cognitive loss seems to be a failure that they take personally.

Stage 6 begins with active steps to prepare for the resolution of the emotions connected with the process. Many people describe this stage as the time when they really admit that their parents are never going to be able to give them advice again, babysit, or travel alone. The healing comes in allowing people to notice the emotions that come with accepting these big changes in reality.

Stage 7 brings the actual physical or emotional discharge. The process can be expressed as laughter, crying, fever, the urge to be physically active, sneezing, coughing, and so on. Resolution

is marked by a deep sense of peace and inner strength. The person will have gone through the six stages, and the release of emotions or movement results in a deep shift away from resistance. *Family and caregivers need to create their own healing experiences separate from or away from the patient with cognitive losses.* When therapists work with the patient with cognitive losses, they must create for the patient a world that works and is safe and respectful of his or her unique abilities. In most cases the profound emotional and physical release that comes with resolution tends only to upset the patient.

At stage 8 affected individuals are emptied and the board has been wiped clean. In the space of nothingness is an opportunity for new possibilities for relating to the patient. *The relationship should not be based on the past but on moment-to-moment information that comes from the patient.* Therapists can now enjoy being with the patient and begin to feel gratitude. Family and caregivers begin to look for ways to make things work more easily.

Stage 9 is a time when the caregivers and family relate to the energy of the universe and begin to see the connections to all life around them. At this stage, involved individuals begin to see that they are also a part of the great flow of time and energy and that an opportunity for joy exists. The process of illness and dying becomes the focus of awe and a reason to connect with other people and appreciate other people because they are a part of the whole process of life.

Stage 10 is the time to connect with the creative force of the universe. The spiritual process is brought to the issue at hand. A sense of great wisdom and oneness with all creation is felt. *When working from this state of being, the caregiver has the unique capacity to speak or act to bring out the best in others.* In health care, some caregivers have the special gift of allowing themselves to step into the mental world of the other person and thereby create communication that will be heard and that can be acted on even by those with limited mental capacities. The most interesting thing is that the patients can often tell if a caregiver is in this unique state because they will come and sit next to the caregiver or want to hold hands. This state of ease and connection can be learned. A possible resource for exploring these skills is an organization called Landmark Education ([415] 981-8850; www.landmarkeducation.com), which provides programs and courses that examine how people listen, what bias they bring to the communication process, and specific speech strategies to bring out the best in others.

Epstein’s stage 11 is when people live day to day without being attached to the situation. Epstein notes that in this stage, “we communicate with ourselves and others through our wounds instead of from them.” As healing progresses, caregivers become part of the solution in the care of the patient with cognitive losses. They know they can make a positive difference and take action to create what needs to be done. *They are able to sort out the facts of a situation from the first impression, which is often loaded with judgments and wishful thinking. As caregivers relate to the verifiable facts, they speak to the issues at hand with power and create positive outcomes in which “win-win” becomes the norm.*

In the last stage, caregivers bring their unique individuality to the service of the community. They become aware that the limits to what they can bring to the community are connected to the limits to their sense of wholeness. This insight sends them back to their earlier stages of healing to create further self-awareness and healing on other issues.

In-service training can offer a basic introduction to strategies for lifelong learning, healing, and self-awareness. “What works for me?” “What is the easiest way to learn new skills?” “What strategies enhance adaptability?” This type of learning is nonlinear and is the model a scientist uses to conduct an inquiry. Recently more attention has been paid to managing stress and the role of spirituality in processing grief and loss among caregivers and family.¹⁴¹⁻¹⁴³

Nonlinear Learning

Nonlinear learning begins with the posing of a question. Then data and information are collected, and additional questions are generated that are related to the first question. At some point an “Aha!” moment or insight occurs. A new relationship is suddenly made possible that was not possible before. Nonlinear learning is not about small gradual steps of progress but occurs as learning balance occurs when riding a bicycle—one minute balance is impossible, and the next is the breakthrough moment. Nonlinear training offers precise strategies that can enhance communication with someone who has cognitive deficits. Nonlinear learning is built on scientific communication that operates on the basis of verifiable facts at the present moment. Nonlinear learning invites each person to examine all strategies for communication to be sure that problems are not occurring as a result of misinterpretation of the facts. Communication can occur without verbal language, and fear does not need to be present. When a patient has cognitive deficits, the art and science of human interaction need to be precise so that caregivers do not speak in words that are not understandable to the patient. Which caregiver prejudgments are brought to the interaction with the patient needs to be understood: experiencing the stage of awe, sharing joy in the moment, or suffering because the person is “difficult”? The care and therapy provided to a person with cognitive disturbances need to be created based on the facts of the moment and carried out in a state of gratitude, vulnerability, and nurturing for the staff and the patient.

Role of the Physical Therapist: Development of Interventions and Caregiver Training

All persons with cognitive losses should have access to caregivers who are trained to manage emotional responses in order to provide precise strategies for communication with those with dementia. A gracious and secure existence is possible even when cognition is diminished if the caregivers are committed to adapting the environment and its demands to match the capacity of the patient. The challenge for health care is designing training programs that truly prepare families and caregivers to be effective, empowering communicators. All caregivers need training to create this experience for a person with cognitive deficits.

As a part of the rehabilitation program, caregiver training for this group of patients needs to emphasize reassurance, hands-on interventions, and communication to allow treatment to proceed at a pace perceived as reasonable by the patient.⁶⁷ In the early and middle stages of all dementias, physical therapy intervention usually can prolong the ability to move with ease in ADLs and IADLs and maintain the ability to participate in some social activities. This is extremely important for caregivers because deficits in the patient’s ability to perform ADLs and IADLs often relate to the inability to physically perform these activities under supervision.⁴⁷

The ability to walk is lost late in most dementias, but gait and coordination disturbances are common and can benefit from physical therapy.¹⁴⁴⁻¹⁴⁶ Therapeutic intervention to assist the patient and train the caregivers involves facilitation of ease of movement and motor planning and developing or refining environmental and cognitive cues to assist in carrying out complex tasks. Ultimately, caregivers require training in how to move, lift, and otherwise assist the patient.

Although not able to reverse the progressive cognitive decline, the exercise intervention that the physical therapist can develop may improve the level of function, confidence, vitality, and safety of the patient and ease the burden of care for the caregivers. Research is beginning to establish an important role for exercise in maintaining physical activity^{147,148}; contributing to general health and slowing of cognitive decline¹⁴⁹⁻¹⁵²; as well as maintaining strength and aerobic conditioning.¹⁵³ Guidelines for exercise prescription include aerobic, strength, balance, coordination, and flexibility activities determined by direct assessment, and suggestions for motivational and problem-solving strategies. The Seattle Protocols are an important contribution in this area.^{154,155} Research shows that exercise not only increases strength, coordination, and aerobic capacity but also creates beneficial changes in brain plasticity.¹⁵⁶⁻¹⁵⁸ Further studies need to be done to work out more clearly what types of exercise are beneficial in what ways for what populations.¹⁵⁹

Cognitive impairment is a key limiting factor in the performance of ADLs and IADLs as well as a limiting factor for participating in rehabilitation. Accurate assessment and training by the therapist helps the caregiver provide only the help that is absolutely needed, with patients continuing to perform for themselves as many ADLs as possible. For example, when brushing the teeth, the patient needs to be able to remember the command to brush, must recognize the toothbrush, and must perform a complex but repetitive motor action. The patient may only need the help of someone placing the toothbrush in his or her hand and slowly guiding it to the mouth to be able to safely brush the teeth.

The accurate assessment of IADLs and ADLs is more reliable than medical diagnosis for predicting the amount of assistance and interaction a person will need in a nursing home (see [Table 27-1](#) and [Appendix 27-A](#)).¹³⁶ The first goal of rehabilitation for patients with dementia is to create a supportive emotional and physical environment. In other words, the environment must actively work to compensate for the patient’s cognitive and functional losses as they occur. The ultimate goal is to help patients feel they are capable so that they will continue to try to do those things for themselves that they can do safely, whether they remain in their home or live in an institution. Orientation and training of significant others is also important so they feel comfortable allowing the patient to participate safely in activities and basic self-care tasks modified to their cognitive level.

The Alzheimer’s Association ([800] 272-3900; www.alz.org) is a resource for professionals and caregivers of people with dementia. The goals of the association are the following:

- To support research related to the diagnosis, therapy, cause, and cure of AD and related disorders
- To aid in organizing family support groups; to educate and assist affected families
- To sponsor educational programs for professionals and laypersons on the topic of AD

- To advise government agencies of the needs of the affected families and to promote federal, state, and private support of research
- To offer help in any manner to patients and their caregivers to promote the well-being of all involved

The Alzheimer's Association promotes the provision of humane care to the patient with dementia or related disorders throughout the course of the illness. Other support groups have been tried in communities in which spouses have worked to develop ongoing respite care.¹⁶⁰

As a member of the rehabilitation team, the physical or occupational therapist can conduct an inventory of services as a part of the annual review of the quality of care that is provided for a patient with dementia. Surveys of persons caring for patients with dementia listed the following services in their perceived order of importance^{83,161}:

1. A paid companion who can come to the home a few hours each week to give caregivers a rest (respite)
2. Assistance in locating people or organizations to provide patient care
3. Assistance in applying for government programs, such as Medicaid, disability insurance, and income support programs
4. A paid companion who can come to the home for overnight care so caregivers can go away for one or more days (respite)
5. Personal home care for the person with dementia to help with activities such as bathing, dressing, or feeding in the home
6. Support groups composed of others who are caring for persons with dementia and other cognitive deficits
7. Special nursing home care programs only for persons with dementia and other cognitive deficits while the caregiver is away
8. Adult day care providing supervision and activities away from the home
9. Visiting nurse services for care at home

In the home care category, information about the availability of services and government programs and various forms of respite care were also ranked high in the survey. Overall, caregivers (family and friends) of the patient are often able and willing to provide care for the patient throughout the illness if appropriate professional consultation can help them cope with problematic situations and if adequate respite time is provided to the caregiver(s).

Not mentioned in this chapter was the need for psychological support for caregivers. The stress on caregivers is extreme, and symptoms of anxiety and depression are common. Because of the relative lack of counseling services for caregivers, however, the use of (and probable abuse of and dependence on) psychotropic medications by caregivers is high.^{60,162} Because these medications may impair the cognitive functioning of caregivers, the risk of harm to the patient with dementia is also high.

DEMENTIA AND DELIRIUM: NEW FRONTIERS

Most current research in delirium and dementia is focused on AD. The Alzheimer's Association is the largest private foundation funding research on dementia, supporting on average about 100 projects totaling almost \$15 million annually. Research is underway to explore possible causes of dementia, including work that examines the roles of neurotransmitters,

structural brain changes, nutrition, viruses, drugs, immunological deficits, and heredity in the etiology of AD. Studies to increase the diagnostic accuracy of different forms of dementia, including making a distinction between cortical and subcortical dementia¹⁶¹ or using *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) criteria¹⁶³ or neuropsychological criteria, are also underway. Newer diagnostic models of dementia, including that caused by stage II or III human immunodeficiency virus infection, are also being studied.^{164,165} New research that may shed light on the mechanisms of the early stages of AD relates to other neurodegenerative diseases. Persons with dementia who also have parkinsonian symptoms, delusions, and hallucinations have been reported to experience faster decline than those who do not.¹⁶⁶ This research team found a relation between the presence of Lewy bodies (abnormal structures in the brain that contain a protein called *synuclein*) and parkinsonian symptoms; affected individuals had lower survival rates than those with either symptom present by itself.

The most exciting area of research is pharmacology (see Chapter 36). The advent of tacrine, a drug that slows down the progression of AD in some patients, has produced an explosion of research on drugs aimed at stabilizing or reversing the symptoms of this disease. Although no cures are available, some drugs, such as physostigmine, ondansetron, and nerve growth factor, have shown some promise. These studies have spawned a search for new drugs to treat both AD and the symptoms of other dementias.¹⁶⁷⁻¹⁶⁹

Research is also being funded that is investigating the best ways to provide care and support in the home and at long-term residential settings.³³

SUMMARY

Why some people stay lively and creative in their older years is not known; Michelangelo designed St Peter's when he was nearly 90; Picasso painted at 90; and Arthur Rubenstein, Pablo Casals, and Martha Graham all worked creatively in their older years. What is clear is that lonely, isolated older people are much more likely to be confused and disoriented than their peers who remain actively involved with family and friends. Perhaps what is needed is to invite the world to explore rules of conduct in which older persons are honored and included.

In working with an older person with dementia or delirium, the therapist can do much to make the quality of life better for the patient, family, and caregivers.⁹⁹ A thorough listing of the details needed to develop an environment and process of care for elderly persons with cognitive deficits can be found in other texts (see www.alz.org/living_with_alzheimers.asp).^{99,131}

Specific examples of modifications of physical and occupational therapy examination and treatment may include working in collaboration with the family, close friends, and other members of the rehabilitation team and developing a consultative relationship with key caregivers (professional and nonprofessional and all shifts of institutional staff) to encourage problem solving and patient participation in self-care. Another important modification includes the evaluation of each patient's communication abilities before the therapy assessment to adapt the assessment in such a way as to promote patient participation. Case Study examples are presented later in this chapter (refer to *Case Studies 27-1* and *27-2*) to provide clinical scenarios and corresponding physical and occupational therapy examination and treatment strategies.

CASE STUDY 27-1 ■ THE COMPLEXITY OF AGING

The patient was a 78-year-old woman who had the following deficits on the MMSE: was not aware of where she lived, the date, or the year; had poor short-term memory; could not spell the word “world” backward; could not copy two overlapping pentagons. The patient was generally happy and enjoyed having someone sit with her. The patient had fractured her femur and because of the location of the fracture site, a surgical procedure was performed to allow total weight bearing. The surgeon and the psychiatrist decided that partial weight bearing would not be a concept that the patient could understand. The physical therapist and assistant worked together with the family and caregivers in the nursing home to develop a plan of care. At the initial care conference, the main question was whether the patient should receive physical therapy. The family was fearful that the patient would fall again if she were taught how to walk. The focus of the conference was to educate the family and other staff regarding the importance of physical therapy so the patient could learn how to participate in and eventually perform transfers from wheelchair to toilet as well as to bed. The decision was made to begin physical therapy, with the initial goal being to achieve all functional ADL transfers with standby physical assistance.

The patient was not interested in walking and was fearful of falling. The key change in physical therapy intervention was in the style of communication used to teach basic bed mobility and the components of transfer skills. Through use of trial and error it was determined that the patient responded best to a smile, verbal encouragement, hand signals, and gentle manual pressure to indicate the desired task to be performed. If the task was broken down and components were identified, the patient became frustrated and refused to participate. If the patient was invited by manual cues and verbal reassurance to stand up and sit on the bed, the patient would hesitate for up to 1 minute and then she would attempt to perform the task. It became obvious that the patient needed at least 30 to 60 seconds of waiting time between when a verbal request was made and when she was ready to act on the request. If additional time was not given, the patient appeared to get frustrated and would refuse to cooperate. A sign was placed over her bed with instructions for communication: smile, reassure, use your hands to guide her to perform the desired action, and wait 60 seconds; let her feel there is plenty of time.

A sliding board was introduced in therapy, and the patient enjoyed the idea. The board allowed transfers for all ADLs to involve no lifting for the staff. The patient would lean her head on the shoulder of the staff member while sitting and then she would assist in sliding across on the board. All transfers for ADLs using the sliding board were possible within five visits of physical therapy. A bed was located that was 17 inches high to facilitate bed-to-wheelchair transfers. The bed could be raised to assist the nursing aide in cleaning activities. The decision was made to leave the bed at 17 inches unless the nursing staff needed to perform special in-bed procedures with the patient. The wheelchair footrests were modified so that they formed a solid flat surface to allow the patient to rest in a natural position.

The patient was only 5 feet 2 inches tall, and the standard wheelchair allowed her only to comfortably put both feet on one foot pedal and sit with her weight mostly on one buttock. A smaller wheelchair and the adapted footrest gave the patient an equal pressure on both sitting bones, and the patient began to sit at rest in a natural upright posture. The other goal of physical therapy was to teach the patient wheelchair mobility by using her hands to push the chair. Once the patient was given gloves for her hands (she did not like germs), she was willing to try to push the wheelchair. The patient was instructed in the physical therapy department during two visits. The patient was next seen by the therapist on the unit to allow the nurse's aide to be a part of the physical therapy instruction. The rationale was that the nurse's aide would need to help reinforce the skills and encourage practice of wheelchair mobility skills as a part of daily activities. During the last visits the physical therapist watched daytime, afternoon, and evening staff practice with the patient and addressed new situations that arose. All caregivers on three shifts were trained to ensure consistency of verbal and manual cuing for the patient.

Before discharge to restorative nursing, the patient's current level of functional abilities was documented by using an ADL chart that specified time of day when tasks were easiest, task(s), equipment needs, special positioning, clothing and other assistive devices, verbal cuing, and other communication requirements for each critical task that had been mastered in physical therapy. The cataloging of functional skills reminded the nurse's aide of the ingredients involved for the patient to successfully perform ADLs. The other advantage of the detailed discharge summary to the nursing staff was that new staff could use the document and, as needed, contact physical therapy for clarifications if the patient suddenly were not able to perform the tasks (a signal of possible medical or psychosocial problems).

KEY POINTS

1. Common goals were identified and agreed on among all team members and the patient's significant others.
2. Education was provided as needed to allow for consistency of verbal and manual cuing to the patient.
3. Physical therapy treatment began in a quiet, undisturbed area where the patient could concentrate. As mastery of a skill was achieved, the skill was practiced with supervision, and instruction of other staff was provided as needed.
4. Equipment and furniture were adjusted to help the patient perform tasks with minimal assistance.
5. Discharge from therapy involved providing nursing staff with a detailed description of functional abilities and the conditions required to help maximize patient participation, sense of safety, and control (as had already been reviewed with all aides working with the patient).
6. The physical therapist was designated as a resource person for nursing staff for simplifying functional tasks in patient care, problem solving, communication, and movement-related issues.

CASE STUDY 27-2 ■ A CLIENT IN THE EARLY STAGE OF ALZHEIMER DISEASE

The patient was a 64-year-old man who until 1 month ago was working. He was forced to retire because he kept forgetting the natural sequences of the work tasks. For example, his partner would see him direct someone to wait for him in the waiting room and then he would forget the person was in the waiting room. On the MMSE, he had difficulty with date and year and would try to redirect the question in an apparent attempt to cover up for loss of short-term memory. He could not or would not spell the word “world” backward, and he poorly copied the overlapping hexagons (looked more like squares). He was a runner but now he apparently could not remember how to get home, and he would pretend to be hurt and get someone to drive him home. The man reported feeling restless.

The patient, his wife, and two sons were seen by the team at a psychiatric clinic. The wife was very upset and the family was asking for help. The role of therapy at this early stage of AD involved the following:

1. Functional assessment of basic ADLs and IADLs and home assessment.
2. Orientation of spouse and significant caregivers regarding the functional changes that could occur in the near future and how to compensate for current functional losses (e.g., patient had difficulty dressing in the morning and would get frustrated).
3. Orientation to the role of therapy in hands-on treatment related to techniques to help the patient relax. After initial evaluation, the team decided to teach caregivers massage techniques identified by the therapist as soothing and relaxing for the patient. (Note: The emphasis in hands-on intervention is to create slow, predictable, and nurturing contact that is perceived by the patient as soothing and relaxing.)
4. Orientation of caregivers to the use of manual contact and hand signals to communicate and reinforce the intention. Kinesthetic contact and the ability to follow kinesthetic cues can help the patient with ADL tasks at home. At this time the kinesthetic cuing may not be critical for the patient, but the caregivers need to get in the habit of cuing the patient as a compensatory tool for future cognitive losses.
5. Orientation of caregivers to the benefits of a ritualized schedule of daily events for the patient and assistance in developing the daily schedule. The predictability of the ritual would help the patient feel safe and in control. The ritualizing would be especially helpful to address the frustrations with dressing in the morning.
6. Written information about local support groups, day treatment centers, and the availability of the rehabilitation team, including therapy for problem solving.
7. Participation in evaluation of patient and family need for placement in a day treatment center or use of a home health aide. Supervision was needed for cooking (he would leave burners on), working in the woodshop (he would leave power tools running), and in self-care to ensure his safety. Supervision in the home was decided, with family members sharing the load. The idea of going to a new place was not positively received by the patient. (Note: The patient may function better in the environment where he or she has lived for a long time because of the familiarity with the details of the surroundings.)
8. The therapist participated in development of the home care plan and provided for home visits to accomplish tasks described in items 1 through 7. The next contact that the family made with therapy was 1 month later to address the patient’s inability to settle down and be able to go to sleep at night. A home visit was made to evaluate the bedtime ritual, the relaxation strategies being used, and communication with the physician about current medications taken. The patient disliked bathing and undressing for bed. After discussion with caregivers the patient was allowed to go to bed in his clothes without bathing and undressing (bathing and undressing would be carried out in the morning when he was less tired). Relaxation massage was modified to involve the face, neck, hands, and feet, and the caregivers were instructed and practiced during two visits under the supervision of the therapist. A satisfactory bedtime ritual was developed, and home health care was workable for the patient and the caregivers.

The next request for therapy consultation came 4 months later when the wife and the daughter-in-law (who had been taking turns being the primary caregiver) both felt the need to hire and train an attendant-companion for the patient for 8 hours a day. At this time the patient preferred to be in the home, walk in the yard, or take long walks in the local park. The therapist, in cooperation with other team members, trained the patient and aide in how to sequence for ease in ADL tasks; use of kinesthetic cuing; how to facilitate ADLs, bathing, and dressing with a slow pace and ritualized format; and how to sequence the tasks and relaxation techniques to help the patient settle down and go to sleep. Foot massage was the only technique that the patient now allowed and appeared to enjoy. After three physical therapy visits over a 2-week period, the attendant was able to carry out home health care effectively for the patient.

The last request for help occurred when the family was concerned because the patient was trying to run away. The therapist made a home visit and found that the patient sat most of the day. The MMSE showed that he could not give his own first or last name and had no short-term memory. Based on the evaluation, the therapist proposed that the family or attendant go with the patient for a walk when the patient showed an interest in leaving the house. This strategy worked for a few months, but then the patient began to sit down on the sidewalk when he was tired. Another visit was made after a wheelchair was ordered to train the caregivers in use of the wheelchair and to orient the patient to the desired procedures and to reassure the patient. After this visit the patient showed gradually less interest in leaving the home over the next few months until he eventually stayed in the house constantly. At this time the patient also became incontinent of bowel and bladder. The patient refused to use the toilet and the decision was made to seek nursing home placement.

CASE STUDY 27-2 ■ A CLIENT IN THE EARLY STAGE OF ALZHEIMER DISEASE—cont'd**KEY POINTS**

1. Physical (or occupational) therapy is a part of the team providing guidance and care for the patient and the family of the patient with AD and other dementias.
2. Evaluation of functional skills, communication related to functional skills, and home modifications to enhance patient participation in self-care can be continued as long as the caregivers request support and help problem solving.
3. Problem solving with caregivers and educating caregivers are the primary roles once the therapist has identified the intervention of choice to solve the key functional problems.
4. All therapy intervention needs to be coordinated with actions of others providing care for the patient (family, neighbors, and friends as well as other health care providers).

Modifications of treatment include the use of gentle, non-verbal neurological rehabilitation techniques (e.g., the Feldenkrais Method). The key is to acknowledge the now well-established research finding that nondeclarative learning and memory (procedural) are available long after declarative learning and memory (ability to consciously learn and remember facts and events) are lost for a person with AD. Motor ability is one of the last areas to be affected by AD.¹⁷⁰ Assisting a person with AD to edit procedural memory and increase walking safety is therefore possible. The functional outcomes of this learning can include a decrease in abnormal muscle tone, enhanced sensory awareness and organization for the position of the eyes and head in space, an increase in the ease of movement, an increase in the ease of breathing, enhanced endurance, minimized anxiety, minimized resting muscle rigidity in the chest, and increased patient coordination. The therapist needs to modify the process of neurological facilitation by decreasing patient effort and adding extra cuing and more frequent breaks for integration of learning. Tasks may need to be simplified so that the patient can perform them, and the caregiver is trained to perform only those tasks that the patient cannot perform.

Each month the therapist, treatment team, patient, and caregiver(s) need to identify safe physical activities that the patient can be encouraged to perform for recreation, relaxation, and overall fitness. The goal is to enhance the performance of simple ADL and IADL tasks (e.g., washing socks, setting the table), which can enhance patient self-esteem. In addition, the physical therapist, along with other members of the rehabilitation team and caregivers, needs to monitor the patient for new signs and symptoms of concurrent delirium or reversible dementia so that treatment can be initiated early and further deterioration can be prevented.

A hospital and nursing home patients' "Bill of Rights" defines the minimal quality of care required for any patient. The concepts presented apply to the care of patients with cognitive deficits no matter what the setting. The provision of considerate and respectful care for the patient with dementia or other cognitive deficits is possible and necessary. Well-planned and gentle care prevents unnecessary distortions in cognitive function brought on by feelings of fear or being rushed and thereby maximizes all remaining cognitive function. To use his or her remaining emotional and cognitive resources, the patient with cognitive deficits needs to live in an environment and experience a process of care that is modified to meet the special needs created by delirium or dementia.

Major efforts are underway in research to discover a cure for AD. In 1997 a consensus conference on the diagnosis and treatment of AD and related disorders was organized by the American Association for Geriatric Psychiatry, the Alzheimer's Association, and the American Geriatrics Society. The conclusions of the conference included the following statement:

"AD is the most common disorder causing cognitive decline in old age and exacts a substantial toll on society. Although the diagnosis of AD is often missed or delayed, it is primarily one of inclusion, not exclusion, and usually can be made using standardized clinical criteria. Most cases can be diagnosed and managed in primary care settings, yet some patients with atypical presentations, severe impairment, or complex co-morbidity benefit from specialist referral. AD is progressive and irreversible, but pharmacologic therapies for cognitive impairment and non-pharmacologic and pharmacologic treatments for behavioral problems associated with dementia can enhance quality of life. Psychotherapeutic intervention with family members is often indicated, as nearly half of all caregivers become depressed. Health care delivery to these patients is fragmented and inadequate."³⁶

Physical and occupational therapy are key resources for the creation of a therapeutic environment and for the effective and timely assessment and treatment of the patient with cognitive deficits (presuming that the therapy can take into account the need to affect procedural learning directly—i.e., the Feldenkrais Method). The goal of therapy is to create a process of care in which the patient feels safe and the caregivers are given training and support in problem solving to guide the patient to participate in self-care, ambulation, and recreation as long as it is safe and functionally possible.

Caregiver agreements can enhance the capacity of older persons with dementia to participate in daily life—exploring the possibility of living a life with safety, dignity, and love. Following is a brief list of basic environmental supports for encouraging procedural memory to be activated:

1. I will ask my patient if he or she would like to pray or worship today, and I will make arrangements to meet those needs.
2. I will speak or communicate in a way that is functional and workable for the patient.
3. I will repeat what I hear and perceive back to the patient to ensure that I capture her or his perspective.
4. I will encourage natural participation by creating a pace that is pleasant for the patient.
5. I will close doors quietly.
6. I will not raise my voice and shout except in a real emergency.

7. I will talk to someone on staff when I get upset or take something personally so I can have peace with co-workers, creating a positive atmosphere for the patients to live in.
8. I will offer to warm up the patient's tea or coffee and make sure it is not so hot that it could cause a burn.
9. I will create only one choice at a time so the patient can understand and then choose yes or no.
10. I will know what "my" patient has eaten on my shift.
11. I will know my patients' timing for toileting so I can support their continence and dignity.
12. I will tell the patient I am going to touch him or her before I do so, to avoid surprises.
13. I will walk (rolling or ambulating) with every one of my patients outdoors as often as possible or at least every 3 days to encourage good sleep and mental and physical stimulation.
14. I will sit and visit with each of my patients for 10 minutes (every shift).
15. I promise to listen with an open heart to the patients' perception of life at the moment.
16. I promise to close the blinds in every room at night (unless the patient requests otherwise) and open blinds every morning to reinforce day-night orientation.
17. I will discover and use the "personal" get ready for bed routine for all patients so they sleep well.
18. I promise to talk and walk at a pace that encourages a sense of safety for my patients.
19. I promise to be self-nurturing and come to work well rested and ready to share myself.
20. I promise to avoid confrontational actions and body language except in an emergency.
21. I promise to respect the unique ergonomics of each patient and adapt as needed.
22. I promise to offer to add support to explore ways to increase comfort.
23. I promise to notice how my patients relate so no one agitates or bothers another.
24. I promise to be kind to myself, other staff, and my patients.

25. I promise to be of service and adapt to meet my patients' needs.
26. I promise to report problems (equipment, environment, relationships) to the person who can do something about them.
27. I promise not to gossip (talk about others so that it leaves a negative impression and no resolution of the problem).
28. I promise to leave my workspace clean and restocked after I have taken care of the patient (or at least to leave a note to alert the next shift about what has not been done).

DEDICATION

A personal note: This chapter was written for my grandmother. She had depression and related cognitive disturbances after World War II. She gradually got worse and worse in her ability to remember new information, but she could hold my hand and show me how to feed the ducks. We were great friends. I helped her remember to turn off the stove, and I remembered where she put her glasses. She could make sandwiches, and I could always find her comb. We empowered each other. Over 15 years she gradually grew more and more helpless in the adult skills of life. Even then she could give great hugs and loved to sit and drink tea with me. I remember her as a very frail woman. I watched the nurse's aide tuck her in, kiss her on the cheek, and hold her hand while they said prayers. The aide hummed a familiar song as she left the room. It was like those familiar songs that come from our childhood, and they wrap us in a sense of warmth and love and safety—we declare that all is well with the world and we go to sleep and dream of peaceful things.

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 170 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

APPENDIX 27-A ■ Rating Guidelines for Barthel Index*

1. Feeding
 - 10 = Independent. The patient can feed himself or herself a meal when someone puts the food within reach. Patient must put on an assistive device if needed to cut up the food alone. The patient must accomplish this in a reasonable time.
 - 5 = Some help is necessary (with cutting up food, and so on, as listed above).
2. Moving from wheelchair to bed and return
 - 15 = Independent in all phases of this activity. Patient can safely approach the bed in the wheelchair, lock brakes, lift footrests, move safely to bed, lie down, come to a sitting position in the wheelchair if necessary to transfer back into it safely, and return to the wheelchair.
 - 10 = Either some minimal help is needed in some step of this activity or the patient needs to be reminded or supervised for safety in one or more parts of this activity.
 - 5 = Patient can come to a sitting position without the help of a second person but needs to be lifted out of bed, or he or she transfers only with a great deal of help.
3. Doing personal toileting
 - 5 = Patient can wash hands and face, comb hair, clean teeth, and shave. He may use any kind of razor but must put in blade or plug in razor without help as well as get it from drawer or cabinet. Female patients must put on own makeup.
4. Getting on and off toilet
 - 10 = Patient is able to get on and off toilet, fasten and unfasten clothes, prevent soiling of clothes, and use toilet paper without help. If a bedpan is necessary instead of a toilet, patient must be able to place it on a chair, empty it, and clean it.
 - 5 = Patient needs help because of imbalance or with handling clothes or using toilet paper.
5. Bathing self
 - 5 = Patient may use a bathtub or a shower or take a complete sponge bath. Patient must be able to do all the steps involved in whichever method is used without another person being present.
6. Walking on a level surface
 - 15 = Patient can walk at least 50 yards without help or supervision. Patient may wear braces or prostheses and use crutches, canes, or a walker (but not a rolling walker). Patient must be able to lock and unlock braces, if used; assume the standing position and sit down; get the necessary mechanical aids into position for use; and dispose of them when sitting. (Putting on and taking off braces is scored under dressing.)
 - 10 = Patient needs help or supervision in any of the above but can walk at least 50 yards with a little help.
- 6a. Propelling a wheelchair
 - 5 = Patient cannot ambulate but can propel a wheelchair independently. Must be able to go around corners, turn around, and maneuver the chair to a table, bed, toilet, and so on. Must be able to push a chair at least 50 yards. (Do not score this item if the patient gets a score for walking.)
7. Ascending and descending stairs
 - 10 = Patient is able to go up and down a flight of stairs safely without help or supervision. Patient may and should use handrails, canes, or crutches when needed. Must be able to carry canes or crutches when ascending or descending stairs.
 - 5 = Patient needs help with or supervision during any one of the above items.
8. Dressing and undressing
 - 10 = Patient is able to put on, remove, and fasten all clothing as well as tie shoelaces (unless adaptations are necessary). The activity includes putting on, removing, and fastening corset or braces when these are prescribed.
 - 5 = Patient needs help putting on and removing or fastening any clothing. Patient must do at least half the work. Patient must accomplish this in a reasonable time. Women need not be scored on use of a brassiere or girdle unless these are prescribed garments.
9. Continence of bowels
 - 10 = Patient is able to control bowels and have no accidents. Can use a suppository or take an enema when necessary.
 - 5 = Patient needs help in using a suppository or taking an enema or has occasional accidents.
10. Controlling bladder
 - 10 = Patient is able to control his or her bladder day and night. Patients who wear an external device and leg bag must put them on independently, clean and empty bag, and stay dry day and night.
 - 5 = Patient has occasional accidents or cannot wait for the bedpan or get to the toilet in time or needs help with an external device.

Modified from Mahoney FI, Barthel DW: Functional evaluation: the Barthel index, *Md State Med J* 14:63, 1965.

*A patient scoring 100 is continent, feeds, dresses, gets up and out of bed and chairs, bathes himself or herself, walks at least a block, and can ascend and descend stairs. This does not mean that he or she is able to live alone. The patient may not be able to cook, keep house, and meet the public but is able to get along without attendant care. A score of 0 is given in the activity when the patient cannot meet the criteria as defined.

Neurological Disorders and Applications Issues

CHAPTER 28 Disorders of Vision and Visual-Perceptual Dysfunction

Laurie Ruth Chaikin, MS, OTR/L, OD, FCOVD

KEY TERMS

anatomy of the eye
eye diseases
functional visual skills
refractive error
strabismus
treatment
visual-perceptual dysfunction
visual rehab
visual screening

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify and analyze visual anatomy and physiology as they pertain to visual function.
2. Analyze the functional visual skills and how visual dysfunction may affect functional performance.
3. Identify the symptoms of visual dysfunction.
4. Develop the skill necessary to take a visual case history by use of behaviors and clinical observations.
5. Identify the difference between phoria and strabismus.
6. Identify and evaluate the difference between visual field loss and unilateral neglect.
7. Identify and differentiate various pediatric and age-related disease conditions that may affect vision.
8. Clearly differentiate nonoptical and optical assessment and intervention adaptations for patients with low vision.
9. Differentiate basic tools for vision screening.
10. Identify when and why to refer and the tools necessary to document that decision.

Vision is an integral part of development of perception. Some aspects of vision, such as pupillary function, are innate, but many other aspects are stimulated to develop by experience and interaction with the environment. Visual acuity itself has been demonstrated to rely on the presence of a clear image focused on the retina. If this does not occur, a “lazy eye,” or amblyopia, will result. Depth perception develops as a result of precise eye alignment. This ability will be delayed, less precise, or absent if correction of eye misalignment is not done within the first 7 years of life. Research has demonstrated that, in fact, most visual skills such as acuity, binocular coordination, accommodation, ocular motilities, and depth perception are largely intact by age 6 months to 1 year.¹ Visual skill development parallels postural reflex integration and provides a foundation for perception.

Early in infancy visual input is associated with olfactory, tactile, vestibular, and proprioceptive sensations. The infant is driven to touch, taste, smell, and manipulate what

he or she sees. Primitive postural reflexes such as the asymmetrical tonic neck reflex help to provide visual regard and attention.

At some point the young child is able to look at an object and determine both the texture and the shape without having to touch or taste it. In adults, vision has moved to the top of the sensory hierarchy, providing full multisensory associations from sight alone. Even the visualized image of eating an apple can recreate the smell, sound of crunching, taste, and feel of the experience.

Early visual impairment and later acquired impairment can affect the quality of the image presented to the brain and thus affect the learning process. In addition, damage to association centers involved with spatial perception, figure-ground, and directionality can interfere with learning and performance. Altered function may be the result of congenital and developmental disorders, birth trauma, physical trauma, or neurological or systemic diseases. It is important,

therefore, to isolate the primary visual processes of seeing from the secondary or associational processes of perceiving in the evaluation of perceptual disorders. The identification of a vision problem becomes part of the differential diagnosis of a perceptual deficit. Visual screening must be done before perceptual evaluation so that visual problems do not bias or contaminate the perceptual testing. It is just as important to eliminate vision as a contributing factor to a perceptual problem as it is to find a possible vision problem.

Our understanding of the ability to improve vision or recover visual function frequently needs to be updated as we apply new research and understanding of neuroplasticity. Principles of visual rehabilitation involve understanding how to provide visual feedback to the system in an optimal learning environment for the patient. The boundaries of improvement are slowly expanding as we refine this understanding.

ANATOMY OF THE EYE

An operational analogy of the eye as a camera may be useful up to a point in understanding the physical function of the structures. Once an image hits the retina and image enhancement begins, however, metaphors must change to match our ever-changing comprehension of brain function. Using computer analogies such as microprocessing of feature detectors comes closer. Many aspects of how we see remain a mystery inside the “black box” of our brain.

Eye Chamber and Lens

Structures and function are discussed from anterior to posterior (Figure 28-1). The first structure that light hits after it is reflected from an image is the cornea. (Technically, light first hits the tear layer, which has its own structure and rests on the corneal surface.) Corneal tissue is completely transparent. Light is refracted, or bent, to the greatest degree by the cornea because the light rays must pass through different media, which change

Figure 28-1 ■ Horizontal section of the eye. (Modified from Wolff E: *Anatomy of the eye and orbit*, ed 7, London, 1976, HK Lewis.)

in density, as in going from air to water.² The refraction of light can be observed by noting how a stick placed into water appears bent where it enters the water (Figure 28-2).

Damage to the cornea from abrasions, burns, or congenital or disease-related processes can alter the spherical shape of the cornea and disturb the quality of the image that falls on the retina. Radial keratotomy, a surgical procedure done in the 1980s to reduce nearsightedness by placing spokelike cuts in the cornea, sometimes had the side effect of scarring the cornea and causing distorted vision. This surgery is no longer done. The newer surgeries such as laser-assisted in situ keratomileusis (LASIK) are far superior and more predictable in their reduction of refractive error (nearsightedness, farsightedness, or astigmatism) and induce virtually no scarring or distortion. In keratoconus the cornea slowly becomes steeper and more cone shaped, distorting the image and causing reduced vision.³

Iris

Behind the cornea is the iris, or colored portion, which consists of fibers that control the opening of the pupil, the dark circular opening in the center of the eye. The constriction and dilation of the pupil control the amount of light entering the eye in a similar fashion to the way the f-stop on a camera changes the size of the aperture to control the amount of light and the depth of field.⁴ Under bright light conditions the opening constricts, and under dim light conditions it dilates, allowing light in to stimulate the photoreceptor cells of the retina. This constriction and dilation are under autonomic nervous system (ANS) control, with both sympathetic and parasympathetic components.⁵ Under conditions of sympathetic stimulation (fight or flight) the pupils dilate, perhaps giving rise to the expression “eyes wide with fear.” Under parasympathetic stimulation the pupils constrict. The effect of drugs that stimulate the ANS can be observed.⁶ For example, someone who has taken heroin will have pinpoint pupils.

Exercise 28-1: Observation of Pupillary Constriction and Dilation

Observe pupillary dilation and constriction on a willing subject (or on yourself in a mirror) by flashing a penlight at her or his pupil. Observe the decreased size of the pupil. Remove the light and watch the pupil dilate.

Lens

Behind the iris is the lens. The lens is involved in focusing, or accommodation. It is a biconvex, circular, semirigid, crystalline structure that fine-tunes the image on the retina. In a camera the lens is represented by the external optical lens system. The ability to change the focus on the camera is achieved by turning the lens to change the distance of the lens from the film, which effectively increases or decreases the power of the lens, allowing near or distance objects to be seen more clearly. The same effect, a change in the

Figure 28-2 ■ Refraction: bending of light at air-water interface.

power of the lens, is achieved in the eye by the action of tiny ciliary muscles, which act on suspensory ligaments, thereby changing the thickness and curvature of the lens. A thicker lens with a greater curvature produces higher power and the ability to see clearly at near distances. A thinner lens and flatter curvature produces less optical power, which is what is needed to allow distant objects to be clear (Figure 28-3). The process of lens thickening and thinning is accommodation.^{4,5}

Ideally the lens will bring an image into perfect focus so that it lands right on the fovea, the area of central vision. If the focused image falls in front of the retina, however, then a blurred circle will fall on the fovea (Figure 28-4). In this case the lens is too thick, having too high an optical power. One simple remedy is to place a negative (concave) lens externally in front of the eye in glasses (or contact lenses) to reduce the power of the internal lens and allow the image to fall directly on the fovea. In presbyopia (old eyes), the flexibility of the lens fibers decreases and the lens becomes more rigid.⁷ Accommodation gets weaker until the image can no longer be focused on the retina. Normal-sighted individuals first begin to notice these changes in their early forties. When this occurs, a plus (positive) lens (or bifocals, progressive lenses, bifocal or monovision contact lenses) may be worn to aid in reading.⁴

Other solutions to the problems of aging can be implemented during the time of cataract surgery, where a bifocal

implant may be inserted, or monovision implant correction performed in each eye.

The lens can be affected by the age-related process of cataract development, in which the general clarity of vision is impaired from a loss of transparency of the crystalline lens. Incoming light tends to scatter inside the eye, causing glare problems. When vision is impaired to such a degree that it affects function, the lens may be removed surgically and replaced with a silicone implant placed just posterior to the iris.

Vitreous Chamber

The space behind the lens, which is filled with a gel-like substance, is called the *vitreous chamber*. As we age, the gel tends to liquefy, and some of the remnants of embryological development that were trapped are released to float freely. This can cause the very common perception of “floaters,” the shadows cast by these particles onto the macular region. They can be disturbing but generally float out of view over time.⁵

Retina

The retina at the back of the eye is the photosensitive layer, like the film in a camera, receiving the pattern of light reflected from objects. The topography of the retina (Figure 28-5) includes the optic disc, which is where the optic nerve exits and arteries and veins emerge and exit. This is also the blind spot because there are no photoreceptor cells on the disc. The macula is temporal to the optic disc and contains the fovea, providing central vision. The surrounding retina provides peripheral vision and defines a 180-degree half-sphere.⁵

Exercise 28-2: Blind Spot

Your blind spot may be observed by doing the following: draw two dots 3 inches (7.5 cm) apart on a piece of paper. The dots can be ¼ inch (0.5 cm). Cover your left eye and look at the dot on the left. Starting at about 16 inches (40 cm), slowly bring the paper closer. Make sure you can see the two dots—one you are looking at directly and the other peripherally. At approximately 10 inches (25 cm) the dot on the right will disappear. This is your blind spot! Why can this exercise only be done monocularly (with one eye)?

Visual Pathway

The visual pathway begins with the photoreceptor cells, which begin a three-neuron chain exiting through the optic nerve. This chain consists of the rods and cones, which synapse with bipolar cells that synapse with ganglion cells (Figure 28-6).^{5,8}

Figure 28-3 ■ Accommodation. **A**, Looking far away. **B**, Looking up close.

Figure 28-4 ■ Refractive error. **A**, Image focused on retina; no refractive error. **B**, A nearsighted or myopic eye. **C**, A farsighted or hyperopic eye.

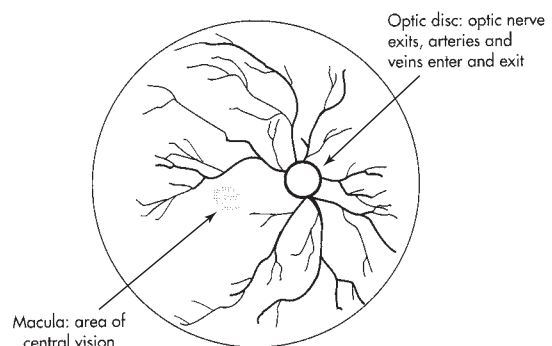

Figure 28-5 ■ Retinal topography.

Figure 28-6 ■ The connections among retinal neurons and the significance of prominent layers. The neurons shown are photoreceptors (*R*), horizontal cells (*H*), bipolar cells (*B*), interplexiform cells (*I*), amacrine cells (*A*), and ganglion cells (*G*). It has been suggested that ganglion cells dominated by bipolar cell inputs represent newer circuitry. The arrow indicates the direction of light as it passes through the retina to reach the photoreceptors. (From Beme RM, Levy MN, editors: *Physiology*, St Louis, 1988, CV Mosby.)

There are two types of photoreceptor cells: rods and cones. The cone or rod shape is the dendrite of the cell. Variation in shape and slight variation in pigment give each one different sensitivities. The rod cell has greater sensitivity to dim light but less sensitivity to color, whereas the cone cell has greater sensitivity to color and high-intensity light and less to reduced light conditions. The highest concentration of cone cells is in the fovea and macula, with decreasing concentration of cone cells and increasing concentration of rod cells moving concentrically away from the macula. The high degree of low-light sensitivity can be most appreciated in survival mode conditions such as being lost in the woods on a moonless night. By swinging the eyes side to side one can maximize the image and keep the macula from interfering.

The phenomenon responsible for the high degree of neural representation of the foveal region and that accounts for the tremendous conscious awareness of the central view is called convergence.⁵ At the periphery of the retina the degree of convergence is great; many photoreceptor cells synapse on one ganglion cell, which accounts for poor acuity but high light sensitivity. The closer to the macula, the less the degree of convergence, until, finally, at the fovea there is no convergence. This means that one photoreceptor cell synapses with one bipolar cell and one ganglion cell.

The awareness of what is seen is directly related to the amount of convergence, which reflects the extent of neural representation. The 1:1 correspondence between photoreceptor and ganglion cell at the fovea means that there is a high degree of neural representation of the foveal image in the brain. It is even greater than the neural representation of the lips, tongue, or hands.⁹ This accounts for the primary awareness of what is in the foveal field and secondary awareness of the peripheral field. Conscious awareness of the environment is whatever is in the foveal field at the moment. But continuous

information about the environment is flowing over the peripheral retina, usually subconsciously. Attention quickly shifts from foveal to nonfoveal stimulation when changes in light intensity or rapid movement are registered. This type of stimulus arouses attention immediately because it could have specific survival value. For example, a person is driving down the street and senses rapid motion off to the right. The foveas swing around immediately to identify a small red ball bouncing into the street. This information goes to the association areas, in which “small ball” is associated with “small child soon to follow.” Frontal cortical centers are aroused and a decision is made to initiate motor areas to take the foot off the accelerator and put it onto the brake, while simultaneously moving the wheel away from the ball and scanning for the object of concern, that is, the child.

Exercise 28-3: Peripheral Central Awareness

We have a unique ability to change our awareness by consciously shifting attention from our foveal or central awareness to our peripheral awareness. For example, as you read these words, become aware of the background surrounding the paper; note colors, forms, and shapes; continue to expand your awareness to include your clothes, the floor, walls, and ceiling if possible. You are consciously stimulating your primitive, phylogenetically older visual system. The ability to do this has considerable therapeutic value because a typical pattern of visual stress is associated with foveal concentration to the exclusion of peripheral information. The ability to expand the peripheral awareness at will is a skill that can help you to relax while you drive, can improve reading skills, and can be used in visual training techniques.

The moment light hits the retina, the photographic film model must be abandoned for the image processing or computerized image enhancement model. The primary visual pathway at the retinal level is a three-neuron chain. From back to front the first neuron is the photoreceptor cell, rods or cones. They synapse with a bipolar cell, which in turn synapses with a ganglion cell. The axon of the ganglion cell exits by means of the optic nerve. Image enhancement occurs at the two junctions of the three-nerve-cell pathway. Lateral cells at the neural junctions have an inhibitory action on the primary three-neuron pathway, and through the inhibition of an impulse the image is modulated. For example, at the first junction between photoreceptor cell and bipolar cell, there are horizontal cells. These cells enhance the contrast between light and dark by inhibiting the firing of bipolar cells at the edge of an image. This makes the edge of the image appear darker than the central area, which increases the contrast and thereby increases attention-getting value. After all, it is by perceiving edges that we are able to maneuver around objects. In a similar manner, amacrine cells act at the second neural junction between bipolar and ganglion cells to enhance movement detection.¹⁰

This image enhancement process continues throughout the visual pathway. The process has been likened to the way in which a computer enhances a distorted picture of outer space received from a satellite. The image goes through a series of processing stations in the inner workings of the computer. The computer-generated, enhanced image shown on the screen is like the end product in the brain: the perceived image.

The visual pathway continues through the brain (Figure 28-7). The ganglion cell axons exit the eyeball by

Figure 28-7 ■ Visual field disturbances at various points along the optic pathway. **A**, Retinal lesion: blind spot in the affected eye. **B**, Optic nerve lesion: partial or complete blindness in that eye. **C**, Optic tract or lateral geniculate lesion: blindness in the opposite half of both visual fields. **D**, Temporal lobe lesion: blindness in the upper quadrants of both visual fields on the side opposite the lesion. **E**, Parietal lobe lesion: contralateral blindness in the corresponding lower quadrants of both eyes. **F**, Occipital lobe lesion: contralateral blindness in the corresponding half of each visual field but with macular sparing. (Courtesy Smith, Kline & French Laboratories, Philadelphia, Pennsylvania.)

means of the optic nerve, carrying the complete retinal picture in coded electrochemical patterns. From there the patterns project to different sites within the central nervous system (Figure 28-8). Projections to the pretectum are important in pupillary reflexes; projections to the pretectal nuclei, the accessory optic nuclei, and the superior colliculus are all involved in eye movement functions.⁵ The largest bundle, called the *optic tract*, projects to the lateral geniculate body in the hypothalamus, where additional image enhancement and processing occurs. The next group of axons continues to the primary visual cortex and from there to visual association areas.

At what point does the retinal image become a perception, and with what part of the brain does one see? Current theory regarding visual perception is the result of Nobel prize-winning research by Hubel and Wiesel in the 1960s called the *receptive field theory*.¹¹ This theory states that different neurons are feature detectors, defining objects in terms of movement, direction, orientation, color, depth, and acuity. Research in 1990 by Hubel and Livingstone¹² was able to locate a segregation of function at the level of the lateral geniculate body. They identified two types of cells, one type being larger and faster magno cells, which are apparently phylogenetically older and color blind but which have a high contrast sensitivity and are able to detect differences in contrast of 1% to 2%. They also have low spatial resolution (low acuity). They seem

Figure 28-8 ■ Visual tract system: *a*, optic nerve; *b*, optic tract; *c*, geniculate-occipital radiators; *d*, retinocollicular radiation; *e*, retinopretecto tracts; *f*, superior colliculus (midbrain); *g*, pretectal area (tegmentum); *h*, lateral geniculate.

to operate globally and are responsible for perception of movement, depth perception from motion, perspective, parallax, stereopsis, shading, contour, and interocular rivalry. Through linking properties (objects having common movement or depth) emerges figure-ground perception. Much of this perception occurs in the middle temporal lobe.

The other type of cell, called the *parvo cell*, is smaller, slower, and color sensitive and has a smaller receptive field. These cells are less global and are primarily responsible for high-resolution form perception. Higher-level visual association occurs in the temporal-occipital region, where learning to identify objects by their appearance occurs. It appears that these two types of cells are functionally and structurally related to the two visual systems represented in retinal topography—the foveal (central) and peripheral visual systems.

Eye Movement System

The eye movement system consists of six pairs of eye muscles: the medial recti, lateral recti, superior and inferior recti, and superior and inferior obliques (see Figure 28-8). Together they are controlled by cranial nerves III (oculomotor), IV (trochlear), and VI (abducens). The eye movement system has both reflex and voluntary components. Reflexive movements are coordinated through vestibular interconnections at a mid-brain level. The vestibuloocular reflex (VOR) functions primarily to keep the image stabilized on the retina. Through connections between pairs of eye muscles and the semicircular canals, movement is analyzed as being either external movement of an object or movement of the head or body. From this information the VOR is able to direct the appropriate head or eye movement.⁵

Two types of eye movements are the result. Smooth, coordinated eye movements are called *pursuits*, and rapid localizations are called *saccades*. Voluntary control of both these motions indicates cortical control. Pursuits are used for continuously following moving targets, and they are stimulated by a foveal image. Saccades are stimulated by images from the peripheral system, where a detection of motion or change in light intensity results in a rapid saccadic eye movement to bring the object into the foveal field. Either difficulties in the

eye movement system or altered functioning of the vestibular system can affect the coordinated, efficient functioning of eye movement skills.

A third type of eye movement is specifically related to eye aiming ability. This is the coordinated movement of both eyes inward toward the nose, as in crossing the eyes, or outward along the midline, as when looking away in the distance. The inward movement is called *convergence*, and the outward movement is called *divergence*. The most important result of efficient vergence abilities is depth perception, or stereopsis. Small errors in aiming can dramatically affect stereopsis. Problems such as double vision, wandering eyes, and strabismus are discussed in greater depth in a later section.

Exercise 28-4: Pursuits, Saccades, Convergence

Pursuits. Follow a moving target such as a pencil point as you move it across your field of gaze, while keeping your head still. Continue to move it in different directions, vertically, horizontally, diagonally, and circularly to stimulate all pairs of eye muscles. For a more challenging demonstration, find a fly and follow its flight path around the room. If you lose sight of it, note that the detection of the movement of the fly will signal your eye movement directly toward it.

Saccades. Hold two pencils about head width apart. Shift your eyes from pencil to pencil without moving your head. Note that your awareness is of the two pencils, not of the background between them. Generally, perception occurs the moment the eyes are still, rather than while moving during saccades. For a more challenging exercise, move the pencil you are not looking at, then shift quickly to it; move the other pencil while looking at the one you just moved. In other words, you will pick up the location of the other pencil peripherally and direct your eyes to the foveal region. The size and degree of blur of the peripheral image will tell the brain where the image is and how far to move the eyes. This ability again is a result of the function of neural convergence, which is related to neural representation.

Convergence. Hold a pencil at arm's length along your midline. Slowly bring the pencil closer in toward you along your midline. Feel your eyes moving in (crossing). Try to bring the pencil to your nose, keeping the pencil visually single. (It is okay if you cannot.) Move the pencil away now, and your eyes are diverging.

FUNCTIONAL VISUAL SKILLS

Refractive Error

Before discussing binocular coordination and the individual visual skills, it is important to describe refractive errors and how they can affect binocular coordination. Three common types of refractive errors are myopia or nearsightedness, hyperopia or farsightedness, and astigmatism.^{5,10}

The myopic eye is too long, or the cornea is too steep, so the focused image falls in front of the retina. It is easily corrected with a negative or minus lens, which optically moves the image back onto the retina.

The hyperopic eye is too short, or the cornea is too flat, such that the focused image falls behind the retina. A positive or plus lens optically moves the image onto the retina. A young hyperopic person will be able to use accommodation to bring the image focus back onto the retina, but because accommodation is finite, this can cause reading difficulties

earlier than normal or can affect binocular coordination at near distances.

An eye will have astigmatism if it is not perfectly spherical. An aspherical eye will cause the image to be distorted, where part of the focused image will be in front of the retina and part on or in back. A person with astigmatism may see vertical lines clearly and horizontal lines as blurry, depending on the specific aspherical shape. A cylindrical type of lens is used to correct astigmatism. This lens corrects the distortion of the image so that it is placed right on the retina.

The following are examples of different refractive errors:

−5.50 DS (diopter sphere): myopia

+4.00 DS: hyperopia

+1.50 \bar{c} − 1.50 × 180: astigmatism (Note: × stands for the axis of the cylinder correction.)

When significant refractive errors are uncorrected, they can reduce vision. Uncorrected refractive error also can interfere with binocular coordination. The symptoms are described in greater detail in the next section.

Binocular coordination is the end result of the efficient functioning of the visual skills (Box 28-1). The individual visual skills include accommodation, eye alignment or vergence, eye movements with normal vestibular coordination, stereopsis (depth perception), and peripheral and central coordination. During normal activities, all the skills are inseparable.

Accommodation

Accommodation is the ability to bring near objects into clear focus automatically and without strain. Relaxation of accommodation allows distant objects to come into focus. The primary action is that of the ciliary muscles acting on the lens, and the primary system of control is the ANS, with sympathetic and parasympathetic components.⁵

Both accommodation and pupil size changes are reflexes that work in concert: as accommodation relaxes the pupil dilates and as accommodation increases the pupil constricts.⁴ As a person focuses on a near object, the lenses thicken, allowing the near object to come into focus. At the same time the pupils constrict to increase depth of focus (just as in a camera). As a person looks into the distance, the lens gets flatter, relaxing accommodation, and the pupil dilates, decreasing the depth of field.

Accommodative ability is age dependent. A young child can focus on small objects just a few inches in front of the eyes. At about the age of 9 years, the accommodative ability slowly begins to decrease. By the mid 40s the reserve focusing power diminishes to the point that near objects begin to blur. At this stage, reading material is pushed farther away

BOX 28-1 ■ BINOCULAR COORDINATION

- Corrected refractive error

- Central and peripheral coordination
- Efficient eye movement skills

until the arms are not long enough, and then reading glasses are needed. This is called *presbyopia* (old eyes).

Problems in accommodation may contribute to myopia, hyperopia, and presbyopia. Symptoms include blurriness at either near or far distance, depending on the age and the problem.

Accommodation is important mainly for up-close activities: reading, hygiene, dressing (specifically, closing fasteners), use of tools, typing, tabletop activities, and games.

Exercise 28-5: Accommodation

Accommodation cannot be directly observed, but it can be implied indirectly through observation of pupillary constriction while doing an accommodative task. Cover one eye. Hold a finger in front at about 10 inches (25 cm). Focus on the finger, making sure that the fingerprint is clear. Shift focus to a distant object. Continue shifting far to near and near to far while a partner observes the pupil. The partner should be able to observe pupillary constriction with near focus and dilation with far focus.

Vergence

Vergence includes convergence and divergence. It is the ability to smoothly and automatically bring the eyes together along the midline to singly observe objects that are near (convergence) or conversely to move the eyes outward for single vision of distant objects (divergence). Specific brain centers control convergence and divergence.

With regard to reflexes, vergence is associated with accommodation: convergence with accommodation, and divergence with relaxation of accommodation. The function of this reflex is to allow objects to be both single and clear, at either near or far positions. Vergence has both automatic and voluntary components. Most of the time it is not necessary to think about moving the eyes inward while looking at a close object; yet if asked to cross the eyes, most people can do this at will.

Problems can occur in vergence ability when the eye movement system is out of sync with accommodation or from damage to cranial nerves III, IV, or VI. Problems can be slight, in which there is merely a tendency for the eyes to converge in or out too far, or the eyes can be grossly out of convergence. Tendencies to underconverge or overconverge are called phorias and are not visible except by special testing in which they are elicited. An individual may be asymptomatic, but symptoms may occur under conditions of increased stress or fatigue such as excessive reading or working at a computer terminal or from drug side effects (prescription and recreational).

Some phorias may worsen to the extent that binocularity breaks down, at which point the individual becomes strabismic. There are two main types of strabismus: esotropia and exotropia. An esotropia is an inward turning of the eye, and an exotropia is an outward turning. A third, less common type of strabismus is hypertropia, in which one eye aims upward relative to the other eye. Strabismus and dysfunctional phorias are discussed in greater detail in the next section.

Vergence ability is needed for singular binocular vision; thus it is basic to all activities. At near positions the patient may have difficulty finding objects; eye-hand coordination may be decreased, affecting self-care and hygiene tasks; and

reading may be difficult. Distance tasks that may be affected include driving, sports, movies, communication, and, frequently, ambulation. Individuals with impaired vergence ability may also have difficulty focusing and may have decreased or no depth perception. Interpreting space can be quite difficult and confusing. If decreased vergence is a result of traumatic head injury or stroke, it may contribute to the patient's confusion, and he or she may not be able to identify or communicate the problem.

Exercise 28-6: Vergence

Hold a pencil in front of you at eye level at about 12 inches (30 cm). Look at the pencil. Look away into the distance. Looking at the pencil is convergence, and looking into the distance is divergence. As you converge and diverge slowly back and forth, note any changes you may feel: changes in how relaxed you feel, how focused or spaced out you feel, feelings of dreaminess, or nothing at all. Observe a partner's eyes as he or she shifts back and forth as well.

Pursuits and Saccades

Eye movement skills consist of pursuits and saccades. Pursuits are the smooth, coordinated movements of all eye muscles together, allowing accurate tracking of objects through space. Perception is continuous during pursuit movements. Saccades are rapid shifts of the eyes from object to object, allowing quick localization of movements observed in the periphery. The systems involved in eye movement skills are the oculomotor system with the VOR, in conjunction with coordination of the central and peripheral visual systems. The peripheral visual system is finely tuned for detecting changes in light levels and small movements.

Problems in pursuits or saccades can be the result of a dysfunction of any individual muscles, the VOR, or areas of the brain controlling pursuits or saccades.¹³⁻¹⁵ Because the VOR helps to stabilize the image on the retina and to differentiate image movement from eye movement, simple tracking can be more difficult. In addition, visual field loss, either central or peripheral, can dramatically affect localization ability. People with blind half- or quarter-fields can be observed to do searching eye movements rather than directly jumping to the object.

Activities affected include searching for objects; visually directed movement for fine motor tasks, gross movement, and ambulation tasks; eye-hand coordination; self-care; driving; and reading.

Memory also may be affected by an eye movement dysfunction. Research by Adler-Grinberg and Stark¹⁶ and Noton and Stark¹⁷ examined patterns of eye movements as subjects looked at a picture. Distinct eye movement patterns, called scan paths, became apparent. When the subject was asked to recall the picture, the same eye movement pattern was elicited as when the subject originally saw the picture. It would appear that a type of oculomotor praxis is involved in recall. Applying this idea to the clinical setting, if a patient has inaccurate eye movement with poor pursuits or excessive saccades, then perhaps the stored memory is less efficiently stored and consequently more difficult to reconstruct from memory. Additionally, if a patient has a type of brain damage with generalized dyspraxia, the eye movement system could quite likely be affected and might be involved in the patient's perceptual dysfunction.

Another more recent example of the relationship between eye movements and memory is the use of eye movement desensitization and reprocessing (EMDR) therapy to help individuals with posttraumatic stress disorder reintegrate traumatic experiences.¹⁸ Although the exact mechanism is at this time unknown, the prevailing hypothesis is that the lateral eye movements elicit an orienting response, scanning the environment for further danger, and that this is an investigatory reflex associated with a relaxed physical state.¹⁹

SYMPTOMS OF VISUAL DYSFUNCTION

History

The identification of a visual problem begins with case history. It is important to get some idea of the client's prior visual status or any history of eye injury, surgery, or diseases. Information can be elicited by direct questioning of the client or family members or by clinical observation. Sample questions include the following:

- Are you having difficulty with seeing, or with your eyes?
- Do you wear glasses? Contact lenses? For distance, near, bifocals, or monovision (one eye near, other distance)?
- Does your correction (glasses, contact lenses) work as well now as before the (stroke, accident, and so on)?
- Have you noticed any blurriness? Near or far?
- Do you ever see double? See two? See overlapping or shadow images?
- Do you ever find that when you reach for an object that you knock it over or your hand misses?
- Do letters jump around on the page after reading for a while?
- Are you experiencing any eye strain or headaches? Where and when?
- Do you ever lose your place when reading?
- Are portions of a page or any objects missing?
- Do people or things suddenly appear from one side that you did not see approaching?
- Do you have difficulty concentrating on tasks?

Clinical observations of the client performing various activities are a valuable source of problem identification. Therapists in general are in an ideal position to observe clients in a variety of functional tasks that require near vision, far vision, spatial estimations, depth judgments, and oculomotor tasks. This situation varies considerably from the physician's observations in the more contrived environment of the examination room. In addition, the therapist's initial observations can be used in documenting difficulties within the therapy realm that may be amenable to visual remediation in terms that can be applied to reimbursement of therapy.

Clinical observations include the following:

- Head turn or tilt during near tasks, or postural adjustments to task
- Avoidance of near tasks
- One eye appears to go in, out, up, or down
- Vision shifts from eye to eye
- Seems to look past observer
- Closes or covers one eye
- Squints
- Eyes appear red, puffy, or irritated or have a discharge (Notify nurses or physician of these observations.)

- Rubs eyes a lot
- Has difficulty maintaining eye contact
- Spaces out, drifts off, daydreams
- During activity, neglects one side of body or space
- During movement, bumps into walls or objects (either walking or in a wheelchair)
- Appears to misjudge distance
- Underreaches or overreaches for objects
- Has difficulty finding things

Near Point Blur

Blurred vision up close is not a symptom that by itself is indicative of a problem in any one area. It could indicate farsightedness (hyperopia), astigmatism, or reduced accommodative ability (insufficiency). The client may move objects or the head farther or closer, may complain of eye strain or headaches, may squint, or may even avoid near activities as much as possible. The therapist might observe excessive blinking, and the patient may complain of glasses not working well.

Distance Blur

Distance blur could also have a number of different causes, including nearsightedness (myopia), a pathological problem (such as beginning cataracts or macular degeneration), or accommodative spasm. Most people have some experience with accommodative spasm. After spending long periods of time either studying or reading a novel and then glancing up at the wall across the room, it may be blurry and then clear up slowly. For some individuals, this spasm eventually develops into nearsightedness if the reading habits continue for a long time.

Clients with distance blur may make forward head movements and frequently squint in an attempt to see. They may not respond or orient quickly to auditory or visual stimuli beyond a certain radius. The therapist may also note excessive blinking and a withdrawn attitude because the patient cannot see well enough to interact with the environment.

Visual hygiene can be recommended to assist in the development of good visual habits. This should include attention to good lighting and posture, taking frequent breaks, and monitoring the state of clarity of an environmental cue such as a clock across the room.

Phoria and Strabismus

The next area of eye alignment problems can be divided into two types of problems: phoria and strabismus. A *phoria* can be defined as a natural positioning of the eyes in which there is a tendency to aim in front of or behind the point of focus. It may or may not be associated with symptoms. Fusion is intact, and depth perception may also be intact to some degree.

Everyone has a phoria, just as everyone has a posture. It may be within normal range, or, just as someone may have scoliosis, a high phoria may cause problems. The following phorias may cause problems:

- Esophoria: The eyes are postured in front of the point of focus.
- Exophoria: The eyes are postured in back of the point of focus.

Phoria is measured in units of prism diopters, which indicate the size of the prism needed to measure the eye position in or out from the straight-ahead position.⁴

Phorias tend to produce subtle symptoms. These include having difficulty concentrating, frontal or temporal headaches, sleepiness after reading, and stinging of the eyes after reading.

A strabismus, or tropia, is a visible turn of one eye, which may be constant, intermittent, or alternating between one eye and the other. The person may have double vision, or if the strabismus is long term, the person may suppress or “turn off” the vision in the wandering eye. Suppression is a neurological function that is an adaptation to the confusing situation of double images. In the developing brain the individual must choose (unconsciously) which eye is dominant, and the image is confirmed by motor and tactile inputs as being the “real” image. The other fovea’s image is then neurologically suppressed. The peripheral vision in the suppressing eye is still normal, and the eye still contributes to other aspects of vision such as orientation and locomotion.

The essential concept in understanding the difference between phoria and strabismus is that in strabismus fusion and depth perception are not present. Definitions of different types of strabismus are presented in Box 28-2. It is not a conclusive list; many other types and permutations are beyond the scope of this discussion. The intent here is to expose the therapist to different terms that may be used by the physician in diagnosing the type of strabismus.

In strabismus, one eye appears to go in, out, up, or down, and there is frequently an obvious inability to judge distances, especially if the strabismus is of recent onset (acquired). The client may underreach or overreach for objects, cover or close one eye, complain of double vision, or exhibit a head tilt or turn during specific activities. He or she may appear to favor one eye, have difficulty reading, appear

spaced out, or avoid near activities. In addition, especially if the patient sees double but is unable or unwilling to talk about it, she or he may be confused or disoriented.

Certain postures may facilitate fusion for some clients. The eye doctor will be able to determine which head position may be best. Frequently, many clients will automatically move around to the best position. At other times, however, head position will be used to avoid using one eye. Head and body position, therefore, are important aspects to consider.

Many convergence problems are amenable to vision therapy,²⁰⁻²² but some are not.²³ Whether a particular problem can be helped by vision therapy can be determined by an eye doctor, who can prescribe specific exercises.

Oculomotor Dysfunction

Oculomotor dysfunction is a very common sequela of neurological deficits, with an incidence as high as 90% according to Ciufredda and colleagues.^{24,25} Commonly the smooth pursuit system will be affected, such that the smooth movement is interrupted by a series of fixation stops and the movements appear jerky. Damage anywhere along the visual motor pathway may cause a variety of eye movement disorders. This includes injury to the pontine and mesencephalic reticular formation, oculomotor nucleus in the brain stem, caudate nucleus and substantia nigra, cerebellum, and vestibular nuclei.²⁴

Patients with oculomotor disorders frequently also experience dizziness, nausea, and balance difficulties. Many times an eye movement will elicit dizziness and disorientation. It is thought that these symptoms are in part caused by a loss of integration of information coming from the two aspects of the visual system that process central vision (parvocellular pathway) and peripheral vision (magnocellular pathway).

As mentioned previously, detection of peripheral targets serves to direct an eye movement with a specific velocity and direction to bring the foveas in line for purposes of identification. Therapy for rehabilitation of eye movement disorders should be directed at using peripheral awareness with slow controlled eye movement toward the target. Once these movements are tolerated, head movement can be added, then slowly body movement.^{26,27}

While doing any sort of tracking activity, the client is encouraged to maintain peripheral awareness. This technique will help the client keep her or his place. The oculomotor system is guided by the peripheral location of an object.

Visual Field Defects—Hemianopsia and Quadrantanopsia

Visual field loss may indicate damage that is prechiasmatic, at the optic chiasm, postchiasmatic, in the visual radiations of the thalamus, or in the visual cortex. The resultant visual field loss is characteristic (even diagnostic) in each case. The visual field loss pattern will generally reflect the location of the lesion. It could be bitemporal (outer half of each field), half-field loss (hemianopsia) with or without macular involvement, or quarter-field loss (see Figure 28-7). Some symptoms of field loss are an inability to read or starting to read in the middle of the page, ignoring food on one half of the plate, and difficulty orienting to stimuli in a specific area of space.

BOX 28-2 ■ TYPES OF STRABISMUS

Esotropia: One eye turns in.

Exotropia: One eye turns out.

Hypertropia: One eye turns up relative to the other eye.

Intermittent: The person is strabismic at times and phoric (fusing) at times. Fatigue or stress may bring out the strabismic state.

Alternating: The person switches from using the right eye to using the left eye. The person also switches the suppressing eye. If using the right eye, the person suppresses the left, and while using the left eye, the person suppresses the right; otherwise the person would see double.

Constant strabismus: One eye is always in or out (up or down), always the same eye.

Comitant and noncomitant strabismus: The amount of eye turn is the same regardless of whether the person is looking up, down, right, left, or straight ahead. People who have had the condition for a long time usually have comitant strabismus. People with new or acquired strabismus (i.e., from stroke or head injury) usually have noncomitant strabismus, in which the amount of eye turn changes depending on the direction in which the eyes are looking.

Hemianopsia is a loss of half of the visual field in each eye, and quadrantanopsia is loss of a quarter of the visual field in each eye. *Homonymous hemianopsia* refers to the inner or nasal half and the outer or temporal half of each eye being affected. The retina itself is intact, but a neurological lesion has interrupted the ability of the visual cortex to receive recognition of the image. Vision processing may be occurring at lower centers, such as the lateral geniculate body, but if signals are not being received by the cortex, then they are not recognized as “seen.” In 1979, Zihl and von Cramon²⁸ published their findings that damaged visual fields could be trained by use of a light stimulus presented repeatedly at the border of the visual field defect. Balliet and co-workers²⁹ (when attempting to repeat the experiment, adding controls for oculomotor fixations) proposed that subjects were actually learning to make small compensatory eye movements rather than experiencing true improvements in the visual fields. In the 1980s and 1990s a group of German researchers developed a computer-based field training system for researching the question of visual field training. They found in their research that visual fields did expand on average by 5 degrees, with functional improvements noted by more than 80% of their patients (Figure 28-9).³⁰⁻³⁴ A company called NovaVision introduced the computer-based visual field restitution training program in the United States with good results (see Appendix 28-A). This author has also noted documentable and functional improvements in visual fields even when trained with less sophisticated methods.

Compensation training may also be required to allow the client to resume activities such as reading. Compensation techniques include use of margin markers and reading with a card with a slit in it (typoscope) to isolate one line or a couple of lines at a time. Holding reading material vertically also can help.

Figure 28-9 ■ Visual field defect (inferior temporal) as measured on Humphrey visual field tester.

SUMMARY OF DISORDERS OF VISION

Table 28-1 summarizes primary visual deficits. Once a therapist or other specialist has eliminated the possibility of primary visual deficits, the clinician must assess whether the identified problem is resulting from central associative processing that is causing visual-perceptual dysfunction.

EYE DISEASES

Areas addressed in this section are common ocular and systemic diseases of the pediatric and geriatric populations, an introduction to low vision, and recommendations for adaptations of the treatment plan. If reduced vision (low vision) is a result of eye disease, the client may be assisted by magnification aids. Also, the therapy treatment program may need to be altered to accommodate any special visual needs of the client (lighting, working distance, inclusion of magnifiers, use of filters, contrast-enhancing devices).

Pediatric Conditions

Retinopathy of Prematurity

The incidence of retinopathy of prematurity is increasing because of the improved survival of premature infants as a result of improved ventilation.³⁵ Immature retinal vessels are sensitive to high oxygen tension. The effect on the vessels is vasoconstriction, eventually leading to obliteration of the vessels. This creates a state of ischemia, which stimulates the growth of new blood vessels. These small, fragile vessels bleed easily, leading to fibrosis and traction on the retina. As a result of the traction, the macula gets stretched, interfering with the function of central vision.

The temporal vessels are most affected because they develop last. The degree of damage may be mild or severe, depending on the amount of prematurity.⁷

Retinoblastoma

Retinoblastoma is the most common malignant tumor in children.¹ The current incidence is 1 in 20,000 live births, a rate that has been increasing over the past 30 years, apparently owing to inheritance of a mutated gene.

The young child may have a strabismus resulting from impaired vision in the eye with the tumor. As the tumor grows, the pupil may appear milky white. If not detected early, the tumor will lead to loss of the eye; and if the tumor invades the brain, death will occur. Clearly, early detection is critical.

Mental Retardation

There are a higher number of visual problems in the mentally retarded populations.¹ These individuals have a higher incidence of refractive error (myopia, hyperopia, astigmatism), strabismus, nystagmus, and optic atrophy than do children with normal intelligence.

Cerebral Palsy

Therapists who work with children with cerebral palsy may have noticed a high incidence of vision problems. Many studies confirm these observations. A study by Scheinman³⁶ examining the incidence of visual problems in children with cerebral palsy and normal intelligence found the following incidences: strabismus in 69%, high

TABLE 28-1 ■ PRIMARY VISUAL DEFICITS ASSOCIATED WITH CENTRAL LESIONS, FUNCTIONAL SYMPTOMS, MANAGEMENT, AND TREATMENT

VISUAL DEFICIT	FUNCTIONAL DEFICIT	MANAGEMENT	TREATMENT
Decreased visual acuity (distance or near)	Decreased acuity for distance or near tasks (reading)	Provide best lens correction for distance and near vision	May not be correctable May be appropriate for low vision
Inconsistent accommodation	Inconsistent blurred near vision	Ensure appropriate lenses are worn for appropriate activities Determine whether bifocal is usable; if not, provide separate lenses for distance and near vision Enlarge target, control density, use contrast and task lighting	Accommodation training may be appropriate
Cortical blindness	Marked decrease in visual acuity Severe blurring uncorrectable by lenses	Evaluated by vision specialist to determine areas and quality of residual vision Present targets of appropriate size and contrast in best area of visual field	Use headlamp to improve visual localization (i.e., functional use of residual vision) Multisensory input
Visual field deficits include homonymous hemianopsia, quadrantanopsia, scotoma, visual field constrictions	Blindness or decreased sensitivity in affected area of visual field	Be aware of normal field position in all meridians of gaze Ask patient to outline working area before beginning task Partial press-on Fresnel prism to facilitate compensation	Scanning training to facilitate compensation Training in use of prism NovaVision VF training
Pupillary reactions	Slow or absent pupillary responses	Sunglasses to control excessive brightness	
Loss of vertical gaze (external ophthalmoplegia)	Inability to move eyes up or down	Raise target or working area to foveal level Teach patient head movement to compensate	Prism glasses to allow objects below to be seen as directly in front
Conjugate gaze deviation	Inability to move or difficulty in moving eyes from fixed gaze position		
Lack of convergence	Diplopia or blurred vision for near tasks Decreased depth perception for near tasks	Convergence exercises prescribed by vision specialist	
Oculomotor nerve lesion (strabismus)	Intermittent or consistent diplopia in some or all meridians of gaze Loss of depth perception	Fresnel prism to fuse image in select cases Occlude deviant eye	Oculomotor and binocular exercises with prism use prescribed by vision specialist
Pathological (motor) nystagmus	Movement or blur of image during reading, near activities, decreased activities	Enlarge print or target to decrease blur Contact lens provides feedback, reduces movement, and increases acuity	Rigid gas-permeable contact lens prescribed by vision specialist
Poor fixations, saccades, or pursuits	Erratic scanning Unsteady fixation	Decrease density of material Isolate targets during evaluation and treatment Sensory integration activities Scanning training Use of kinesthetic and tactile systems to lead visual system (eye movements)	Oculomotor exercises prescribed by vision specialist

phorias in 4%, accommodative dysfunction in 30%, and refractive errors in 63%.

Hydrocephalus

Various studies have found that the most common visual problem in children with hydrocephalus is strabismus, with an incidence of 30% to 55%. The strabismus may develop either from the hydrocephalus itself or from the shunting procedure.

Fetal Alcohol Syndrome

Children affected by fetal alcohol syndrome have several characteristic features and visual problems. They have a higher incidence of strabismus, myopia, astigmatism, and ptosis. These children frequently have some degree of mental retardation as well and are of small stature.

Age-Related Conditions

Cataracts. The most common malady affecting vision in elderly persons is cataracts. General clarity of vision is impaired from a loss of transparency of the crystalline lens of the eye.

In the senile cataract the lens slowly loses its ability to prevent oxidation from occurring, and liquefaction of the outer layers begins. The normally soluble proteins adhere together, causing light scatter.³ Vision slowly declines as opacification and light scatter increase, until the lens must be removed.

Age-Related Macular Degeneration. Age-related macular degeneration (AMD) is the leading cause of blindness in the Western world and is the most important retinal disease of the aged (affecting 28% of the 75- to 85-year-old age group).⁷

Loss of central vision results from fluid that leaks up from the deeper layers of the retina, pushing the retina up and detaching it from the nourishing layer. New vessel growth and hemorrhage and atrophy further destroy central vision. There is much research going on regarding treatments for AMD. The most promising at this time is the use of bevacizumab (Avastin) or ranibizumab (Lucentis), which is injected into the eye; then the eye is treated with a laser. The drug targets the neovascular network of blood vessels, and the laser treatment obliterates the vessel network, sparing the photoreceptors.³⁷

This condition has significant implications for independent functioning. Mobility tends to be less impaired because the peripheral visual system is still intact. All activities involving fine detail such as reading, computer use, sewing, and cooking are affected. Safety also can be affected.

Arteriosclerosis. In arteriosclerosis, vision may or may not be affected. There is a hardening of the retinal arteries, which may eventually lead to ischemia, with the areas of retina deprived of sufficient oxygen eventually dying.

Hypertension. Hypertension is usually accompanied by arteriosclerosis. There may be retinal bleeding and edema, which can affect central vision if the macula is involved.

Diabetes. Diabetes can affect the lens. In the diabetic “sugar cataract,” sorbitol collects within the lens, causing an osmotic gradient of fluid into the lens, which leads to disruption of the lens matrix and loss of transparency. As the fluid increases and decreases within the lens, the patient’s vision

also can fluctuate, depending directly on the sugar level. This makes prescribing glasses during this time quite difficult. The cataract will need to be removed if vision is worse than 20/40.

The retinal effects include microvascular damage and the development of microaneurysms. Central vision may be reduced as a result of retinal ischemia. The ischemia leads to new blood vessel growth (neovascularization). These new vessels are weak, frequently leaking and causing hemorrhage. The hemorrhage leads to fibrosis, which puts traction on the retina, pulling it off and leading to retinal detachment and blindness. Laser treatment of the bleeding retinal vessels will stop the bleeding but also burns photoreceptors, creating blind spots. This result is far preferable to total retinal detachment and blindness.

Glaucoma. Glaucoma occurs in 7.2% of the 75- to 85-year-old age group.⁷ It is generally caused by an increase in the intraocular pressure. This pressure interferes with the inflow and outflow of blood and nutrients at the optic disc. As it progresses, glaucoma can cause tunnel vision and, in some, complete blindness. Because of the type of vision loss affecting the periphery, mobility and safety are significantly impaired. Try walking around holding a paper towel tube to your eye while closing the other eye, and see what happens to your ability to maneuver around obstacles or find your destination.

A less common type of glaucoma is low-tension glaucoma, in which the internal eye pressures are essentially normal. The mechanism is not understood, and the disease is treated with eye drops to lower internal pressure, just like the other types of glaucoma.

In one type of glaucoma, called *open-angle glaucoma*, the outflow of aqueous humor is reduced, leading to increased intraocular pressure. There are no overt symptoms. In another type, closed-angle glaucoma, the outflow is blocked by the iris. Symptoms are a painful, red eye, which may be confused with conjunctivitis.

Corticosteroids used to treat many conditions in the elderly for long periods of time may have side effects in some people, such as glaucoma and cataracts.

Eye Muscle Dysfunctions. Eye muscle dysfunctions causing double vision may result from several disease conditions including thyroid disease (Graves disease and others), multiple sclerosis, myasthenia gravis, and tumors. The underlying condition must be diagnosed and treated.

Visual Field Loss. Visual field loss may be either central (macular degeneration, glaucoma, or retinal disease) or peripheral field loss from glaucoma, retinal damage, or stroke at any point in the visual pathway. This is potentially the most functionally disabling form of visual impairment (see Figure 28-7).

Implications for Functional Performance

Lighting

Lighting conditions are important and vary depending on the nature of the condition. The person with presbyopia requires more light because the aging pupil gets smaller. The smaller pupil has the advantage of increasing the depth of focus, allowing the presbyope to see clearly over a wider range, but it has the disadvantage of eliminating more light from the eye. Thus, providing a good source of

direct lighting, especially on fine print, is helpful. Lighting for the low-vision client is critical. Direct sources of low-glare light such as halogen seem to work best. This is, however, quite individual, in that some clients actually see better in lower-light conditions.

Glare

People who have problems with glare, such as those developing cataracts or other disease conditions, can be helped by several approaches. Incandescent or halogen lighting is preferred over fluorescent lighting. The use of a visor or wide-brimmed hat will reduce one source of glare, improving overall comfort. For some individuals who have trouble reading because of the glare coming off the white page, a black matte piece of cardboard with a horizontal slit in it (called a *typoscope*) can be used to reduce the surrounding glare and enhance reading. Various colored filters can be quite helpful; frequently a light amber color reduces glare while enhancing contrast. Other colors such as light green, plum, or yellow can be tried. The improvement noted is quite individual to the client. Special photochromic, tinted antiglare lenses developed by Corning are available by prescription through the ophthalmologist or optometrist. An antireflective coating may also help.

Low-Vision Aids

Many types of low-vision optical and nonoptical aids are available, usually by prescription by a low-vision specialist. Clients with damage to their central vision as in AMD or diabetic maculopathy and who still have some reduced central vision may be able to use various types of magnification aids.

Hand and Stand Magnifiers. One type is a stand magnifier, which is placed directly on the reading material and is useful for patients who have a tremor. Hand magnifiers are held in the hand and moved away from the page to the focal point of the lens, which may range from half an inch to 5 inches, depending on the amount of magnification. Some are equipped with their own internal illumination, some with halogen lighting systems.

Telescopes. Telescopes can be used for a number of different functions. To increase independence in orientation and mobility, a “spotting” telescope is held in the hand and looked through to identify approaching bus numbers, public transportation signs, stop or walk signs, or aisle signs. There are also telescopes that are worn on the head for hands-free usage or for viewing the computer screen. A telescope system can be attached to the patient’s glasses frames. Special driving telescopes called *bioptic telescopes* are ground into the patient’s glasses, angled in such a way as to allow viewing straight ahead and, with a tip of the head, viewing through the scope to read a sign. The best corrected visual acuity needs to be at least 20/100, but regulations vary from state to state. The greatest disadvantages of scopes are the small visual field and the additional training required to learn how to effectively use them.

The implantable telescope is an exciting new option available for patients with end-stage AMD. After careful evaluation the patient may be considered to be a good candidate for implantation. The tiny telescope is surgically implanted near the lens inside the eye. It has the benefits of having magnification immediately available for use for distance targets and

reading; however, the peripheral vision in the implanted eye is significantly reduced. Similar to someone adjusting to monovision contact lenses, the patient with the implanted telescope learns to look through either the telescopic eye or the other eye (Figure 28-10).³⁸⁻⁴⁰

Microscopes. Microscopes are high-powered reading glasses in which the magnification is created in the glasses rather than in the hand. The disadvantage of these is the close viewing distance, depending on the power. The viewing distance could be as close as 1.5 inches, creating discomfort in reading for many.

Electronic Digital Magnifiers. The best systems for severely impaired clients are the electronic digital magnifiers such as closed-circuit television (CCTV). The CCTV system consists of a camera housed in a device that can be directed at the object to be viewed. The scope of magnification is significantly larger, ranging from low power to 50 \times . Additional benefits include no distortion like that caused by optical magnifiers and a field of view limited only by the size of the screen. The housing for the camera may be in a stand, with a screen above, or portable, held in the hand or strapped to the head. Examples are the Merlin, Jordy, and MaxPort by Enhanced Vision Systems and the portable digital magnifiers such as Compact mini by Optelec.⁴¹

Nonoptical Aids. Nonoptical aids include large-print materials, available at many libraries, typoscopes, mentioned earlier, and reading stands. Talking books are available for those for whom reading is an important hobby. New developments include text-to-speech synthesizers, large-print computers, and image intensifiers. Other simple aids are available such as lined paper with dark slightly raised lines, felt-tipped pens for writing, talking clocks, needle threaders, and many cooking and measuring aids.

Visual Field Expansion. For clients with field losses, specially designed prism or mirror systems may be used. These frequently require training to get used to and are not useful for everyone. Compensation training also can be helpful, particularly in the use of eccentric viewing, or learning how to use a portion of the intact field by aiming the eye off center. Use of margin markers or reading slits and holding the book sideways so that the print is vertical are other helpful techniques.

Current Research. Areas of research have included mounting a video camera onto spectacles and then transducing the visual information to electrodes implanted in visual

Figure 28-10 ■ Eye with implanted 3x telescope.

cortical centers. In one study this system allowed a low-vision patient to see the large E (20/400) and detect large contours.⁴²⁻⁴⁴ Recently a company called Second Sight Medical Products developed the Argus II, which includes implantation of a 60-electrode grid on the retina, which is used in conjunction with a video camera mounted on eyeglasses. A wireless microprocessor with battery pack is worn on the waist. Altogether the system enables rudimentary perception of shapes and forms, allowing improved mobility in patients whose vision has been impaired by retinal diseases such as retinitis pigmentosa.⁴⁵

VISUAL SCREENING

Primary visual dysfunction must be differentiated from a visual-perceptual disorder so that appropriate treatment can be addressed for each problem. Gianutsos and colleagues⁴⁶ found that more than half the individuals in their study admitted for general head injury rehabilitation who were eligible for cognitive services had visual sensory impairments sufficient to warrant further evaluation. Visual screening can identify the need for referral for a complete eye examination. The results of the examination become part of the differential diagnosis regarding a perceptual dysfunction. **Box 28-3** presents key elements in vision screening.

This section describes vision screening tools and adaptations for various populations. The following principles should be kept in mind:

- **Acuities:** Acuities should always be tested first because decreased acuities will bias other tests except for ocular motilities and the peripheral field test.
- **Positioning:** The body and head should be in good alignment or straightened with positioning devices, with the head in midline.
- **Glasses:** If the client normally wears glasses, for either distance or near vision, the patient should be wearing glasses for tests for which spectacle correction is required. When in doubt, try it both ways, record the best response, and note whether glasses were worn.

Observations during Testing

The client's response during the test can provide important qualitative information about his or her visual system, including postural changes (head forward or back, body forward or back, head tilts or rotation [turning to either side]), squinting, closing one eye, excessive blinking, rubbing, signs of strain or fatigue, and holding the breath. Clients should be encouraged to relax, breathe normally, and not squint.

BOX 28-3 ■ KEY ELEMENTS IN VISION SCREENING

1. Distance and near visual acuities
2. Oculomotilities (pursuits, saccades, near point of convergence)
3. Measure of eye alignment to detect strabismus or high phoria
4. Measure of depth perception (stereopsis)
5. Measure of the visual fields

Distance Acuities

Equipment

Needed to measure distance acuity are a distance acuity chart, an occluder, a 20-foot measure, and the patient's corrective lenses if worn for distance.

Setup

A distance chart is taped on a well-lighted wall at the patient's eye level, and a distance of 20 feet is measured from the chart.

Procedure

One of the patient's eyes is covered and the patient is asked to read the smallest letters that he or she can see. Exposing one letter or line at a time can help if tracking or attention is a problem. The examiner should encourage the patient to guess and instruct the patient not to squint. The number of letters that were missed on the smallest line that the patient is able to see is noted. The procedure is repeated by covering the patient's other eye, and then both eyes are tested unoccluded.

Record

The smallest line the patient was able to read is recorded. If the client missed any letters on that line then the number of letters missed is subtracted. For example, if the client read four letters correctly on the 20/30 line but missed the other two, then it is recorded as 20/30-2. The scores for the client's right eye, left eye, and both eyes together are recorded.

If the patient is unable to see the top line at 20 feet, the patient is asked to move forward until able to identify the top letters. Then the distance and letter size (top line) are recorded. For example, if the patient had to move up to 4 feet to see the top line, then 4/100 is recorded. To calculate 20-foot equivalence, an equation is used where x equals the size of the letter (e.g., $4/100 = 20/x$); thus, $4x = 2000$ and $2000/4 = 500$. The client's vision is 20/500 (**Box 28-4**).

For clients whose attention is poor, the testing distance may need to be as close as 2 feet. Other testing stimuli can be used for children, such as the Broken Wheel Test* or the Lighthouse cards.* Acuity in low-functioning clients or infants can be evaluated by use of preferential looking methods. Targets are usually high-contrast grating patterns of decreasing size. One such type is the Teller cards.†

Implications

A patient who fails this test may require glasses or a change in the current prescription.

Near Acuities

Equipment

A near-point test card, an occluder, and the client's corrective lenses if normally worn for near vision are needed.

Procedure

The procedure is the same as for distance acuity. The standard test distance is usually 16 inches (40 cm).

BOX 28-4 ■ INTERPRETATION OR REFERRAL

20/20 is considered normal.

20/40 is required by the Department of Motor Vehicles (DMV) in most states for full-time day and night driver's license, although requirements vary in different states.

20/80 is required by the DMV for daytime driver's license.

20/40 or worse indicates referral to an eye doctor.

20/200 corrected (with spectacle prescription) is considered legally blind.

A difference of two lines or more between the two eyes indicates referral to an eye doctor (e.g., right eye is 20/20, left eye is 20/30).

Record

The smallest line read is recorded.

Interpretation and Referral

A test result of 20/20 is considered normal, 20/40 is required for reading newspaper-sized print, and 20/100 is needed for large print. Referral to an optometrist or ophthalmologist should be made if vision is 20/40 or worse or if a difference of two lines exists between the two eyes. Neurological damage can affect the accommodative system. Sometimes it corrects itself spontaneously, but not always.

Visual retraining of the focusing system may be appropriate, depending on the patient's age. This can be determined by an optometrist familiar with vision therapy.

Pursuits**Equipment**

Any target that holds the patient's attention can be used, such as a pencil or small toy.

Setup

The patient is seated facing the screener.

Procedure

One pencil is held 16 to 20 inches in front of the client, and the client is asked to look directly at one part, such as the eraser, and to keep the head still, holding it if necessary. The pencil is moved around in the pattern shown in Figure 28-11, which is designed to incorporate all directions of gaze. The examiner should observe for smooth following, noticing and recording jerks and jumps, where they occur, or if the eyes stop at a certain point. If one or both eyes stop tracking, the client is encouraged to look at the pencil. If the patient is unable to do this, then the movement pattern is repeated with each eye separately and where the movement stops is recorded. Clients who have had a cerebrovascular accident (CVA) or head injury should be tested first monocularly (each eye separately).

Record

Results are rated as follows:

- Poor = Difficulty following target with any accuracy, jerky or jumpy, nystagmoid movements, incomplete range of motion

Then move from e→f, b→f, f→b, c→e to observe diagonal and midline pursuit patterns.

Figure 28-11 ■ Pursuit patterns.

- Fair = Generally able to follow target but goes off target occasionally (one to two times), with slight jerkiness
- Good = Eye movements smooth with no jerkiness

If one eye stops tracking at a certain point or if the client reports double vision (diplopia) in certain directions, the examiner should record which eye or in which direction the problem is noticed (e.g., the right eye does not pass midline when moving from left to right, or diplopia is reported on upward right gaze). This specific information can be helpful to the ophthalmologist or optometrist.

Saccades**Equipment**

Tracking pencils can be used, although a few saccadic tests are available. One is the King Devick Saccadic Test; the other is the Developmental Eye Movement Test.* These both require form perception (number reading) and may be difficult, depending on the client's cognitive level.

Setup

The patient is seated facing the screener.

Procedure

A pencil is held in each hand about 17 to 20 inches from the client, and the client is told that he or she is going to be asked to look at one pencil while the other pencil is moved but not to look at it until told to do so. The client is to move the eyes only, keeping the head still. While the client looks at the first pencil, the other pencil is moved as the screener says "shift" or "look at this pencil." The screener then moves the other pencil, says "shift," then moves the pencil, says "shift," then moves the pencil, and so on, until a pattern of movement can be discerned.

*Bernell/USO, 4016 North Home Street, Mishawaka, IN 46545; (800) 348-2225. Complete Visual Screening Kit: Laurie R. Chaikin, OD, OTR/L, 420 F Cola Ballena, Alameda, CA 94501; Laurie.chaikin@gmail.com.

This call-shift is repeated about 10 times, moving into different fields of gaze. The screener continues until the client is seen to respond. The screener observes for overshooting or undershooting the target, for the ability to isolate the eyes from the head (hold head still), for controlled eye movement, and for ability to wait until the verbal command to look. It is important to observe for the client's ability to shift to all fields of gaze. A lower level of testing would be to ask the client to move the eyes from one target to the other as quickly as possible (Figure 28-12).

Record

Results are rated as follows:

- Poor = Inability to control eyes with verbal command, consistent undershooting or overshooting, inability to isolate eyes from head
- Fair = Ability to maintain eyes on target with verbal command 50% of the time, with slight undershooting or overshooting, and ability to isolate eyes from head with verbal reminders
- Good = Ability to follow verbal commands 90% of the time, with no undershooting or overshooting, and complete eye from head isolation

Near Point of Convergence

Procedure

A pencil is introduced about 20 inches away from the client's midline. The client is asked whether the pencil looks single. If it is not, it is moved farther away. The client is told that the pencil will be moved toward her or him and that it will be getting blurry but to keep watching it as far in as possible. When the pencil appears single, it is moved toward the nose at a moderately slow rate (but not too slow). The screener should watch the client's eyes. As long as the client's eyes are tracking the pencil, the pencil is kept moving toward the nose. At the point where one eye moves out, both eyes move out, or the eyes simply stop tracking, the distance of the pencil to the nose is measured. If the client is wearing bifocals, it is important to make sure the patient is looking through the reading segment.

Figure 28-12 ■ Developmental eye movement test.

Record

The break point is the distance at which the eyes were observed to stop tracking the pencil. If the client was able to track the pencil all the way to the nose, then record this fact.

Interpretation and Referral

A score of poor or fair on saccades or pursuits suggests the need for training. A near point of convergence with a break point of 5 inches or more is suggestive of convergence problems, and recommendations for referral should be made.

Implications

Difficulties with smooth pursuit, accurate saccades, or convergence can all present tracking difficulties for the patient. These difficulties can cause loss of place in reading, rereading of words or lines, skipping lines, and lower comprehension and concentration. Inaccurate eye movements also may affect visual memory.

An eye movement problem may be the result of direct damage to the eye muscles themselves (Figure 28-13) or to the nerves controlling them, as in the case of a head injury. Damage to the vestibular center also may involve visual components. Neurons from cranial nerves III, IV, and VI synapse in the vestibular nuclei. Reflex control of eye movements occurs through the VOR and the optokinetic system.

Cover Tests

Purpose

There are two cover tests. The cover-uncover test is used to determine whether strabismus is present. The alternate cover test determines what type of phoria is present. The magnitude of the phoria generally determines the extent of the client's symptoms.

Equipment

An occluder and a tracking pencil or a small, distinct target is needed.

Setup

The client is seated facing the screener, who is also seated.

Figure 28-13 ■ Cranial nerves III, IV, and VI. Oculomotor, trochlear, and abducens nerves and their innervation of the extraocular muscles. (Courtesy Smith, Kline & French Laboratories, Philadelphia, Pennsylvania.)

Procedure

A pencil is held approximately 16 inches in front of the client, and the client is asked to look directly at the target and to keep it in focus.

Near Cover Tests

Cover-Uncover Test. The movement of the uncovered eye is observed. The client's right eye is covered, and the left eye is observed for movement in, out, upward, or downward. This is repeated a few times, allowing the eyes to be uncovered for about 2 seconds between trials. Then the left eye is covered to observe for movement in the right eye.

Alternate Cover Test. Eye movement is observed as the eye is uncovered. An occluder is held over the right eye for a few seconds while the client looks at a near target. The occluder is moved from the right eye to the left eye while the right eye is observed for movement in, out, up, or down. After a few seconds, the occluder is moved back to the right eye, observing the left eye for movement. This is repeated back and forth several times until the screener is sure of what is seen.

Far Cover Tests

The preceding procedure is repeated with the patient looking at a distant target.

Interpretation and Referral. Any visible eye movement seen during the cover-uncover test with good maintenance of fixation on the target indicates a strabismus. If there is no previous history of strabismus, referral is indicated. A large eye movement seen with the alternate cover test, along with the presence of symptoms such as eye strain, headaches, or apparent difficulty in making spatial judgments, also indicates referral. In the clinic the therapist may notice that the client has difficulty finding objects in a drawer, or that the client appears cross-eyed or seems to be looking past the target. He or she may have difficulty with spatial judgments in reaching for objects or in mobility, especially with stairs or curbs.

A visible eye movement may be part of a post-CVA client's premorbid pattern. This should be determined by asking the client or the family members before making a referral. Or the condition may be the result of neurological damage to cranial nerve III, IV, or VI from CVA, head injury, or cerebral palsy. Eye muscles are striated muscles, under voluntary control. Like other striated muscles that can be affected by neurological damage, they may recover spontaneously, they may not recover at all, or they may benefit from visual retraining. Many learning-disabled children with vestibular dysfunction have poor binocular skills. An ophthalmologist or optometrist specially trained in visual remediation can determine a patient's potential for vision therapy. Some published research has demonstrated the success of vision therapy for post-CVA patients.⁴⁷

Stereopsis (Depth Perception)**Equipment**

Any test that uses either Polaroid or red-green filters can test for stereopsis ability. Examples are the Titmus stereo fly, reindeer, and butterfly.*

Procedure

The client is asked to point to or say which test object appears closer. If the client is able to grasp for the object in space, some stereo ability is present.

Record

The client's response should be immediate. Long delays could indicate borderline ability.

Interpretation and Referral

If the client fails this test, a referral to an ophthalmologist or optometrist is recommended. The patient must have best-corrected acuities for this test; otherwise, the results are invalid.

Implications

A deficit in depth perception can interfere with all activities involving spatial judgments, in particular fine motor and eye-hand type activities in which judgments of relative depth are required (e.g., threading a needle, placing toothpaste on a toothbrush, hammering). Although ambulation itself may not be affected, ambulation involving curbs or stairs will be affected.

Vision therapy training can be helpful for clients with problems in binocular coordination. Proper diagnosis and therapy prescription are essential.

Visual Field Screening**Equipment**

An occluder or eyepatch is required, and a black dowel with a white pin on the end or just a wiggling finger can be used as a peripheral target.

Setup

The client is seated facing the examiner.

Procedure

The client holds the occluder over the left eye. The examiner explains that he or she is going to wiggle a finger out to the side and that the patient is to say "now" when he or she first detects the movement of the wiggling finger. The client should look at the screener's nose the entire time and ignore any arm movement. The test is begun with the examiner's hand slightly behind the client about 16 inches away from the client's head. The hand is brought forward slowly while a finger is wiggled. Different sections of the visual field are randomly tested in 45-degree intervals around the visual field. The left eye is then tested after the client's right eye is occluded. Alternatively, if a dowel is used, it is slowly brought in from the side until the client reports seeing the small pin at the end of the dowel.

These confrontation field tests are considered gross tests compared with a visual field perimeter test. Many clients cannot do the perimeter test because it requires a higher cognitive level. Confrontation fields will reveal a hemianopsia and a quadrantanopsia (quarter-field cut). For lower-functioning clients the examiner can observe eye movements in the direction of the target to get a general idea of peripheral function once clients have seen it.

Record

The portion of field missing for each eye is noted.

*Bernell/USO, 4016 North Home Street, Mishawaka, IN 46545; (800) 348-2225. Complete Visual Screening Kit: Laurie R. Chaikin, OD, OTR/L, 420 F Cola Ballena, Alameda, CA 94501; Laurie.chaikin@gmail.com.

Interpretation and Referral

If any hemianopsia or quadrantanopsia is noted, the patient is referred to an optometrist or an ophthalmologist.

Implications

A visual deficit has significant implication for the safe performance of many functional activities, including driving and mobility. Visually guided movement through space becomes impaired, as are efficient eye movements; if central field loss is present, reading and any other near activities are affected. The reader is referred to the discussion of assessment of unilateral inattention for differentiation between neglect and hemianopsia.

REFERRAL CONSIDERATIONS

The final outcome of the visual screening is referral to an optometrist or ophthalmologist, ideally to someone with an orientation toward visual rehabilitation. It is important not to make diagnostic statements but rather to indicate whether the client passed or failed the vision screening. By law, only optometrists or ophthalmologists can diagnose visual conditions.

It is not always clear when to refer a client or to whom. Many doctors do not test all areas of visual function. Generally, behavioral or developmental optometrists have a functionally oriented philosophy quite similar to occupational therapy models of functional performance.*

Recommended referral guidelines are shown in [Box 28-5](#).

Rehabilitation Optometric Evaluation

Once the client has been referred for evaluation, the eye doctor will evaluate any changes in the refractive error and the need for new correction to achieve the best possible vision. The eye alignment will be quantified, and determination will be made regarding whether there is an eye muscle paresis, which cranial nerve is involved, whether strabismus or phoria is present, and whether the eye deviation is better or worse in particular directions of gaze.

Oculomotilities will be evaluated grossly, and more specific tests may be done. One test is the Developmental Eye Movement Test (see [Figure 28-12](#)). Another test is the Visagraph ([Figure 28-14](#)). This instrument records eye movements while the client is reading text. It will measure total reading rate, number of fixations and regressions per 100 words, span of recognition, and reading comprehension. The tool is excellent for in-depth evaluation and monitoring the progress of treatment over time.

Ocular health testing will include glaucoma testing, examination for cataracts, and retinal health evaluation. For visual field testing, either a screening field or a threshold visual field will be done on some type of automated perimeter such as the Humphrey Visual Field Analyzer or the Octopus. Threshold testing is done to determine the extent and depth of a defect, and it can help to determine whether

BOX 28-5 ■ REFERRAL GUIDELINES

1. Failure of either the distance or near acuity test (with glasses on). This could indicate an uncorrected refractive error, a disease process, or a neurological problem.
2. Failure of the oculomotility section only does not indicate referral because treatment of oculomotor dysfunction is currently within the scope of practice for rehabilitation. *Exception:* Failure of the pursuit test as a result of a reduced ocular range of motion in any direction of gaze, which indicates cranial nerve involvement.
3. Failure of the cover-uncover test indicates strabismus and is an indication for referral unless there is a history of an eye turn.
4. A large eye movement seen on the alternate cover test, along with apparent difficulties in stereopsis, such as spatial judgments, or symptoms, such as headaches, eyestrain, or difficulty with comprehension, constitutes an indication for referral.
5. Failure of the stereopsis test alone is an indication for referral if there is no history of an eye turn and if there is movement on either cover test.
6. Patients with quarter-field loss and half-field loss (hemianopsia) should be referred.

there is potential for visual field retraining. In [Figure 28-9](#) the black portions of the visual field are areas of absolute damage. The areas of white with small dots are intact visual fields. At the border of the damage area is a gray zone, which theoretically is amenable to training.³⁰⁻³³

The optometrist or ophthalmologist will deliver a report of the findings with recommendations for the treatment plan.

Visual Intervention

Early intervention is recommended when possible to identify ways in which a vision problem may be interfering with other therapies.⁴⁷⁻⁵⁰ Some treatments may be applied early

Figure 28-14 ■ The Visagraph (boy with goggles) measures eye movement while the subject is reading.

*College of Optometrists for Vision Development has a list of behavioral doctors: 234 North Lindberg Boulevard, Suite 310, St Louis, MO 63141; or Optometric Extension Program, 1921 East Carnegie Avenue, Suite 3L, Santa Ana, CA 92705-5510. Neuro-Optometer Rehabilitation Association, www.nora.cc/index.html.

on, as well. For example, if the client has an eye muscle palsy, range of motion exercises to the involved muscle can prevent the development of a contracture of the unopposed muscle.

In cases in which the client has double vision, a patching regimen can be instituted. One regimen is to alternate patching the eyes daily, allowing some time to experience diplopia, so that the eyes may attempt to make a fusion response. The stimulus to fusion is double vision. If one eye is always patched, spontaneous recovery may be slowed. Another patching regimen is binasal taping, and another is to use partially opaque materials to allow peripheral vision in the occluded eye. The patching regimen should be prescribed by an optometrist or ophthalmologist.

In some cases of double vision, a temporary plastic (Fresnel) prism can be applied to the client's glasses to reduce or eliminate the diplopia. This may significantly enhance the client's functioning in other therapies, particularly when spatial judgments are being made (e.g., in fine motor tasks or ambulation).

Documentation

Vision problems should be documented in functional performance terms—that is, how the vision problem affects activities of daily living. Improvement can then be monitored according to function. This will also help in reimbursement. For example, a client with an eye muscle dysfunction will have difficulty with spatial judgments such as placing toothpaste on a toothbrush, spearing objects, reaching for a cup handle, doing pegboard tasks, and using vision for balance.

THERAPEUTIC CONSIDERATIONS

Once a referral has been made, the client has been seen, and the examination report has been received, what else can be done? How the dysfunction affects therapy can be considered, and some visual training, prescribed by the optometrist, can be initiated.

Accommodative Dysfunction

If the client has an accommodative dysfunction, the treatment may be the prescription of glasses for reading or tabletop tasks or possibly near-far focusing exercises,⁴ depending on the age of the client. “Flipper bars” are special lenses that exercise the focusing system.⁵¹

If the client needs glasses for near but cannot get them for some reason, the therapist can try moving the task farther away and increasing the lighting on the task.

Eye Alignment Dysfunction

If the client has a problem in the eye alignment system, several factors should be considered. If the client is able to fuse some of the time but loses fusion, seeing double when stressed or tired, then the most difficult tasks should be attempted when the client is least fatigued. Otherwise, if the client has constant double vision or the client is seeing double at the time the therapist is working with her or him, patching may be prescribed by the ophthalmologist or optometrist. This will reduce the client's confusion and increase attention to the task. For clients with acquired double vision, however, it is important to provide time without a patch so that the eyes will attempt to regain fusion. Wearing the patch constantly

will discourage any attempts by the brain to overcome the double vision.

Visual Dysfunction and Balance Disorders

It is important to recognize the close interplay between the visual and the balance systems, including vestibular, proprioceptive and tactile receptors, in maintaining balance. Altered visual input can affect perception of space, even with something as simple as getting a new pair of glasses. The nonneurologically impaired individual will eventually adapt and reset the coordination of information. Neurologically impaired patients can have much greater difficulty in resetting the coordination of sensory information from multiple systems, resulting in a feeling of sensory overload or being overwhelmed. Conversely, damage to areas of the brain that process vestibular or somatosensory information can create altered maps of space, also affecting balance as the individual attempts to interact with the environment.

Therapy may be directed at both areas: improving balance by enhancing balance and proprioceptive mechanisms and/or by enhancing visual input through visual rehabilitation techniques. There has been recent research involving the strategic placement of small weights on the torso, which has had immediate and sometimes dramatic effects on balance.^{52,53} Interestingly, these types of inputs to the torso can also affect visual processing (observations by BalanceWear vest developer Cindy Gibson-Horn, RPT, and me). It is hypothesized that the mechanism for this change may be mediated by cerebellar-visual pathways.⁵⁴

VISUAL-PERCEPTUAL DYSFUNCTION

This discussion of visual-perceptual disorders is divided into a number of categories: unilateral spatial inattention; cortical blindness, defective color perception, and visual agnosia; visual-spatial disorders; visual-constructive disorders; and visual analysis and synthesis disorders. Cortical blindness is a disorder of primary visual input; however, because its variations may influence perceptual interpretation, it is discussed here. All other disorders listed involve direct problems with the interpretation of visual stimuli. Although each of these terms represents symptoms recognized by many authors, the reader is reminded that there are no clear boundaries between one deficit and another or one system and another. Apraxia and body image disorders are not discussed under separate categories because they are not considered “visual”-perceptual disorders per se, although their presence may influence and complicate an already dysfunctional visual-perceptual system.

Problems of Unilateral Spatial Inattention

Identification of Clinical Problems

General Category. In its purest form, unilateral spatial inattention is defined as a condition in which an individual with normal sensory and motor systems fails to orient toward, respond to, or report stimuli on the side contralateral to the cerebral lesion. Although this condition is not often seen in its pure form, inattention has been documented in persons who demonstrate no accompanying visual field defect (homonymous hemianopsia) or limb sensory or motor loss.⁵⁵ In most cases, however, unilateral spatial inattention

is not seen alone but is associated with (although not caused by) accompanying sensory and motor defects such as homonymous hemianopsia and decreased tactile, proprioceptive, and stereognostic perception along with paresis or paralysis of the upper limb.⁵⁶

It is easy to become confused by the numerous terms used in the literature, for example, *unilateral spatial agnosia*, *unilateral visual neglect*, *fixed hemianopsia*, *hemi-inattention*, and *hemi-imperception*. All terms describe the same deficit. Unilateral spatial inattention is used in this chapter because (1) in severe cases the syndrome most likely involves tactile and auditory as well as visual unawareness (i.e., a total spatial unawareness) and (2) the syndrome results in an involuntary lack of attention to stimuli contralateral to the lesion, whereas the term *neglect* implies a voluntary choice not to respond.

Unilateral spatial inattention occurs most frequently in individuals with a diagnosis of stroke (CVA), traumatic brain injury, or tumor. Most authors agree that unilateral spatial inattention occurs more often with right hemisphere than with left hemisphere lesions.⁵⁷⁻⁶¹ This frequency supports theories that the right hemisphere is dominant for visual-spatial organization. It is clear, however, that inattention may be present in individuals with left hemisphere lesions, but that the inattention tends to resolve more quickly.⁶² The clinician should remember that, although the chances are statistically lower, the client with right hemiplegia may exhibit inattention to right stimuli.

Unilateral spatial inattention has been associated with lesions in both cortical and subcortical structures. It is most commonly seen in inferior parietal lobe lesions⁶⁰ but has also been observed in lesions in the inferior frontal cortex, the dorsolateral frontal lobe, the superior temporal gyrus, and the cingulate gyrus⁶³ and with basal ganglia, thalamic,⁶⁴ and putaminal hemorrhage.⁶⁵⁻⁶⁷ Finally, lesions in the brain stem reticular formation have induced inattention in cats⁶⁶ and monkeys.⁶⁴

Although a number of theories have been postulated regarding the mechanism underlying unilateral spatial inattention, no mechanism has been validly documented in human subjects. The one fact that is clear from all theoretical postulates is that inattention is a hemispheric deficit. LeDoux and Smylie⁶⁸ demonstrated this point effectively in an interesting case study of a right-sided lesion. During full visual exposure (bilateral hemispheric) of visual-perceptual slides, the affected individual made visual-spatial errors in left space. However, when the same slides were directed only to the right visual field (left hemisphere), performance improved substantially. It is as if the deficient hemisphere fails to receive or orient toward incoming information while the intact receiving hemisphere remains oblivious and goes about its own business. Treatment for inattention is problematic mainly because the mechanisms underlying unilateral spatial inattention are not clearly understood.

Theories on mechanisms underlying unilateral spatial inattention have attempted to explain it as an integrative associative defect as opposed to simply a problem of decreased sensory input. Theories include a unilateral attentional hypothesis, suggesting that inattention results from a disruption in the orienting response—that is, the corticollimbic

hemisphere is underaroused during bilateral input, and therefore stimuli presented to that hemisphere are neglected.^{60,63} Another theory is the oculomotor imbalance hypothesis, which suggests that individuals with inattention have a visual-spatial disorder worsened by oculomotor imbalance. The hypothesis suggests that the lesion disconnects the frontal eye fields in the damaged hemisphere from their sensory afferent nerves, resulting in an oculomotor imbalance deviating the gaze toward the lesion. This imbalance can be compensated for only momentarily by a voluntary effort to gaze toward the opposite hemisphere (i.e., neglected space).⁶⁹

Unilateral Spatial Inattention with Homonymous Hemianopsia. Inattention occurs more commonly with visual field defects and is generally better when the macular projections are not involved. Individuals with pure hemianopsia are aware of their visual loss and spontaneously learn to compensate by moving their eyes (foveae) toward the lost visual field to expand their visual space and thereby gather information right and left of midline. On visual examination other individuals may demonstrate no visual field defect on unilateral stimulation; however, during bilateral stimulation they extinguish the target contralateral to the lesion. Other persons may perceive both targets simultaneously, yet when engaged in activity they may not respond to visual stimuli in one half of the visual space contralateral to the lesion. These individuals are unaware of their inattention. Careful observation of their activity reveals few eye movements into the neglected space. The fovea does not appear to be directed to gather information in this space.

Unilateral Visual, Auditory, and Tactile Inattention. Inattention has been described as a multimodal sensory associative disorder involving not only visual but also tactile and auditory unawareness. Clinicians are well aware of the client with left inattention who continues to direct the head and eyes toward the right throughout an entire conversation although the therapist is standing on the client's left side. When one conceptualizes unilateral spatial inattention as a dynamic decrease or loss of sensory information within one half of the sensory-perceptual sphere (irrespective of hypothetical mechanism), the peculiar behaviors exhibited by these clients are more easily understood.

Unilateral Spatial Inattention and Body Image. Body image is often disturbed in individuals with inattention. The defect in these persons is unusual because it affects only that half of the body that is contralateral to the lesion, for example, the left side of the body in right-sided lesions. There appears to be a lack of spatial orientation and attention for one half of intrapersonal space. Those with severe inattention fail to recognize that their affected extremities are their own and function as though they are absent. They may fail to dress one half of the body or attempt to navigate through a door oblivious to the fact that the affected arm may be caught on the doorknob or door frame. In severe cases, individuals may deny their hemiparesis, or they may deny that the extremity belongs to them. This phenomenon is called *anosognosia*.

Behavioral Manifestations of Unilateral Spatial Inattention. Persons with inattention orient all their activities toward their "attended" space. The head, eyes, and trunk are rotated toward the side of the lesion for much of

the time, including during gait. Careful observation of eye movements (scanning saccades) during activities indicates that all or almost all scanning occurs on only one side of the midline within the attended space; the individual never spontaneously brings the eyes or head past midline into contralateral “unattended” space. Oculomotor examination always shows full extraocular movements and no apraxia for eye movements.

Inattention, like all other perceptual disorders, may occur on a scale from mild to severe. Mild cases of inattention may go unrecognized unless behavior is carefully observed. Scanning is symmetrical except during tasks requiring increasingly complex perceptual and cognitive demands. Leicester and colleagues⁷⁰ believe that inattention occurs mainly when the individual has a general perceptual problem with the material, that is, some other problem with processing the task. This performance difficulty or stress brings on the additional inattention behavior; for example, neglect in matching auditory letter samples is more common in those with aphasia than in those with right hemisphere involvement without aphasia.

Independence in activities of daily living is often impossible because of inattention to both the intrapersonal and the extrapersonal environment. The individual may eat only half the food on the plate, dress only half the body, shave or apply makeup to only half the face, brush teeth in only half the mouth, read only half a page, fill out only half a form, miss kitchen utensils, carpentry tools, or items in the store if they are located in the unattended space, collide with obstacles or miss doorways on the unattended side, and, when walking or driving a wheelchair, veer toward the attended space rather than navigating in a straight line.

Assessment

Because most tests used to measure cognitive, language, perceptual, and motor skills require symmetrical visual, auditory, and tactile awareness, it is most important to rule out inattention early in the evaluation process of any client with a central lesion. The two most common methods used to distinguish inattention from primary sensory deficits are double simultaneous stimulation testing and assessment of optokinetic nystagmus reflexes. Double simultaneous stimuli should be applied in three modalities: auditory, tactile, and visual. Initially, stimuli should be presented to the abnormal side. If primary sensation is impaired (e.g., a visual field loss), this evaluation cannot proceed because double simultaneous stimulation testing is invalid in that modality. If responsiveness is normal, however, bilateral simultaneous stimuli should be applied. Unilateral stimuli should be interspersed with bilateral stimuli to ensure valid responses. Lack of awareness (extinction) of stimuli contralateral to the lesion during bilateral stimulation should be noted. Clients with extinction in only one sensory system often do not demonstrate inattention behaviors; however, those with extinction in more than one modality (e.g., tactile and visual) often demonstrate these behaviors. If critical diagnosis of inattention is necessary, the client may be referred for optokinetic nystagmus testing.

One of the best evaluation tools is a keen sense of observation. The position of the client’s head, eyes, and trunk should be observed at rest and during activity. Persistent deviation toward the lesion may indicate unilateral inattention.

The individual should be asked to track a visual target from space ipsilateral to the lesion into contralateral space and maintain fixation there for 5 seconds. The therapist may ask the client to quickly fixate on visual targets both right and left of midline on command. Problems with searching for targets in contralateral space should be noted. Some erratic oculomotor searching is normal when making saccades into a hemianoptic field because saccades are centrally preprogrammed by peripheral input. Slow searching or failure to search should be considered indicative of inattention.

Asymmetries in performance should be noted during spatial tasks. Specific spatial tasks have been designed for detection of inattention, including the following:

- Cancellation tasks. The client may be given a sheet of paper with horizontal lines of numbers or letters and asked to cross out all the 8s or As.
- Crossing-out tasks. In this standardized test the client is asked to cross out diagonal lines drawn at random on an unlined sheet of paper.
- Line-bisection tasks. The client is asked to bisect a 4- to 8-inch line on a piece of paper placed at the midline.
- Drawing and copying tasks. The client may be asked to draw or copy a house, clock, or flower or to fill in the numbers of a clock drawn by the examiner. For copying tasks, it is important that the copy be placed in the client’s attended space.

Clients with inattention demonstrate one or more of the following behaviors: failing to cancel figures or cross out lines in the unattended space; bisecting the line unequally, placing their mark toward the side of the midline ipsilateral to their lesion; placing their drawing toward the edge of the paper ipsilateral to their lesion rather than in the middle of the page; drawing only the right or left half of the house, flower, or clock; crowding all the numbers of the clock into the right or left half of the clock; or completing numbers on only one half of the clock (Figure 28-15), and demonstrating differences in reaction time.⁷¹ When interpreting performance, the examiner is looking specifically for asymmetries in performance. Clients with inattention often have other visual-perceptual deficits that result in faulty performance on these tasks; however, these deficits are always symmetrical, that is, evident in any space to which the individual attends.

Figure 28-15 ■ Drawings of a clock and house by a client with a right hemisphere parietal lobe tumor. Note the left unilateral spatial inattention in the drawings.

Asymmetries in performance should be carefully observed during functional activities such as eating, filling out a form, reading, dressing, and maneuvering through the environment. The therapist may note unawareness of doorways and hallways in the unattended space; turns may be made only toward one direction. As a result, these clients lose their way in the hospital or even in the therapy clinic. This behavior should be distinguished from a topographical perceptual deficit in which the individual cannot integrate or remember spatial concepts well enough to find his or her way without getting lost. The Behavioral Inattention Test has recently been published as a standardized measure of functional inattention.⁷²

Finally, various studies have shown that inattention may occur during testing that requires visual processing and therefore may invalidate test results.^{57,73,74} Unresponsiveness to figures on one side of the page during visual, perceptual, cognitive, or language assessments may be subtle but must be documented to rule out the influence of inattention on raw score; that is, if the patient did not see the entire test display for an item, that test item is invalid. Responses to figures on the right half and left half of the test page should be counted. If the frequency of answers is noticeably less on one half of the page than would normally be expected, inattention may have occurred during testing. This may be used as additional evidence of inattention; but more important, this factor should be accounted for when computing the test score. Only those test items in which the correct answer was located in the attended space should be scored; that is, only those items in which the correct answer was right of midline in a client with left inattention should be scored.

Interventions

As previously stated, the mechanisms underlying unilateral spatial inattention are not well understood; however, recent research has uncovered a strong correlation between nonspatial aspects of attention called *tonic* and *phasic attention* and spatial aspects of neglect. Tonic attention is intrinsic arousal that fluctuates on the order of hours to minutes and contributes to sustained attention and preparation for more complex cognitive tasks. Phasic attention is a rapid change in attention in response to a sudden and brief event and is related to orienting responses and selective attention.⁷⁵ This research has postulated that nonspatial attention mechanisms affect spatial and nonspatial behavior. Some highly successful training protocols using these attentional mechanisms have been developed, and the researchers have been able to demonstrate improved responses with carryover in the environment (see Appendix 28-A). They also demonstrated that this remediation approach was more effective than just scanning strategies. A number of studies have investigated the remediation of unilateral spatial inattention. They have attempted to (1) define effective remediation techniques and (2) measure changes in trained tasks and generalization to untrained tasks, that is, determine whether inattention training in one task carries over to other unrelated tasks such as activities of daily living. Treatment techniques used in all these studies resulted in less inattention during trained tasks.^{58,76,77} An overview of these studies suggests that training may decrease inattention, although extent of change and generalization to other tasks may vary widely.

Discrepancies in these results may be related to neurological variables in the various client samples, severity of inattention, sample size, or tasks measured. A discussion of general principles of remediation follows.

Efforts should be made to increase the client's cognitive awareness of the inattention. The individual should be made keenly aware of what a peripheral visual field loss is and how it is affecting her or his view of the world. The person with normal visual fields but with visual extinction should be treated the same as the individual with an actual visual field loss because the visual experience is similar. Pictures of the visual field deficit may be drawn for illustration. Actual performance examples in the environment should be pointed out to the client to demonstrate the biased field of view.

Visual scanning should be emphasized. Initially, the client should be made aware of how eye and eye-head movements may be used to compensate for the deficit. The individual should be trained to make progressively larger and quicker pursuits and saccades and longer fixations into the unattended space. Training may be accomplished with interesting targets held by the therapist, for example, targets secured to the tips of pencils, such as changeable letters, colored lights, or bright small objects. Pursuit or tracking movements of the target leading the eye from attended into unattended space should be stressed first, followed by saccades into the unattended space. Initially the client may be allowed to move the head during scanning exercises; however, eye movements without head movements should be the major goal. Individuals with inattention often move the head into the unattended space while the eye remains fixed on a target in the attended space (i.e., the visual field remains the same). The client should be taught to independently carry out a daily right-left scanning program with targets appropriately positioned by the therapist. Eventually these targets can be moved farther into the unattended space.

Increased awareness and scanning abilities should be incorporated in increasingly complex visual-perceptual and visual-motor tasks. Because inattention often increases as task complexity increases, the therapist must select and structure tasks carefully. Examples of simple yet specific scanning tasks might include surveying a room repetitively, rolling toward and touching objects right and left of midline, assembling objects from pieces strewn on a table or the floor, completing an obstacle course, or selecting letters from a page of large print.

Scanning should be stressed during functional activities, for example, dressing, shaving, or moving through the environment. The client may be taught to constantly monitor the influence of inattention on functional performance, for example, "When something doesn't make sense, look into the unattended space and it usually will."

Diller⁷⁸ has designed a number of specific training techniques to decrease inattention during reading and paper and pencil tasks. With a little creativity, these techniques may be applied to other activities. For example, when the client is reading, a visual marker is placed on the extreme edge of the page in unattended space. The individual is instructed not to begin reading until he or she sees the visual marker. The marker is used to "anchor" the client's vision. As inattention

decreases, the anchor is faded. Each line may also be numbered and the numbers used to anchor scanning horizontally and vertically. To control impulsiveness, which often accompanies inattention, clients are taught to slow down or pace their performance by incorporating techniques such as reciting the words aloud. Underlining and looping letters or words can also be used as a method to slow down impulsive scanning (Figure 28-16). Finally, the density of stimuli is reduced; decreased density appears to decrease inattention in these tasks.

To stimulate tactile awareness in clients with tactile extinction, Anderson and Choy⁷⁹ suggest stimulating the affected arm as the individual watches. A rough cloth, vibrator, or the therapist's or client's hand may be used. Eventually, this activity may be done before activities that require spontaneous symmetrical scanning, such as dressing or walking through an obstacle course.

During the early phases of treatment, when inattention is still moderate to severe, the client should be approached from the attended space during treatment for inattention or other deficits such as apraxia, balance, or speech. This ensures that the individual comprehends and views all demonstrations and treatment instructions. Subsequently, as orientation and scanning improve, activities should be moved progressively into the unattended space and the therapist should be positioned in the unattended space during treatment. In the final stages of treatment, the client should be able to symmetrically scan regardless of the therapist's position (i.e., the therapist should vary position).

To enhance the integration of scanning behavior during functional tasks such as gait and dressing, the client should be reminded of scanning principles and carried through a series of scanning exercises before initiation of the activity. If inattention reappears during the activity, the therapist should stop and assist the client in becoming reoriented before the activity is resumed. Inattention results in confusion, and confusion increases inattention. As will be pointed out repeatedly in the following pages, the therapist must control the perceptual environment continuously so that the client is able to sequence bits of information together meaningfully to learn or relearn.

Problems of Cortical Blindness, Color Imperception, and Visual Agnosia Identification of Clinical Problems

Cortical Blindness. Cortical blindness is considered a primary sensory disorder as opposed to a secondary associative disorder. It is discussed here, however, because of the many variations of this lesion that may result in problems with interpretation of visual stimuli. Cortical blindness, also known as *central blindness*, is a total or almost total loss of vision resulting from bilateral cerebral destruction of the visual projection cortex (area 17). Similar destruction limited to one hemisphere results in hemianopsia.⁵⁵ The lesion may be ischemic, neoplastic, degenerative, or traumatic. The client may perceive the defect as a "blurring" of vision or as a marked decrease in visual acuity or may be unaware of the complete nature of the disability and even deny it, blaming the problem on eyeglasses that are too weak or a room that is too dark.

Color Imperception. Color perception may be impaired in the client with brain damage. This symptom is usually associated with right hemisphere or bilateral lesions.⁸⁰ This deficit is different from color agnosia, in which there is a problem with naming colors correctly. Clients with defective color perception may see colors as "muddy" or "impure" in hue, or the color of a small target may fade into the background, decreasing the ability to differentiate it from the background.^{61,81} Total loss of color monochromatism is rare, but it can occur.

Visual Agnosia. A lesion circumscribed to the visual associative areas (areas 18 and 19) results in a number of unique visual disorders that are categorized as some form of visual agnosia. Lesions are usually bilateral with combined parietooccipital, occipitotemporal, and callosal lesions. Visual agnosia is defined as a failure to recognize visual stimuli (e.g., objects, faces, letters) although visual-sensory processing, language, and general intellectual functions are preserved at sufficiently high levels.⁸² It also has been described as perception without meaning; perception apparently occurs, but the percept seems "disconnected" from previously associated meaning. In this pure form, visual

Figure 28-16 ■ Underlining during visual discrimination tasks helps control eye movements (scanning).

agnosia is a relatively rare syndrome, and there is controversy as to whether it is simply an extension of primary visual sensory deficits (variations of cortical blindness) or whether it should be considered as a separate neuropsychological entity.

Three types of agnosia have been recognized: visual, tactile, and auditory. Agnosia is most often modality specific; that is, the individual who cannot recognize the object visually will usually give an immediate and accurate response when touching or hearing the object in use. In visual agnosia, then, poor recognition is limited to the visual sphere.

Visual agnosia is divided into a number of types: visual object agnosia, simultanagnosia, facial agnosia, and color agnosia. These deficits may be seen in isolation or in various combinations, depending on the size and location of the lesion.

Visual Object Agnosia. During evaluation for the presence of visual object agnosia, the individual is presented with a number of common objects (e.g., key, comb, brush) and asked to name them. The evaluator may assume that the object is recognized if the client (1) names, describes, or demonstrates the use of the object or (2) selects it from among a group of objects as it is named by the examiner. If the person recognizes (describes or demonstrates) but is unable to name the object, failure is most likely a result of an anomia rather than an agnosic defect. Individuals with real visual agnosia have no concept of what the object is.⁸²

Simultanagnosia. Along the same vein are visual disorders that constrict or “narrow” the visual field during active perceptual analysis (i.e., when perceptions are tested separately, the visual field is within normal limits). Simultanagnosia is a disorder in which the person actually perceives only one element of an object or picture at a time and is unable to absorb the whole. As the individual concentrates on the visual environment, there is an extreme reduction of visual span. The problem is functionally similar to tubular vision. The narrowing of the functional perceptual field decreases the ability to simultaneously deal with two or more stimuli. It appears as if the person has bilateral visual inattention with macular sparing, although perimetric testing reveals full visual fields. A typical example is the individual whose visual attention is focused on the tip of a cigarette held between the lips and fails to perceive a match flame offered several inches away.⁸³

Facial Agnosia. Another special type of agnosia that has been documented is failure to recognize familiar faces. The disorder is also known as *prosopagnosia*. The individual is able to recognize a face as a face but is unable to connect the face and differences in faces with people he or she knows. This person is unable to recognize family members, friends, and hospital staff by face. One must be careful not to confuse this with generalized dementia. There may be categorical recognition problems with items involving special visual experience, for example, recognition of cars, types of trees, or emblems. Facial agnosia is usually seen in combination with a number of other deficits, including spatial disorientation, defective color perception, loss of topographical memory, constructional apraxia, and a left upper quadrant visual field loss. These other symptoms are most likely not causative but rather a result of the similar neurological location of these functions.⁸⁴

Color Agnosia. Finally, the individual may have difficulty recognizing names of colors, that is, an inability to name colors that are shown or to point to the color named by the examiner.⁸⁵ This defect is considered agnosic (as opposed to a defect in color perception) because the client is able to recognize all colors in the Ishihara Color Plates⁸⁶ and is also able to sort colors by hue. The determining factor here appears to be a problem with visual-verbal association. Color agnosia is most common in clients with left hemisphere lesions and is often accompanied by the syndrome of alexia without agraphia.⁸²

Assessment

Cortical blindness and variations of it should be thoroughly assessed by the vision specialist. Assessment for agnosia must be preceded by a thorough assessment for visual acuity problems, visual field deficits, and unilateral visual inattention because these primary visual sensory and scanning deficits are often mistaken for agnosic performance. Next, basic color perception should be measured by use of the Ishihara Color Plates⁸⁶ and color-sorting or color-matching tasks. Individuals with defective color perception will have difficulty with some visual-perceptual tasks because contextual cues related to color and shading are unavailable to them. Agnosia is a valid diagnosis only if (1) the aforementioned primary visual skills are intact and (2) language skills are intact (i.e., there should be no word-finding difficulty in spontaneous speech).

Although there are no standardized tests for agnosia, commonly used assessment methods have been included. The presence of simultanagnosia is determined by keen observation of performance that indicates perception limited to single elements within objects, for example, describing only the wheel of a bicycle or, within the environment, describing only one part of a room or an activity.

Object agnosia is tested for by placing common real objects (e.g., comb, key, penny, spoon) in front of the client and asking the client to name or point to the item chosen by the examiner. In pointing and naming tasks, the therapist must be sure that the client is fixating on the appropriate target. The response is considered normal if the object is named correctly or described or its functional use demonstrated. Abnormal responses will be confabulatory or perseverative, with the individual often giving the name of a previous or similar object. Responses may also be completely bizarre and unrelated. The examiner may also present objects at an unusual angle. Abnormal responses will show lack of recognition or rotation of the head or body to try to view the object in the “straight on” position. The diagnosis of visual object agnosia is further confirmed if the individual can identify the object by touch or by hearing it in use, both of which should be attempted with vision occluded.

Color agnosia is evaluated by having the client name a color and point to colors named by the examiner. Facial agnosia is evaluated by presenting the individual with photographs of famous world figures, actors, politicians, and family members.⁶¹

Interventions

There are no reliable studies regarding treatment of cortical blindness, color imperception, or visual agnosia. Treatment principles presented here are based on the experience of

Bouska and Biddle⁷³ and Bouska and Kwatny.⁵⁷ If cortical blindness or simultanagnosia is suspected, the therapist must first attempt to increase the client's knowledge of foveal versus peripheral vision, that is, where the client is fixating. A small headlamp attached to the client's forehead may be used under conditions of subdued lighting. The headlamp should not be used in a completely darkened room because the client needs to use normal spatial cues from the environment. The movement of the projected light in the environment and kinesthetic input from the neck receptors augment knowledge of where the eye is fixed. To carry out this task, the client must learn to position the eyes in midline of the head. The individual is asked to move the light (i.e., head and eyes) to locate and discriminate fairly large, bright stimuli placed on a plain background (e.g., yellow block on a brown table). As acuity and localization skills improve, stimuli and background should be made smaller and more complex (e.g., paper clip on a printed background or letters printed at different locations on a large page). The client should be encouraged to accurately point to or manipulate targets once located with the light or to keep the light on a target as he or she slowly moves the target with one hand. Thus the kinesthetic input from the limb can augment visual localization abilities.⁷⁶ In patients with color imperception, treatment should initially involve materials and tasks with sharp color contrasts with minimal detail and should progress to less contrast (more hues) with more detail.

If the assessment has revealed a narrowing of the perceptual field, treatment should be aimed at progressively increasing the perception of large, bright, peripheral targets. For example, the client may be asked to fixate on a centrally placed target while another bright target is brought in slowly from or uncovered in the periphery.^{87,88} The individual is encouraged to maintain fixation on the central target while remaining alert for the presence of another target somewhere in the periphery. As the client improves, targets should be smaller, multiple, and exposed for briefer periods. Peripheral targets should always have bright surfaces that reflect light because the peripheral receptors in the retina are mainly rods (light as opposed to color receptors). Another powerful variation of this technique is to involve hand use in peripheral location of objects. For example, the patient senses the presence of a peripheral object then reaches with the hand to pinpoint location, then shifts the eyes to identify it. This can further help to differentiate between central and peripheral vision.

The treatment of clients with object agnosia should progress according to the abilities that return first in spontaneous recovery from agnosia. Common real objects should be used before line drawings in treatment. Presentations should be given "straight on" rather than at an angle or rotated. The client should be asked to point to objects named by the examiner before being asked to name them. Manipulation of the object with simultaneous visual input should be attempted. This may help recognition, or it may simply confuse the client; each case is unique. In general, tactile input with or without simultaneous visual input should be encouraged as a compensation method, although it may not be helpful during treatment sessions.

Color and facial agnosia may be approached by simply drilling the individual with regard to two or three names of colors or names of faces of people important to her or him.

The client may be helped to pick out or memorize cues for associating names with faces.⁶¹

Problems of Visual-Spatial Disorders

Identification of Clinical Problems

Individuals with brain lesions, particularly in the right posterior parietal and occipital areas, may have difficulties with tasks that require a normal concept of space.⁵⁵ Disorders of this nature have been termed *visual-spatial disorders*, *spatial disorientation*, *visual-spatial agnosia*, *spatial relations syndrome*, and numerous other names. Visual-spatial abilities are complexly interwoven within the performance of many perceptual and cognitive activities such as dressing, building a design, reading, calculating, walking through an aisle, and playing tennis. An attempt is made here, however, to discuss spatial disorders in their purest form—that is, basic disorders—before dealing with visual-constructive disorders and disorders of analysis and synthesis. Constructional tasks require spatial planning, a type of planning that involves the building up and breaking down of objects in two and three dimensions. Constructional apraxia is viewed as a particular type of spatial-perceptual disorder and therefore is discussed separately under visual-constructive disorders and disorders of analysis and synthesis. Similarly, although perceptual skills such as figure-ground, form constancy, complex visual discrimination, and figure closure involve spatial concepts, tasks involving these skills often require the intellectual operations of synthesis and deduction. They, too, are discussed in the section dealing with analysis and synthesis.

All visual-spatial disabilities involve some problem with the apprehension of the spatial relationships between or within objects. Benton⁸⁹ has categorized them as the following disabilities:

1. Inability to localize objects in space, to estimate their size, and to judge their distance from the observer. The client may be unable to accurately touch an object in space or indicate the position of the object (e.g., above, below, in front of, or behind). Relative localization may be impaired so that the individual may be unable to tell which object is closest. There may be difficulty determining which of two objects is larger or which line is longer. Holmes⁹⁰ reported cases of gross disorder in spatial orientation revealed through walking; affected individuals, even after seeing objects correctly, ran into them. In another example a man intending to go toward his bed would invariably set out in the wrong direction. Difficulty in estimating distances may also extend to judgments of distances of perceived sounds and lead to overly slow and cautious gait or fear of venturing into public areas.
2. Impaired memory for the location of objects or places. An example is not being able to recall the position of a target previously viewed or the arrangement of furniture in a room. Individuals with this difficulty often lose things because they have no spatial memory to rely on for recall.
3. Inability to trace a path or follow a route from one place to another. Persons without this ability, known as *topographical orientation*, have difficulty understanding and remembering relationships of places to

one another, so they may have difficulty finding their way in a space, as in locating the therapy clinic in a hospital or locating the housewares department in a store previously familiar to them. Normally functioning individuals often have mild signs of topographical disorientation. Everyone is familiar with the disoriented feeling of not knowing how to get out of a large department store or losing a sense of direction in a familiar city. Many of the topographical errors made by clients result from unilateral spatial inattention. For example, someone with left inattention may make only right turns. Topographical disorientation, however, may be seen in a person with no signs of unilateral inattention. This individual will demonstrate route-finding difficulties at certain points and will apparently randomly choose a direction.

4. Problems with reading and counting. These high-level tasks require directional control of eye movements and organized scanning abilities. Eye movements (saccades) during reading bring a new region of the text on the fovea, the part of the retina where visual acuity is the greatest and clear detail can be obtained from the stimulus. During reading, the line of print that falls on the retina may be divided into three regions: the foveal region, the parafoveal region, and the peripheral region. The foveal region subtends about 1 to 2 degrees of visual angle around the reader's fixation point, the parafoveal region subtends about 10 degrees of visual angle around the reader's fixation point, and the peripheral region includes everything on the page beyond the parafoveal region. Parafoveal and peripheral vision contribute spatial information that is used to guide the reader's eye.⁹¹ Visual-spatial disorders appear to interfere to varying degrees with the spatial schema of a page of type or numbers and the dynamic organizational scanning that must take place to gather information appropriately. Clients with unilateral spatial inattention will miss words or numbers located on one half of the page. Other spatial problems unrelated to unilateral inattention include skipping individual words within a line or part of a line, skipping lines, repeating lines, "blocking" or having the inability to change direction of fixation, particularly at the end of a line, and generally losing the place on the total page. Performance usually deteriorates progressively as the individual continues to read. Eventually such persons cannot make sense of what they read, or if counting they complain of being lost or confused. This type of reading or counting disorder has nothing to do with recognition or interpretation of letters or numbers or their spatial configuration; rather, it represents a problem with dynamic sequential visual-spatial exploration during cognitive processing.

Other visual-spatial problems may include loss of depth perception, problems with body schema, and defective judgment of line orientation. There may also be difficulties with discrimination of right and left. Although unilateral spatial inattention is considered a visual-spatial disorder by many, it has been discussed separately in this chapter to increase clarity. Problems with judging line orientation (slant) or

unilateral spatial inattention often interfere with a client's spatial ability to tell time with a standard watch or clock. Perception of the vertical may also be considered a visual-spatial skill. Verticality perception is the interpretation of internal and external cues to maintain body balance. This maintenance is a complex neuromuscular process involving visual, proprioceptive, and vestibular systems. Clients with right lesions, particularly in the parieto-occipital region, have more difficulty perceiving verticality than those with left lesions. This may affect posture and ambulation.⁹²

Assessment

The client should be asked to accurately touch a number of targets in all parts of the visual field while fixating on a central point. Mislocalization should be noted as well as the part of the visual field in which it occurred. Mislocalization within the central field is infrequent; however, defective localization of stimuli on one or both extramacular fields is more frequently seen.⁵⁵ The client should be asked to determine which of a number of small cube blocks (placed perpendicularly in front of the client) is closest, which is farthest, and which is in the middle. Differences in binocular (stereoscopic) and monocular viewing should be measured in this and other tasks. Impairment in both of these types of depth perception and subsequent inaccuracy in judging distances have been described in individuals with brain injury.⁸⁹

With regard to memory for the location of objects or places, clients should be asked to describe the position of objects in their room from memory. They may also be asked to duplicate from memory the position of two or more targets (on a table or piece of paper) that have been presented for a 5-second period. As the number of targets increases, individuals with short-term memory for spatial localization will begin to make errors in spatial placement. Visual memory per se should be ruled out as a conflicting variable.

Topographical sense is assessed by asking clients to describe a floor plan of the arrangement of rooms in their house or to describe familiar geographical constellations, such as routes, arrangement of streets, or public buildings. After therapy these persons may also be asked to find their way back to their rooms after being shown the route several times. Failure suggests a topographical orientation problem. Finally, such a client may be asked to locate states or cities on a large map of the United States. In all of these procedures, the examiner must be sure to separate unilateral spatial inattention errors from topographical errors.

The influence of spatial dysfunction on reading and counting written material may be measured simply by asking the client to read a page of regular newsprint. The examiner should observe performance carefully and document type and frequency of errors. If errors occur, eye movements should be observed to gather additional information. Pages of scanning material (letters or numbers) often give additional information on spatial planning during reading. These are pages of print in which the size and density of the print are controlled. Scanning behavior may be demonstrated by asking the client to circle specific letters. Switching direction in the middle of a line, skipping letters or lines, perseveration, or any other abnormal performance behavior should be noted. Benton's Judgment of Line Orientation

Test⁹³ may be used to document problems with directional orientation of lines. If there is no indication of apraxia, the client may simply be given a ruler and asked to match it to the directional orientation of the examiner's ruler.

Interventions

Treatment for visual-spatial deficits should follow basic developmental considerations, progressing from simple to more complex tasks. As with children, if the evaluation suggests disorders in body scheme, tactile or vestibular input, or right-left discrimination, these should be dealt with first.

Clients who do not know where they are in space need to internalize a spatial understanding before they can make judgments regarding the space around them. In gross motor spatial training, clients can be asked to roll and reach toward various targets. Supine, prone, sitting, and standing, with vision occluded, clients should try to localize tactile stimuli (various body locations touched by the therapist) and auditory stimuli (e.g., snapping fingers or ringing a bell) presented above, below, behind, in front of, and to the right and left of their bodies. The individual should state where the stimulus is and then point, roll, crawl, or walk toward it; this verbal, kinesthetic, and vestibular input augments spatial learning. In the occupational therapy kitchen, the client, once oriented to the room, may be asked to retrieve one type of object (e.g., cup) from “the top cupboard above your head,” from “the bottom cupboard below your waist,” from “the table behind you,” or from “the drawer on your right [or left].” These clients may also place objects in various positions within a room. They should then stand in the middle of the room, close their eyes, and from memory visualize, verbalize, and point to where the objects are in relation to themselves. Having localized them, the clients should then walk through the space and retrieve the objects in sequence. Functional carryover should always be emphasized, such as having individuals remember through visualization where they put their glasses in the living room before they begin searching. Visualization is defined as the internal “seeing” of something that is not present at that moment: a vision without a visual input or internal visual imagery.⁹⁴ Visualization (spatial and other) is part of all perceptual tasks and may be used effectively as a treatment strategy. As previously discussed, a small feedback light placed in the middle of the client's forehead can help teach spatial localization through eye-hand movements.

More complex spatial skills may be taught by asking clients to “partition” space and then localize within it. An excellent activity is one in which clients use a yardstick to divide a blackboard into four or more equal parts and then number each section.

Objects may be presented to clients, who must select the largest, the farthest away, or the one placed at an angle; they may be asked to place various objects in certain relationships to one another. As shape, size, and angle begin to “make sense” to these individuals, form boards, simple puzzles, and parquetry blocks may be added to training.

Topographical abilities should improve as clients begin to better conceptualize space; however, they may be trained directly. The therapist may help such clients organize a basic floor plan of the hospital room and the furniture within it while looking at the room. They may then be asked to do

this from memory. Activities can progress to drawing plans or larger areas with a number of rooms. These clients should first “navigate” tactually through the area with a finger. Eventually, they should walk or wheel through the route themselves, visualizing and repeating the route until spatial concepts are learned. Imaginary routes also may be taken through maps of cities, states, or countries.

Organized visual-spatial exploration (eye movements) during reading or other scanning and cancellation tasks may be taught. Number and letter scanning sheets may be used for such training. Initially the size of numbers and the spaces between numbers should be large; this places less stress on visual acuity while training scanning. Before beginning, clients should orient themselves to the page spatially by numbering the right and left edges of each line. These numbers are used as additional spatial localization cues if needed during the scanning task.⁴⁵ Clients should then be asked to circle a specific number (or numbers) whenever it occurs. To control erratic or impulsive eye movements, they should be instructed to use a pencil to underline each line and then loop the selected letter as it comes into view (see Figure 28-16). They may also be asked to read each letter. Underlining allows the kinesthetic and tactile receptors of the arm to control eye movements; verbalization allows the language and auditory systems to influence eye movements. Visual-spatial exploration exercises should progress to large-print magazines, books, or newspapers. The *New York Times* and *Reader's Digest* are both available in large print. In all training activities it is most important that before the activity begins the clients fully comprehend the total space in which they will work. It is equally important that they reorient themselves at any point where errors occur. Those who lose their place during reading will eventually lose it again if the therapist simply points to where they should be. Chances are better that they will not lose their place again if they reorient themselves to the page spatially when an error occurs.

Problems of Visual-Constructive Disorders

Identification of Clinical Problems

Clients with lesions in either the right or left hemisphere may have problems when trying to “construct.” Lesions in the parietal, temporal, occipital, and frontal lobes have been documented in individuals with visual-constructive disorders.^{55,95} The normal ability to construct, also known as *visual-constructive ability* and *constructional praxis*, involves any type of performance in which parts are put together to form a single entity. Examples include assembling blocks to form a design, assembling a puzzle, making a dress, setting a table, and simply drawing four lines to form a square (graphic skills). The skill implies a high level of dynamic, organized, visual-perceptual processing in which the spatial relations are perceived and sequenced well enough among and within the component parts to direct higher-level processing to sequence the perceptual-motor actions so that eventually parts are synthesized into a desired whole. Visual-constructive ability may be compromised if any part of this process is disturbed.

Typical tasks used to measure this ability include building in a vertical direction, building in a horizontal direction, three-dimensional block construction from a model or a

picture of a model, and copying line drawings such as of houses, flowers, and geometric designs.⁸⁴

Clients with visual-constructive deficits, especially those with right lesions, often also have visual-spatial deficits. These individuals may rotate the position of a part erroneously, place it in the wrong position, space it too far from another part, be oblivious to perspective or a third dimension, or simply be unable to complete more than two or three steps before becoming entirely confused. This is usually evidence of breakdown because of faulty or inadequate spatial information.

Other clients, usually those with left lesions, have an “executorial” or apraxic problem; they seem to have difficulty initiating and conducting the planned sequence of movements necessary to construct the whole. The problem seems to be in planning, arranging, building, or drawing rather than in spatial concepts. This deficit in its purest form is known as *constructional apraxia*. Constructional apraxia lies clinically outside the category of most other varieties of apraxia and is considered a special kind of “perceptual” apraxia. It occurs frequently in aphasic individuals; therefore the underlying mechanisms of aphasia and constructional apraxia may be related.⁹⁶

Assessment

Constructional abilities are generally measured through tasks that require (1) copying line drawings of, for example, a house, clock face, flower, or geometric design (drawing may also be done without copying); (2) copying two-dimensional matchstick designs; (3) building block designs by copying or from a model; or (4) assembling puzzles. Table 28-2 lists common tests. The more complex the picture or design to be copied, the more complex are the constructional tasks. The following are examples of drawing and block construction deficits:

1. Clients may crowd the drawing or design on one side of the page or in one corner of the page or available space on the working surface, usually a result of the influence of unilateral spatial inattention.
2. Lines in drawings may be wavy or broken, too long or too short.
3. One line may not meet another accurately, or lines may transect one another; in block designs, parts may not be neatly placed but rather may have small gaps.
4. There may be “overdrawing” of angles or parts of the figure because of graphic perseveration (scribble), spatial indecision, or problems with executive planning.

5. Clients may superimpose their copy on the model or superimpose one of their drawings on top of another. In block design construction, they may become confused between the model and their reproduction and use part of the model to complete their design. This has been termed the “closing-in” phenomenon, a failure to distinguish between model and reproduction.⁵⁵
6. Parts of the drawing or design may be reversed. Horizontal reversals are more common than vertical reversals.

A note might be appropriate here regarding dressing apraxia. This problem occurs most frequently with right hemisphere damage. It is considered a “perceptual” apraxia rather than a motor apraxia because the inability to dress is believed to result from body scheme, spatial, and visual-constructive deficits rather than difficulty in motor execution. Persons with dressing apraxia cannot correctly orient their clothes to their body. They often put clothes on backward or inside out. Failure to dress one side of the body is also often noted and is directly related to unilateral spatial inattention.

Interventions

It must be remembered that both visual-constructive and visual analysis synthesis skills are often used almost simultaneously during task performance. Thus, treatment should not separate the two types of skills but rather should be a precise interrelationship of activities that require finer and finer levels of each facility. For example, arranging an office filing system is both an analytical-synthesis and a visual-constructive task. The individual must first analyze overall needs and translate them into an imagined visual-spatial plan (preliminary synthesis of the whole) that will help organization. Then the organizer begins to use the hands to categorize (segment visual space). This building is a visual-constructive task. Intermittently during building, new ideas of the whole surface, and visual-constructive tasks change in response to a “better idea” (final synthesis of the whole). Task performance, except for tasks that are rote, usually follows similar perceptual processes. Treatment therefore must be integral. Visual-constructive skills, however, may be emphasized more than visual analysis and synthesis skills or vice versa.

As previously mentioned, visual-constructive disorders are thought to result from different underlying problems in different individuals (e.g., visual-spatial disorders in persons with right hemisphere lesions and executive, planning, or synthetic disorders in those with left hemisphere lesions).

TABLE 28-2 ■ COMMON TESTS USED TO ASSESS VISUOCONSTRUCTIVE SKILLS

TEST	STANDARDIZATION
Drawing pictures or shapes with or without an example to copy	Not standardized
Reproducing matchstick designs	Not standardized
Assembling puzzles	Not standardized
Bender Visual Motor Gestalt Test	Standardized for children only
Kohs Blocks Test	Standardized for adults
WAIS Block Design Test	Standardized for adults
Benton’s Three-Dimensional Constructional Praxis Test	Standardized for adults

There are few reliable studies on treatment strategies for visual-constructive disorders. One possible treatment strategy is known as *saturational cuing*.⁹⁷ This method involves presenting controlled verbal instruction on task analysis and sequence and presenting cues on spatial boundaries (cuing is also response related).

If there are problems with planning and sequencing of steps necessary to accomplish a visual-constructive task, the therapist should begin with simple tasks that require only three or four steps, such as positioning one place setting at a table. The client should discuss the plan and sequence of steps before initiating the activity, while looking at the parts to be used, such as silverware, plate, and glass. These steps may even be written down for additional input. The client should be helped to reorient the plan at any point during task breakdown. Eventually, tasks should increase in complexity (e.g., setting a table for five), and the client should be encouraged to function more independently. Another technique often used by clinicians is known as backward chaining. This involves presenting a partially completed task and asking the client to complete the final steps, for example, placing the knife and glass on a partially completed place setting. The perceptual cues of the task already begun appear to stimulate constructional abilities. As the client progresses, he or she should complete more steps.

Intervention for problems with spatial planning during visual-constructive tasks should begin with the simple spatial exercises discussed previously. If problems still exist, the individual may be asked to draw around shapes (blocks) one by one. These shapes should first have been placed in a simple two-dimensional design. The client is then asked to rebuild the design with the shapes alone. Therapy should progress from horizontal to vertical to oblique designs, from two-dimensional to three-dimensional designs, and from tasks with common objects to tasks involving abstract designs. For example, spatial problems with drawing, such as placing windows in a house or numbers on a clock face, are usually a result of an underlying spatial disorder. The client should use a ruler or protractor to segment the space and plan placement before drawing. Dot-to-dot tasks may be designed that actually lead and sequence the drawing into a spatial whole. Simple puzzles also may be used to increase visual-spatial abilities during visual-constructive tasks. Finally, if task breakdown results from impulsive visual or motor behavior, these symptoms should be dealt with before further visual-constructive treatment continues.

Examples of visual-constructive tasks that may be designed for therapeutic use include the following:

- Setting a table for one to five people
- Wrapping a gift
- Assembling a piece of woodwork, a toy, a tool, a motor
- Changing a tire on a car
- Organizing a shelf in a library or a kitchen
- Organizing a filing system or cabinet
- Putting pieces of a sewing pattern together
- Addressing an envelope
- Rearranging furniture according to a preset plan
- Assembling a craft according to a preset plan
- Drawing from memory or copy

- Copying two-dimensional block designs
- Copying three-dimensional designs with oblique components

The key to effective visual-constructive learning, however, is not the task itself but rather how carefully the therapist organizes it and monitors performance. Clients with visual-constructive disorders are often visually or motorically impulsive; they often move or draw parts before analysis has taken place. Once a part is placed inappropriately, it begins to confuse the whole visual-perceptual process. This confusion increases anxiety and contributes to further breakdown in analysis and synthesis. Treatment should be directed at the underlying causes of task breakdown if these can be determined.

Problems of Visual Analysis and Synthesis Disorders

Identification of Clinical Problems

This separate discussion of visual analysis and synthesis is arbitrary. There is never any clear demarcation among the processes of visual-spatial orientation, visual construction, and visual analysis and synthesis. Analysis of likes and differences, relationships of parts to one another, and reasoning and deduction occur simultaneously with more basic spatial and constructive percepts. The final visual concept of a task (e.g., what a place setting on a table should look like) is necessary before the task is begun. Similarly, synthesis of one part of a task may be necessary before synthesis of the entire task can occur. For example, the person who is setting a table for four people must be able to conceptualize one place setting before conceptualizing the table with four place settings. Those points during perceptual processing when there is a colligation or blending of discrete impressions into a single perception are known as *synthesis*. This final stage of coordination and interpretation of sensory data is thought to be deficient in many individuals with perceptual problems. Deficits may be present with either left or right hemisphere damage but are more common and more severe with right lesions.^{61,98}

Visual-perceptual skills considered to be analytical and synthetic in nature include making fine visual discriminations, particularly in complex configurations; separating figure from background in complex configurations (figure-ground); achieving recognition on the basis of incomplete information (figure closure); and synthesizing disparate elements into a meaningful entity, as, for example, conceptualizing parts of a task into a whole.⁵

Assessment

Many tests have been designed to measure the capacity for analysis and synthesis. Test items include complex figures in which small parts of a figure differ from another figure. The client is asked to select the one that is different. Studies have shown that basic discrimination of single attributes of a stimulus such as length, contour, or brightness is intact in many clients.⁹⁹⁻¹⁰¹ The problem appears when these individuals are asked to discriminate between more complex configurations with subtle differences. Tests also measure figure-ground ability; the client must select the embedded figure from the background. Functional examples of this problem are the inability of a client to find her or his glasses if they are lying on a figured background, to find a white

shirt on a white bedspread, and to find his or her wheelchair locks. Figure closure is measured by asking the client to complete an incomplete figure, such as part of the outline of a common shape. Finally, synthesis of parts into a whole, also known as *visual organization*, is measured by asking the client to conceptualize and organize the whole picture by, for example, looking at separate segments of the picture (e.g., cup or key) that have been divided and placed in unusual positions. This type of synthesis is necessary for high-level constructional tasks. Table 28-3 outlines examples of tests used to evaluate visual analysis and synthesis.

Interventions

Intervention for deficits in visual analysis and synthesis should follow developmental considerations described in the children's section. Visual discrimination tasks should begin with simple figures and obvious differences in complex figures. Color, size, texture, lighting, and verbal direction may help the client "cue in" on subtle differences among objects or figures. The therapist should determine the threshold at which the client is capable of discriminating differences and vary the dimension, contrast, and functional activity at this level. For example, if the individual cannot select a can of vegetables from a kitchen shelf stocked with cans of similar size, the therapist may simply change the task to fit that person's level of visual discrimination by removing some of the cans (decreasing the density of the display), replacing some of the cans with boxes of food (increasing the spatial contrast), moving the can to be selected forward or to one edge of the display (decreasing figure-ground difficulty), removing the label from the can (increasing the light and color contrast), or giving cues regarding what to search for (verbal direction). This example is described not as a method of compensation but rather as an approach to be used therapeutically in slowly building the client's visual discrimination abilities. Eventually, high-level visual discrimination skills should be incorporated within tasks requiring three or more steps, such as selecting a can of vegetables, opening the can (which involves selecting the can opener from the utensil drawer), and emptying the vegetables into a specific bowl (which involves selecting the bowl from among other bowls). Visual discrimination and figure-ground skills may appear normal until the client is required to do multiple-step activities, is given time constraints, or becomes anxious or confused. Tabletop games that require high levels of visual discrimination along with cognitive strategies may be therapeutic and motivating. Examples include Monopoly and card games such as solitaire. Matching and sorting tasks also may be helpful

in enhancing visual discrimination. Examples include matching picture cards and sorting laundry, tools, silverware, or files.

Drawings of figures with subtle differences also may be used for therapy. The client should be encouraged to point to, verbalize, or outline the subtle differences in two or more pictures; this enhances visual attention to detail. If the individual cannot select the discrepant detail(s) among three or more figures, the problem most likely results from an inability to select one feature and compare it with elements in the other figures. This is a fairly high-level skill that requires selective attention and analysis with internal visualization while the individual is still viewing the complete figures. This type of client should practice feature detection and then begin systematic comparisons of similarities and differences between two figures, eventually progressing to three or more figures. The therapist may number or outline similar areas of each figure to help the client (1) direct attention to similar areas of all figures and (2) sequence comparisons appropriately. The client should verbalize, draw, or write details concerning similarities and differences in individual aspects of the figures. This enhances visual analysis and also informs the therapist about how the individual is selecting and comparing features. Eventually, speed should be stressed, the highest level being presentation of tachistoscopic designs.

Visual organization may be emphasized by presenting the client with activities that have multiple parts that must be sequenced together into a whole. Activities involving this type of synthesis are discussed in the preceding section on treatment of visual-constructive disorders. Figure closure may be emphasized by presenting parts of figures or objects (e.g., half a plate covered by a towel) and asking the client for identification. Figure-closure task difficulty may be increased by placing many objects on a table, some of which partially occlude others. Identification of objects in such a task requires figure closure simultaneous with figure-ground abilities.

Visual analysis and synthesis deficits reflect a disruption in cognitive function with specific regard to visual-perceptual features. The affected client may function normally when analytical tasks require another system, for example, language. In others with generalized brain damage (e.g., traumatic head injury and senile dementia), general cognitive analysis and synthesis may be at fault rather than visual analysis. Because most cognitive performance requires visual processing, however, increased ability to analyze and synthesize visual-perceptual material often generalizes to an increase in cognitive function.

PERCEPTUAL RETRAINING WITH COMPUTERS

During the past 15 years, numerous computer programs have been developed for rehabilitation of brain damage symptoms, including those affecting cognition (e.g., attention, sequencing, or memory) and perception. Because the computer is so highly visual, it becomes an obvious tool for treatment of visual-perceptual dysfunction. Treatment with computers has been named *computer-assisted therapy*. There is a growing interest in development of and research into programs for rehabilitation, for Alzheimer's prevention, and in normal healthy aging adults. The largest treatment study of 487 subjects was able to demonstrate statistically significant improvements in memory and attention by using a plasticity-based adaptive training program.¹⁰² A number of other studies are in progress. Advantages of computer-assisted therapy include control and flexibility of perceptual variables during treatment (e.g., number, size, speed), immediate feedback regarding performance, automatic control for learning (e.g., items are repeated if incorrect to facilitate learning), and being motivational. Visual-perceptual training with computers, if used, should be viewed as one part of a patient's treatment program. One should always remember that the computer, monitor, and keyboard are just that: they do not require the many perceptual, vestibular, and motor responses typical of daily performance (e.g., scanning requirements may be bilateral, but they are not global and associated with head movement). A patient's total program may include computer-assisted therapy as an additional tool; however, it should never be substituted for more significant training within the multidimensional environment. Some computer programs for visual-perceptual training are listed in Box 28-6.

SUMMARY OF VISUAL-PERCEPTUAL DYSFUNCTION

Careful organized evaluation should delineate deficits well enough to result in a visual-perceptual function profile for each client, including both primary and associative visual skills. Clients rarely come with isolated visual-perceptual deficits; more often they exhibit a combination of visual-perceptual deficits usually interrelated with motor, language, and cognitive dysfunctions. For example, a visual-perceptual function profile may reveal strabismus, left unilateral visual inattention, visual-spatial deficits, visual-constructive deficits, and problems with visual analysis and synthesis, all affecting daily function. Treatment should be organized to progressively build skills, emphasizing one component more than another. The goal of treatment is eventual generalization of improvements in individual skills to spontaneous high-level function.

The presentation of information in this chapter is an attempt to use isolated and mechanistic terms to define a system that is extremely subtle, integrated, and complex. The reader is reminded that much of the normal and abnormal perceptual system has not been well defined. Preliminary studies cited throughout this chapter, however, suggest that

Pelvic Floor Treatment of Incontinence and Other Urinary Dysfunctions in Men and Women

BEATE CARRIÈRE, PT, CAPP, CIFK

KEY TERMS

functional training exercises
incontinence
pelvic floor dysfunction
recoordination of the functions of the abdominal compartment

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Discuss factors that lead to incontinence.
2. Understand the neurophysiology involved in pelvic floor dysfunctions.
3. Describe the different layers of the pelvic floor and their functional connections.
4. Understand the importance of coordinating diaphragmatic breathing with pelvic floor activity.
5. Correct faulty breathing patterns to facilitate normal pelvic floor activity.
6. Apply motor learning and motor control principles when teaching exercises.
7. Select the most appropriate intervention to improve pelvic floor function.

OVERVIEW OF THE CLINICAL PROBLEM

History of Pelvic Floor Exercises

A different focus on how to view the pelvic floor and the problem of incontinence has evolved from new knowledge about neurophysiology, neuroplasticity, motor learning, motor control, and functional brain imaging.^{1,2} Kegel³⁻⁵ is considered the great American pioneer who, in the late 1940s, recognized the importance of exercises to help women with urinary incontinence (UI). Dr. Kegel, a Los Angeles physician, found that many women did not have any awareness of the function of the pelvic floor and that they were not always successful with the exercise he prescribed, which is drawing in the perineum. He therefore developed a pneumatic apparatus, the perineometer, which measured each muscle contraction in a manner visible to the patient. He instructed his patients to perform the exercise for 20 minutes three times daily, or a total of 300 contractions, and suggested weekly visits for instruction.^{3,4} Kegel also recognized that evidence of bladder weakness was present in some women before childbearing and emphasized the importance of training the pubococcygeus muscle to achieve continence.^{4,5} Considered visionary at that time, his approach to exercises demonstrates visual feedback combined with declarative learning. However, the treatment has not changed much since.⁶⁻⁹ Kegel exercises are stereotypical and highly repetitive (300 repetitions until improvement, then 80 per day for life) with little functional value. More recent studies have investigated the effectiveness of Kegel's exercises.

Our current understanding of pelvic floor function shows the complex relationship of the pelvic floor with many systems and subsystems of the body, such as the nervous system (central, peripheral, autonomic, sensory, and limbic), musculoskeletal system, cardiopulmonary system, lymphatic system, and integumentary system, as well as with different

organs in the abdominal cavity. The environment also has a profound influence on its function.

Given the complexity of the role of the pelvic floor muscles, procedural learning, sensory awareness, and functional retraining are now part of intervention strategies for an individual with pelvic floor dysfunction. Interventions may include breathing exercises, manual lymph treatment, visceral mobilization, manual therapy, connective tissue mobilization, and treatment of scars.

Prevalence of Urinary Incontinence

The prevalence of UI in men and women is high and costly. Mardon and colleagues,¹⁰ who conducted a study of managed care beneficiaries, found the overall incidence of UI to be consistent with previous estimates. Fantl and colleagues¹¹ reported in 1996 that 10% to 35%, or 13 million adult Americans, have UI. In 2000 Hu and co-workers¹² estimated that 17 million community-dwelling persons had daily UI and 34 million had overactive bladder (OAB) syndrome, with 2.9 million of those reported to have had incontinence episodes.

In 1996 more than half of the 1.5 million nursing home residents in the United States were estimated to be incontinent. This condition is reported to be the most common reason for placing a family member in a home.¹¹⁻¹³ The number of adults in institutional care had risen to 1.89 million in 2000, and 945,000 of those were estimated to have UI.¹² Women older than 60 years have twice the prevalence of incontinence as men of that age.¹¹ The majority of patients with incontinence are parous women and older persons.¹³ Goode and colleagues¹⁴ report that UI is a common geriatric syndrome affecting at least one in three older women. "UI is not a normal result of aging, it is a medical problem that is often curable and should be treated."¹⁵ Britton and co-workers¹⁶ conducted a study of urinary symptoms in 578 men older

than 60 years. Thirty percent of the men reported increased daytime frequency, and 27% reported urgency and a variety of other urinary symptoms, defined as OAB if nocturia (getting up at least once in the night to urinate) is included. Incontinence can also be found in the younger population. Nygaard and colleagues¹⁷ investigated UI in nulliparous elite athletes and found that individuals who participate in gymnastics and sports that include jumping, high-impact landings, and running appear to score higher in the prevalence of UI than those who swim or play golf. Because exercises and activities during field training of soldiers can be strenuous, one third of 450 female soldiers experienced UI according to Sherman and Davis.¹⁸ Baumann and Tauber¹⁹ reported that 17% of boys aged 5 to 14 years are incontinent. Adedokun and Wilson²⁰ and Diokno and colleagues²¹ provided thorough epidemiological overviews, collecting data from various sources all over the world.

Risk factors for incontinence include the following:

Obesity: This is a risk factor and can contribute to incontinence and make the treatment more difficult.^{22,23}

Cigarette smoking: Smoking augments incontinence for three reasons: (1) it has been shown to interfere with collagen synthesis, (2) neuromuscular and anatomical changes likely occur from smoking that result in decreased functionality of the bladder, and (3) it causes coughing, which increases the strain on the weak pelvic floor muscles.²⁴ Moreover, cigarette smoking has been linked to erectile dysfunction and has an effect on sperm quality in men. In women, it is related to increased incidence of miscarriage and cervical cancer and reduced chance of conception.²⁵ It has been reported that smoking cessation, weight reduction, and regulation of bowel movements may reduce the risk of UI.²⁶

Diabetes: Hunter and Moore²⁷ state that an estimated 13% of seniors have diabetes. Of these individuals, 32% to 45% have associated bladder dysfunction. The presence of UI in diabetics can be attributed to decreased bladder sensation, increased bladder capacity, and impaired detrusor contractility. Lee and colleagues²⁸ studied voiding patterns in women with type 2 diabetes and stated that peripheral neuropathy was an important factor associated with diabetic voiding dysfunction. They found that patients with diabetes had predominantly nocturia and a weak urinary stream, abnormal nocturnal urine production, and decreased voiding volumes and functional bladder capacity. In the same study, researchers noted impaired detrusor contractility, with 13.9% of 194 female patients having high postvoiding residual (PVR) urine of over 100 mL. The researchers suspected that the dysfunction in detrusor contractility was secondary to diabetes. Moreover, 14.4% of the women in the study had less than 70% efficiency of emptying the bladder.

Neurologic diseases associated with UI include the following:

Brain injuries: Leary²⁹ investigated incontinence after brain injury and reported that 50% of the patients had impaired bladder and bladder subscores on admission. Even though 90% of those patients were set goals for self-care and mobility, only 3.5% of the patients were

set multidisciplinary goals addressing bladder and bowel function. The Agency for Health Care Policy and Research³⁰ reported that UI is most prevalent in persons with spinal cord injuries (SCIs) and people with multiple sclerosis (MS). Eighty percent of patients with SCI will have had at least one urinary tract infection (UTI) by their sixteenth year postinjury.

MS: Seventy percent to 90% of individuals diagnosed with MS develop bladder dysfunction, which places them at high risk for UTIs (Agency for Health Care Policy and Research). McClurg and colleagues³¹ state that in patients with MS, bladder storage problems often coexist with inadequate emptying of the bladder because of detrusor sphincter dyssynergy. In their research with 30 patients with MS, they showed that a combined treatment of pelvic floor training and advice combined with electromyography biofeedback and neuromuscular electrical stimulation may reduce urinary symptoms in these patients. Schulte-Baukloh and colleagues³² injected 11 women and five men with MS and drug-resistant OAB symptoms with botulinum toxin type A and found significant improvement for 4 weeks to 3 months (but not at 6 months), with reduction in frequency, nocturia, and pad use; however, buildup of residual urine remained a problem.

Spina bifida: Patients affected by spina bifida also can have various neurogenic urinary tract dysfunctions. Depending on the severity of the dysfunction, they may become socially dry with conservative therapy.³³

Alzheimer disease: In patients with Alzheimer disease cognitive and central regulating mechanisms contribute to incontinence.³⁴ According to Holstege,¹ research has shown that “lesions in the pathway from prefrontal cortex and limbic system, to the PAG (periaqueductal gray) probably cause urge incontinence in the elderly.”

Cerebrovascular accident (CVA): Brittain and colleagues³⁵ state that UI after a stroke is associated with poor outcome and depression in stroke survival and care. The overall prevalence of UI is high (32% to 79%) in older patients with stroke admitted to the hospital. At discharge the incidence of UI is 25% to 28%, and 12% to 19% continue to experience UI for months after the stroke. The inability to communicate, transfer, or walk and the use of drugs complicate matters. UI in stroke patients is similar to UI in patients without stroke and probably results from muscle weakness on the affected side. The patients may demonstrate stress UI (SUI), but urgency UI (UII) and mixed incontinence are also common. Studies published from 1985 to 1997 suggest that 31% to 40% of hospitalized stroke patients have fecal incontinence on admission and 18% at discharge, and 7% to 9% still experience fecal incontinence 6 months after the stroke.³⁶ Unfortunately, treatment for these problems is rarely prescribed, even though it is very effective.³⁷

Parkinson disease: In individuals with Parkinson disease, the prevalence of lower urinary tract symptoms (LUTSs) is 27% to 39%, most frequently nocturia (86%); 71% of patients have reported frequency, and 68% have reported urgency. According to a study by Winge and colleagues,³⁸ the patients were bothered

most by the urgency symptoms. The authors inferred that the reason could be a progression of gait difficulties, decreased ability to separate and integrate sensory input, or both at a later stage of the disease. Zein and colleagues³⁹ agreed with increased incidence of voiding dysfunction with the progression of the disease. They also describe incomplete emptying (40%) and hesitation (37.3%) as problems in their prospective study of 110 patients with Parkinson disease. Fowler and Griffiths² suggest that the pathways from the PAG to the thalamus and insula do not conduct signals properly in Parkinson disease. Deep brain stimulation can restore the conduction.

Parkinsonian syndrome: Multiple system atrophy (MSA) is described in detail by Yamamoto and colleagues^{39a} and Wenning and colleagues,^{39b} who state that the clients have autonomic, cerebellar, and extrapyramidal symptoms. The syndrome presents as a more severe form of Parkinson disease and includes MSA, idiopathic Parkinson's, vascular parkinsonism, and supranuclear palsy. Clients with MSA can have severe blood pressure variations and sudden orthostatic hypotension secondary to autonomic system problems in addition to more severe bladder dysfunctions such as higher incidence for urinary urgency, retardation in initiating urination and incomplete emptying of the bladder that may require catheterization. Prolongation of urination and constipation are also more common in MSA clients than those with Parkinson disease. The physical treatment has to address more symptoms and it is more complex and more difficult to improve the client's quality of life.

Guillain-Barré syndrome (GBS): The prevalence and mechanism of bladder dysfunction were evaluated by Sakakibara and colleagues.⁴⁰ In their study of 65 consecutive patients urinary dysfunction was observed in 27.7%. Of those patients, 9.2% experienced retention, 24.6% had voiding difficulties, and 7.7% complained of urgencies. Overactive and underactive detrusor activity were the major urodynamic findings. The underlying mechanism, according to the authors, appeared to involve hypoactive and hyperactive lumbosacral nerves.

Cost of Incontinence

Wilson and colleagues⁴¹ state that the cost for women over 65 years of age with UI is twice that for women younger than 65 years. Affecting 17% to 55% of community dwellers and up to 50% of nursing home residents, UI is one of the most prevalent chronic diseases. Only one-quarter to one-half of affected individuals seek medical attention. Within a 10-year period the direct cost increased considerably, more than could be accounted for by medical inflation. Hu and colleagues¹² adjusted and reported the cost of UI and OAB syndrome in 2000: \$19.5 billion and \$12.6 billion, respectively. Thirty-four million individuals had OAB syndrome, and 17 million had UI. Because individuals with OAB have fewer incontinence episodes, the per-person cost is higher in patients with UI—35% of patients with UI have SUI, which can involve expensive surgeries. However, the days spent in the hospital have declined since 1995.¹² The cost of UI escalated from \$8.2 billion in 1984 to \$16.4 billion in

1993 and to \$26.3 billion, or \$3565 per individual with UI, in 1995. Wagner and Hu⁴² attributed this increase to the following three major changes in the previous 10 years:

- Introduction of more continence-related products to the marketplace
- Change in the age composition of the U.S. population
- Change in prevalence of UI

The authors stated that the cost for people younger than 65 years was not included in the study and that the true cost may be much higher because UI is underreported.

Definition of Incontinence

UI is defined as involuntary loss of urine.⁴³ Incontinence can have one or more causes, and in more than 90% of cases it can be improved or cured.¹³ Treatment should be instituted only after a careful, thorough history and physical examination.¹³

SUI is defined as involuntary loss of urine on effort or physical exertion, for example, sporting activities or sneezing or coughing.⁴³

UII is considered to be involuntary loss of urine associated with urgency.⁴³

Mixed UI is the complaint of involuntary loss of urine associated with urgency and also with effort or physical exertion, sneezing, or coughing.⁴³

Symptoms associated with bladder storage disorders include the following:

Increased daytime urinary frequency: Micturition (emptying of the bladder) occurs more frequently during waking hours than previously deemed normal by the patient.⁴³

Nocturia: Patient wakes up from sleep one or more times because of the need to micturate. Each void is preceded and followed by sleep.⁴³

Urgency: A sudden, compelling desire to pass urine that is difficult to defer.⁴³

OAB syndrome: Cluster of symptoms of urinary urgency, usually accompanied by frequency and nocturia in the absence of UTI.⁴³

Symptoms associated with voiding disorders include the following:

Hesitancy: Delay in initiating micturition⁴³

Straining to void: A need to make an intensive effort to either maintain or improve the urinary stream⁴³

Feeling of incomplete bladder emptying: Report that the bladder does not feel empty after micturition⁴³

Urinary retention: Inability to pass urine despite persistent effort⁴³

In patients with nonneurological conditions, the most common forms of incontinence are SUI, OAB syndrome, UII, and mixed incontinence. Weak pelvic floor muscles usually cause SUI. SUI occurs when the abdominal pressure is greater than the urethral pressure, resulting in a loss of urine with coughing, laughing, sneezing, lifting, and so forth. OAB syndrome, or detrusor overactivity, is associated with involuntary bladder muscle contraction during the filling phase, causing frequent urination; nocturia; and strong, sudden, and sometimes unpredictable urges to urinate but not always resulting in incontinence.⁴⁴

UII can be caused by detrusor instability, an involuntary contraction of the muscle of the bladder before it is full. It is associated with a sudden urgent need to void. The urgency

can be so irresistible that it results in loss of urine before the individual reaches the bathroom.

ETIOLOGY

The causes of SUI and UII in individuals with nonneurological conditions are as follows (Figure 29-1):

1. Functional causes include the inability to undress in a timely fashion and not being able to reach the bathroom in a timely fashion because of obstacles (e.g., no light, cannot enter the bathroom with the walker without maneuvering).
2. Weakening of the pelvic floor structures can result from childbirth (overstretching of muscles, injuries to the pudendal nerve, or ligaments), hysterectomy, prolapse (rectocele, cystocele, vaginal prolapse), straining with constipation, poor biomechanics when lifting, falls on the buttocks with shift of the pelvis affecting muscle length or stretching the nerves, and poor coordination of the pulmonary diaphragm with the pelvic floor, back, and abdominal muscles.^{45,46} Scars in the perineal and pelvic area, aging (loss of muscle mass), obesity, smoking, poor posture, and pain in the pelvic area also can contribute to muscle weakness.
3. OAB syndrome and UII can be caused by UTIs and other conditions that irritate the bladder: neoplasia, post-bladder or post-bowel surgery status, bladder outlet obstruction, anxiety, nervousness, and poor toileting habits. The condition can also be idiopathic. Some clients also have urgency to eliminate the bowels.
4. Over-the-counter medications with anticholinergic agents can cause retention (an inability to empty the bladder completely), overflow (leakage of urine when the bladder is overextended), and frequency; antipsychotic medications can cause sedation, rigidity, and immobility; and diuretics can worsen impaired continence. Medication for treatment of hypertension can also contribute to incontinence.^{11,13,27,47,48}
5. Retention in nonneurological clients can occur in men with prostate problems; the enlarged prostate makes the passage of urine difficult.^{16,49} Other causes in men and women are the hyperactive pelvic floor syndrome (HPFS),⁵⁰ an inability to relax the pelvic floor muscles. This can be caused by pelvic pain syndromes, by painful bladder syndrome (formerly *interstitial cystitis*), or by habits: trying to void in a hurry, squeezing rather than relaxing the muscles, and being unable to void because of stressful situations.
6. An overdistended bladder can cause overflow incontinence. It can manifest as constant or intermittent dribbling, sometimes combined with urgency or symptoms of stress incontinence. Patients often have high residual urine levels and feel that their bladder does not empty properly; sometimes secondary to sensory problems, the patients are unaware of the filling of the bladder.
7. Inadequate fluid intake (either too much or too little) and fluids that may be stimulants to the bladder can cause urgency incontinence or frequent trips to the bathroom. Smoking, obesity, and postmenopausal estrogen deficiency contribute to the problem.^{11,22,24,47,48}

Neurogenic causes of bladder dysfunctions are as follows:

1. Lesions in the higher cortical areas and suprapontine lesions can be found in patients with MS, stroke, Alzheimer disease, Parkinson disease, traumatic brain injury, tumors, and dementia. Lateral prefrontal cortex activation probably regulates the desire to void and to remain continent.² Lesions in the pathways from the prefrontal cortex and limbic system to the PAG probably cause urgency incontinence in the elderly.¹ The emotional motor system (EMS) uses the cell group of the pontine micturition center (PMC), close to the locus coeruleus, which sends long descending fibers to the parasympathetic motoneurons to the sacral cord. Through inhibitory interneurons, fibers reach the nucleus of Onuf. Stimulation of the PMC therefore results in complete micturition.¹ Neurological diseases can cause many other symptoms such as retention and an inability to control the micturition reflex. Detrusor hyperreflexia (overactive detrusor during the filling phase) with coordinated urethral relaxation interferes with normal tonic inhibition of the parasympathetic pathways and the balance between facilitatory and inhibitory mechanisms in the PMC.^{44,47,48,51}
2. Lesions in the upper motor neurons (UMNs) affect the spinal cord. Common problems resulting in urinary dysfunction are SCI, MS, cauda equina syndrome, tumors, inflammatory diseases such as transverse myelitis, infectious diseases such as syphilis (tabes dorsalis), injuries to the spinal column, prolapse of a disc, or stenosis of the spinal canal. A typical bladder problem is detrusor hyperreflexia without coordinated urethral relaxation (detrusor-sphincter dys-synergy).^{47,48,51,52}
3. Lesions of the peripheral or lower motor neurons (LMNs) such as injuries from childbirth, traumatic injuries, diabetes, radiculitis (e.g., from herpes zoster), or tabes dorsalis can cause retention and detrusor areflexia. The inability to feel when the bladder is full can lead to an overflow bladder with symptoms of dribbling and incomplete or strained voiding. Patients may need to learn clean intermittent catheterization.^{11,13,48,51,53}
4. Lesions stemming from injuries to the autonomic nervous system can be caused by surgery in the pelvic area, such as hysterectomy, rectum resection, and radical prostatectomy; injury; or inflammations such as chronic cystopathy in diabetic patients. Autonomic lesions can contribute to diffuse pain,⁵⁴ swelling, and altered sensory awareness. Patients with urinary problems can describe the feeling of having cold feet.^{55,56} Patients with diabetic cystopathy (DC)—in addition to their symptoms of weak stream, hesitancy in starting urination, dribbling, and overflow from high residual urine levels (caused by decreased bladder sensation and increased bladder capacity, and impaired contractility)—may also have other symptoms of autonomic dysfunction. These can include orthostatic hypotension, nocturnal fall of blood pressure, and changes in heart rate.^{7,27} Altered central nervous system (CNS) monoamines (serotonin and noradrenaline) can cause both depression and OAB.

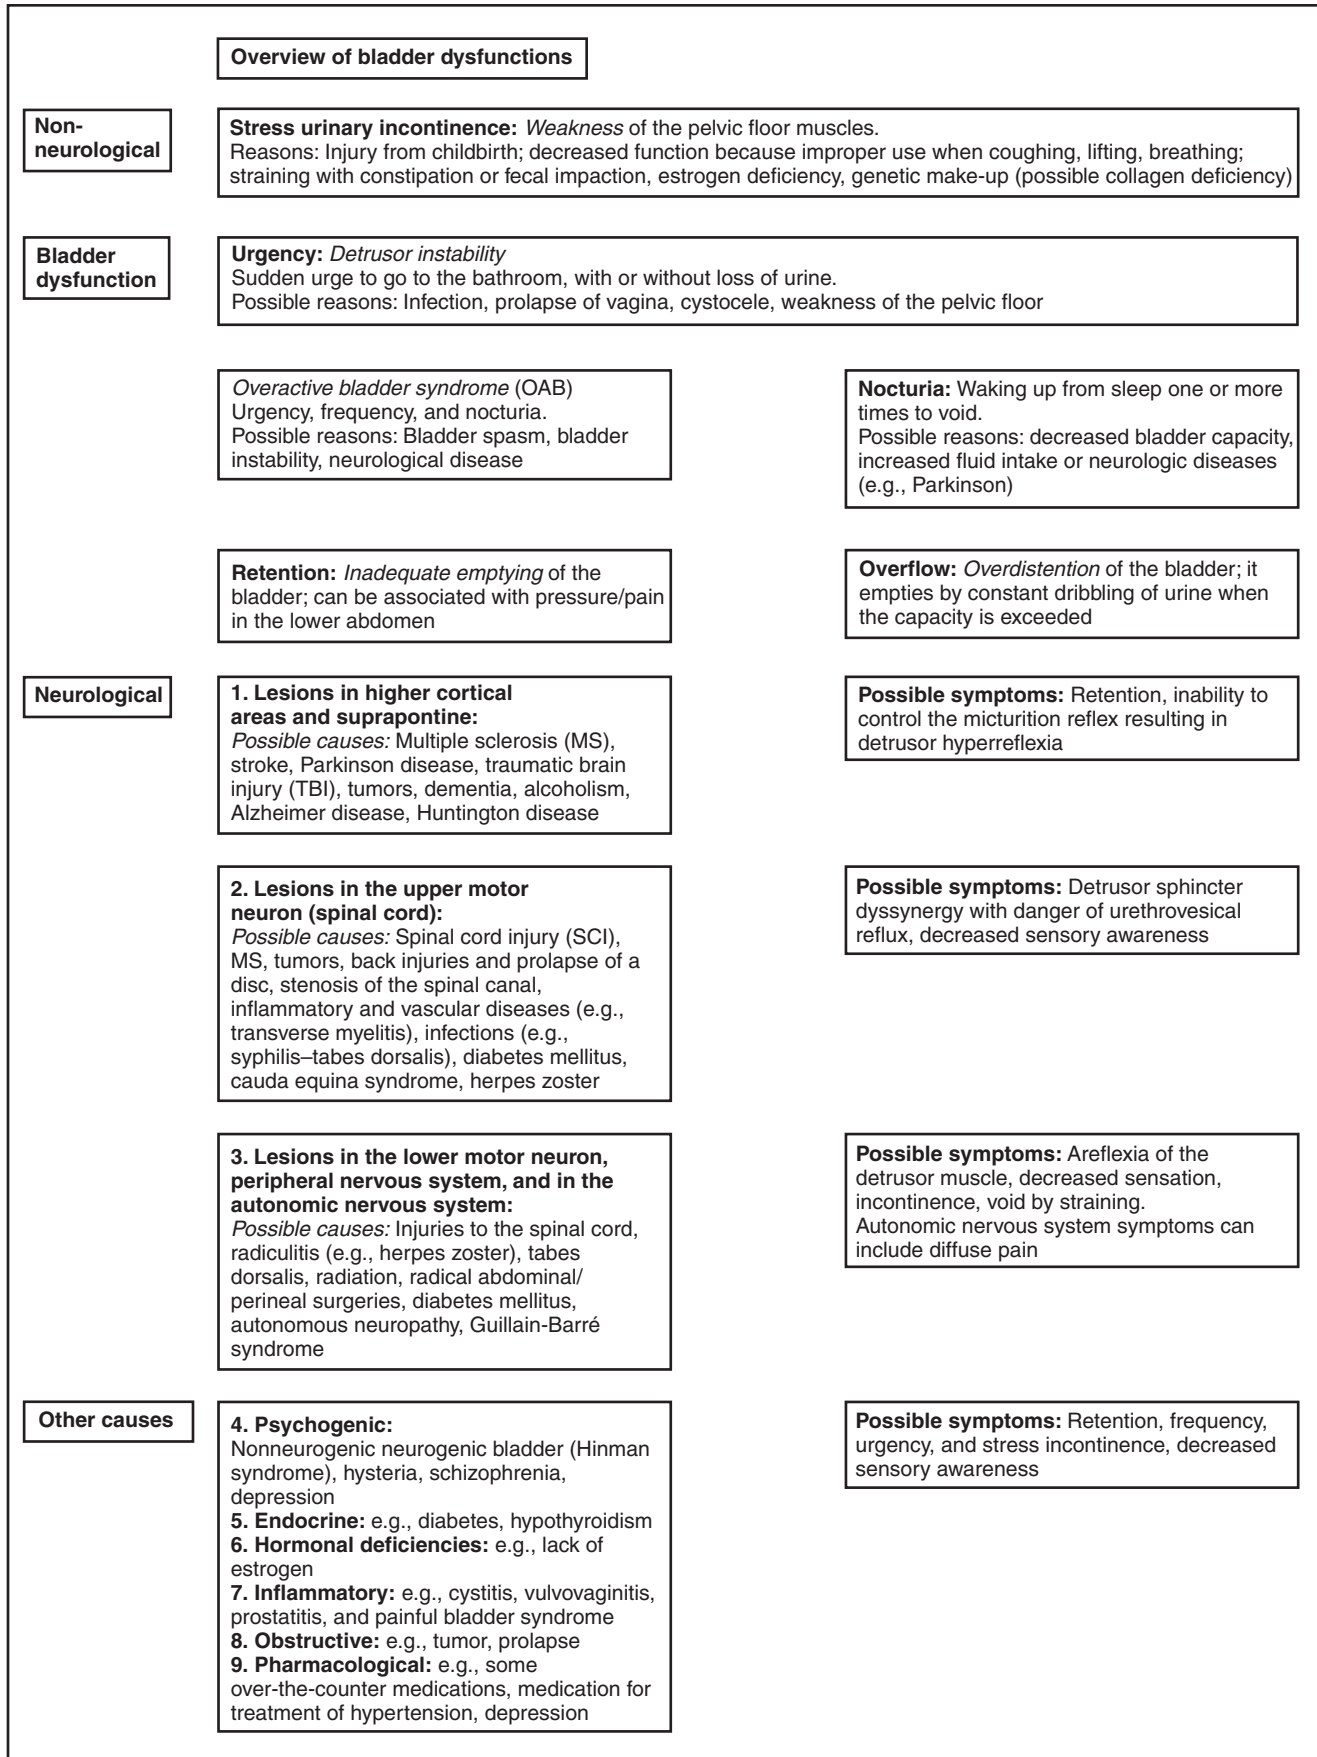

Figure 29-1 ■ Overview of reasons for incontinence of nonneurological and neurological causes.

Correction of some neurologic disorders can eliminate both depression and urgency incontinence.⁵⁷

5. Psychogenic causes of urinary dysfunction include schizophrenia and depression. Patients can experience incontinence, hesitation, retention, and pain.
6. A nonneurogenic neurogenic bladder is called *Hinman syndrome*.⁴⁷
7. Endocrine causes are hypothyroidism and diabetes, which may lead to a flaccid or areflexic bladder and require clean intermittent self-catheterization.^{47,53} Diabetes can also increase the frequency of urination.

ANATOMY AND PHYSIOLOGY OF THE PELVIC FLOOR

The pelvic floor consists of all the muscles that close the pelvic cavity. It is part of the abdominal compartment that can be defined by the pulmonary diaphragm cranially, the pelvic diaphragm and perineal membrane caudally, the muscles of the abdominal wall ventrally, and the muscles of the back dorsally. This compartment houses the internal organs and the viscera.^{13,45-47,58-61} All muscles of the abdominal compartment interact and support one another, providing postural stability and the ability to breathe, talk, and eliminate. The pelvic floor is essentially composed of three layers: the endopelvic fascia, the pelvic diaphragm, and the perineal membrane.

Endopelvic Fascia

The endopelvic fascia suspends and supports the organs within the pelvis. It is a mesh of connective tissue composed of collagen, elastin, blood and lymph vessels, and nerves. A thick, fibrous part of the endopelvic fascia, the pubocervical fascia, attaches to the cervix in a slinglike fashion and assists in supporting the urethra and the bladder. Laterally it connects to the fascia white line, the tendinous arch of the levator ani muscle. Injuries to this important fascial support can contribute to weakness of the pelvic floor, prolapse, and leakage with increased abdominal pressure.^{13,48,61} One study⁶² has shown that fascia may be able to contract in a smooth muscle-like manner and therefore may have the ability to influence musculoskeletal dynamics. This underlines the importance to not neglect the fascial structures surrounding the abdomen when treating pelvic floor dysfunctions. They are not purely passive structures.

Pelvic Diaphragm

The pelvic diaphragm consists mostly of the paired levator ani muscle (Figure 29-2). The levator ani is shaped like a hammock and has several parts. In the sagittal plane the muscle originates at the pubic bone and attaches to the coccyx, hence the name *pubococcygeus muscle*. The medial part of the pubococcygeus joins behind the rectum and therefore is named the *puborectalis muscle*. This part of the levator muscle provides continence of bowel by increasing the anorectal angle. Inability to relax the puborectalis therefore contributes to constipation in patients with HPFS. Other fibers of the levator ani form a sling around the vagina or prostate (pubovaginalis and levator prostate muscles). Each side of the muscle meets in the midline with the other half and attaches to the perineal and anococcygeal bodies. The compressor urethrae muscle is part of the external urethral complex. It originates from the rami of the ischium and pubis

and runs fanwise forward and medially to arch over the anterior part of the urethral surface. The sphincter urethrovaginalis is part of the puborectalis.⁶³

The posterior part of the levator ani has two paired sections. The coccygeus (or ischiococcygeus) muscle covers the sacrospinous ligament. The muscle arises at the spine of the ischium and extends to the lowest part of the sacrum and the coccyx. The iliococcygeus lies between the coccygeus and the puborectalis and passes in a diagonal direction between the coccyx to the spine of the ischium and the tendinous arch of the levator ani. This fibrous band of the arcus tendineus is suspended between the pubic bone and ischial spine.^{13,47,48,61,63-65} The levator ani is a skeletal muscle with a high resting tone; it consists of approximately 70% slow-twitch fibers and 30% fast-twitch fibers.^{48,61,66-68} Wall and colleagues⁴⁸ and Bump and colleagues⁶⁶ consider the high resting tone critical for pelvic support and for keeping the hiatus of the levator closed. Because the levator ani muscle is under voluntary control, it can be actively contracted and provide closure during an increase in abdominal pressure, such as when coughing or sneezing.^{48,67-69} According to Retzky and Rogers,¹³ the innervation of the levator ani muscles is under dual control: on the pelvic surface by motor efferents of the sacral nerve from S2 to S4, and on the perineal surface by the pudendal nerve.

Perineal Membrane

The perineal membrane (formerly *urogenital diaphragm*) is the outer layer of the pelvic floor. It is a thick, fibrous, and muscular layer of triangular shape immediately below the levator ani. In women the perineal membrane attaches the edges of the vagina to the ischiopubic ramus; in men it forms an uninterrupted sheet of tissue. The fibers of the deep and superficial transverse perineal muscles run primarily in a frontal plane and contain many fibrous tissues,⁷⁰ the ischio-cavernosus muscle in a diagonal direction, and the bulbospongiosus muscle in a sagittal plane. The external sphincter muscle of the anus is part of the perineal membrane and is connected to the transverse perineal and bulbospongiosus muscle by the perineal body, which contains fibrous tissue. The dorsal attachment of the perineal membrane is achieved through the anococcygeal raphe, which connects the external anal sphincter (EAS) to the coccyx.^{48,64,67,70}

The muscles of the perineal membrane include both smooth and striated muscles. The muscles become tight when the levator ani tone remains relaxed.⁴⁸ The anterior portion of the perineal membrane is closely connected to the urethral musculature. According to Wall and colleagues,⁴⁸ the perineal membrane does not substantially contribute to pelvic support; it is mostly the levator ani, which has much greater strength and bulk and can exert upward traction when contracting to maintain outlet support. The ischiocavernosus, bulbospongiosus, and superficial transverse perineal muscles function mainly in sexual responsiveness, serving to enhance and maintain penile erection in males and maintaining erection of the clitoris in females.^{48,61} Trigger points in these muscles can cause a degree of impotence and pain with intercourse. According to Claes and colleagues,⁷¹ Van Kampen and colleagues,⁷² and Dorey,⁷³ strengthening exercises of the muscles of the perineal membrane can significantly improve impotence. In women the perineal membrane is often torn or injured during childbirth,

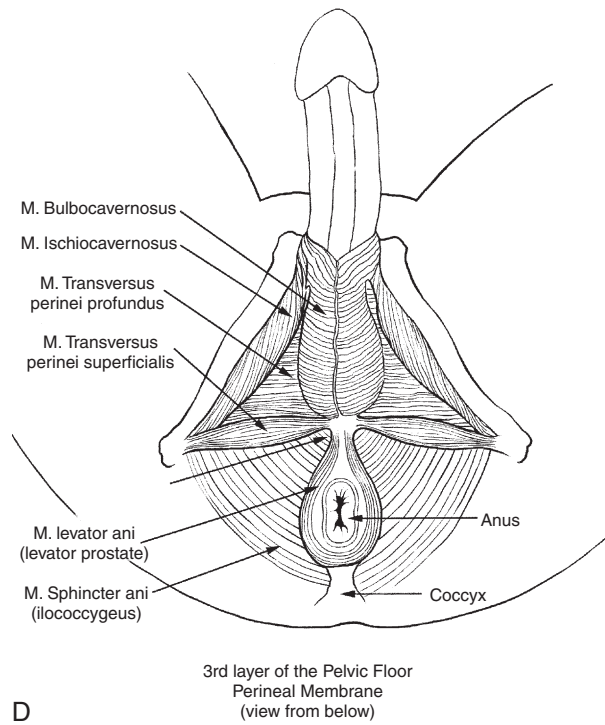

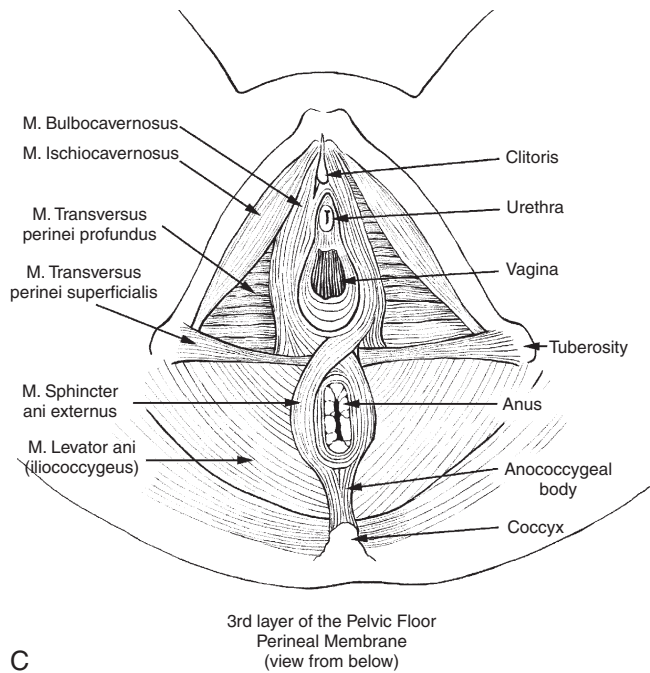

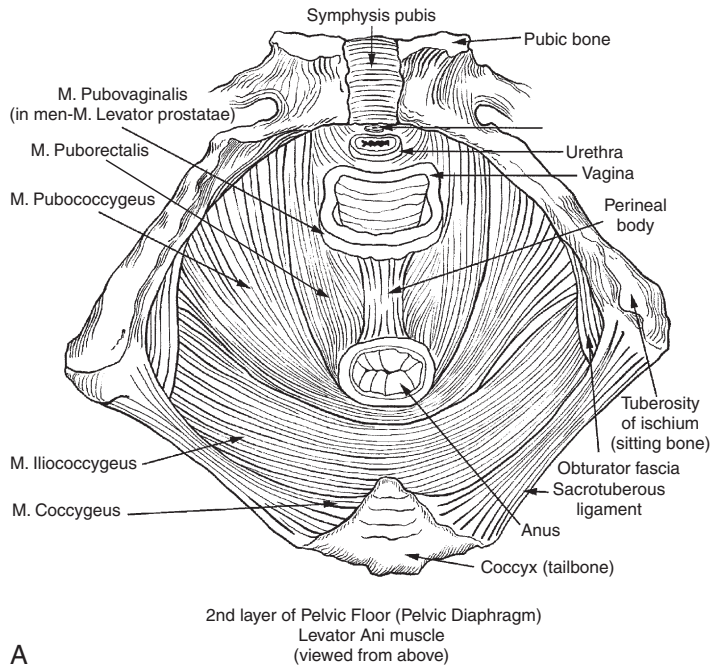

Figure 29-2 ■ Anatomy of the pelvic floor. **A**, Second layer of the pelvic floor, pelvic diaphragm viewed from above. **B**, Second layer of the pelvic floor, pelvic diaphragm viewed from the side. **C**, Third layer of the pelvic floor, perineal membrane viewed from below (female). **D**, Third layer of the pelvic floor, perineal membrane viewed from below (male).

and, if not properly repaired, injuries can cause sexual dysfunction, pelvic pain, and low self-esteem.

The complicated autonomic innervation of the pelvic area and its clinical relevance, including the perineal area, has been well described by Wessellmann and colleagues⁵⁴ as well as Fritsch and Umphred.⁷⁰ The pudendal nerve diverges from the sacral plexus, intermingles with the autonomic

nerves, and then branches into several directions, innervating the EAS and the anterior perineal muscles.

Mucosal Coaptation of the Urethra

In addition to the three pelvic floor layers, an important contributor to continence is the mucosal coaptation, which is the arteriovenous complex between the epithelial lining

and the smooth muscle coat of the female urethra. It is sensitive to estrogen, and with deficiency of this hormone the resting pressure of the urethra can decrease and cause leakage.¹³ Wall and colleagues⁴⁸ compared it with an “inflatable cushion” helping to fill the urethral wall and sealing the 3- to 4-cm-long urethra in women. Because of possible serious side effects of estrogen treatment, it is now prescribed and applied to the vaginal area in low dosage and with caution. It can help some menopausal women increase the resting tone of the urethra and improve closure. The male urethra is not estrogen dependent. Its mucosal coaptation is highly vascular and probably influenced by testosterone. In addition, the prostate gland and the length of the male urethra may contribute to a sealing effect.

Internal Sphincter of the Urethra

The internal sphincter muscle at the junction of the bladder and urethra (urethrovesical junction) is an involuntary smooth muscle under autonomic control in both males and females. Its shape is circular and formed by the trigone, a smooth muscle in the bladder, and two U-shaped loops of muscles that derive from the bladder muscle. In females the urethra rests on a hammock of connective tissue (pubocervical fascia) and is held in a position that prevents descent into the vagina. The external sphincter muscle is able to close the middle portion of the female urethra.¹³

Incontinence usually happens when several factors come together. For example, men frequently leak after radical prostatectomy because the smooth internal sphincter urethra may have been damaged by the surgery and the pelvic floor muscles have to learn to substitute and provide closure of the urethra. A patient with dementia may not feel the need to go to the bathroom because of lesions in the limbic system or the cortex.^{1,2} Parkinson disease may cause bladder outlet obstruction because of a noncontractile detrusor, resulting in large volumes of residual urine or lack of activation of the PMC.^{2,74} In addition, the inability to quickly undress complicates an already existing problem of incontinence in such a client.

In healthy individuals the external sphincter and levator ani muscles serve as a backup system for continence. However, weakness of these structures leads to decreased bladder neck and urethral support and can lead to incontinence, especially with activities that increase the abdominal pressure.

VOIDING MECHANISM OF THE BLADDER

Many of the neurophysiological connections involved in functioning of the bladder and the surrounding muscles are not fully understood. A complicated coordination of many systems is involved in a properly functioning bladder and other pelvic organs. Elaboration on all the neural interactions, which take place at all levels, is not possible in this chapter. Wesselmann and colleagues⁵⁴ and Burnett and Wesselmann⁷⁵ provide comprehensive information about the neurobiology of the pelvis.

Sympathetic Innervation

The sympathetic innervation to the bladder, rectum, and sexual organs originates from the thoracolumbar segment of the spinal cord (T10 to L1-L2) as well as from the hypogastric plexus (the sympathetic hypogastric nerve), which

descends from the aortic plexus (Figure 29-3). The hypogastric nerve feeds into the inferior hypogastric (pelvic) plexus, which is the major neuronal integrative center for multiple pelvic organs.^{54,75} Both the sympathetic and parasympathetic divisions of the autonomic nervous system innervate the pelvic viscera, which are also innervated by the somatic and sensory nervous systems. The sympathetic innervation inhibits the bladder and increases bladder storage ability (it is sympathetic to be dry) and stimulates the muscles of the trigone and the internal sphincter muscles of the bladder as well as the muscles of the rectum. Attention should be paid to the T10 to L1-L2 segments in patients with tailbone pain and pain in the pelvic floor (e.g., testicular, buttock, scrotal pain) because the pain may be referred from that area. I recall a case in which tailbone pain disappeared instantly after treatment of the thoracolumbar area in a client who had fallen on the back in a flexed position. Doubleday and colleagues⁷⁶ described a case of a patient who for 5 years had complained of testicular and buttock pain along with posterior leg paresthesias. Treatment of the T10 to L1-L2 area (central disk protrusion at T12-L1) with direct and guided physical therapy resulted in complete symptom resolution.

Parasympathetic Innervation

The parasympathetic innervation exits the spinal canal at the level of S2 to S4. The nerves join the splanchnic nerve before entering the inferior hypogastric plexus (see Figure 29-3, A). The parasympathetic fibers stimulate the bladder and other pelvic organs, including the sexual organs.^{54,75,77} The parasympathetic fibers ending in the bladder are especially sensitive to overstretching, infection, and fibrosis.⁴⁷ This explains the frequent urgency to urinate under such conditions. The parasympathetic nerve helps bladder contraction by stimulating muscarinic receptors in the fundus of the bladder. Parasympathetic nerve activation also helps colonic mobility. Therefore in an SCI when LMNs are injured (parasympathetic cell bodies in the cauda equina and conus medullaris), the result can be slowed stool propulsion with areflexic bowel. LMN injury causes constipation and increases the risk of incontinence from lax EAS, as described by Benevento and Sipski.⁵²

In contrast an UMN lesion such as those from MS causes hyperreflexia with no voluntary control over the EAS. The patient cannot relax the EAS to defecate even though reflex coordination and stool propulsion are present. Urinary and fecal retention and constipation are common in such UMN injuries.⁵²

Detrusor sphincter dyssynergia (DSD), caused by impaired coordination between bladder contraction and the external sphincter urethra, can be attributable to hyperreflexia or uncontrolled muscle spasm of the detrusor. This condition is common in patients with SCI⁵² as well as MS but not in clients with cerebral vascular accident (CVA).

Somatic Innervation

The somatic innervation of the pelvic floor comes from the sacral plexus of S2 to S4 (see Figure 29-3, A). The pudendal nerve leaves the spinal cord at S2 to S4 and branches to innervate the striated muscles of the levator ani, the external sphincter muscles of both the urethra and rectum, the labia and clitoris, and the muscles of the perineal membrane. The

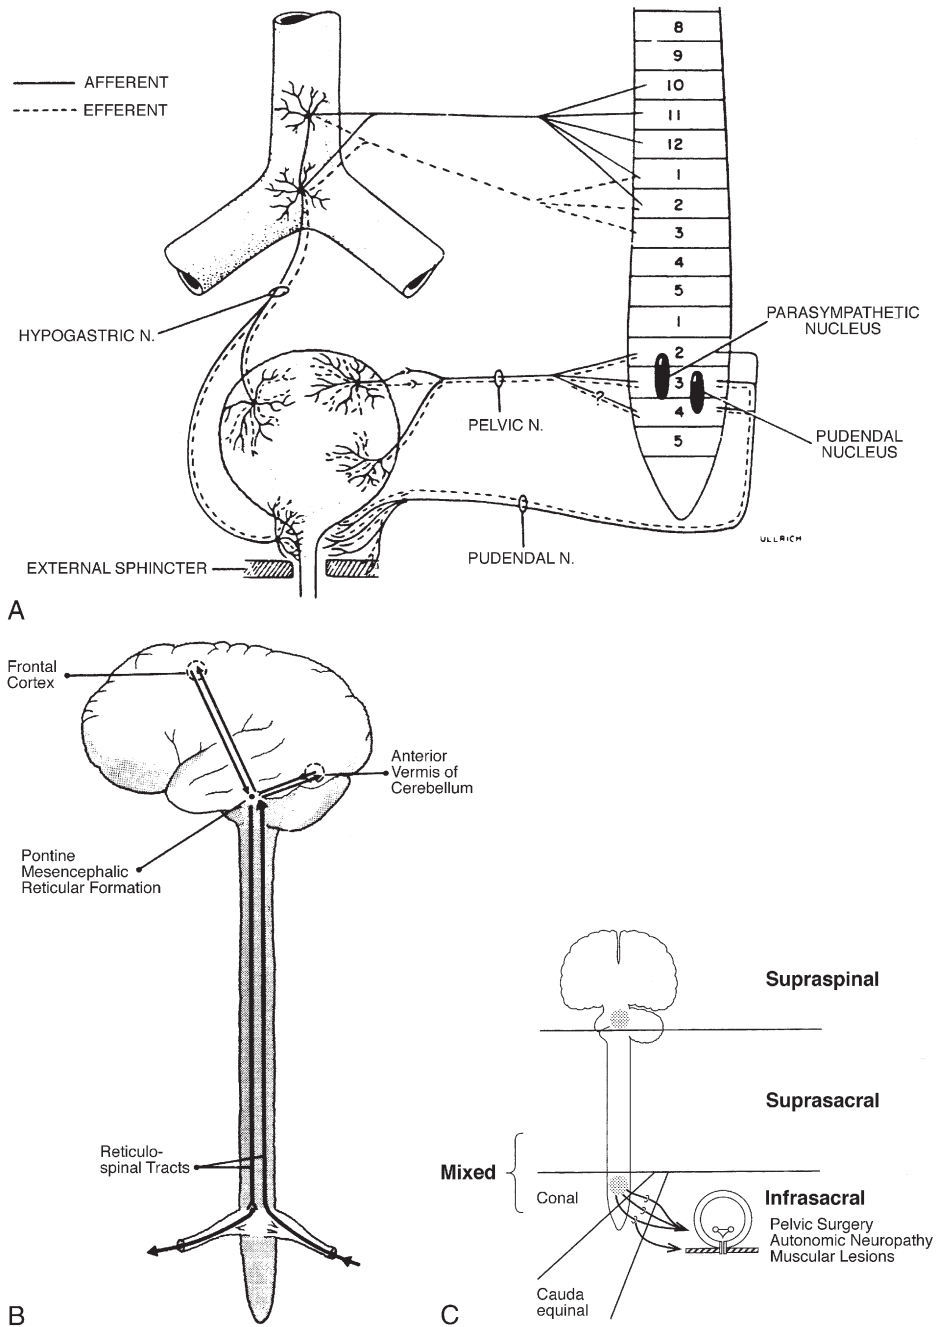

Figure 29-3 ■ Neurophysiology of the pelvic floor. (A from Blaivas JG: Management of bladder dysfunction in multiple sclerosis, *Neurology* 30:12, 1980; B from Bradley WE, Brantley SF: Physiology of the urinary bladder. In Harrison JH, Gittes RE, Perlmutter AD, et al, editors: *Campbell's urology*, Philadelphia, 1978, WB Saunders; C from Braddom RL: *Physical medicine rehabilitation*, ed 2, Philadelphia, 2000, WB Saunders.)

sacral plexus provides both efferent and afferent innervation; some of the fibers of the pudendal nerve intermingle with the autonomic pelvic nerves.^{47,54,77} The somatic nerves can modulate the autonomic system. The complexity of the innervation of the pelvis and the influence of neurotransmitters in the bladder wall, as well as the control of higher CNS regulation (see Figure 29-3, B and C), can be appreciated in observing the filling and emptying phases of the bladder.

Because of its topographical position the pudendal nerve is susceptible to nerve injury from stretching or compression (Alcock canal) from a fall on the buttocks or from slamming on the brake pedal during a motor vehicle accident (may alter pelvic alignment). Patients with pudendal nerve injury often have no problems when supine or standing but pain when sitting. Childbirth, especially during delivery of large babies, also can cause pudendal nerve injury.¹³

Sensory Innervation

The sensory innervation in the pelvic region is important to evaluate and restore in clients with motor control problems because sensation drives motor responses. The pudendal nerve carries both sensory and motor fibers. Absence of feeling in the perineal area can be caused by stress and memory of pain (e.g., abuse). For example, a client with symptoms of incontinence and pain with sexual intercourse and a history of considerable continuous stresses stated after few treatments, “I thought my pelvic region was dead; I had no clue how little I could feel before sensory awareness training. Feeling the pelvic floor, I can now contract and relax the muscles much better.” Sensory innervation of the bladder comes primarily from proprioceptive nerve endings in the bladder and urethra. The afferent neuronal visceral system probably enters the spinal cord by way of the sacral and lumbar segments. These afferent nerve tracts may regulate pain, the absence of pain, and the feeling of having a full bladder.^{47,77}

Filling and Storage Phase

The bladder is a smooth involuntary muscle with voluntary control. It stores the urine until it is emptied voluntarily. The normal bladder is a low-pressure system that accepts urine without a concomitant rise of internal pressure.^{13,48} This is produced by sympathetic stimulation of the β -adrenergic receptors in the bladder wall. The sympathetic nervous system inhibits the parasympathetic activity while sympathetic stimulation of the α -adrenergic receptors in the internal sphincter muscle causes constriction and a rise in urethral pressure.^{13,48} During the filling phase the bladder is inactive until it holds approximately 350 to 500 mL of urine, even though a first sensation of filling may occur with 150 to 250 mL of urine in the bladder.⁷⁷ When the bladder is full the receptors send a signal to the cortical centers of the brain, and as a result a voluntary micturition reflex is initiated to empty the bladder (see Figure 29-3, B).^{13,48,77}

Involuntary contractions of the detrusor during the filling phase cause frequency and urgency (OAB syndrome). In neurological patients this is called *hyperreflexia*; if idiopathic, it is considered bladder instability.^{47,48} Individuals with a hypersensitive bladder or painful bladder syndrome (interstitial cystitis) empty their bladders frequently to avoid pain, which results in a functionally small bladder. When the sensation of bladder filling is decreased or absent, the bladder will overflow and urine can back up into the kidneys, causing dysfunction. Symptoms of overflow from the over-stretched bladder frequently cause dribbling. All these problems require thorough medical investigation of possible causes.

Preconditions for a normal storage phase as described by Henschel⁷⁸ include good distensibility of the bladder, stable bladder without premature detrusor contractions (adequate bladder sensation, i.e., intact CNS and peripheral nervous system), no obstruction between kidney and bladder, and positive urethral closure at rest and under load.

Emptying Phase

Micturition, or voiding, depends on the coordinated activity of the urethra and the detrusor muscle. The pelvic floor (levator ani and external sphincter muscles) has to relax when

the detrusor muscle contracts. This occurs with activation of the parasympathetic cholinergic receptors in the bladder muscle. An afferent stimulus from the pelvic nerve (see Figure 29-3, A) reaches the PMC by way of the spinal cord. Efferent tracts inhibit the activity of the pudendal nerve, which results in relaxation of the external sphincter and levator ani. At the same time, sympathetic activity at the bladder neck is inhibited and postganglionic parasympathetic neurotransmitters are stimulated. This results in detrusor contraction.^{13,19,47,77}

From the PMC, signals are also sent to the cerebral cortex, which allows voluntary control. An individual therefore can override the signal to empty the bladder and wait to empty it later or can empty the bladder when there is no signal that it is full. Suprapontine control of bladder function is a result of the modulating control of the brain stem, hypothalamus, and cerebral cortex.^{1,77}

Many reflexes are involved in urine storage and voiding at various levels. The sacral reflex, for example, can be elicited by light stroking at the lateral aspect of the anus and should result in a symmetrical contraction of the anal sphincter (“anal wink”). Absence of the anal wink can be an indication of a neurological problem at S2 to S4, resulting in weakness or paralysis of the pudendal nerve.¹³ The micturition reflex, on the other hand, depends on an intact PMC in the brain stem.⁷⁷

Prerequisites for a normal emptying phase include intact neural control, adequate functioning of the detrusor, no increase in resistance to voiding by obstruction, and adequate pelvic floor relaxation.⁷⁸

Pharmacological Treatment of Pelvic Floor Dysfunction

The great number of receptors in the bladder wall, as well as the ability to influence skeletal muscles with muscle relaxants, is the basis for pharmacological treatment of the symptoms found in patients with incontinence. Other treatments for urinary dysfunction address hormonal deficiency. Estrogen, for example, was prescribed for many postmenopausal women with symptoms of leakage and a feeling of dryness in the vaginal area.^{13,47,48,51} However, treatment with oral estrogen is controversial, and reports of its efficacy for treatment of UI are mixed.²⁶ Topical vaginal application of Premarin and other drugs may be beneficial in the treatment of UI because estrogen deficiency decreases the turgor of the submucosa around the urethra.

Individuals with enuresis (bedwetting at night) or urge incontinence are frequently prescribed oxybutynin (Ditropan). Another prescribed drug is imipramine, an antidepressant. Patients with instability of the detrusor often receive anticholinergic agents or antispasmodic medications.

α -Adrenergic agents such as phenylpropanolamine or ephedrine increase striated muscle tone and are therefore used with SUI. α -Adrenergic antagonists, such as drugs for treatment of hypertension, can worsen incontinence. Caffeine, alcohol, and diuretics can increase urinary frequency, urgency, and SUI.^{11,13,47,79} Antipsychotic agents are also α -adrenergic antagonists and reduce urethral pressure and can be used for treatment of urinary retention.¹³ The problem with pharmaceutical treatment is the side effects, some of which may affect the pelvic floor adversely (e.g., constipation). Other clients describe severe dryness

in the mouth and the need to drink or suck on candy constantly. Many other side effects have been described by the people taking these drugs, including dizziness, blurred vision, somnolence, confusion, hypertension or hypotension, and dryness of the mucosal membranes of the mouth, vagina, and eyes.²⁷

New drugs have entered the market promising fewer side effects and help for patients with OAB syndrome and urinary frequency. Duloxetine, for example, works at the level of the spinal cord, inhibiting serotonin and regulating noradrenaline and thereby increasing the time between voids.

Solifenacin succinate is an antimuscarinic agent that blocks muscarinic receptors on bladder smooth muscles, relaxing them. It is therefore indicated for relief of urinary frequency, urgency, and UI associated with OAB syndrome. Other commonly prescribed antagonists of muscarinic acetylcholine receptors include darifenacin, fesoterodine, oxybutynin, propiverine, tolterodine, and trospium.⁸⁰

These muscarinic receptor antagonists work on the OAB by relaxing the smooth muscle tissue in the bladder.

For clients with MS, anticholinergic medication is recommended for the treatment of neurogenic overactivity of the bladder. Intravesical treatments with vanilloids and botulinum toxin have been proposed, as well as sublingual cannabinoids. DasGupta and Fowler⁸¹ also state that sildenafil citrate has been shown to be efficacious as a proerectile agent. Sildenafil (Viagra) has been shown to be efficacious in men with SCI; it also may improve arousal in women with SCI and is being evaluated for female patients with sexual arousal disorder.^{82,83}

Intravesical resiniferatoxin (an analog of capsaicin with more than 1000 times its potency in desensitizing C-fiber bladder afferent neurons) is a new therapy for detrusor hyperreflexia for SCI, MS, and other neurologically impaired patients.⁸⁴

The motivation to achieve a functioning pelvic floor without full dependence on drugs is high. Physical therapy may be the main contributor to reaching that goal. The combination of drug therapy and physical therapy can be helpful, and the therapist should know which medications the client is taking as well as their side effects.

EXAMINATION, EVALUATION, AND INTERVENTION

Medical Evaluation

Before a referral to physical therapy, a physician, preferably a urologist or gynecologist, should evaluate a patient with any urinary dysfunction. The patient's history will lead the physician to select appropriate diagnostic tests, including a urodynamic test, which helps explore the extent of the lesion, rule out causes that require other treatments, and determine if physical therapy may help.^{13,47,48} Adams and Frahm⁷⁹ provide an excellent overview of the causes and the examination and intervention possibilities. Part of the evaluation process should be a bladder diary or voiding log completed over a several-day period (if possible including a weekend day) so that a clear picture emerges about fluid input and output as well as when frequency and incontinence episodes occur and to what extent. Patients can also weigh their pads or liners for 24 hours and that way get a

clear picture of the loss of urine in 24 hours. Both “tests” can be repeated after a series of treatments to measure progress. If the physician has not done these tests, they should be included in the physical therapy evaluation.

Physicians should also include a muscle strength test of the levator ani when seeing a client with symptoms of UI to determine how much the muscle weakness contributes to the problem.^{48,67,79}

Physical Therapy Examination

It is important to take a history of the client's problem in a quiet and pleasant setting. The ideal situation is a private room because it may be very uncomfortable for the client to discuss very private matters between curtains. Handouts and pictures of anatomy should be available in order to explain anatomy and physiological processes to the client. During the first visit a bladder diary and other evaluation tools or outcome measures such as the female NIH symptom index (NIH-CPSI), the Incontinence Impact Questionnaire—Short Form (IIQ-7), or other available questionnaires should be used. This enables the therapist to understand the extent of the problem. The same questionnaires should be used for reevaluation to verify progress and outcome. Only if the therapist listens carefully and attentively will the client provide necessary information. The therapist should always ask herself or himself what system of the body may be involved and require treatment. For example, a client who complains of feeling bloated or congested in the abdomen may have “trapped” fluid in the abdominal cavity and may benefit from manual lymph drainage (MLD). Lack of leakage of urine and difficulty initiating a urinary stream may be caused by hyperactive pelvic floor muscle, in which case strengthening exercises would be of no value. Urgency and frequency symptoms may necessitate bladder training, “Cold feet” or difficulty sleeping can indicate an autonomic system dysfunction. A frustrated and depressed state could be a result of limbic system dysfunction and could alter posture and pelvic floor muscle tone.

Careful observation of the client and good listening skills will help establish the client's level of functioning. At the same time, it validates the client's feelings, observations, and concerns, making the client feel taken seriously. This promotes client-therapist interaction and effective treatment. It is very important for the therapist to make sure the client understands why he or she has the problem and to empower the client to be part of the solution. The focus will be regaining the client's health. The first session also needs to be educational, with pictures or models of the pelvic floor, so that the patient understands how this invisible structure of the body works. The therapist should be able to explain to a 78-year-old patient with difficulty voiding after UTI that the advice of her doctor 20 years ago “to void each time she sees a bathroom” had decreased the volume of the bladder severely (maximum voiding was $\frac{2}{3}$ cup, whereas the bladder can normally hold 2 cups) and this probably had decreased her ability to empty her bladder completely.

Usually, physical therapists trained in women's health assess the muscle strength of the pelvic floor of their clients by digital internal palpation. This may not necessarily take place on the first visit, and the patient must consent to such an evaluation. Because of the danger of re-traumatization,

internal examination and use of instruments in the vagina (such as biofeedback probes) should not be applied to clients who have been abused.^{85,86} Therapists should be reminded that such patients may say yes when they mean no because of their past experiences. It is possible to perform external palpations with the consent of the client and use other tests for evaluation of the extent of leakage and weakness with stress incontinence as described earlier, or the pad test, which can be performed by physicians or therapists.^{47,48,79,87}

Conceptual Framework for Treatment

Therapy begins with a patient interview and appropriate tests and measures, which are necessary to determine which structures and systems are involved and what kind of impairment or activity limitations can be identified.^{8,88,89} The information gathered leads to the development of a diagnosis and prognosis and selection of the intervention and, hopefully, the most efficacious treatment outcome.

Therapists working with female clients with incontinence have to ask about childbirth and related trauma or surgery, prolapses, and procedures such as cesarean delivery, hysterectomy, episiotomy, or sling suspension. Different questions need to be asked when a male patient is evaluated because the reason for his pelvic floor dysfunction will likely be quite different.

Evaluation of Female Clients with Incontinence

An example of an examination-evaluation process that might be used for female clients with incontinence is shown in Figure 29-4.

Question 1

This information gives the therapist a general idea of why the client was sent, how long the problem has existed, whether other illnesses may have contributed to the problem, and which body systems may be involved. Does the problem contribute to the inability to be socially active, travel, see friends, or pursue hobbies?

Question 2

The therapist learns from this information whether damage to the muscles or nerves supplying the pelvic floor muscles may be present as well as whether the surgery coincided with worsening, improvement, or the onset of symptoms. Because surgery produces scars, the possibility of scars being part of the problem should be considered. The therapist may also inquire if, for example, lifting the baby out of the crib increases the symptoms.

Even in older patients the questions about childbirth are important because, for example, a difficult delivery may cause problems much later in life. In some patients questions about the onset of menstruation or menopause may be indicated if, for example, hormone imbalance may be a contributing factor to vaginal dryness and pain with intercourse. It could also be that only later in life does fecal incontinence become a problem, although it originally stemmed from an injury sustained during delivery.

Thought Process. If the heaviest child weighed 9 pounds at birth, pudendal nerve damage could be contributing to the pelvic floor problem. The question of diabetes is

important in the medical history because diabetic mothers are known to sometimes have big babies. The scars must be examined, especially if the client reports pain or constipation. With a hysterectomy, the bladder is not “stabilized” by the vagina, which normally leans against the bladder.

Question 3

Scars, especially in the pelvic and abdominal region, can cause pain, which can radiate to the hips or pelvic region. They can also contribute to constipation. Scarring may also necessitate more extensive examination of the thoracolumbar junction and mobility of both hips. The quality and intensity of pain may hint to autonomic or musculoskeletal dysfunction.

Thought Process. Any surgery can cause scar tissue or muscle weakness in the area surrounding the pelvic floor. Observation and palpation of the abdominal cavity may be necessary. If the surgery was recent, vigorous exercises should be avoided, and a review of body mechanics and lifting may be indicated.

Question 4

Diabetes and heart conditions can lead to increased fluid input and output. Diabetes also often causes a decreased sensory awareness of the bladder and decreased bladder contractility. Cancer can cause bony involvement, swelling, pain, and so on. Back pain can be caused by injuries to the back or injuries to the pelvic area, including the viscera. Pulmonary conditions may cause frequent coughing and leakage, which may prevent the patient/client from leaving the house for social activities.

Thought Process. Urine output can be increased in a patient with diabetes. A patient with frequent bladder infections may not drink enough water. The type of drink may stimulate the bladder, and the influence of medications on the medical condition may affect the muscle tone of the pelvic floor. Exercises need to be altered in clients with back pain or metastasis. Emphasis on tightening the pelvic floor before coughing needs to be addressed first in clients with pulmonary conditions. Weakness of the pelvic floor muscles can also contribute to low back pain and highlights the importance to look at the entire abdominal compartment. In addition to the pelvic floor muscles the patient may need to strengthen the transverse abdominis muscle to stabilize the back. Diaphragmatic breathing has to be addressed as well.

Question 5

Remember that antihypertension drugs, diuretics, antidiuretics, and cough medicines can affect continence.

Thought Process. Is the client aware of what drugs may affect the incontinence problem? Coffee and alcohol are also considered drugs and can increase frequency of urination. For example, patients who have undergone prostatectomy and who already do well staying dry usually report problems of incontinence when drinking alcohol.

Question 6

This section obtains information about the extent of the problem of the pelvic floor dysfunction and what other areas may need to be addressed.

EVALUATION FORM	
<p>1. Medical diagnosis:</p>	<p>Onset:</p>
<p>2. Childbirth information: <i>How many gestations? births?</i> <i>weight of heaviest child?</i> <i>Cesarean, Y/N episiotomy</i> Vaginal/abdominal surgeries: <i>bladder suspension, hysterectomy, other?</i></p>	<p>3. General surgical history: <i>Abdominal surgeries (please circle): hernia, appendix, gallbladder, kidney, laparoscopy, hemorrhoids, other?</i></p>
<p>4. Medical history: <i>Diabetes: Y/N heart problems Y/N</i> <i>hypertension Y/N cancer Y/N</i> <i>kidney/bladder infections Y/N</i> <i>back pain Y/N neck pain Y/N asthma Y/N</i> <i>bronchitis Y/N</i> <i>other (e.g., neurological conditions)</i></p>	<p>5. Medications:</p>
<p>6. Current symptoms: <i>Do you have (please circle if yes) any leakage: with coughing, sneezing, straining?</i> <i>While running and going up- or downstairs?</i> <i>When resting? Are any other activities causing leakage?</i> <i>Do you have: hesitancy, urgencies, do you push or strain?</i> <i>(Please circle when applicable)</i> <i>Does your problem cause you to have sexual dysfunction?</i> <i>Do you have any pain? If yes, please describe:</i></p>	<p>7. Urination pattern: <i>How often do you have to urinate?</i> <i>day night</i> <i>How often do you leak?</i> <i>daily times a week infrequent</i> <i>Do you use one of the following during the day (d) or night (n)?</i> <i>(Please circle and indicate how many):</i> <i>liners d n pads d n</i> <i>adult protection d n</i></p>
<p>8. Daily fluid intake (cups, glasses): <i>How much do you drink?</i> <i>water coffee tea soda</i> <i>alcohol citrus</i> <i>other:</i></p>	<p>9. Bowel habits: <i>Regular Y/N, incontinent of bowel Y/N, gas Y/N, constipation Y/N. Do you use stool softeners Y/N, fiber rich-diet Y/N?</i></p>
<p>10. History of treatment: <i>Have you ever been treated for this condition before? Y/N Did you do Kegel exercises? Y/N</i> <i>Other treatments? Y/N</i> <i>Please describe:</i></p>	<p>11. Psychosocial history: <i>Current/previous employment: does it involve lifting?</i> <i>Hobbies, sports:</i></p>
<p>12. Treatment goal of client:</p>	
<p>13. Objective: <i>(Evaluate posture, ability to do diaphragmatic breathing, pelvic tilt, ability to "feel" the activity of pelvic floor muscles; evaluate muscle tone and strength of the pelvic floor muscles and of the surrounding muscle if indicated; evaluate scar tissue when applicable; check for contraindications.)</i></p>	
<p>14. Evaluation/Goal:</p>	<p>15. Intervention:</p>

Figure 29-4 ■ Evaluation form.

Thought Process. Which impairment needs to be addressed first, and does the medical diagnosis match the symptoms? Are any physical or emotional reasons causing sexual dysfunction and pain? Inability to have orgasm, pelvic pain, and dyspareunia (pain during intercourse) may be caused by hyperactive pelvic floor muscles and necessitate relaxation exercises for the pelvic floor muscles. Retention and hesitancy may also indicate tightness of the pelvic floor muscles. Urgency and frequency may benefit from bladder training to enable the patient to be socially

active and participate in traveling, going to the theater, and so on.

Question 7

The pattern must be seen in light of the history and daily fluid intake. The information of the voiding diary should match the urinary pattern. Normal urination is six to eight times per day at a volume of at least 250 mL (9 oz), with a maximum of 500 mL. Many adults normally get up once a night to urinate; elderly people may need to get up twice each night.⁴⁷

Question 8

Women normally drink and void 1500 to 2500 mL/day (50 to 80 oz). Aside from water, drinks that are carbonated, coffee, tea, citrus drinks, alcohol, and spicy foods are bladder irritants and can cause urgency or frequency.

Thought Process. A client who drinks below-average amounts of fluid may develop urinary frequency because the bladder is no longer used to store normal volumes. This prevents a patient from going to concerts and other events and being socially active. A person who drinks soda or alcohol before going to bed needs to evaluate if a change in drinking habits affects the incontinence or urgency. This can improve nocturia and help the patient to have a restful night.

Question 9

Many reasons exist for constipation; it can be related to difficulty going to the bathroom at work, being always in a hurry, or not relaxing the pelvic floor because of improper leg support when sitting on the toilet.⁹⁰ HPFS, eating hastily, and consuming constipating foods can contribute as well. Gastrointestinal problems, especially when combined with chronic pelvic pain or low back pain, can be the result of sexual abuse.⁹¹ Fecal incontinence can result from weakness of the anal sphincter muscle, occult injuries or tears from difficult deliveries, hemorrhoids, insufficient fiber intake, poor bowel habits, and so on.

Thought Process. Eating habits may have to be reviewed as well as behavior during defecation. Pressing down, holding the breath, and straining during defecation as a result of constipation weaken the pelvic floor muscles and do not help clients who have prolapse. The abdomen needs to be evaluated and possibly treated (e.g., teach client colon massage, postural correction when sitting on the toilet, and diaphragmatic breathing). Should sexual abuse be suspected for any reason? Does the client appear to have low self-esteem? Are signs of fear or nervousness present during the evaluation, or a cluster of symptoms that could indicate sexual abuse?

Question 10

The therapist must find out if the patient has been treated for this condition before and whether the treatment was successful.

Thought Process. To motivate a patient, do not begin a treatment with exercises or modalities that have been used unsuccessfully in the past. The selection and explanation of the treatment intended are critical to success. Teach exercises the patient can do easily during the day, possibly combined with functions of daily life (lifting the baby), getting up from a chair, or favorite exercises. Custom tailor the exercises to activities the patient wants to do again (e.g., at home, practice delaying micturition while doing activities in house or garden to increase the time span between voids).

Question 11

Information about employment gives the therapist input about how work may contribute to the problem. How much does posture affect the pelvic floor dysfunction? How can exercises be integrated with activities at work? Hobbies and sports can be important motivational factors, but how the exercises or hobbies are done must be reviewed.

Thought Process. If poor postural alignment is part of the problem, stretching and strengthening exercises may have to be practiced for a neutral posture to be achieved. A client who can train the pelvic floor while doing his or her favorite exercises will be highly motivated. If the exercises can be performed while lifting at work, for example, the training effect will be greater.

Question 12

Client and therapist goals should ideally match, and goals should be directed toward activities the patient was able to do before he or she had the problem, such as travel without fear of leakage or embarrassment, and so on.

Thought Process. If a great discrepancy is present, more explanations or other questions may be required in the objective evaluation. Try to set a goal with the client that is achievable within a reasonable time frame. Then set new goals. Initially the goals can be having fewer episodes of wetness, sleeping through the night, having to wear a reduced number of pads, or urinating less frequently.

Question 13

Summarize the findings and consider the general cognitive status of the client and her or his mood. The therapist's goal should reflect the prognosis and the extent of the impairment or disability. The treatment intervention should be geared to an achievable goal that allows for more activity and participation and reduces social isolation.

Thought Process. A client who is cognitively impaired may require a different treatment approach. Individuals with good body awareness usually learn exercises and correct breathing patterns much faster and may require fewer treatments before seeing changes.

Question 14

Many treatment possibilities are available to choose from. Often various concepts lead to the same goal. The selection also depends greatly on the therapist's experience and preference for a certain type of treatment. The summary of the evaluation should be based on the International Classification of Functioning, Disability and Health (ICF).

Thought Process. The therapist should determine the patient's/client's level of functioning and consider the influence of the environment: Are there stairs that are obstacles within the home or that prevent access to the garden? Is help available from family or friends? The therapist also needs to think about which treatments or interventions can maximize the client's functioning and measure the outcome.

Body function and structures have to be evaluated to determine the extent of the impairment. The activity limitations and participation restrictions have to be considered in order to work to improve the activity level and achieve participation in various life situations. This has to be considered in connection with environmental factors that can help the patient to live a fulfilled life.

CASE STUDIES

Case Studies 29-1 and 29-2 give insight into how physical therapy can help clients with incontinence. Before presenting another case study, the conventional treatment approach to incontinence is discussed briefly, and then the Heller and Tanzberger concepts⁹²⁻⁹⁸ are described in more detail.

CASE STUDY 29-1 ■ FEMALE CLIENT WITH INCONTINENCE

A 56-year-old woman was sent to therapy for biofeedback training and proper instruction in Kegel exercises. This alert librarian had a long history of mixed incontinence. Its onset had been approximately 19 years previously, but the condition had improved for 3 to 4 years after a hysterectomy and bladder suspension surgery in 1989. The client had had two vaginal deliveries and one episiotomy, and her heaviest child had weighed 8½ pounds. The client had urgencies more than once an hour and used one or two pads a day; wetting occurred one to three times a week. The client drank one cup of coffee in the morning and approximately two sodas per day. Her diet was regular, but she had constipation and took stool softeners.

The client liked to do brisk walking but had problems pursuing this activity because of the leakage. The client had received instructions for Kegel exercises elsewhere, but they did not help her. She had a history of chronic back and sciatic pain. The objective evaluation revealed good sitting and standing posture. Because the client exhibited a sensory awareness of the pelvic floor muscles, an internal strength test at that time was deferred. Her general strength appeared to be good, and the muscle tone of the abdomen was within functional limits.

IMPAIRMENT

The client had a poor awareness of a pelvic tilt motion and was a chest breather. There was incoordination of breathing with activity of the abdominal and back muscles and the pelvic floor muscles.

Activities

The client was unable to exercise without leakage and was required to wear one or two pads during the day. The assessment revealed a client who appeared motivated to achieve goals.

Participation

The patient no longer went to the theater, because of her urgencies.

GOALS

Goals included the ability to cough and sneeze without leakage, elimination of the need to wear pads during the day, ability to resume walking, ability to perform home exercises independently, and ability to participate in social activities without fear of leakage of urine.

INTERVENTION

She received a total of 10 treatments within 3 months based on the Klein-Vogelbach and Heller and Tanzberger concepts.^{92-98,116-118} Treatment included breathing exercises, coordination of diaphragmatic breathing with pelvic floor contraction, and instruction in Swiss ball exercises for strengthening the pelvic floor muscles in all planes and during bouncing.^{97,119,120} Colon massage,¹²¹ treatment of scar tissue,¹²² and biofeedback and electrical stimulation were considered as options if no improvement with the previous exercises had occurred after three to five treatments.

The client returned 6 days after the initial visit and reported decreased leakage with laughing. She received a colon massage and gentle scar tissue massage as well as more challenging exercises with the Swiss ball and elastic bands. Instruction in proper lifting with contraction of the pelvic floor was part of the treatment. A return visit was scheduled 3 weeks later for an additional treatment for the abdomen and exercises. The client reported feeling better, with improvement of the back pain, which she had had for 2 years. The abdomen had felt much looser after the treatment, and leakage with coughing and sneezing was further reduced. The plan was to review the exercises in 4 to 6 weeks. The client called 3 months later to report that she did not need further treatments.

TREATMENT OUTCOME

The client was able to hold urine for 2 to 3 hours without wearing pads. She had no more wetting episodes, and for safety she wore pads only when doing brisk walking for 45 minutes. Only occasionally did the client need to get up at night to urinate. She was able to travel and participate in all social activities she desired.

CASE STUDY 29-2 ■ MALE CLIENT WITH INCONTINENCE

Adjustments are required when taking the history of a man with pelvic floor problems (Figure 29-5). The client's answers are written in script typeface. A summary of treatment for one case follows.

The patient reported urgency, weakness of pelvic floor muscles (lost urine with straining and lifting the legs), and nocturia. He was educated about bladder training to improve the urgency by increasing his sensory awareness of the voiding pattern. He was instructed to count during urination and to keep a record of when he had gone to the bathroom last, what he had been drinking, and how much in order to evaluate whether the signal to void was correct. The patient knew that a high count during urination meant that the bladder was holding a greater volume than when the number was low. He therefore became more aware of when the urgency did not meet the need and learned

to become his own "master" over the bladder. He also was instructed to do deep breathing to control the urge and to do quick flicks while standing without moving for one minute until the urgency disappeared.

In addition, the patient was instructed in fast fiber training and coordination with breathing. Before coughing or sneezing the client was instructed to do a quick contraction of the pelvic floor muscles. Slow muscle fiber contractions were taught as well, with submaximal contractions held for 6 to 10 seconds, increasing the repetitions until he could hold 10 times for 10 seconds with relaxation and breathing exercises between repetitions.

By the first return visit 4 weeks after the initial examination, the client was able to hold urine for longer periods and only needed to get up once during the night. The client also

Continued

CASE STUDY 29-2 ■ MALE CLIENT WITH INCONTINENCE—cont'd

reported being able to attend water aerobics classes without loss of urine. He was exercising for approximately 20 to 30 minutes each day. The exercises, based on the Heller,^{94,95} Klein-Vogelbach, and Tanzberger concepts,^{92,93,96-98,116-120} were reviewed with the client and new exercises were added. The client purchased a Swiss ball, and a return visit was scheduled approximately 3 weeks later. Before the next scheduled visit the client called to report that he was doing fine.

IMPAIRMENT

Impairments included weakness of the pelvic floor muscles, discoordination of breathing and pelvic floor contractions, and absence of tightening of the pelvic floor muscles before coughing, sneezing, or lifting his legs. The patient also had symptoms of OAB, including urgency and nocturia.

Activity

The patient had stopped doing water aerobics for fear of leakage and was worried about his urgency when teaching school at night.

Participation

Because of fear of leakage the patient's sexual life and intimacy were more stressful than he desired.

OUTCOME

The client no longer had leakage, and did not need to wear pads at night. He resumed all activities without problems, and intimacy and sexuality no longer caused stress and anxiety. He was able to exercise at home independently and did not require further treatment. His next attempt was to maintain his condition without the bladder medication tolterodine (Detrol).

CONVENTIONAL TREATMENT OPTIONS FOR STRESS URINARY INCONTINENCE, URGENCY URINARY INCONTINENCE, MIXED INCONTINENCE, AND OVERACTIVE BLADDER

Most therapists treating patients with incontinence are familiar with biofeedback, electrical stimulation, and vaginal cones, which are often used in combination with Kegel exercises. Kegel exercises have provided only limited success. Henalla and colleagues⁹⁹ found that 65% to 69% of patients in two hospitals became dry or significantly improved with exercises only. Wall and Davidson⁶⁸ stated that exercise programs have a place in the treatment of genuine SUI. Miller and colleagues⁶⁹ demonstrated how tightening the pelvic floor muscles before a cough significantly diminished leakage from the bladder. Bø and colleagues^{100,101} found that intensive exercises taught by physical therapists over a long period provided better results, which was in agreement with a Danish study by Tilbæks.¹⁰² Meaglia and colleagues¹⁰³ stated that motivation, close supervision, and encouragement are important for successful treatment. Holley and colleagues¹⁰⁴ found that a great number of patients stopped exercising because of lack of motivation. Bø and colleagues¹⁰⁵ found that intensive pelvic floor muscle training seen short-term was not maintained 15 years later. Bump and colleagues⁶⁶ found that brief verbal instructions in Kegel pelvic floor muscle exercises were not sufficient. Byl and colleagues¹⁰⁶ investigated the effect of repetitive movements (three to 400 trials per day) in skeletal muscle in primates compared with variable repetitive movements and found that the repetitive movements caused interference with motor control. Repetitive movements are also a problem in patients with focal dystonia. Stereotypical and nearly simultaneous movement causes problems in the brain.^{107,108} Variable trials preserved motor control. The question must be asked: Is performing Kegel exercises 300 times a day beneficial? The question is appropriate because these exercises train the muscle in isolation and not as part of a functional activity. Do individuals believe that Kegel exercises do not help and therefore discontinue them? Similarly, a therapist would not ask a client to perform isometric exercises

of a skeletal muscle 300 times a day and continue 80 times a day for the rest of the client's life once improvement became noticeable. This action does not seem any more appropriate if done with the pelvic floor muscles.

In a 1999 study by Salamey and Nof,¹⁰⁹ approximately 72% of the questioned therapists stated that they felt prepared to instruct patients in pelvic floor (Kegel) exercises. Only 18% of therapists were prepared to discuss UI with their patients, and the majority were not prepared to perform electrical stimulation, biofeedback, or other conservative treatments. For many years Kegel exercises were what the majority of therapists learned in the United States as treatment for incontinence.

Biofeedback and electrical stimulation, as well as vaginal cones, are recognized treatments for SUI. They are used either in combination with exercises or alone.^{101,110-112} The effect of electrical stimulation alone on stress and urgency incontinence has been conflicting.^{101,113} Bø¹¹³ recommended its use only when a person is not able to contract the pelvic floor muscles and proposed continuing with the exercises when the individual is able to contract the pelvic floor muscles. Another study by Bø and colleagues¹⁰¹ found pelvic floor exercises to be superior to electrical stimulation, vaginal cones, and no treatment.

The OAB syndrome was first defined by the International Continence Society (ICS) in 2002. Abrams describes this bladder storage problem as a combination of urgency with or without loss of urine, frequency, and nocturia.¹¹⁴ Its prevalence is high, and it affects men and women. Twenty-four percent of men and 31% of women in a study by Temml and colleagues¹¹⁵ reported a negative impact of OAB on sexuality. Even though it is common to treat the patients with antagonists of muscarinic acetylcholine receptors, physical therapy is very beneficial, and treatment has to address all three symptoms and include bladder training.

Exercises based on the Klein-Vogelbach and the Tanzberger and Heller concepts, the most common form of exercises for incontinence and pelvic floor dysfunction taught in Germany,^{92-98,116-118} have been introduced and taught in a modified version in the United States by Carrière.^{119,120}

Evaluation of Male Clients with Incontinence including Treatment Example

Name: _____ **DOB:** 1926, 72 years old

Tel # _____

MD: _____ **Therapist:** _____

Diagnosis: Status post prostate surgery 10 years ago

Onset: 1989

Surgical history: Abdominal surgeries (please circle): hernia, appendix, gallbladder, kidneys, laparoscopy, prostate, hemorrhoids, other? *Hernia, appendix, radical prostatectomy 10 years ago; hip and knee surgery 3 years ago*

Medical history: DM: heart problems NCA pulmonary disease bladder or kidney infections history of bed-wetting? other: _____

Medication: *Detrol for the urgency, Dilosec for heartburn, medication for depression; sleep medication causes urinary accident*

Current symptoms and examination process:

Do you have difficulty urinating because of strictures (scar tissues in urinary tract, enlargement of prostate)? If yes, does your doctor know? Was any procedure done? *Strictures from the surgery were treated several times*

Do you have (please circle if yes) any leakage; with coughing, sneezing, straining? while running and going up or downstairs? *With straining and lifting the legs* when resting? Are any other activities causing leakage? *No*

Do you have: hesitancy, dribbling, urgencies? do you push or strain? (Please circle if applicable) *urgencies*

Do you have erectile dysfunction? *No*

How often do you have to urinate during the day? *Within normal limits* **night?** *Two times*

Do you have any pain? (If yes, please describe): _____

Daily fluid intake: (cups, glasses) **How much do you drink?** *6-8 glasses*

Water *at night* coffee *tea herb* soda alcohol *1 martini* citrus other: _____

Do you urinate: sitting down? *At night* Or standing? (please circle)

Do you use one of the following during the day or night? (Please circle and indicate how many):

Liners: **n pads:** **adult protection:** *at night only*

Bowel habits:

Regular incontinent of bowel gas constipation Do you use stool softeners? fiber-rich diet

History of treatment:

Have you ever been treated for this condition before? **Did you do Kegel exercises?** *Yes, the exercises did not help.*

Other treatment? Describe: _____

Psychosocial history:

Current/previous employment: does it involve lifting? *Teaching night classes*

Hobbies, sports: *Water aerobics*

EVALUATION PROCESS

What is your treatment goal? *To be able to lift legs and do water aerobics without leaking, not to have to wear "Healhtdry" at night.*

Objective: (evaluate posture, ability to do diaphragmatic breathing, pelvic tilt, ability to "feel" the activity of pelvic floor muscles; evaluate muscle tone and strength of the pelvic floor or surrounding muscles when applicable; evaluate scar-tissue when applicable)

Patient with a good posture and good mobility of the pelvis. Because the patient became aware of his pelvic floor during the evaluation, muscle testing of the pelvic floor was deferred. The patient was also a chest-breather and was instructed in diaphragmatic breathing.

Impairment: *poor awareness of the pelvic floor muscles, dyscoordination of diaphragmatic breathing with the pelvic floor while lifting legs, coughing, etc.*

Functional Limitation: *unable to lift legs or do water aerobics without leakage of urine. Leakage at night, urgencies at night*

Assessment: *very motivated client who stated during the evaluation that he now understood the function of the pelvic floor.*

Intervention: *teaching of diaphragmatic breathing and coordination of breathing with the muscles of the entire abdominal compartment.*

Goal: *having to get up at night no more than once. No Healhtdry at night; ability to lift legs, do water aerobics without leakage of urine.*

Plan: *teaching correct breathing and functional exercises based on the Tansberger concept⁷¹ to restore pelvic floor function in 6-8 treatments over 3 months or until patient feels independent with the home exercise program.*

SIGNATURE: _____ **Date:** _____

Figure 29-5 ■ Evaluation of male clients with incontinence, including treatment example.

The goal of the exercises is to integrate the function of the entire abdominal compartment as a procedural program.¹¹⁹ The exercises should teach patients fast and slow muscle fiber training, isometric, concentric and eccentric strengthening exercises, and relaxation of the pelvic floor muscles. Correct use of the pelvic floor muscles also requires restoration of diaphragmatic breathing, as does coordination with all muscles of the abdominal compartment. Hodges⁵⁹ and Massery^{45,46,58} highlight the importance of integration of posture and breathing and treatment of all muscles of the abdominal compartment in order to restore the health of the pelvic floor. The Swiss ball allows for skill and coordination exercises and provides position to decrease the load of the pelvic floor muscles.

Client Education

A client needs to know where the pelvic floor muscles are, what their function is, and how they work with other systems of the body. The therapist should provide a clear picture of these muscles so that the client can visualize them and understand their function. Educational material and handouts are recommended.

Restoration of Proper Diaphragmatic Breathing

Every breath changes abdominal pressure. Forced exhalation increases the pressure; so do coughing and sneezing. Leaning forward or backward also changes abdominal pressure. Clients should learn to coordinate the contraction of the pelvic floor with changes of pressure. In addition, these activities cannot be done without the cooperation of the abdominal and back muscles. All abdominal muscles are important for posture and breathing.^{58,59} Exercises designed to restore pelvic floor function must therefore include coordination of all muscles involved. A great number of individuals with incontinence are chest breathers, possibly because of the poor habit of constantly pulling the stomach in to appear more slender. Restoration of diaphragmatic breathing is therefore the first priority for clients with incontinence.^{119,120}

Better breathing patterns may also help provide more oxygen to the pelvic region. Knowing how to control breathing may help a client relax when nervous or anxious (Figure 29-6).

Sensory Awareness of the Pelvic Floor

The pelvic floor muscles are in the shape of a hammock. Their resting tone is high, and relaxing the pelvic floor is required during urination and defecation as well as during delivery and sexual activity.^{67,70} Thus sensory awareness is an important aspect of retraining the pelvic floor muscles. For all individuals, activities such as coughing, sneezing, lifting, and sexual activity require contraction and relaxation of pelvic floor muscles. The ability to relax and contract these muscles is a problem for clients with incontinence. For individuals to regain this control and sensitivity within the pelvic floor, certain treatment protocols must be established.

First, a client can feel landmarks such as the coccyx, the pubic bones, and ischium. Sitting on a firm surface, the client can first contract the gluteal muscles, then relax them, then try to feel the contraction of the anal sphincter and the muscles around the vagina by imagining holding a small

Figure 29-6 ■ Diaphragmatic breathing. **A**, Inhalation; **B**, exhalation.

object with those muscles without activation of the gluteal muscles. Imagery of voluntary movements of fingers, toes, and tongue has been shown to activate the appropriate sections in the contralateral primary motor cortex.¹²³ It is therefore probable that imagery of striated pelvic floor muscles would also activate sections in the primary motor cortex assigned to this body part.

In the side-lying position, the client can place a hand over the gluteal muscles while touching the anal sphincter with a fingertip (Figure 29-7). The client can then try to pucker the anal sphincter, similar to puckering the mouth.

Figure 29-7 ■ Feeling the pelvic floor.

The contraction can be faint but is correct if the gluteal muscles remain relaxed. Tightening of the levator ani can be palpated at the perineum, between anus and vagina, or at the side of the tip of the coccyx. It can also be palpated deep in the groin and often can be distinguished from a contraction of the transverse abdominis. Clients learn that contraction of these muscles must precede any contraction of the surrounding pelvic floor muscles, such as the gluteal, adductor, and abdominal and back muscles. In the same position the client can also feel how a cough moves the pelvic floor muscles in a caudal direction. During proper breathing a gentle, rhythmical downward movement occurs during inhalation (eccentric for the pelvic floor and concentric for the pulmonary diaphragm). The client then tries to tighten the pelvic floor muscles before coughing and feels less caudal movement of the pelvic floor muscles.^{119,120} Sensory awareness of relaxation of the pelvic floor muscles may require education, visualization, and tactile feedback. It may be very difficult to learn to relax muscles that have been tight for a long time.

Coordination of Breathing with Pelvic Floor Muscle Activity

The client learns to contract the pelvic floor muscles while exhaling (eccentric activity for the pulmonary diaphragm, concentric activity for the pelvic floor muscles) and relax those muscles while inhaling. This can be done in different positions, such as supine, side lying, on all fours, sitting, or standing. When coughing, sneezing, lifting, and changing positions, such as from supine to side lying, the pelvic floor contraction must precede the activity (Figure 29-8). In contracting the pelvic floor before saying an explosive word such as a forceful “kick,” then relaxing the pelvic floor by slowly saying “aaaaand,” before tightening once more before saying “kick” again, the sequence of contraction and relaxation is learned.^{119,120}

Strengthening Exercises

Strengthening exercises of the pelvic floor muscles must include fast-twitch muscle fiber training with quick fast-twitch muscle contraction, which can be done by bouncing on the ball as demonstrated in Figure 29-9.

Slow-twitch muscle fiber training requires holding the contraction at the end for 5 to 10 seconds. This is demonstrated in Figure 29-10; the client tightens the pelvic floor, gives herself resistance in a diagonal direction, and holds the contraction of the pelvic floor muscles for 5 to 10 seconds. The right ischial tuberosity initiates the movement toward the left knee, which should not move in space, as indicated by the X. The chest also is a “fixed” point marked by an X. All movement comes from the pelvis.

Because the pelvic floor muscle fibers run in a sagittal and frontal plane as well as in a diagonal direction, movements in different directions should be included to maximize the benefit of strengthening exercises. The Swiss ball allows movement in all directions as a functional activity. When two persons sit back to back on a ball (Figure 29-11), one person can pull the ischium in the direction of the knees, which do not move, while the other person tries to slow down the movement. This requires eccentric activity of the pelvic floor muscles. Isometric muscle activity occurs when both pull at the same time with the same force. In Figure 29-12,

Figure 29-8 ■ Turning from lying on the back (A) to turning to the side while tightening the pelvic floor (B).

Figure 29-9 ■ A, Training fast fibers by bouncing on a double ball. B, Tightening the pelvic floor while lifting up.

two 12-year-old children tighten their pelvic floor muscles during exhalation while pulling the ball with the feet. Many exercises with or without the ball can be adapted with the Heller and Tanzberger concepts.^{92,95,97,119,120} Muscle strengthening is not done in isolation but is trained during functional movement activities such as lifting a grocery bag or hitting a tennis ball.

Figure 29-10 ■ Training of the slow muscle fibers by holding the contraction for 5 to 10 seconds at the end of the movement.

Figure 29-12 ■ Two children work on strengthening the pelvic floor during exhalation.

Teaching relaxation of the pelvic floor muscles is as important as strengthening exercises, especially in all clients with HPFS 60.

Programming of Functional Activities

Pelvic floor muscle activities must be tied to a function, such as getting up from a chair and tightening the pelvic floor muscles during exhalation (Figure 29-13). The exercises must be repeated many times in different combinations until they become automatic. The process of acquiring these skills is part of procedural learning.^{7,8,124-128} The client must be empowered to make changes in lifestyle activity and be motivated to achieve the changes. Only then will the client be willing to exercise for months until the

Figure 29-11 ■ Two adults sitting back to back on a ball doing eccentric and concentric pelvic floor contractions.

Figure 29-13 ■ A and B, Sit to stand can be done with integration of pelvic floor activity.

task becomes automatic.^{8,9,124-128} To improve motor control of a task, the exercises selected must be meaningful and varied as well as challenging. Mental practice, visualization, part-to-whole task practice, prepractice instructions, appropriate feedback, and guidance are all part of motor learning and are incorporated in the Heller and Tanzberger approaches.¹²⁴⁻¹²⁸

Precautions

For clients who do not feel safe on a ball, a double ball, a ball base, or a flat ball that fits onto a chair (Figures 29-14 and 29-15) can be used. All are commercially available. Exercises also can be performed between two chairs or in a corner so that the ball cannot roll away. When learning the exercise, a belt can be used at first to hold onto a client. The ball should not be used if a severe cognitive deficit in the client makes the activity unsafe. Any medical condition that endangers a client on a ball makes these exercises contraindicated and requires a change of exercise and equipment.^{119,120,129} Many possibilities for functional exercises exist that are based on motor learning and motor control principles as described by Umphred.¹⁰⁸ The client can walk or perform favorite gym exercises by incorporating pelvic floor strengthening and breathing coordination after learning how to do the exercises correctly. Functional training can also be achieved by incorporating the pelvic floor activity into certain movements that are done every day, such as lifting a child or grocery bag, getting up from a chair or out of a car, or turning in bed.

In addition, therapists must be aware of the involvement of other systems, such as the autonomic system or the limbic system. The patient may be nervous or fearful,

Figure 29-14 ■ Flat ball (sit fit).

Figure 29-15 ■ Exercise for the pelvic floor; sitting on a flat ball.

depressed, and sleep deprived or may have pain in addition to the incontinence problem.^{108,130} Some clients may have been abused, which may be manifested in multisystem involvement.⁹¹ An environment of trust, understanding, and sensitivity toward the client's problems must be created.

Clinical Application of the Heller and Tanzberger Concepts

After a therapist has defined the aspects of pelvic floor dysfunction that require retraining, a specific exercise program can be custom tailored to the patient.

Case Studies

None of the four clients discussed in this chapter underwent biofeedback or electrical stimulation for treatment, and most of the clients had performed Kegel exercises without success. In clients who are unable to learn to feel their pelvic floor muscles, electrical stimulation or biofeedback may be helpful. Functional activities, including proper breathing, should be performed during biofeedback. Isolated contractions of the pelvic floor muscles by using a device without incorporating functional activities does not seem to restore the many different functions of the pelvic floor. Therefore the use of cones without proper pelvic floor muscle training remains questionable. All the clients mentioned in the case studies were extremely motivated, which is not uncommon in patients who have pelvic dysfunctions. They are more than willing to follow their regimen. Problems arise when the client is cognitively impaired or when an illness affects motivation (Case Studies 29-3 and 29-4).

CASE STUDY 29-3 ■ FEMALE CLIENT USING A WHEELCHAIR

A 25-year-old female client who used a wheelchair as a result of myelomeningocele was referred to therapy for upper-extremity strengthening exercises. The diagnosis was left biceps tendonitis, left wrist strain, and lumbar discogenic pain. During treatment the young woman was questioned about her bladder and bowel condition.

The patient had a history of bladder surgery as a child; placement of a suprapubic catheter and bowel reconstruction surgery were done at age 15. She reported that 50% of the time she leaked loose stool and she frequently did not make it to the bathroom in time. She was wearing up to two pads per day.

The client was shown a model of the pelvic floor muscle to illustrate visually how to contract her pelvic floor muscles. Although her sensory awareness of the perineal area appeared to be reduced, she stated that she could feel a faint contraction when trying to pucker the anal sphincter. The client was a chest breather and was instructed in abdominal breathing techniques. She then was instructed to try to coordinate the puckering of her anus with exhalation and work on relaxation of the pelvic floor, especially during defecation. She was told to place a stool in front of the toilet so she could rest her short legs when sitting on the toilet.

The highly motivated client returned 3 weeks later and stated, "I am very happy, I do not leak anymore and did not have to use any pads the last few weeks. I also feel my sphincter

muscle now." The client had a total of six treatments. Four treatments were devoted to her arm and trunk problems (which resolved) and the last two treatments to the pelvic problem. Treatment then was discontinued because all goals had been met.

IMPAIRMENT

Impairments included anal incontinence, urgency, weakness of the anal sphincter, decreased sensory awareness of muscle contraction, and breathing dysfunction and discoordination.

Activity

The client needed to carry heavy pads to school; she worried about leaking stool and smelling bad.

Participation

The client felt social embarrassment with fear of leaking stool and smelling bad, and did not want to date. Because she was wheelchair dependent, it was difficult for her to find toilets where she could change her pads.

OUTCOME

The client, who was 25 years old, had never been given pelvic floor muscle training and had no clue that she could contract and strengthen her external sphincter anus. She was delighted to find out that she could exercise her pelvic floor muscles. Her student life became much better when she no longer was required to carry a bag of pads around. She no longer felt socially inept and was looking forward to socializing.

CASE STUDY 29-4 ■ CLIENT WITH VAGINAL PROLAPSE, ANAL SPHINCTER WEAKNESS, AND MIXED INCONTINENCE

A 38-year-old woman was referred to therapy because of anal sphincter weakness and incontinence of flatus for 5 to 6 years. She stated that she also had a prolapse. The client reported having SUI when laughing and running and during sexual intercourse, which affected her self-esteem (as she explained during a later visit). She had urgency, which made her run to the bathroom every hour during the day and get up twice each night. The bladder was painful when full. She also had pain in the lower abdomen. The client had constipation and had to strain during defecation. The surgical history was remarkable for difficult labor and delivery, one with forceps and two others with episiotomies. The patient also had had gallbladder surgery and hysterectomy over 10 years previously. The possibility of surgery for treatment of the prolapse and reconstruction of the vaginal area was discussed with the client and her physician. She had been instructed to perform Kegel exercises but they did not help. The client worked in an electrical assembly plant. The client's goals were to rid herself of the flatus and avoid surgery.

Objectively, she had decreased muscle tonus in the abdominal area and weakness of the abdominal and gluteal muscles. In addition, the client had incoordination between breathing and pelvic floor function. She developed some awareness of the pelvic muscles during the first evaluation. The impairment and the disabilities were considerable and the prognosis more guarded, but the goal was still to achieve anal continence, prevent surgery, and decrease urgency. The client was motivated.

The client was seen in therapy for 15 visits over a 7-month period, at first weekly, then every 2 weeks, and then for periodic reexaminations 3 to 4 weeks apart. Treatment began with teaching diaphragmatic breathing exercises and sensory awareness of the sphincter muscle. The client was able to distinguish between the activities of the anal sphincter and gluteal muscles and was also able to feel a faint contraction in the vaginal area. At first she had difficulty coordinating breathing with contraction and relaxation of the pelvic floor muscles, even when she practiced at home. At the second visit the client received a colon massage and gentle mobilization of the abdominal scars with connective tissue massage.^{56,121,122} Home exercises for breathing and pelvic floor contraction and relaxation were reviewed with the client. At the third visit, the client reported that the flatus problem had improved and that the abdominal treatment lessened the constipation. New exercises were taught with the Swiss ball in supine and sitting positions. At the fourth visit, the client said, "I have less flatus, and I am able to control the sphincter. The pelvic floor is still a problem because of the prolapse; I have no more back pain after the visceral treatments." The client was also instructed regarding how to perform exercises with decreased load on the pelvic floor (supine, supine with the feet on the ball, side-lying, on all fours, and so on). The client was also instructed in how to self-massage the abdomen. At the fifth visit, the client said, "I am now taking medicine to help control the urgency and can hold urine for

CASE STUDY 29-4 ■ CLIENT WITH VAGINAL PROLAPSE, ANAL SPHINCTER WEAKNESS, AND MIXED INCONTINENCE—cont'd

3 hours. My husband massages my abdomen, which decreases the constipation. The bowel movements are now every 1 to 2 days instead of once a week.”

The client reported only occasional pain with a full bladder, a reduction in the number of times she had to get up at night, and her ability to hold urine for 3 hours without pressure from the prolapse. The grateful client stated that her self-image had improved because she was no longer leaking urine during intercourse. According to the client’s wishes, surgery was deferred. As the strength of the pelvic floor improved, the client stopped taking medication for the urgency and was still able to hold urine for 3 hours and sleep through the night. The client continued occasional follow-up sessions to monitor her progress and provide her with more challenging exercises.

IMPAIRMENT

Impairments included prolapse secondary to weakness of the pelvic floor muscles and difficult labor and delivery; urgency, nocturia and EAS weakness; constipation; and breathing dysfunction.

Activity

The patient had to go to the bathroom every hour. She could not laugh, cough, or run without leaking urine; she leaked urine during sexual intercourse, which caused embarrassment.

Participation

She avoided going out with friends, participating in sports, and having sexual intercourse.

OUTCOME

After treatment as described, the client could hold urine for 3 hours instead of 1 hour and could sleep through the night. Her bowel movements improved to one to two per day instead of one per week. The client could control flatus and was enjoying intimacy and sexual intercourse without fear of leakage of urine. Her self-esteem was restored, and at the time of discharge she no longer considered surgery. The client resumed her social activities.

TREATMENT OPTIONS FOR PELVIC FLOOR DYSFUNCTION

Cognitively Impaired Clients

Adjustments must be made and functional barriers decreased to help cognitively impaired clients maintain or achieve continence (Table 29-1). Prompted voiding, timed voiding,^{16,131-133} and medicine can be used when a client has cognitive problems and cannot go to the bathroom independently. In prompted voiding, clients (e.g., with Alzheimer disease) are asked at regular intervals whether they have to go to the bathroom. In timed voiding, a client is placed on a commode or toilet at regular intervals. Many clients who are cognitively impaired probably would not be incontinent if they could reach a bathroom and if help were available to unbutton or unzip clothes, open a door, or assist in other aspects of toileting. Timely assistance could prevent falls (and therefore fractures) and incontinence episodes.¹³⁴

Clients with a Cerebrovascular Accident, Multiple Sclerosis, or Parkinson Disease

Clients who have neurological deficits are usually not asked whether they have a urinary dysfunction. Not all clients with such diseases are incontinent; some had incontinence before the onset of the neurological disease. OAB syndrome and UUI are common in CVA,³⁵ MS, and other neurological diseases, whereas detrusor-sphincter dyssynergy is common in MS and SCI.^{30,33} Patients with Parkinson disease can also have nocturia and retention. No matter what the cause, improvement can often be achieved by identifying the dysfunction, explaining the anatomy and physiology to the client, and then offering treatment options. Coordination of diaphragmatic breathing with pelvic floor muscle activity can improve self-control to relax the pelvic floor and improve oxygen supply to the pelvic region. Improving the posture and sensory awareness training can also be integrated to

varying degrees. The therapist can help the client improve afferent sensory input and use visualization to learn to contract and relax the muscles properly. A client with retention can learn to emphasize relaxation of the pelvic floor muscles during urination through breathing, proper seating on the toilet, and self-relaxation. Double voiding technique encourages the patient with an overextended bladder to time voiding to every 2 to 4 hours during the day. The patient then attempts to empty the bladder by staying on the toilet longer and trying to void more than once with each trip to the toilet, with supportive cues and timed voiding when the patient has cognitive impairment.^{34,131,133} Often, functional barriers can be eliminated or help can be provided. With clients who also need strengthening exercises for the pelvic floor and have difficulty sitting on a ball, a flat ball can be used in a chair, or exercises can be adapted to the client’s ability without any devices.

Overdistended Bladder

Whether or not the overdistended bladder is neurogenic, the client must learn to time herself or himself to void at regular intervals. In other cases the client may learn to do clean intermittent catheterization and carefully monitor the output of urine. The residual urine in the bladder should be low, approximately 50 mL; measurements consistently higher require further evaluation by a urologist.⁴⁷ Proper relaxation of the pelvic floor is important; men often can relax the pelvic floor better when urinating in a seated position. Abdominal breathing and coordination with pelvic floor muscle activity are important for these clients and should be restored if a problem is present.

Areflexia

Education is always the most important part of intervention and is done at the beginning. Many clients may need to learn clean intermittent catheterization and timed intervals. In

TABLE 29-1 ■ POSSIBLE COMBINATIONS OF TREATMENT OPTIONS FOR BLADDER AND ANAL DYSFUNCTIONS

	FUNCTIONAL EXERCISES AND BREATHING	BIOFEEDBACK	ELECTRICAL STIMULATION	CONES	PROMPTED VOIDING	TIMED VOIDING	ABDOMINAL TREATMENT, SCAR TREATMENT	SELF- CATHETERIZATION	RELAXATION OF PELVIC FLOOR MUSCLES

Areflexia of bladder, anus	(x)	(x)	X		(x)	X	(x)	X	(x)

X means recommended therapeutic intervention; (x) means additional treatment option. These options may be beneficial interventions, but evidence is mixed and outcomes may be patient specific.

some clients electrical stimulation or biofeedback may help restore some function of the pelvic floor activity; exercise may improve the strength of the pelvic floor muscles once some function returns. Obviously, all therapeutic interventions depend on the extent of the lesion, but as described in [Case Study 29-3](#), discussion with the client regarding the exploration of treatment options is important. This client probably could have been spared wearing diapers for the previous 10 years. She also could have been condemned to wearing diapers for the rest of her life without intervention. All that was needed in her case was to ask about the problem and instruct her in achieving continence.

Anal Incontinence

The inability to hold gas or leaking stool can occur in neurogenic and nonneurogenic disorders. Clients who have had resections of the colon may have anal urgency incontinence. They must learn to evaluate what they ate, when the urgency is appropriate, and when a signal is false. They often cannot distinguish gas, liquid stool, and solid stool. A client, after instruction and explanation of the defecation process, stated, “I got it; it is mind over matter.” He was also instructed to use deep abdominal breathing and quick flicks (activation of the fast fibers) and distraction to control the urgency. This helped him to stop and to control the need or motor program that could be identified as running to the bathroom every 30 minutes. He was asked to throw that program out consciously and replace it with breathing and reevaluation of each urgency, which enabled him in a short time to regain control, sleep through the night, and increase the intervals during the day. As with all clients with pelvic floor dysfunction, careful evaluation and education must be completed before beginning the treatment. In the presence of constipation, a careful abdominal evaluation and possible treatment of the viscera,¹³⁵ such as with colon massage,¹²¹ may be

indicated because constipation can also be present in clients who leak stool. The client needs to be educated about eating properly. Individuals who eat too much fiber need to drink large volumes of fluid to keep the stool soft. A client with a brain stem injury, for example, had bowel movements only every 5 days. When the family changed the breakfast to fruit and only minimal fiber, the client had daily regular bowel movements.

Electrical stimulation or biofeedback can in some cases be an adjunct or precede treatment of functional exercises of the abdominal compartment. It can be used to retrain when to contract the pelvic floor muscles and also to improve sensory awareness.

SUMMARY

Every client with UI, whether male or female, requires a thorough examination. To give the best possible chance for recovery, exercises must be custom tailored and modalities used with discretion. Electrical stimulation and biofeedback cannot replace functional exercises. Modalities may be helpful at the beginning of the treatment if the client has no sensory awareness of the pelvic floor but should be used in combination with exercises. Treatment of the viscera by a knowledgeable therapist should be considered in some clients to achieve full rehabilitation of the pelvic floor dysfunction.¹³⁵

KEY TERMS

aerobic training
cardiovascular fitness
deconditioning
exercise tolerance
rating of perceived exertion

OBJECTIVES

After reading this chapter, the student or therapist will be able to:

1. Explain the physiological principles related to cardiovascular responses to exercise testing.
2. Discuss the evidence behind cardiovascular fitness and describe the factors that contribute to the deconditioned state in adults with neurological disorders.
3. Explain the adaptive responses to aerobic training in populations with neurological disorders and the factors underlying these responses.
4. Discuss general guidelines for designing exercise programs to improve cardiovascular health and fitness.

The cardiopulmonary health of individuals with residual movement dysfunction after a neurological insult is now regarded as a topic of interest in neurorehabilitation. In traditional practice, the state of the neuromuscular system preoccupied the attention of clinicians in the quest to optimize neurological recovery. Most interventions were based on strategies to improve the capacity of that system—an approach that has met with limited success in terms of restoring functional independence. It is now clear that recovery cannot be explained solely on the basis of improved neuromuscular function. For example, Roth and colleagues¹ determined that less than one third of the variance in functional limitations after a stroke can be explained by the extent of neurological impairment. Nevertheless, the current approach to neurorehabilitation is somewhat puzzling. Evidence has accumulated indicating that many people with neurological disabilities are woefully deconditioned. There has been widespread acknowledgement of the central role that aerobic exercise plays in improving cardiopulmonary health and fitness. Furthermore, application of the principles of exercise physiology in cardiac rehabilitation has been widely endorsed. Yet neurorehabilitation clinicians have been observed to practice without full knowledge of their patients' cardiac status or without monitoring heart rate (HR) and blood pressure (BP).² Moreover, there is evidence to suggest that patients with neurological insults have not been challenged enough in therapy to induce the metabolic stress needed to enhance their cardiopulmonary fitness.^{3,4} A troubling explanation offered for these observations is that clinicians lack either an understanding or an appreciation of the basic physiological principles of exercise.^{5,6}

Fortunately, attention has turned to the introduction of interventions that encompass the neuromuscular, cardiovascular, and pulmonary systems and promote a more holistic approach to neurorehabilitation. The challenge of improving cardiopulmonary health and fitness in these populations is

not trivial. For individuals with chronic conditions, fitness is affected by a host of interacting influences such as the location and extent of the lesion, the presence of comorbidities (particularly cardiovascular disease), and the premorbid activity level. To complicate matters further, testing and training protocols for individuals with compromised motor and postural control need to be tailored to ensure safety and effectiveness.

This chapter begins with an overview of physiological principles related to cardiovascular responses to exercise testing. A summary of the evidence of cardiopulmonary fitness levels in adults and children with neurological disabilities is followed by a description of factors that contribute to the deconditioned state. Possible mechanisms responsible for reduced exercise capacity are then reviewed. Adaptive responses to aerobic training in patients with neurological conditions are examined, as are factors underlying these responses. The chapter closes with a summary of guidelines for the design of exercise programs that can be used to improve cardiopulmonary health and fitness. [Appendix 30-A](#) at the end of this chapter clearly identifies the meanings of the abbreviations used throughout the chapter.

PHYSIOLOGICAL RESPONSES TO EXERCISE

At rest the human body consumes roughly 3.5 mL of oxygen (O₂) per kilogram per minute, or 1 metabolic equivalent (MET).⁷ In the resting state, skeletal muscle activity accounts for less than 20% of the body's total energy expenditure; the brain, making up only 2% of body weight, also consumes 20% of the available O₂.⁸ Activities at rest such as breathing and contracting of the heart can be sustained indefinitely because the power demands of these activities are met by the rate of energy turnover. In other words, these activities occur well below the *critical power* of the muscles, defined as the maximal rate of work that can be endured indefinitely.⁹ Any physical activity beyond the resting state

requires more O_2 ; the increase is dependent on the intensity of the effort involved. The rise in metabolism relies on O_2 transport by the pulmonary and circulatory systems and O_2 usage by the active skeletal, cardiac, and respiratory muscles to convert chemical potential energy to mechanical energy.¹⁰ The components of the O_2 transport system are outlined in Figure 30-1.

Selective distribution of the increased blood flow to regions with heightened metabolic demands—the working

Figure 30-1 ■ Diagrammatic representations of the components of the O_2 transport system. (1) \supseteq During inspiration O_2 from the air is delivered to the alveolar gas space by the process of respiration. (2) $\not\subset$ O_2 diffuses across the blood-gas barrier into the pulmonary capillary blood, where almost all of the O_2 is bound to hemoglobin. (3) \subset The heart acts as a pump and (4) \subseteq the vascular system acts as the plumbing to transport O_2 to the various tissues, including the exercising muscle (5) \in where it diffuses from the red blood cells into the mitochondria within the myocytes. Reduced conductance of any component impairs O_2 transport, whereas improved conductance of any component augments O_2 transport.

muscles—is largely a result of local vasodilation mediated mainly by metabolites acting on the vascular smooth muscle (e.g., carbon dioxide [CO_2], hydrogen ions [H^+], nitric oxide, potassium ions, adenosine) and vasoconstriction in tissues with low metabolic demands.¹¹ Blood flow to other vascular beds (e.g., renal and splanchnic bed) either is unchanged or decreases through active vasoconstriction resulting primarily from increased sympathetic discharge. Cerebral autoregulation maintains regional and total cerebral blood flow and normal tissue oxygenation over a wide range of BPs¹²; thus, cerebral blood flow and O_2 delivery during exercise either remain stable^{13,14} or increase slightly.^{15,16} As exercise intensity increases, systolic BP (SBP) increases markedly, whereas diastolic BP (DBP) either remains unchanged or lowers slightly, resulting in a moderate increase in mean arterial pressure.¹⁷

Extraction of O_2 from the muscle capillary blood to mitochondria is dependent on an adequate O_2 diffusion gradient. During a progressive increase in workload, the arterial hemoglobin saturation and arterial O_2 content remain relatively constant, whereas the venous O_2 content decreases substantially as a result of increased O_2 extraction in the active muscles.¹⁸ As the metabolic rate rises, the minute ventilation (i.e., respiratory rate multiplied by the tidal volume) increases to remove CO_2 and to regulate pH balance of the active muscles. At low-intensity exercise, ventilation (mainly tidal volume) increases in a linear manner relative to the volume of O_2 use ($\dot{V}O_2$) and CO_2 production ($\dot{V}CO_2$). Above the critical power, the energy demand of the muscle exceeds the capacity of the aerobic process to supply energy for muscle contraction; the additional energy is supplied by the anaerobic glycolytic system.

During more intense exercise, ventilation is extremely variable among individuals; the respiratory rate usually increases without a substantial change in tidal volume.¹⁷ The point at which the rate of glycolysis exceeds that of oxidative phosphorylation is called the *anaerobic threshold* (which approximates the ventilatory threshold or lactate threshold).¹⁷ Pyruvic acid is converted to lactic acid, which completely dissociates to lactate and H^+ , resulting in a rise in blood lactate levels and a fall in intramuscular pH. Exercise-induced muscular fatigue is caused by the exponential accumulation of lactate and a drop in intramuscular pH, with negative effects on the actin-myosin turnover rate, enzyme activities, and excitation-contraction coupling.

Maximal oxygen consumption ($\dot{V}O_{2max}$) is defined as the highest O_2 intake an individual can attain during physical work.¹⁷ The Fick equation describes the relationship between cardiovascular function and $\dot{V}O_{2max}$:

$$\dot{V}O_{2max} = Q_{max} \times a-vO_{2diffmax}$$

where Q_{max} is the maximal cardiac output and $a-vO_{2diffmax}$ is the maximal arteriovenous O_2 difference. Given that Q_{max} equals the product of maximal heart rate (HR_{max}) and maximal stroke volume, (SV_{max}),

$$\dot{V}O_{2max} = HR_{max} \times SV_{max} \times a-vO_{2diffmax}$$

Thus $\dot{V}O_{2max}$ reflects both O_2 transport to the tissues and O_2 usage by the tissues. Increases in $\dot{V}O_2$ during exercise are caused by increases in both cardiac output and $a-vO_{2diff}$, with HR and stroke volume (SV) increasing progressively over the lower third of the workload range. Thereafter, HR

continues to increase while SV remains essentially constant,^{19,20} resulting, at maximal effort, in a cardiac output three to six times greater than baseline levels. An increase in SV (50% over resting volume) is caused by enhanced myocardial contractility and increased venous return resulting from compression of the veins by contracting muscles and reduced intrathoracic pressure.²¹ At low-intensity exercise the increase in HR is mainly a result of decreased vagal tone, but as exercise intensifies, sympathetic stimulation and circulating catecholamines play a greater role, yielding, at maximal workloads, a rise in HR 200% to 300% above the resting level.²²

MEASUREMENT OF CARDIOPULMONARY FITNESS

Exercise (aerobic) capacity is the principal determinant of the ability to sustain the power requirements of repetitive physical activity. VO_2max is generally accepted as the definitive index of exercise capacity and cardiopulmonary fitness.²³ VO_2max is a relatively stable measurement; variability of repeated measures of VO_2max has been reported to be 2% to 4%²⁴ or 0.2 L/min.²⁵ Accurate determination of VO_2max requires (1) adequate duration and work intensity by at least 50% of total muscle mass, (2) independence from motivation or skill of the subject, and (3) controlled environmental conditions.²⁶ Also, because test performance is sensitive to time of day, the time of repeat testing should be consistent.

Before any fitness test, a 3- to 5-minute warmup of slow treadmill walking on a level grade or unloaded pedaling that raises the metabolic rate twofold above resting should be performed.²⁷ A proper warmup prevents excessive local muscle fatigue from occurring before VO_2max has been attained.²⁸ Furthermore, a 3- to 5-minute cool-down should follow test completion to aid in venous return to prevent blood pooling in the peripheral vasculature and a subsequent drop in DBP. The intensity of exercise can be increased in a continuous progressive manner (i.e., step or ramp protocol) or, less commonly, in a discontinuous progressive manner (i.e., subject rests between stages). Throughout testing, continuous monitoring of the electrocardiogram and periodic monitoring of BP are essential. The optimal duration of a graded exercise test is 8 to 12 minutes, with testing terminated when the subject can no longer generate the required power, is limited by symptoms, or is unable to continue safely.²⁹ Variables of interest during exercise testing include VO_2max expressed in absolute terms (liters of O_2 per minute) or relative to body mass (milliliters of O_2 per kilogram of body weight per minute), MET level, percent of predicted HRmax, respiratory exchange ratio (RER; ratio of VO_2 to CO_2), peak power, minute ventilation, tidal volume, respiratory rate, and rating of perceived exertion (RPE) according to the Borg scale.³⁰ Because there is considerable variability in HRmax among healthy individuals, the percent of predicted HRmax attained is not a robust indicator of exercise capacity.³¹ Similarly, because both total exercise time and peak exercise intensity (or power attained, i.e., peak treadmill speed and grade or peak power on bike) are dependent on the test protocol, neither is a reliable measure of exercise capacity.^{32,33} In addition, noninvasive estimation of the anaerobic threshold by identifying the point of nonlinear increases in minute ventilation and VCO_2 can be highly subjective and thus unreliable.³⁴

The principal marker of exercise capacity is attainment of a plateau in VO_2 beyond which there is a change of less than 100 mL/min, with further increases in workload dependent solely on anaerobic metabolism.²⁹ In cases in which a VO_2 plateau is not observed (typically in deconditioned or elderly individuals or in patients with heart disease), the preferred term for the value obtained is *peak VO_2* ($\text{VO}_{2\text{peak}}$).³⁵ Criteria for attainment of $\text{VO}_{2\text{peak}}$ include achieving the age-predicted HRmax, RER in excess of 1.15, minute ventilation greater than the predicted maximal voluntary ventilation, tidal volume greater than 90% of the inspiratory capacity, and obvious patient exhaustion.²⁸

Testing Modality

The modality of testing (e.g., treadmill walking, cycling, stepping, arm cranking) can affect VO_2max values. The treadmill has the greatest potential to recruit sufficient muscle mass to elicit a maximal metabolic response, particularly in deconditioned individuals.²⁶ Bike ergometry yields 85% to 90%, and arm ergometry 70%, of the VO_2max achieved with a treadmill.²⁶ Ideally the mode of exercise should be consistent with the patient's typical activity. Thus the treadmill is often preferred because the pattern of muscle activation during treadmill walking is similar to that for most mobility tasks. In patients with neuromuscular conditions, however, impaired balance and motor control often preclude the use of standard treadmill testing protocols. To resolve this limitation, we devised and validated an exercise protocol using a body-weight support system to permit safe and valid testing of VO_2max early after stroke.³⁶ For subjects with paraplegia, tests with wheelchair treadmills are more functionally relevant than those using arm ergometry.

PREDICTING MAXIMAL OXYGEN CONSUMPTION WITH USE OF SUBMAXIMAL EXERCISE TESTS

Although submaximal tests do not measure the systemic response, they are inexpensive to administer and have a low risk of adverse events. The essentially linear relationship between VO_2 and HR permits the estimation of VO_2max from HR measurements taken during submaximal exercise. For example, for healthy people the HR increases approximately 50 beats per uptake of 1 L of O_2 , independent of sex and body size.³⁷ For unfit individuals and patients with cardiac impairment, the increases in HR are greater per liter, except for patients taking β -blockers, who demonstrate blunting of the HR response throughout exercise. The Åstrand-Ryhming nomogram is often used to predict VO_2max from submaximal HR.³⁸ The HR- VO_2 relationship is independent of the exercise protocol. However, HR, unlike VO_2max , is markedly affected by many stresses (e.g., dehydration, changes in body temperature, acute starvation), resulting in substantial error and inaccurate VO_2max estimations.²⁶ In fact, discrepancies between estimated and measured VO_2max in individuals with low exercise capacity can be as high as 25%.³⁹

FITNESS LEVELS IN POPULATIONS WITH NEUROLOGICAL DISORDERS

Documentation of exercise capacity in populations with neurological disorders has been hindered by the lack of testing protocols that can safely and effectively accommodate

the motor and balance disturbances common to these populations. Not surprisingly, the limited evidence to date suggests that most individuals with neurological disabilities are significantly deconditioned. A summary of VO_2 peak data from studies of common neurological conditions is presented in Table 30-1. Variability in the results from a multitude of factors, including differences in testing protocols, as discussed in the previous section, and differences in subject

characteristics; these points are discussed in the following section.

Impact of Low Fitness Levels on Health of People with Neurological Disorders

People with high fitness levels use only a small fraction of the *physiological fitness reserve*⁴⁰ of the cardiovascular, respiratory, and neuromuscular systems to respond to the

BWSTT, Body-weight–supported treadmill training; NR, not reported; *Vo₂peak % normal*, peak oxygen consumption expressed as a percentage of normative values.

metabolic challenge of activities of daily living (ADLs).^{41,42} Thus, small declines in exercise capacity may not be noticeable in carrying out daily activities. In contrast, relatively minor reductions in capacity can substantially influence performance of ADLs by deconditioned individuals. Light instrumental ADLs require approximately 10.5 mL of oxygen per kilogram per minute (3 METs), whereas more strenuous activities have metabolic costs of about 17.5 mL/kg/min (5 METs).⁴³ Cress and Meyer⁴⁴ reported that the *Vo₂peak* of 20 mL/kg/min is needed for older adults to meet the physiological demands of independent living. From the data presented in Table 30-1, it is evident that many people living with neurological disabilities (particularly stroke, tetraplegia, and postpoliomyelitis syndrome) do not have the level of fitness required for the more strenuous ADLs and independent living. Moreover, relative exercise capacities (expressed as a percentage of normative values) associated with the disabilities in Table 30-1, with the exception of Parkinson disease, are of concern, given that *Vo₂peak* values less than 84% of normal are considered pathological.⁴⁵

For individuals with neurological disabilities, the minimum *Vo₂* requirements for ADLs are actually greater than the previously mentioned levels because of the increased energy requirements resulting from gross motor inefficiencies and other related factors.⁴⁶⁻⁴⁸ In other words, the percentage of *Vo₂peak* required for activity at a fixed submaximal workload (termed *fractional utilization*) is increased. When the anaerobic threshold is exceeded prematurely and lactate accumulation is accelerated, accomplishment of low-intensity ADLs is unsustainable for extended periods and achievement of mid- to upper-intensity ADLs is virtually impossible. Moreover, the combination of poor exercise capacity and elevated energy demands results in diminished reserves to support other activities. For example, in the case of people with postpoliomyelitis syndrome, the energy costs of walking are about 40% higher than for healthy peers and are highly correlated with lower-extremity muscle strength.⁴⁹ Thus in the

calculation of fractional utilization for walking, the numerator (*Vo₂* during walking) is increased and the denominator (*Vo₂peak*) is decreased; hence, fractional utilization is substantially increased.

Of the neurological populations, people poststroke are the largest consumer group in need of rehabilitation services. This group also has received the most attention in the literature with regard to functional capacity. Exercise capacities documented in this population are consistently low—from 8.3 mL/kg/min in the subacute period⁵⁰ to 22.4 mL/kg/min in the chronic period.⁵¹ As much as 75% to 88% of *Vo₂peak* (almost twice that of the healthy control subjects) is required to perform household chores⁵² and one-and-a-half to three times the *Vo₂* levels of healthy controls are needed to walk on level ground.^{46,53,54} Not surprisingly, up to 70% of patients complain of fatigue after stroke⁵⁵ and rate poor energy levels ahead of mobility limitations, pain, emotional reactions, sleep disturbances, and social isolation as the area of greatest personal concern.⁵⁶

In addition to contributing to reduced ADL performance and increased fatigability, low fitness levels are associated with higher mortality. Exercise capacity has been reported to be an independent predictor of mortality in persons with coronary artery disease (CAD), a comorbidity prevalent in some populations of people with neurological conditions.^{57,58} Those with a *Vo₂peak* <21 mL/kg/min are classified as the high-mortality group and with greater than 35 mL/kg/min as the excellent-survival group.⁵⁹ Thus, determining an individual's *Vo₂peak* is of clinical value. Individuals who are being encouraged or are internally motivated to perform beyond their capacity and beyond the capabilities of the interaction of multiple systems are in a high-risk category. Conversely, individuals who are undermotivated or depressed and are performing below their capacity can be trained to self-monitor, which empowers them to reach goals that are safe and have the potential to improve the quality of their lives.

Factors Affecting Fitness Levels in People with Neurological Disorders

To identify appropriate measures to improve fitness levels in people with neurological disorders, the myriad factors at play that contribute to the deconditioned state must be considered. A useful conceptual framework to discuss the interaction of these factors is the International Classification of Functioning, Disability and Health (ICF)⁶⁰ (see Chapter 1). The ICF uses a biopsychosocial approach to organize factors related to the health condition into two components: (1) personal and environmental contextual factors and (2) functioning and disability, which are further subdivided into components of body functions and structures, activity, and participation (Figure 30-2). Through application of the ICF framework, the complexity of interacting influences on cardiovascular and pulmonary health and fitness becomes more understandable.

Personal and Environmental Contextual Factors

For both able-bodied and disabled people, personal contextual factors contributing to individual differences in exercise capacity include age, sex, race, and lifestyle habits.

Age

A decline in $\dot{V}O_2\text{max}$ of approximately 1% per year (0.4 to 0.5 mL/kg/min/year) occurs from 25 to 75 years of age.⁶¹ In accordance with the Fick equation, a reduction in $\dot{V}O_2\text{max}$ is caused by reductions in both O_2 transporting (i.e., Q_{max}) and O_2 utilization capacity (i.e., $a\text{-}\dot{V}O_2\text{diffmax}$) associated with cardiac, respiratory, and muscular changes. Decreased Q_{max} is the result of increasing myocardial stiffness and decreased left ventricular contractility, manifested by reductions in both ejection fraction and HR_{max} —hallmarks of cardiovascular aging.⁶² In fact, the reduction in HR_{max} , which decreases 6 to 10 beats per minute (bpm) per decade,

is responsible for much of the age-associated decline in Q_{max} .⁶³ Evidence also suggests that older adults have a smaller SV_{max} ⁶³ and that BP and systemic vascular resistance are higher during maximal exercise in older versus young adults.⁶⁴

With advancing age, reduced elastic recoil of the lung and calcification and stiffening of the cartilaginous articulations of the ribs restrict compliance of the lungs, thus limiting increases in minute ventilation during exercise.⁶⁵ Age-related decline in oxidative capacity of the working muscles and hence decreased $a\text{-}\dot{V}O_2\text{diff}$ during peak exercise⁶⁶ have been attributed to alterations in mitochondrial structure and distribution, oxidative enzyme activity,⁶⁷ and skeletal muscle microcirculation, as well as sarcopenia resulting from a reduced number and size of fibers, particularly type II fibers.⁶⁸ Nevertheless, despite loss of aerobic capacity with aging, people without chronic health conditions retain adequate reserves for daily activities. However, for aging individuals with a neurological impairment, the decrease in aerobic capacity with age can further reduce their reserves and thus threaten living an independent lifestyle. In fact, in a population-based study, age was found to be a significant independent predictor of recurrent stroke.⁶⁹ Particularly disadvantaged are people with cerebral palsy (CP) or other developmental disabilities as a result of an incomplete development of their musculoskeletal and cardiorespiratory systems at the time of the neurological event, which accelerates the aging process.⁷⁰ In the case of people with Down syndrome, however, Baynard and colleagues⁷¹ found that age-related changes in exercise capacity did not follow the typical pattern of decline after the age of 16 years. People with spinal cord injury (SCI) are at an increased risk for cardiac and respiratory complications with age.⁷²

Sex

The absolute and relative $\dot{V}O_2\text{max}$ of women is about 77% of that of men, after adjustment for body weight and activity level.⁷³ For nondisabled older adults, Kohrt and colleagues⁷⁴ reported no significant gender difference in the percentage of improvement in $\dot{V}O_2\text{max}$; women had an increase in $\dot{V}O_2\text{max}$ of $26\% \pm 12\%$ (range 4% to 58%), and men demonstrated a $23\% \pm 12\%$ (range 0% to 51%) increase. Although older men and women generally exhibit similar responses to maximal exercise, older women tend to have lower SBP during maximal exercise.⁶⁴

Race

Little attention has been paid to the differences in exercise capacity among racial groups; however, in one study no differences were found between 66 black and 52 white stroke survivors in the level of physical deconditioning poststroke.⁷⁵

Lifestyle Factors

Smoking is one factor that has been shown to impair exercise capacity in the general population.⁷⁶ Smoking causes increases in HR, myocardial contractility, and myocardial oxygen demand, which can lead to atherosclerosis and acute cardiovascular events.⁷⁷ In the stroke population, smoking doubles the risk of death (equivalent of a 7-year reduction in life span) when compared with the risk in nonsmokers and ex-smokers.⁷⁸

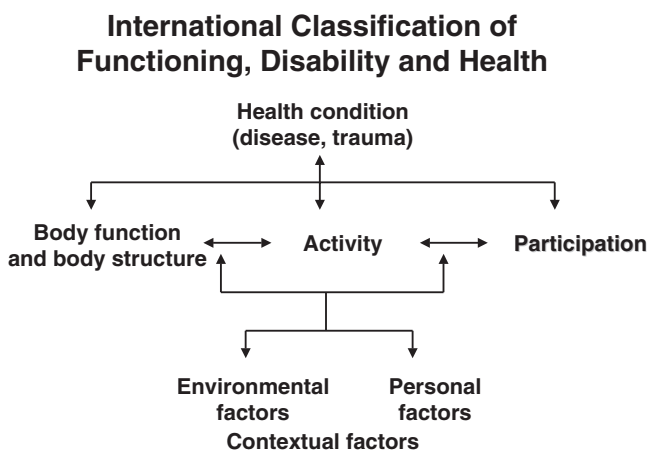

Figure 30-2 ■ Interaction of the various components of the International Classification of Functioning, Disability and Health (ICF). The ICF is a conceptual framework that uses a biopsychosocial approach to organize factors related to health condition into two components: (1) personal and environmental contextual factors and (2) functioning and disability, which are further subdivided into components of body functions and structures, activity, and participation.

Currently the relationship between cardiovascular disease and diet is receiving international attention.⁷⁹ Indeed, obesity increases the risk of cardiovascular risk factors such as impaired glucose tolerance and type 2 diabetes, hypertension, and dyslipidemia.⁸⁰ Specifically, abdominal obesity not only increases the risk of atherosclerotic disease but also the risk of primary ischemic stroke.^{81,82} In addition, when compared with corresponding normal-weight populations, overweight youth with SCI and spina bifida have lower cardiovascular fitness.⁸³ Yet the lifestyle factor that has received the most attention in the literature is habitual activity. There is now irrefutable evidence of the link between physical activity and cardiopulmonary health and fitness.^{76,84-86} In fact, in the stroke population, prestroke physical activity has been found to decrease stroke severity as well as to result in better long-term rehabilitation outcomes.⁸⁷ Cardiovascular alterations resulting from physical inactivity (i.e., reduced VO_2max and Qmax) parallel, in many ways, the changes that occur with aging; in fact, sedentary lifestyles explain a significant proportion of these age-related declines. If physical activity levels and body composition remain constant over time, the expected rate of loss in aerobic power associated with senescence is reduced by almost 50%.⁶⁸ Nonetheless, people with chronic health conditions often rate poorly in terms of daily physical activity, in part because of underlying physical impairments (e.g., paralysis, pain). For example, people with SCI spend as little as 2% of their walking time participating in leisure physical activity,⁸⁸ making them the most sedentary members of society.⁸⁹ Some people with multiple sclerosis (MS) avoid physical activity to prevent elevated body temperature and minimize symptoms of fatigue.⁹⁰ Inactivity can lead to increased cardiovascular risk factors such as hypertension and dyslipidemia as seen in youth with chronic disabilities (including CP and SCI).⁹¹ Bernhardt and colleagues⁹² found that after a stroke, patients spend more than 50% of their time resting in bed. Short periods of bed rest cause rapid decreases in aerobic capacity—a 15% reduction in healthy, middle-aged men after 10 days of recumbency⁹³ and a 28% reduction in healthy young subjects after 3 weeks.⁹⁴ Inactivity-induced reductions in VO_2peak have been attributed to both central changes (decreased SV from impaired myocardial function and increased venous pooling) and peripheral changes characteristic of aerobically inefficient muscle fibers (decreases in oxidative enzyme concentrations, mitochondria, and capillary density).²²

Environmental Factors

Significant associations have been found between physical activity and physical environmental factors such as accessibility, esthetic attributes, and opportunities for activity within the general public.⁹⁵ However, the influence of such factors on cardiovascular and pulmonary fitness of people with neurological disabilities has received little attention in the literature.

Health Condition

Exercise capacity reflects both systemic capacity and the health of the component systems. Thus differences in VO_2peak among individuals with neurological disabilities are a result of not only the contextual factors discussed previously but also pathological conditions involving the neuromuscular, cardiovascular, and pulmonary systems.

Neuromuscular System

For most individuals with neurological conditions, the existence of neuromuscular impairments confounds interpretation of VO_2peak testing. When people with an intact nervous system are tested, normal biomechanical efficiency is assumed; an impaired nervous system increases the complexity of physiological responses. Both primary effects of upper motor neuron damage (e.g., paralysis, incoordination, spasticity, sensory-perceptual disorders, balance disturbances) and secondary “peripheral” changes in skeletal muscle (e.g., gross muscular atrophy⁹⁶ and changes in muscle fiber composition⁹⁷) affect the response to exercise. As a result, people with neurological disabilities manifest not only metabolic but also biomechanical deficiencies, both of which contribute to reduction in functional capacity. Consequently, the decline in exercise capacity is greater than expected (e.g., in people with postpoliomyelitis syndrome, deterioration in VO_2peak over a 3- to 5-year period was 12% greater than the predicted decline⁹⁸).

Paresis reduces the pool of motor units available for recruitment during physical work,⁹⁹ thereby reducing the metabolically active tissue and lowering the oxidative potential.¹⁰⁰ In the case of stroke, an estimated 50% of the normal number of motor units are functioning,¹⁰¹ and a strong relationship between bilateral thigh muscle mass and VO_2peak has been reported.¹⁰² In addition, along with altered joint kinematics and decreased postural reactions,¹⁰³ children with CP exhibit high levels of co-contraction (simultaneous contraction of agonist and antagonist muscle groups), which may prematurely induce skeletal muscle fatigue, further increasing the energy expenditure of walking and decreasing VO_2peak .^{104,105} Thus, when compared with able-bodied individuals, children with CP experience greater levels of fatigue at slower walking speeds.^{104,105} For people with postpoliomyelitis syndrome, muscle weakness of the lower extremities is strongly associated with energy expenditure of walking.⁴⁹ In fact, when compared with healthy age- and sex-matched subjects, energy cost of walking is found to be significantly higher (40%) for people with postpoliomyelitis syndrome.⁴⁹

Altered fiber composition and recruitment patterns of paretic muscle may also contribute to poor fitness.^{97,106} Skeletal muscles are composed of fibers that express different myosin heavy chain (MHC) isoforms. Slow (type I) MHC isoform fibers have higher oxidative function, are more fatigue resistant, and are more sensitive to insulin-mediated glucose uptake; fast (type II) MHC fibers are recruited for more powerful movements, are more reliant on anaerobic or glycolytic means of energy production, fatigue rapidly, and are less sensitive to the action of insulin.¹⁰⁷ Although relatively equal proportions of slow and fast MHC isoforms are found in the vastus lateralis of healthy individuals,¹⁰⁰ elevated proportions of the fast, more fatigable fibers that are less glucose sensitive have been found in the paretic leg of people after a stroke.⁹⁷ Hence it is likely that reduced insulin sensitivity and increased use of the anaerobic processes during dynamic exercise at the level of the muscle contribute to reductions in VO_2peak . Furthermore, alterations in the structure of mitochondria¹⁰⁰ and reduced activity of oxidative enzymes (e.g., succinate dehydrogenase)¹⁰⁸ may contribute to the reduced oxidative capacity of paretic muscles.

Cardiovascular System

Cardiovascular comorbidities, prevalent in populations with neurological disorders, contribute to metabolic inefficiency. In fact, cardiovascular complications are the leading cause of death in persons with stroke,¹⁰⁹ MS,¹¹⁰ and SCI.¹¹¹ About 75% of patients who have had a stroke are hypertensive,¹¹² and the same proportion of patients have underlying cardiovascular dysfunction.¹¹³ In fact, most persons who have had a stroke have atherosclerotic lesions throughout their vascular system,¹¹⁴ and a high correlation has been reported between the number and degree of stenotic lesions in the coronary and carotid arteries.^{115,116} The high prevalence of CAD in this population should not be surprising because stroke and cardiac disease share similar predisposing factors (e.g., older age, hypertension, diabetes mellitus, cigarette smoking, sedentary lifestyle, and hyperlipidemia) and pathogenic mechanisms (e.g., atherosclerosis).¹¹⁷ Metabolic syndrome is a usual construct in identifying patients at high risk for future vascular events (e.g., a second stroke, myocardial infarction).¹¹⁸ *Metabolic syndrome* refers to a constellation of markers of metabolic abnormalities (i.e., hypertension, abdominal obesity, abnormal lipid profile) that interact to accelerate the progression of atherosclerosis and increase the risk of development of cardiovascular or cerebrovascular disease.¹¹⁹ The prevalence of metabolic syndrome in neurological populations is high. A retrospective study reported that about 61% of 200 patients in stroke rehabilitation met the criteria for the syndrome.¹²⁰

Factors that elevate HR for a given Vo_2 , such as CAD, result in attainment of a peak HR (HR_{peak}) at a Vo_2 peak below that predicted for that individual. Cardiac dysfunction contributes to a lower aerobic capacity through two principal mechanisms: ischemia-induced reductions in ejection fraction and SV with exercise¹²¹ and chronotropic incompetence—the inability to increase HR in proportion to the metabolic demands of exercise.²¹ For persons who can attain HR_{max} within 15 bpm of the predicted maximum, limitations in exercise capacity probably do not have cardiovascular causes.

Impaired peripheral blood flow also contributes to reduced cardiovascular fitness. Inadequate blood flow to the periphery impairs O_2 transport and limits energy production in the working muscles, thereby compromising the ability to sustain physical activity. Both resting blood flow and post-ischemic reactive hyperemic blood flow have been found to be lower (approximately 36% less) in the paretic leg of people poststroke.^{122,123} In addition, despite near-normal (above 0.90) mean ankle brachial index values, arterial diameter has been found to be reduced poststroke.¹²² Potential mechanisms responsible for reduced blood flow on the hemiparetic side include altered autonomic function,¹²⁴ enhanced sensitivity to endogenous vasoconstrictor agents,¹²⁵ and altered histochemical and morphological features of the vascular network itself.¹²⁶ However, the relative contribution of each of these factors is unknown. In addition, local metabolic mediators associated with changes in muscle fiber composition in the paretic limb (previously discussed) may contribute to impaired limb blood flow.¹⁰⁰

Trauma to the spinal cord may disrupt the autonomic reflexes and sympathetic vasomotor outflow required for normal cardiovascular responses to exercise.¹²⁷ As a result, reduced venous return and cardiac output (referred to as

circulatory hypokinesia) impair delivery of O_2 and nutrients to and removal of metabolites from working muscles, intensifying muscle fatigue.¹²⁸ For people with paraplegia, an exaggerated HR response may occur during exercise in order to compensate for reduced SV. However, adrenergic dysfunction associated with lesions above the T1 sympathetic outflow prevent this compensatory mechanism,¹²⁹ thereby increasing the risk of cardiovascular disease.

Pulmonary System

Typically in able-bodied individuals the pulmonary system does not limit cardiopulmonary fitness, because the lungs of people without chronic health conditions have a large reserve.¹³⁰ Nevertheless, at maximal workloads as much as 10% of Vo_2 max is needed to support the mechanical work of the diaphragm, accessory inspiratory muscles, and abdominal muscles.¹²¹ In contrast, people with neurological impairments may have limited O_2 availability for exercise as a result of pathological conditions involving the pulmonary system, either as a direct complication of a neuromuscular condition (e.g., muscle weakness, impaired breathing mechanics) or as a result of cardiovascular dysfunction, comorbidities (e.g., chronic obstructive pulmonary disease), or lifestyle factors (e.g., physical inactivity, smoking habits).^{131,132} These impairments can reduce the *ventilatory reserve*, defined as the difference between the maximal available ventilation and the ventilation measured at the end of exercise.¹³³

As previously mentioned, minute ventilation is closely associated with VCO_2 during exercise. At peak exercise, a ratio of minute ventilation to VCO_2 above between 35¹³⁴ and 40¹³⁵ indicates an abnormal ventilatory response. Neu and colleagues¹³⁶ reported an 87% incidence of obstructive pulmonary dysfunction in patients with Parkinson disease, despite the finding that Vo_2 peak levels in this patient group tend to be in the normal range.^{137,138} For children with CP, reduced exercise capacity may be partly caused by respiratory muscle spasticity resulting in reduced breathing efficiency.¹⁰⁵ In the case of stroke, pulmonary function is usually affected to only a modest extent, notwithstanding acute respiratory complications (e.g., pulmonary embolism, aspiration pneumonia).¹³¹ Impaired respiration may be attributed to cardiovascular dysfunction or lifestyle factors (e.g., physical inactivity, high incidence of smoking)¹³⁹ or a direct result of the stroke, particularly brain stem stroke. The overwhelming fatigue felt by some persons after a stroke may be partly caused by respiratory insufficiency as manifested by low pulmonary diffusing capacity, decreased lung volumes, and ventilation-perfusion mismatching.¹⁴⁰ Impaired breathing mechanics with restricted and paradoxical chest wall excursion and depressed diaphragmatic excursion have been also reported.^{131,141} Expiratory dysfunction appears to be related to the extent of motor impairment (e.g., hemiabdominal muscle weakness), whereas inspiratory limitations appear to be related to the gradual development of rib cage contracture.¹⁴²

To summarize, a host of interacting factors are associated with abnormally low cardiopulmonary fitness in people with neurological disorders. Neuromuscular and respiratory dysfunctions are often superimposed on an already-compromised state as a result of comorbid cardiovascular disease and pre-morbid health- and lifestyle-related declines. Paresis and the

subsequent reduction in lean muscle mass, changes in the muscle fiber phenotype, and increased reliance on anaerobic processes for energy production result in high metabolic costs of moving paretic limbs. As a consequence, cardiac reserves available for meaningful activity-level functions are limited, which in turn has a negative impact on participation-level functions. Collectively, impairments in the neuromuscular, cardiovascular, and pulmonary systems converge to promote a sedentary lifestyle and reduced health-related quality of life, which in turn leads to further inactivity and further reductions in cardiopulmonary fitness. The contribution of skeletal system impairments to this downward spiral has received little attention. Pang and colleagues¹⁴³ studied the relationship between bone health and physical fitness in patients who had had a stroke and found a significant correlation between paretic femur bone mineral density and Vo_2max . They concluded that further study is needed to determine the clinical implications of this finding.

ADAPTIVE RESPONSES TO AEROBIC TRAINING IN POPULATIONS WITH NEUROLOGICAL DISORDERS

It is now apparent that healthy young and old individuals who begin participating in regular activity even after years of inactivity can enjoy greater health and fitness than those who remain sedentary.¹⁴⁴ Training studies involving people with neurological disability, although limited in number and sample size and often lacking a control group, provide preliminary evidence of cardiopulmonary adaptations to physical work (Table 30-2). For example, for adolescents with chronic disabilities (including CP, SpinaBefida [SB], and SCI)⁹¹ and children with CP,¹⁴⁵⁻¹⁴⁸ cardiovascular fitness training is found to produce positive results on aerobic capacity and fitness. There is also growing evidence supporting the benefits of aerobic training in people with stroke of mild to moderate severity.¹⁴⁹ Exercise training has also been found to improve the physical capacity of people with

SCI.^{150,151} In the case of people with TBI, evidence regarding the effects of exercise training has been inconclusive.¹⁵² However, in people with neurological disorders, cardiovascular adaptations in response to aerobic training enhance metabolic efficiency, and neuromuscular adaptations in response to strength and gait training improve mechanical efficiency. The result is improved functional capacity with lowered energy costs of ADLs, enhanced fatigue resistance, and increased exercise tolerance (Figure 30-3).

The magnitude of change in VO_2peak in the training studies in Table 30-2 (mean gain of 20%) is comparable to the improvements of 10% to 30%^{153,154} reported for healthy, sedentary adults and 13% to 15% for participants in cardiac rehabilitation.^{155,156} The increases in VO_2peak for clinically stable individuals with CAD have been reported to be 12% to 46%.¹⁵⁷⁻¹⁵⁹ Substantial intersubject variability in results is attributable to many factors, including differences in neurological condition, severity, and time after insult, as well as variations in intensity of training, mode of exercise, and level of compliance with the exercise regimen. Within studies, considerable interindividual differences have been noted, of which only a small portion (about 11%) have been attributed to recognized covariates such as initial fitness status and an even smaller percentage (about 5%) to measurement error.¹⁵⁷⁻¹⁵⁹ The most rapid improvements in exercise capacity are seen in previously sedentary people,¹⁶⁰ and similarly the highest overall gains occur in individuals with the lowest initial values of VO_2peak .¹⁶¹ Age and sex have not been shown to have a substantial effect on exercise trainability.¹⁶²

The dramatic increases in exercise capacity reported in some of the studies (e.g., improvements of 23%^{163,164} to 94%⁵⁰) may not be possible for most people with neurological disabilities. Yet the subtle gains realized in other studies (e.g., 8%,¹⁶⁵ 11%,¹⁶⁶ 15%¹⁶⁷) may yield meaningful dividends by extending the time in which muscle contraction can be sustained through oxidative processes, thus elevating the lactate threshold. Enhanced functional capacity could spell the difference between being dependent and independent. In other words, interventions that result in even small

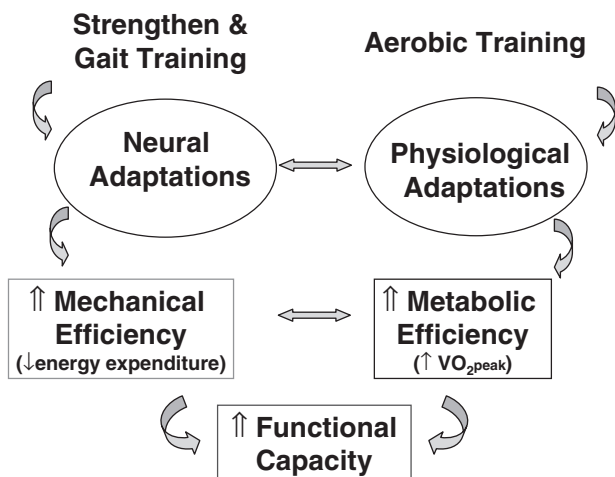

Figure 30-3 ■ Interaction of influences that enhance functional capacity. Neurorehabilitation interventions result in neural and physiological adaptations that in turn increase mechanical and metabolic efficiencies and ultimately improve functional capacity.

changes in aerobic capacity may be of practical significance for people with neurological disorders.

Mechanism of Improved Exercise Capacity in Neurological Disorders

It remains unclear whether training-induced increases in VO_2peak in people with neurological disorders result from central mechanisms or peripheral mechanisms. In healthy individuals both peripheral and central adaptations occur; and in those with CAD and an intact nervous system, central^{168,169} and peripheral^{157,169,170} adaptations have been variably reported. In accordance with the Fick equation, central adaptations rely on improved SV because HR_{max} remains unchanged with training. Enhanced myocardial contractility, together with decreased vasoconstriction in the nonworking muscles and improved venous return, account for the higher Q_{max} ^{171,172} without a concomitant increase in mean arterial pressure.^{171,172} The effect of training on ejection fraction remains unclear,⁵¹ and lack of effect on blood hemoglobin content and coronary blood flow has been documented.^{171,172}

Peripheral adaptations in the exercising muscle tissue include increases in capillary density,^{173,174} size and number of mitochondria,¹⁷⁵ myoglobin levels, Krebs cycle enzymes (e.g., succinate dehydrogenase), and respiratory chain enzymes (e.g., cytochrome oxidase).²² As a consequence of these skeletal muscle adaptations, $a\text{-VO}_2\text{diff}$ and hence VO_2peak increase.⁶¹

The possibility of “spontaneous” increases in exercise capacity during neurological recovery should not be overlooked. There have been several reports of non-exercise-induced adaptations after myocardial infarction.¹⁷⁶⁻¹⁷⁸ In our lab we documented a significant increase (13%) in VO_2peak over the course of a stroke rehabilitation program that lacked an aerobic training component.¹⁷⁹ Haisma and colleagues¹⁸⁰ reported that patients with tetraplegia and paraplegia demonstrated improvements in VO_2peak of 17% and 23%, respectively, over the course of inpatient SCI rehabilitation; however, the extent and mode of aerobic training was not indicated. The authors speculated that the improved capacity could be, in part, a result of natural recovery and recuperation from trauma and complications. Dressendorfer and colleagues¹⁸¹ hypothesized that the metabolic demands of unregulated daily activities after myocardial infarction may have an insidious training effect. In support of this prospect, a review of the threshold exercise intensity to improve cardiorespiratory fitness indicated that for deconditioned participants an effective training intensity is lower than previously reported.¹⁸²

Additional Benefits of Aerobic Training

In addition to increased exercise capacity, other benefits of endurance training realized by healthy people appear to be attainable for individuals with neuromuscular disabilities. However, direct evidence of the impact on ICF-related domains remains limited.

Cardiopulmonary Function

Decreases in HR at a fixed submaximal workload after training have been attributed to increases in total blood volume¹⁸³ and vagal activity and to concomitant reductions in sympathetic-adrenergic drive and resting heart rate (HR_{rest}).¹⁸⁴ However, according to Wilmore and colleagues¹⁸³ the decrease in HR_{rest}

is of minimal physiological significance. Potempa and colleagues¹⁸⁵ reported reduction in SBP at submaximal workloads after a 10-week training program for people after stroke. Related to this finding, training can also reduce the rate-pressure product (product of HR and SBP) at submaximal loads,⁶³ which reflects improvement in cardiac efficiency.¹⁸⁶ After a 4-week single-limb exercise training program with the hemiparetic limb, Billinger and colleagues¹²² reported significant improvements in femoral artery blood flow and diameter compared with the nonhemiparetic limb poststroke. The authors reasoned that in order to maintain homeostasis, the diameter increased to adjust for the coupling of increases in metabolic demand and improved blood flow.

In patients with CAD, training has resulted in decreased ST segment depression (a marker of myocardial ischemia) during submaximal exercise performed at the same baseline rate pressure product,¹⁶⁸ thus raising the anginal threshold and extending the time that submaximal tasks can be performed without triggering myocardial ischemia. Cardiovascular and muscle adaptations also lower minute ventilation at a given submaximal workload, intimating improved ventilatory efficiency.¹⁸⁷ After training, V_{O_2} at a given submaximal workload is either unchanged¹⁹ or modestly reduced¹⁸⁸ because the increased $\text{a-vO}_2\text{diff}$ in trained muscles is offset by reduced blood flow to the working muscles and a less pronounced decrease in blood flow to the nonexercising muscles resulting from depressed sympathetic reflex activity.¹⁷¹ As a result of improved pulmonary function resulting from targeted expiratory¹⁸⁹ and inspiratory¹⁹⁰ muscle training in people with MS, it may be possible for members of this population to increase exercise tolerance.

Cardiovascular Risk Factor Reduction

Although limited physical activity is an independent predictor of risk of stroke,¹⁹¹⁻¹⁹³ the capacity of exercise to confer similar protective benefits against stroke recurrence is unknown. It is clear that endurance exercise training lowers resting BP in both young and older hypertensive adults.¹⁹⁴ Training is also associated with lower fasting and glucose-stimulated plasma insulin levels and with improved glucose tolerance (if initially impaired), insulin sensitivity,¹⁹⁵ and glycemic control in patients with type 2 diabetes.¹⁹⁶ A 6-month treadmill exercise training program reduced insulin resistance in stroke survivors.¹⁹⁷ Evidence suggests that populations with neurological disorders achieve similar training-induced improvements in lipid profile as previously documented for participants in cardiac rehabilitation.¹⁹⁸ Patients with MS showed reductions in triglyceride and very-low-density lipoprotein levels after a 15-week training program.¹⁹⁹ Similarly, an 8-week training program for individuals early after SCI led to improved lipid profiles, with more pronounced changes in response to high-intensity training.²⁰⁰ However, these changes may be a result of training-induced reductions in body fat stores.²⁰¹ The potential for training to reduce intraabdominal fat is particularly significant because it is the body fat depot that increases the most with age and is associated with other cardiovascular disease risk factors.²⁰² Because of the positive effects on glucose homeostasis, lipid lipoprotein profiles, and cardiovascular fitness, exercise training has been found to be effective in reducing the risk of cardiovascular disease and

comorbidities (e.g., type 2 diabetes, hypertension, obesity) in people with SCI.¹⁵¹ Stroke survivors participating in a 10-week cardiac rehabilitation program obtained greater improvements in cardiac risk score when compared with stroke patients in usual care.²⁰³

Impairments in Body Structure and Function

The benefits of training to impairments in body structure and function of people with neurological disabilities, other than improved endurance and exercise tolerance, have not been well documented. In patients who have had a stroke, training studies have noted enhanced balance²⁰⁴ and paretic lower-extremity muscle strength.¹⁶⁴ A 15-week aerobic training program for patients with MS resulted not only in improvement in exercise capacity but also in upper- and lower-extremity strength.¹⁹⁹ Children with CP have shown improved gross motor function after participating in an 8-month circuit-training program.²⁰⁵

An exercise training program designed to improve ambulatory efficiency of patients with traumatic brain injury failed to reduce energy costs of walking despite a 15% improvement in $\text{V}_{\text{O}_2\text{peak}}$.²⁰⁶ In contrast, two studies reported mean reductions in energy costs of walking of 30%⁵³ and 23% after stroke rehabilitation,⁵⁴ and a pilot study reported a 32% reduction in the energy cost of walking in individuals with incomplete spinal cord lesions after a 12-week program of body-weight-supported treadmill training (BWSTT).¹⁹³ Macko and colleagues⁴⁰ interpreted gains observed in ambulatory workload capacity as a reflection of both improved exercise capacity and greater gross motor efficiency. The investigators postulated that central neural motor plasticity, mediated by the repetitive, stereotypic training, underlay these adaptations. In addition, Luft and colleagues²⁰⁷ suggest that training-induced gains in walking ability^{208,209} may be caused by neuroplastic mechanisms involving cerebellum-midbrain circuits.²⁰⁷

In recent years the possible role that dynamic exercise may play in enhancing cognitive function has come under investigation. In fact, in older adult populations without known cognitive impairment and in cardiac populations, there is evidence supporting the benefit of exercise training on improving cognition.²¹⁰⁻²¹² Neepner and colleagues²¹³ observed up-regulation of brain-derived neurotrophic factor (BDNF) in the cerebral cortex of rats housed in an environment with free access to a running wheel. Since then, several researchers have demonstrated increased BDNF production and synaptic plasticity in the brains^{214,215} and spinal cords²¹⁶ of rodent models engaged in voluntary running. Tong and colleagues²¹⁷ reported that these responses appear to be dose dependent. Van Praag and colleagues²¹⁸ contributed to this line of inquiry by providing *in vitro* evidence of neurogenesis in the dentate gyrus of adult mice in response to an enriched environment that included voluntary wheel running. Gordon and co-workers²¹⁹ drew on the findings from these animal studies by suggesting that the improved cognitive function observed in individuals with traumatic brain injury who exercised regularly may be attributable to exercise-induced increases in BDNF or other growth factors. In another animal study, positive effects of aerobic training on neural functioning through the modulation of synaptic plasticity underlying neuroprotective and neuroadaptive processes were found.²²⁰ In terms of fatigue, after an 8-week

hospital-based training program, patients with postpoliomyelitis were found to have reduced levels of fatigue. However, limited evidence exists regarding the effect of exercise on fatigue in patients with Guillain-Barré syndrome²²¹ and MS.²²²

Emotional Well-Being

Increased exercise capacity has been shown to improve mental well-being (reductions in anxiety and depression) in cardiac patients.^{223,224} There is moderate evidence regarding the effect of exercise training on improving mood in patients with MS.²²² Very limited evidence exists to support the relationship between aerobic exercise and emotional well-being poststroke. Yet 18% to 68% of stroke survivors are depressed,¹⁹¹ making this population at an increased risk for depression.²²⁵ High levels of physical disability, cognitive impairment, and severity of stroke have been found to be predictors of poststroke depression.²²⁶ Stuart and colleagues²²⁷ reported that stroke survivors participating in an exercise group improved their average score on the Hamilton Rating Scale for Depression, which for the control group remained constant. In addition, Lennon and colleagues²⁰³ found that greater improvements in depressive symptoms were found in poststroke patients who participated in a 10-week cardiac rehabilitation program than in the usual care group.

Activity, Participation, and Quality of Life

Few investigators have studied training-induced changes in activity, participation, and quality of life for people with neurological disabilities. Evidence has been found regarding the positive impact of exercise training on quality of life for people with MS,^{199,228,229} CP,^{205,230} and postpoliomyelitis.²³¹ Turner and colleagues²²⁸ reported better physical and mental health, as well as social functioning, in veterans with MS who exercised. However, only 26% of the 2996 veterans surveyed reported engaging in physical activity.²²⁸ Dieruf and colleagues²³⁰ found that after a 2-week intensive BWSTT program, children with CP reported improvements on a health-related quality-of-life measure. This finding may indicate that with a physically and psychologically challenging intervention program, along with encouragement from their parents and practitioners, children with CP may gain a better perception of their level of control and health and ultimately improve their quality of life.²³⁰ In stroke survivors gains in walking capacity have been reported in terms of both gait speed^{164,204} and walking tolerance.²⁰⁴ However, there is insufficient evidence to support whether cardiovascular exercise improves quality of life after stroke.^{225,232} Small improvements in VO_2peak can have a substantial impact on the ability to perform daily activities, particularly in individuals with limited cardiac or ventilatory reserves, but there is a lack of documentation of these benefits in people with neurological disorders.

Aerobic Exercise Prescription to Optimize Fitness of People with Neurological Disabilities Safety and Screening

In general terms, the risks imposed by lack of exercise are far greater than those imposed by exercise. Nevertheless, it is of paramount importance to recognize that symptomatic and asymptomatic cardiovascular disease, and related

comorbidities such as diabetes, are much more prevalent in patients with many neurological conditions than in the general population. Because there is limited evidence regarding safety of aerobic exercise for people with neurological disorders, best clinical judgment should be used in aerobic exercise prescription. Thorough review of the health records of potential participants is critical to identify problems that may preclude safe participation in aerobic training programs. Cardiac screening, including a physician-monitored exercise stress test with continuous electrocardiographic and periodic BP monitoring, is essential for those with known or suspected cardiac comorbidities. Table 30-3 provides a compilation of contraindications to testing and training.^{27,233} Before an exercise program is implemented without preliminary exercise testing, the following should be considered: (1) careful screening for possible contraindications must be conducted, (2) training must be done under the close surveillance of trained personnel, (3) a period of continuous electrocardiography and telemetry at the initiation of training is recommended, and (4) monitoring of BP, HR, and signs of exercise intolerance is essential. Furthermore, for subjects with pulmonary comorbidities such as chronic obstructive pulmonary disease, O_2 saturation levels should be monitored, with saturation levels less than 85% as the criterion to terminate exercise.²³⁴

In the past, clinicians were apprehensive about the possibility that the overload necessary to achieve an aerobic training effect could aggravate spasticity in patients with neurological disorders; however, such concerns have not been substantiated.²³⁵⁻²³⁸ On observing that the muscles of most patients (81%) in the subacute stroke period were nonspastic, Sommerfeld and colleagues²³⁷ postulated that focusing on spasticity may be out of step with its clinical importance. Furthermore, there is evidence from studies of cats²³⁹ and humans after SCI²⁴⁰ that treadmill training may, in fact, reduce spasticity by improving stretch reflex modulation.

Another concern raised regarding the implementation of aerobic training in neurological disorders is the potential for eliciting excessive fatigue. For people with MS, increased fatigue levels have been reported after high-intensity exercise²⁴¹; however, exercising at an appropriate intensity has been shown to yield benefits without aggravating fatigue.²⁴² A preliminary study involving people with MS reported that although fatigue was a significant problem for most subjects, a single bout of low- to moderate-intensity exercise had no deleterious effects on fatigue levels immediately after, and at 24 hours after, the exercise session.²⁴³ Dawes and colleagues²⁴⁴ found that for most of their subjects early after traumatic brain injury, increasing the workload during cycling exercises did not elicit a disproportionate increase in VO_2 .

Initiation of Training

Most of the training studies on populations with neurological disorders have involved patients with chronic neurological impairments; however, the optimal time to introduce training is unknown. Macko and colleagues²⁴⁵ expressed caution about training in the early poststroke period, speculating that abnormal cardiovascular responses to exercise (e.g., hypotension, arrhythmia) may impede perfusion of ischemic brain tissue during the period when cerebral autoregulation is most often impaired. Nevertheless, in one

TABLE 30-3 ■ CONTRAINDICATIONS TO EXERCISE TESTING AND AEROBIC TRAINING**ABSOLUTE CONTRAINDICATIONS**

Acute systemic illness or fever
 Shortness of breath at rest
 Suspected or known dissecting aneurysm
 Suspected or known active myocarditis or pericarditis
 Thrombophlebitis or intracardiac thrombi

RELATIVE CONTRAINDICATIONS

Myocardial infarction	Recent or complicated myocardial infarction
Heart surgery	Recent (within 3 months)
Angina	Unstable angina (within past 6 months), uncontrolled with medication, exertional angina at exercise intensities <3 metabolic equivalents (METs)
Ventricular arrhythmia	Uncontrolled with medication
Atrial arrhythmia	Uncontrolled atrial arrhythmia that compromises cardiac function
Resting ST segment displacement	>2 mm displacement
Atrioventricular block	Third-degree block without a pacemaker
Sinus tachycardia	HR _{rest} >120 bpm
Pacemaker	Fixed rate pacemaker
Ventricular ectopy	Frequent or complex premature ventricular contractions at rest or during exercise
Congestive heart failure	Acute or uncompensated failure
Aortic stenosis	Moderate to severe aortic stenosis (peak systolic pressure gradient <50 mm Hg with aortic valve orifice <0.75 cm ² in an average-sized adult)
Carotid stenosis	Severe stenosis
Large vessel intracranial stenosis	Severe stenosis
Systemic or pulmonary embolus	Recent embolus
Emotional distress or psychosis	Significant emotional distress
Hypertension	Resting SBP >200 or resting DBP >110 mm Hg
Valvular disease	Moderate or severe valvular disease
Electrolyte abnormalities	Hypokalemia or hyperkalemia or hypomagnesemia
Metabolic diseases	Uncontrolled diabetes with resting blood sugar >400 mg/dL, thyroiditis, myxedema
Orthostatic hypotension	>20 mm Hg drop with symptoms
Sudden weight gain	>2 kg increase in previous 1-3 days
Cardiac class	New York Heart Association functional class IV
Dizziness	Significant motion-induced dizziness or vertigo
Orthopedic conditions	Severe pain on weight bearing

study, training was initiated 8 to 21 days after stroke without complications.⁵⁰ In addition, an exercise rehabilitation trial, also involving patients in the hyperacute stage poststroke, began early mobilization within 24 hours of stroke onset.²⁴⁶ The intervention group receiving early mobilization training reported fewer nonserious adverse events, and there were no differences in the total number of serious adverse events and fall rate when compared with the group receiving usual care.²⁴⁶ Furthermore, because there is increased plasticity (e.g., axonal sprouting and neurogenesis) of the periinfarct cortex during the first month after an ischemic stroke, early training may accelerate functional recovery.²⁴⁷

Training Environment

High-risk individuals, such as patients in the early stages of neurological recovery or with cardiac comorbidities, should be trained in a setting with quick access to emergency medical equipment and trained personnel. An adverse event protocol should be posted and rehearsed. Lower-risk individuals, after appropriate screening to ensure an appropriate response to exercise, can be trained in supervised community²⁴⁸ or home-based²⁰⁴ aerobic exercise programs. One study involving postpolio patients reported reductions in

fatigue and improvements in quality of life but found no changes in exercise capacity when patients were trained in either a hospital or home setting.²³¹ However, Hassett and colleagues²⁴⁹ reported similar gains in cardiovascular endurance in poststroke patients training in either an unsupervised home-based or a supervised facility-based exercise program. Regardless of the setting, certain safeguards are required. Because thermal dysregulation is common in patients with neurological disability, particularly MS²⁵⁰ and spinal cord injuries,²⁵¹ the ambient temperature should be carefully controlled and fans, spray bottles, towels, and a water cooler are recommended. Hydration before and during exercise and rehydration after exercise should be monitored by use of a water bottle with volumetric indicators. The exercise area should be wheelchair accessible, free of obstacles and blunt objects, and sufficiently large to permit safe transfer to and from exercise equipment.

Preparation of Participants

Participants should be advised to avoid eating 2 hours before training and to empty bowel and bladder before training, when possible, especially for patients with SCI above T6 at risk of autonomic dysreflexia. Comfortable clothing and

supportive footwear, appropriate for dynamic exercise, prepare the participant both physically and psychologically for training.

Scheduling of Sessions

Many patients with neurological involvement report a decline in energy levels in the afternoon. If fatigability is a concern, training should be scheduled for morning hours, when circadian body temperature is at its lowest. For certain patient groups, including people with Parkinson disease, training should be coordinated with the timing of medication to optimize performance.

Duration of Program

A meaningful increase in aerobic capacity (i.e., greater than 10% improvement) of individuals without neurological impairment is unlikely to occur in less than 4 weeks.²⁵² The minimal exposure required for people with neurological disabilities has not been fully investigated. However, da Cunha and colleagues⁵⁰ reported a mean improvement of 35% in VO_2peak after 2 to 3 weeks of treadmill ergometry in six people who had had a stroke less than 1 month previously. Regardless of the minimum, participation in training must be sustained indefinitely to prevent return to the deconditioned state measured at the beginning of the program. Therefore a maintenance program should be followed after termination of formal training sessions.

Frequency and Duration of Sessions

To optimize aerobic training, three to five sessions per week are required, although fitness can improve with twice-weekly sessions.²⁷ Although a minimum of 20 minutes of exercise within the target zone for training per session is required to elicit a training effect,²⁷ we documented that patients engaged in 1-hour sessions of stroke rehabilitation spent, on average, less than 3 minutes per session within the training zone.⁴ For those with low fitness levels or who are very deconditioned (which would include the majority of patients with neurological involvement) training may be initiated with 5-minute exercise “bouts” with rest periods between bouts. Two additional 5-minute periods are required for warmup and cool down; hence the minimal time required to complete a training session is 30 minutes. Incrementally increasing the duration to a target of 40 to 60 minutes of aerobic training is recommended. However, the greater the intensity of exercise, the shorter the duration needed to achieve improvement in cardiopulmonary fitness; conversely, low-intensity exercise can be compensated for by longer duration.²⁵³ As well, accumulation of 10- to 15-minute periods of activity throughout the day can yield similar physiological improvements, provided that the total volume of training is comparable.²⁵⁴

Mode of Training

To induce central adaptations, training must incorporate large muscle mass activities that require elevated levels of VO_2 . Treadmill or overground walking is a preferred mode because of its direct functional nature; however, a variety of disabilities may preclude this approach. Suitable alternatives include the cycle ergometer with toe clips and heel straps, recumbent ergometer, arm-leg ergometer, wheelchair ergometer, and stepping machine and swimming. Indeed,

water-based exercise poststroke has shown positive effects on cardiovascular fitness and coping with life after stroke.¹⁶³ In addition, body-weight-supported treadmill training can also be used during early aerobic training poststroke.⁵⁰ Although arm ergometry activates a smaller portion of total muscle mass, its effectiveness in the aerobic training of patients with quadriplegia has been demonstrated.²⁵⁵ Innovative approaches have been introduced to overcome limitations to exercise training imposed by upper motor neuron damage. For example, a combination of electric stimulation of lower-extremity muscles and voluntary upper-extremity rowing has been applied to augment the muscle activation of patients after SCI.¹⁶⁶ Grealy and colleagues²⁵⁶ piloted use of a virtual reality recumbent ergometer with patients after traumatic brain injury, postulating that the interaction between the training apparatus and the participant might enhance attention to the task of exercising and increase the potential of structural changes in the brain.

A continuous, interval, or circuit training regimen may be used. Typically, training studies involving patients with neurological disabilities have used short bouts of exercise with a gradual transition to continuous training. However, it has been recommended for some time that if continuous training results in either a lack of improvement or a plateau in response, interval training should be instituted.^{153,257}

Muscle Strengthening

Traditionally, aerobic training programs emphasized dynamic exercise. However, the addition of resistance training improves outcome.^{238,258} Moreover, strength training decreases the cardiac demands of daily tasks such as lifting objects or carrying groceries while simultaneously increasing the endurance capacity to sustain these submaximal activities.²⁵⁹ Muscle strengthening exercises should also be carried out 2 or 3 days per week. Key muscle groups (e.g., triceps, biceps, abdominals, hip and knee flexors and extensors, hip abductors, ankle dorsiflexors, and plantarflexors) should be strengthened with one set of 10 to 15 repetitions starting at a low weight and avoiding a Valsalva maneuver.²⁷ Including strength training with aerobic training may produce greater gains in functional and health outcomes. For example, engaging in a combined strength and aerobic training program has been shown to be more effective in improving VO_2peak , walking endurance, and lipid profile in people with type 2 diabetes.²⁶⁰ Improved fitness outcomes have also been reported in people who have had a stroke,²³⁸ despite controversy about whether the benefits of strength training of the paretic upper limb poststroke outweigh the potential risk of increased tone and pain, particularly in the shoulder region. However, the meta-analysis by Harris and Eng²⁶¹ found no reported adverse effects after upper-limb strength training and concluded that upper-limb strength training improves upper-limb strength and function in people poststroke. In people with SCI, increases in fitness level and reduction in shoulder pain have been observed after circuit training involving resistance exercises and arm cranking.²⁶²

Intensity of Training

Determining an appropriate intensity is the most challenging aspect of exercise prescription. The cardiovascular system responds to overload; hence, the metabolic load must be sufficient to provoke central and peripheral adaptations.

TABLE 30-4 ■ FORMULAE USED TO DETERMINE THRESHOLD INTENSITY FOR EXERCISE TRAINING

FORMULA	COMMENTS
Karvonen method: $HR_{rest} + x\%$ of heart rate reserve unfit (HRR), where $HHR = \text{predicted } HR_{max}^* - HR_{rest}$	Training intensities of 40%-85% HHR are recommended, ²⁷ but for patients intensities of 30% HHR can be effective. ¹⁸²
$x\%$ of predicted $HR_{max} = 220 - \text{Age}$, where predicted	Deconditioned individuals can benefit from intensities as low as 55%-64% of predicted HR_{max} . ²⁷
$HR_{max} = 220 - \text{Age}$ OR $HR_{max} = 206.9 - (0.67 \times \text{age})$ ³²⁹ ; if on β -blockers, predicted $HR_{max} = 164 - 0.7 \times \text{Age}$ ²⁶⁹	
$HR_{rest} + x$ beats	The recommended intensity after myocardial infarction is $HR_{rest} + 20$ beats and after cardiac surgery is $HR_{rest} + 30$ beats. ²⁷
$x\%$ of VO_{2peak}	Deconditioned individuals can benefit from intensities as low as 40%-50% of VO_{2peak} . ²⁷

* HR_{max} , Maximal heart rate.

However, excessive stress imposed on the heart and contracting skeletal muscles can evoke abnormal clinical signs or symptoms. The initial exercise intensity and progression must be individualized using the participant's HR or VO_{2peak} data (Table 30-4). The RPE can serve as a valid proxy to more physiological measures³⁰; ratings of 11 ("fairly light") to 13 ("somewhat hard") on the RPE scale of 6 to 20 are recommended for initiation of training.²⁷ The RPE range associated with physiological adaptation to exercise is 12 to 16 on the Borg (6 to 20) category scale or 4 to 6 on the Borg (0 to 10) scale.²⁷ Despite considerable interindividual variation in RPE,²⁶³ the ratings have been shown to correlate well with exercise intensity, even in patients taking β -blockers.²⁶⁴ When exercise intensity is being established, other variables (e.g., anginal symptoms, arrhythmias) should also be considered. Continuous monitoring of HR and periodic monitoring of BP and RPE will ensure that an appropriate intensity is sustained during training.

In addition to the RPE, another proxy measure of intensity is the talk test, in which the participant's intensity is regulated by whether he or she can sing (in which case intensity should be increased) or whether he or she is unable to talk (in which case intensity should be decreased). At an appropriate intensity the participant should be able to talk while exercising, as the point of "hearing your breath" while exercising occurs at or near the ventilatory threshold.²⁶⁵ This relationship was confirmed by Foster and colleagues,²⁶⁶ who reported that the exercise intensity at the ventilatory threshold corresponds to the greatest intensity with which a participant can comfortably speak. Recently, the counting talk test (CTT) was introduced as another proxy measure; it measures how high the participant can count aloud without taking a second breath (e.g., "one, one thousand; two, one thousand...").²⁶⁷ The percentage of resting CTT has been reported to be strongly correlated with the percentage of HR reserve, VO_{2} reserve, and RPE, with moderate intensity coinciding with 50% of CTT.²⁶⁷ It should be noted, however, that the validity of the proxy measures of intensity has yet to be validated in neurological populations. For example, in the SCI population, no association was found between RPE and both HR and VO_{2} .¹²⁹

The American College of Sports Medicine guidelines recommend light- to moderate-intensity physical activities to optimize *cardiopulmonary health*.²⁵⁴ In fact, a meta-analysis

revealed that for very unfit patients (which would include many people with chronic neurological conditions), the initial intensity can be much lower than previously recommended.¹⁸² However, the only consistent beneficial cardiovascular response to low levels of training is reduction in BP in older hypertensive adults. To reduce cardiovascular risk factors and increase *cardiopulmonary fitness*, moderate- or high-intensity exercise appears to be necessary.²⁰² In agreement, Fisher and colleagues²⁶⁸ reported greater consistent improvements in gait parameters (self-selected gait speed, stride length, and step length), hip and ankle joint excursion, and sit-to-stand measures and lengthening of cortical silent period durations measured through transcranial magnetic stimulation in people with Parkinson disease participating in high-intensity BWSTT when compared with low-intensity or zero-intensity exercise programs. Nevertheless, light-intensity to moderate-intensity physical activity programs may prove adequate to reduce the rate of age-associated deterioration in a variety of physiological functions and in the long run may improve both quantity and quality of life.²⁰²

For many people with neurological involvement, determination of an appropriate intensity of exercise is confounded not only by cardiac status but also by the extent of neurological impairment. We have derived guidelines for determining the initial intensity of treadmill training for people after stroke, based on baseline cardiac signs, prescription of β -adrenergic blockade therapy,²⁶⁹ fitness level, and motor control of the involved lower extremity (i.e., Chedoke-McMaster stage of recovery of the leg)²⁷⁰ (Table 30-5).

Music to Pace Exercise

Music, if properly selected, can be helpful in pacing the repetitive, alternating movements characteristic of aerobic exercise such as walking or cycling. Rossignol and Jones²⁷¹ found that with close matching of the cadence of music and alternating movements, music can potentiate muscle activation. Similarly, McIntosh and colleagues²⁷² reported that music facilitated the gait pattern of people with Parkinson disease. (Refer to Chapters 4, 20, and 39 for additional information.)

Progression of Training Program

Exercise progression must be individualized because people with neurological disabilities have a wide range of functional capacities. Progression usually occurs over a 3- to 6-month

TABLE 30-5 ■ GUIDELINES FOR DETERMINING THE INITIAL INTENSITY OF TRAINING OF PEOPLE POSTSTROKE

	LOW INTENSITY	MODERATE INTENSITY	HIGH INTENSITY
Intensity	Minimum target HR = HR _{rest} + 40% HRR	Minimum target HR = HR _{rest} + 50% HRR	Minimum target HR = HR _{rest} + 60% HRR
Cardiac signs	Mild-moderate abnormalities on ECG ± BP ± HR responses	Borderline abnormalities on ECG ± BP ± HR responses	Normal ECG ± BP ± HR responses
Fitness level	Vo _{2peak} <40% predicted	Vo _{2peak} 40%-60% predicted	Vo _{2peak} >60% predicted
Motor control	Chedoke-McMaster stage of leg: 1 or 2	Chedoke-McMaster stage of leg: 3 or 4	Chedoke-McMaster stage of leg: >4

BP, Blood pressure; ECG, electrocardiogram; HR, heart rate; HRR, heart rate reserve.

period from an initial conditioning phase to a training phase and then to a maintenance phase. Generally the first goal of training is to reach a target frequency (i.e., a minimum of 3 days per week), then duration (minimum of 20 minutes), and finally an appropriate intensity (40% to 60% of HR reserve, or 11 to 13 on the Borg scale). Subsequently, exercise duration should be increased as tolerated, every 1 to 3 weeks, with a goal of achieving 20 to 30 minutes of continuous exercise before increasing the intensity.²⁷ Patients with higher baseline fitness levels can be progressed more rapidly than those with lower initial capacities.

Laboratory Outcome Measures

Laboratory tests are useful not only to identify limitations in exercise capacity and establish exercise training protocols but also to evaluate the effectiveness of a training program. The principal indicator of a training effect is attainment of a higher Vo_{2peak} than was achieved in the pretrained state. The greatest increments occur in individuals with the lowest initial Vo_{2peak}.¹⁶¹ Ideally, Vo_{2peak} should be measured directly because indirect methods of predicting exercise capacity are more variable and prone to error. However, because Vo_{2peak} testing requires special equipment and trained personnel, clinicians often resort to clinical measures of functional capacity.

Clinical Outcome Measures

Six-Minute Walk Test. The distance walked in 6 minutes is sometimes used as a clinical surrogate for Vo_{2peak} testing. However, the systemic response to the six-minute walk test (6MWT) is less than that of an incremental test using a treadmill cycle²⁷³ or cycle ergometer.^{274,275} Subjects tend to walk at a constant speed, achieve a Vo₂ steady-state condition after the first few minutes of exercise, and, with practice, walk at a pace approaching critical power.^{275,276} Pang and colleagues²⁷⁷ found a low correlation ($r = 0.402$) between 6MWT distance and Vo₂ in patients after stroke, concluding that the 6MWT alone should not be used as an indication of cardiopulmonary fitness after stroke. The same laboratory recommended that, to enhance the usefulness of the 6MWT, BP and HR should be recorded at initiation and termination of the test.²⁷⁸ Reference equations for the 6MWT can be used to compute the percent of predicted total distance walked in the 6MWT: for men, Distance (m) = $(7.57 \times \text{Height [cm]}) - (5.02 \times \text{Age [yr]}) - (1.76 \times \text{Weight [kg]}) - 309$; for women, Distance (m) = $(2.11 \times \text{Height [cm]}) - (5.78 \times \text{Age [yr]}) - (2.29 \times \text{Weight [kg]}) + 667$.²⁷⁹
