It is important to note that the injury from an HI insult is an evolving and progressive process that begins at the time of the insult and continues through the recovery period (Figure 11-8). The HI insult causes decreased oxygen and glucose delivery to the brain, causing a shift from aerobic to anaerobic metabolism. This causes a decrease in adenosine triphosphate (ATP) production, leading to failure of the membrane-bound $\text{Na}^+\text{-K}^+\text{-ATPase}$ pump. Sodium enters the neuronal cell, causing depolarization and release of excitatory neurotransmitters, specifically glutamate. This initial phase can last several hours and is marked by significant acidosis, depletion of high-energy compounds (energy failure), cellular swelling caused by entry of sodium and water, and cellular necrosis, causing spillage of intracellular contents into the extracellular space. The degree of neuronal necrosis is directly related to the duration and severity of the HI insult. During the subsequent reperfusion phase, free radical production increases and activation of microglia from extruded intracellular contents occurs, causing release of inflammatory mediators. A second phase of energy failure ensues, but without acidosis. Calcium enters the cell and the mitochondria, which then turns on the apoptotic pathway (programmed cell death). During this second phase of energy failure, seizures are often present. Activation of the apoptotic pathway accounts for the majority of cellular death and is the target for treatment.^{27,28} The specific timing of the initiation of the reperfusion phase and the second phase of energy failure is unclear in the clinical setting because the actual timing of the HI insult is not well defined. In animal studies, the latency between the first and second phases of energy failure is several hours.

In term infants with HIE the cerebral damage is located in the deep structures of the brain (basal ganglia, thalamus, and posterior limb of the internal capsule) as well as the subcortical and parasagittal white matter.⁴⁴ Diffusion-weighted MRI (DWI) is a very early diagnostic and sensitive technique to identify damage after the HI insult. As shown in Figure 11-8,

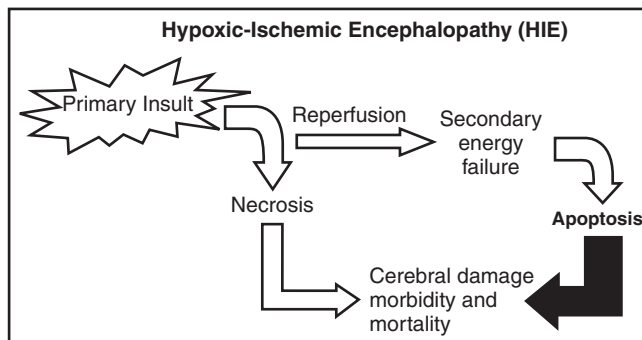

Figure 11-8 ■ Sequential events that occur after hypoxic-ischemic (HI) insult. Initial event leads to cellular necrosis and cerebral damage. Secondary energy failure and initiation of the apoptotic pathway lead to the majority of injury after HI insult. Degree of secondary energy failure as measured by magnetic resonance imaging spectroscopy is highly correlated with neurodevelopmental outcome. (From Adams-Chapman I, Hansen NI, Stoll BJ, et al: Neurodevelopmental outcome of extremely low birth weight infants with posthemorrhagic hydrocephalus requiring shunt insertion. *Pediatrics* 121:e1167–e1177, 2008.)

a marked increase in signal in the subcortical and parasagittal white matter occurs as well as in the deep nuclear structures on DWI. MRI spectroscopy, localized to the basal ganglia or subcortical area, yields information about degree of secondary energy failure by analyzing for the depletion of the high-energy compound *N*-acetylaspartate and the presence of lactate.^{44,45} The degree of secondary energy failure as noted on MRI spectroscopy is predictive of death and poor neurodevelopmental outcome at 1 and 4 years of age.

Classification of the clinical signs associated with HIE is shown in Table 11-3.⁴⁶ Infants with grade 1 HIE rarely have long-term sequelae. Infants with grade 2 or moderate HIE have abnormal tone and reflexes and decreased spontaneous activity, with seizures commonly present. Approximately 10% of infants with moderate HIE will die and up to 30% will have neurodevelopmental delay. Infants with severe HIE (grade 3) exhibit minimal or no spontaneous activity or reflexes. Clinically evident seizures are seldom present, but electrographically evident seizures are more common. Approximately 50% of these infants die, and of the survivors, more than 60% to 80% are profoundly impaired. Long-term consequences of HIE include bulbar palsies with difficulties in sucking, swallowing, and facial movement. These infants have difficulty with secretions and may require tube feeding owing to inability to protect the airway. Upper-extremity involvement is more prominent than lower-extremity deficits because the damage to the cerebral cortex is located in the parasagittal region (see Figure 11-7). The development of epilepsy occurs in about 30% of infants with HIE. Mental retardation and difficulties at school age occur frequently.

Mild hypothermia (33.5° C) from application of cooling blankets or caps is becoming the standard of care for infants ≥ 36 weeks' gestation who have an acute asphyxial event and moderate or severe HIE.⁴⁷ Hypothermia has been shown to decrease cerebral metabolic demand and thus help preserve high-energy compounds. Hypothermia also delays membrane depolarization and decreases neuronal excitotoxicity. Free radical production and microglial activation are decreased. Most important, the activation of the apoptotic pathway is diminished. Transient side effects of hypothermia, such as bradycardia, mild hypotension, thrombocytopenia, and persistent pulmonary hypertension, can be medically treated and are usually not significant.^{48,49} A meta-analysis of published randomized studies comparing infants with moderate and severe HIE treated with either hypothermia or normothermia shows that hypothermic treatment significantly decreases mortality and morbidity (Table 11-4).⁵⁰ Hypothermia appears to be more efficacious in ameliorating brain damage in infants with mild HIE than in infants with severe HIE. It is known that hypothermia is most effective when administered before the onset of the second phase of energy failure. Because the HI insult can occur before delivery, it is postulated that hypothermia should be initiated as quickly as possible after delivery to increase the likelihood that it will diminish the neuronal damage and improve neurodevelopmental outcome.

Maternal Medication

The impact of maternal medications on the developing fetal brain depends on the specific drug as well as on the timing and duration of the drug exposure. Whereas the insults

TABLE 11-3 ■ SARNET SCORING SCALE FOR ENCEPHALOPATHY

	STAGE 1 (MILD)	STAGE 2 (MODERATE)	STAGE 3 (SEVERE)
Level of consciousness	Hyperalert	Lethargy, obtunded	Stuporous
Neuromuscular signs			
Muscle tone	Normal	Mild hypotonia	Flaccid
Posture	Mild distal flexion	Distal flexion	Decerebrate
Movement	Spontaneous	Decreased to little	Noxious stimuli
Stretch reflexes	Overactive	Overactive	Decreased or absent
Primitive reflexes			
Suck	Weak	Weak or absent	Absent gag
Moro	Strong	Weak or incomplete	Absent
Autonomic function	Sympathetic	Parasympathetic	Depressed
	Dilated pupils	Constricted pupils	Pupils nonreactive
	Tachycardia	Bradycardia	Variable heart rate
		Copious secretions	Apnea
		Periodic breathing	Loss of temp regulation
Seizures	None	Common	Uncommon
		Focal or multifocal

From Edwards AD, Brocklehurst P, Gunn AJ, et al: Neurological outcomes at 18 months of age after moderate hypothermia for perinatal hypoxic ischaemic encephalopathy: synthesis and meta-analysis of trial data. *BMJ* 340:c363, 2010.

*Severe disability was defined in the CoolCap and TOBY trials as the presence of at least one of the following impairments: Mental Development Index score of less than 70 (2 standard deviations below the standardized mean of 100) on the Bayley Scales of Infant Development; gross motor function classification system level 3 to 5 (where the scale is from 1 to 5, with 1 being the mildest impairment); or bilateral cortical visual impairment with no useful vision. The NICHD trial defined disability as a Mental Developmental Index score of 70 to 84 plus one or more of the following impairments: gross motor function classification system level 2; hearing impairment with no amplification; or a persistent seizure disorder.

[†]Survival with normal outcome was defined as survival without cerebral palsy and with a Mental Developmental Index score of more than 84, a Psychomotor Developmental Index score of more than 84, and normal vision and hearing.

[‡]Severe neuromotor delay was determined on the basis of a Psychomotor Developmental Index score of less than 70 in survivors.

[§]Severe neurodevelopmental delay was determined on the basis of a Mental Developmental Index score of less than 70 in survivors.

discussed previously cause predominantly cellular necrosis and apoptosis, medications given to the fetus and preterm infant cause alterations in the structure and function of genetic material as well as activation of the apoptotic pathway. The hypothesis that factors acting early in life have a long-lasting impact on development is called the *Barker hypothesis* or the *fetal origins of adult disease*. It is proposed that the biological value of this reprogramming is to prepare the fetus for maximal adaptation through methylation and deacetylation of histones, thereby determining the quantity

of specific proteins that are produced. This topic is too extensive to be covered here and has been previously reviewed.^{51,52} This section will focus on heroin, methadone, cocaine, methamphetamine, and selective serotonin reuptake inhibitors (SSRIs) used in the treatment of maternal depression.

Cocaine

It is difficult to ascertain the exact frequency of cocaine use during pregnancy, but reports indicate that 1% to 45% of females have used cocaine during their pregnancy.²⁸

Cocaine is extracted from the leaves of the coca plant and can be smoked, inhaled, or injected into the bloodstream. Cocaine induces an intense and immediate euphoric state and can be very addictive. Unlike with opioids, physical dependence does not occur, but severe and intense cravings last for several months and can recur for years after cessation of cocaine use.

In the adult the actions of cocaine are mediated through several different neurotransmitter pathways in the brain. Cocaine may cause hypertension, tachycardia, and peripheral and coronary artery vasoconstriction via activation of adrenergic pathways. The sense of euphoria is mediated through dopamine pathways. Alterations in sleep-wake cycles are caused by the blocking of serotonin uptake. During pregnancy, cocaine causes decreased blood flow to the kidneys and is implicated in preterm labor, uterine irritability, premature rupture of membranes, and placental abruption.

Cocaine negatively affects neuronal proliferation, migration, growth, and connectivity, which distorts neuronal cortical architecture. However, the effects of intrauterine exposure to cocaine are difficult to determine because cocaine use is frequently associated with abuse of other illicit drugs, cigarettes, and alcohol. Other confounding variables include poor nutrition and limited prenatal care. In a large prospective blinded study, more infants exposed to cocaine in utero were delivered prematurely and exhibited decreased weight, length, and head circumference compared with matched controls.⁵³ However, cocaine exposure did not affect the incidence of congenital abnormalities.

The vasoconstrictive properties of cocaine increase the risk for HI injury and middle cerebral artery stroke. Neonates with prenatal cocaine exposure demonstrate tremors, hypertonia, irritability, and poor feeding ability. Cocaine-exposed infants have abnormal sleep patterns and are at a threefold to sevenfold increased risk of sudden infant death syndrome (SIDS). No difference was found in developmental testing⁵⁴ between cocaine-exposed infants and matched controls, but the tests did not effectively evaluate arousal, emotional control, and social interaction.⁵⁵ In utero cocaine exposure has been linked to increased incidence of behavioral problems and special education referrals in school-aged children. On fMRI, differences in the right frontal cortex and caudate nucleus are evident and indicate abnormalities in regulation of attention and cognitive abilities referred to as *executive function*.

Opioids

The opioids are used less frequently than cocaine during pregnancy, as less than 5% of pregnant woman test positive for opioids. Morphine, a naturally occurring opiate, and heroin, a synthetic opioid, readily cross the placenta and are highly addictive. Because heroin can be injected intravenously, there is an increased risk for infection, especially endocarditis, hepatitis, and human immunodeficiency virus (HIV) infection. Methadone, a synthetic opioid, is the standard for treatment of opioid dependence and has a significantly longer half-life than heroin and morphine. Over the past several years, a trend for increasing rather than decreasing methadone daily dose during pregnancy has helped to decrease maternal illicit drug abuse without increasing the incidence of withdrawal symptoms in the infant.

Opioid use during pregnancy has been associated with tubal pregnancies, premature rupture of membranes, uterine irritability, preterm labor, and preeclampsia. Infants exposed to opioids in utero are intrauterine growth retarded at birth, but methadone has a less severe impact on fetal growth. Infants exposed to opioids in utero are noted to have a decreased incidence of respiratory distress related to enhanced surfactant production⁵⁶ and decreased hyperbilirubinemia as a result of induction of the enzyme glucuronyl transferase used in the metabolism of bilirubin.

Withdrawal from narcotics occurs 2 to 3 days after delivery, but signs can be evident as long as 2 weeks after delivery. Methadone withdrawal usually occurs later than withdrawal from morphine or heroin related to its long half-life. Infants in withdrawal (neonatal abstinence syndrome [NAS]) exhibit gastrointestinal symptoms of vomiting and watery stools; neurological signs such as tremors; hypertonicity; high-pitched and incessant cry; hyperalert state; and sweating and fever. Infants with NAS have decreased ability to nipple feed despite excessive sucking on a pacifier. Seizures can be present in 2% to 11% of infants with NAS. Two commonly used scoring methods for severity of NAS are the Lipsitz⁵⁷ and the Finnegan⁵⁸ scales. The Lipsitz scale has 11 components that are scored from 0 to 3, with any score over 4 necessitating treatment.⁵⁷ The Finnegan scale is a more comprehensive assessment, with more than 30 elements, and treatment is recommended if the score is greater than 8.⁵⁸ A quiet, dimly lighted environment, decreased auditory stimulation, and swaddling or holding have been used to decrease neonatal irritability and pharmacotherapy. About 30% to 80% of in utero opioid-exposed infants will require medical treatment for NAS with morphine and either clonidine or phenobarbital. The goal of treatment is to decrease irritability, improve nipping efforts, and decrease vomiting and diarrhea.

Infants exposed to opioids in utero continue to demonstrate tremulousness, hypertonicity, irritability, and increased crying episodes. In addition, they are less able to interact with people, demonstrate decreased age-appropriate free play, and have delayed fine motor coordination. The incidence of apnea and SIDS is increased in opioid-exposed infants. An appropriate and nurturing home environment is essential after discharge from the hospital to maximize neurodevelopmental outcome.^{59,60}

Selective Serotonin Reuptake Inhibitors

SSRI medications such as fluoxetine (Prozac, Fontex, Seromex, Seronil), sertraline (Zoloft, Lustral, Serlain, Asenta), paroxetine (Paxil, Seroxat, Sereupin, Paroxat), fluvoxamine (Luvox, Favoxil), escitalopram (Lexapro, Cipralax, Esertia), and citalopram (Celexa, Seropram, Citox, Cital) are commonly prescribed to treat depression and anxiety disorders. The SSRI drugs inhibit serotonin reuptake, potentiating serotonergic neurotransmitter signaling. At least 600,000 infants are born yearly to mothers who have a major depressive disorder during their pregnancy.⁶¹ Medical therapy is the most common form of treatment for depression during pregnancy. Approximately 6% of pregnant woman use SSRIs during pregnancy, and almost 40% of depressed women have been reported to use antidepressants at some time during pregnancy.⁶² The serotonergic system is present early in gestation and is important in brain development.

Perturbations in this system are associated with alterations in somatosensory processing and emotional responses.

The SSRI medications readily cross the placenta and are linked to an increased risk of spontaneous abortion but not an increased incidence of malformations.⁶¹ A recently published meta-analysis found that maternal depression was significantly associated with an increased incidence of preterm labor and neonatal birth weight of less than 2500 g but not intrauterine growth retardation of the fetus.⁶³ Unfortunately, this study was unable to evaluate the effect of SSRI therapy on these outcomes. Infants exposed to SSRIs in the third trimester have symptoms similar to withdrawal from opioid exposure (irritability, tremors, jitteriness, agitation, and difficulty sleeping). Neonatal feeding difficulties are common, and seizures and abnormal posturing are occasionally present. These symptoms are transient, appearing 2 to 4 days after birth and disappearing by the second week of life.⁶⁴ It is difficult to identify any specific adverse neurodevelopmental outcomes in infants exposed prenatally to SSRIs from published studies because of the variability in the specific SSRI taken, the duration and timing of SSRI use, and the confounding factors of maternal depression and the use of multiple medications.⁶⁵

Late Preterm Birth

Preterm births have increased over the last 10 years and now constitute about 13% of all births. Late preterm infants—that is, infants born at 34 to 36 $\frac{1}{2}$ weeks' gestation—make up approximately 70% of preterm births.⁶⁶ Many factors are implicated in the early delivery of late preterm infants, including preterm labor, preeclampsia, premature rupture of membranes, sepsis, and multiple gestation pregnancies. The late preterm infant is at increased risk of respiratory distress from insufficient surfactant production, transient tachypnea of the newborn from decreased pulmonary water absorption, persistent pulmonary hypertension, and complications of mechanical ventilation (pneumothorax). Hospital stay is prolonged in the late preterm infant compared with the infant born at term gestation owing to the increased difficulty with oral feeding, need for phototherapy for hyperbilirubinemia, and continuation of antibiotic therapy for suspected sepsis.

Recent evidence has supported the concept that even healthy late preterm infants are at higher risk for neurodevelopmental delay compared with infants at term gestation. The late preterm infant's brain is vulnerable to injury because a significant portion of brain development and maturation occurs during the last 2 months of pregnancy.⁶⁷ Recent studies have shown that late preterm infants tested lower in reading skills in kindergarten and first grade, but not in math skills, than infants born at term gestation.⁶⁸ However, kindergarten and first-grade teachers rated late preterm infants as not as competent as term infants in math and reading ability. Significantly more late preterm infants required special education in kindergarten and first grade compared with control infants. A trend toward increased enrollment in special education in the third and fourth grade was reported.⁶⁸ Late preterm infants were considered at increased risk for (1) developmental delay at 3 and 4 years of age, (2) retention in kindergarten, and (3) referral for special education.⁶⁹ However, maternal age and education were significantly decreased in late preterm infants compared

with infants born at term gestation. In addition, the use of Medicaid, insufficient medical care, and maternal tobacco use were higher in the mothers of late preterm infants. These multiple factors, as well as the home environment, are significant risk factors in determining the effects of late preterm delivery on long-term outcome. Regardless of the specific insult, late preterm infants are at increased risk of neurodevelopmental disabilities and should receive timely developmental follow-up to identify potential underachievement and behavioral problems.

CLINICAL MANAGEMENT: NEONATAL PERIOD

Pediatric therapists with preceptor, subspecialty training in neonatology and infant therapy approaches can expand neonatal services by creating clinical protocols and pathways designed to optimize the development and interaction of neonates and parents. The therapeutic partnership between parents and neonatal therapists during developmental intervention in the NICU sets the stage for parental competency in caregiving and compliance with follow-up in the outpatient period. General aims of NICU clinical management of infants at risk for neurological dysfunction, developmental delay, or musculoskeletal complications are to (1) promote posture and movement appropriate to gestational age and medical stability; (2) support symmetry and biomechanical alignment of extremities, neck, and trunk while multiple infusion lines and respiratory equipment are required; (3) decrease potential skull and extremity musculoskeletal deformities and acquired joint-muscle contractures; (4) foster infant-parent attachment and interaction; (5) modulate sensory stimulation in the infant's NICU environment to promote behavioral organization and physiological stability; (6) provide consultation or direct intervention for neonatal feeding dysfunction and oral-motor deficits; (7) enhance parents' caregiving skills (feeding, dressing, bathing, positioning of infant for sleep, interaction and play, and transportation); and (8) prepare for hospital discharge and integration into home and community environments.

Educational Requirements for Therapists

Examination of and intervention for neonates are advanced-level, not entry-level, clinical competencies. Neonatology is a recognized subspecialty within the specialty areas of pediatric physical therapy⁷⁰ and pediatric occupational therapy.⁷¹ No amount of literature review, self-study, or experience with other pediatric populations can substitute for competency-based, clinical training with a preceptor in an NICU. The potential for causing harm to medically fragile infants during well intentioned intervention is enormous.⁷²⁻⁷⁴ The ongoing clinical decisions made by neonatal therapists in evaluating and managing physiological and musculoskeletal risks while handling small (2 or 3 lb), potentially unstable infants in the NICU should not be a trial-and-error experience at the infant's expense. Therapists with adult-oriented training and even those with general pediatric clinical training (excluding neonatal) are not qualified for neonatal practice without a supervised clinical practicum (2 to 6 months). The NICU is not an appropriate practice area for physical therapy assistants, occupational therapy assistants, or student therapists on affiliations for reasons outlined by Sweeney and colleagues⁸: "handling of vulnerable infants in

the NICU requires ongoing examination, interpretation, and multiple adjustments of procedures, interventions, and sequences to minimize risk for infants who are physiologically, behaviorally, and motorically unstable or potentially unstable.” The physical or occupational therapy assistant and student therapist are not prepared, even with supervision, to “provide moment-to-moment examination and evaluation of the infant and have the ability to modify or stop preplanned interventions when the infant’s behavior, motor, or physiological organization begins to move outside the limits of stability with handling or feeding.”⁷⁸ Appropriate nonhandling experiences for physical therapist or occupational therapist students in the NICU are delineated by Rapport and colleagues,⁷⁵ with a wide range of observational learning experiences with a preceptor recommended in this specialized practice environment. Refer to [Box 11-1](#) for appropriate nonhandling experiences for entry-level students.

Delineation of advanced-level roles, competencies, and knowledge for the physical therapist⁷⁵⁻⁷⁷ and the occupational therapist⁷¹ in the NICU setting have been described separately by national task forces from the American Physical Therapy Association and the American Occupational Therapy Association. These practice guidelines provide a structure for assessing competence of individual therapists working in NICU settings and offer a framework for designing clinical paths for specific neonatal therapy services.

A gradual, sequential entry to neonatal practice is advised by building clinical experience with infants born at term gestation as well as with physiologically fragile older infants and children and their parents. The experience may

include managing caseloads of hospitalized children on physiological monitoring equipment, external feeding lines, and supplemental oxygen or ventilators. Participating in discharge planning and in outpatient follow-up of high-risk neonates are other options for providing exposure to examination, intervention, and family issues when the infants and parents are more stable. This clinical experience and a competency-based, precepted practicum in the NICU offer the best preparation for appropriate, accountable, and ethical practice in neonatal therapy.⁷⁶⁻⁷⁸ In-depth study of perinatal and neonatal medicine and related obstetrical, neonatal nursing, high-risk parenting, and neonatal therapy literature is recommended before pediatric therapy clinicians begin to participate on the intensive care nursery team.

Indications for Referral

Research efforts in recent years have been directed toward determining which neonates will have adverse neurodevelopmental outcomes. Specific prenatal, perinatal, and neonatal conditions associated with an increased likelihood of long-term neuromotor disability have been identified as risk factors. However, the predictive value of these risk factors is compromised by the absence of uniform or consistent definitions, differences in the study samples and follow-up procedures, and lack of standard measures of neurodevelopmental outcome. In addition, ongoing changes in obstetrical and neonatal procedures limit the applicability of findings from longitudinal studies of infants born in earlier eras of NICU care.

Tjossem’s⁷⁹ categories of biological, established, and social risk combined with risk factors for adverse neurodevelopmental outcome⁸⁰ provide a framework for categorizing indicators for neonatal therapy referral. An overview of developmental risk categories and risk factors for neonatal therapy referral is listed in [Box 11-2](#) to assist clinicians in developing a referral mechanism for a clinical protocol based on risk categories.

Biological Risk

Biological risk refers to neurodevelopmental risk attributable to medical or physiological conditions in the prenatal, perinatal, or neonatal period.⁷⁹⁻⁸¹ Biological risks include placental abnormalities, labor and delivery complications, prenatal infection, and teratogenic factors. Examples of biological risk factors include asphyxia, neonatal seizures, prenatal exposure to drugs or alcohol, and the brain lesions previously described. Birth weight is a strong predictor of outcome; in general, lower birth weight is associated with greater risk of adverse developmental outcomes.^{82,83}

Respiratory disease is generally considered an important risk factor for motor and cognitive disability in infants born preterm ([Table 11-5](#)).⁸⁴ Although the presence of respiratory disease alone does not appear to be predictive of neurodevelopmental outcome, severity of disease does appear to be related to long-term outcome.⁸² Infants with chronic lung disease or bronchopulmonary dysplasia have been found to be at increased risk for CP and other neurodevelopmental abnormalities compared with preterm infants without bronchopulmonary dysplasia.^{85,86} Prolonged mechanical ventilation and duration of supplemental oxygen were associated with increased risk of neurodevelopmental disability.⁸⁷ Administration of surfactant in the neonatal period has

BOX 11-1 ■ NEONATAL INTENSIVE CARE UNIT (NICU) OBSERVATIONAL EXPERIENCES FOR ENTRY-LEVEL STUDENTS⁷⁵

- Reviewing neonatal literature and neonatal therapy clinical practice guidelines^{71,75-77} before site visit to NICU
- “Shadowing” neonatal nurses to observe:
 - Neonatal equipment (refer to [Table 11-6](#))
 - Caregiving routines
 - Teaching styles with parents and grandparents
 - Feeding procedures and equipment
 - Unique culture of the NICU compared with adult intensive care units
 - Skin-to-skin holding by parent
 - Environmental adaptations (light, sound, clustered handling)
- “Shadowing” neonatal therapist to observe:
 - Chart reviews
 - Interdisciplinary rounds
 - Discharge planning conferences
 - Behavioral and physiological baseline examinations
 - Examination and intervention procedures adapted for medically stable infants at varying gestational ages, acuity levels, and behavioral organization
 - Parental teaching
 - Collaboration with neonatal nurses for positioning, feeding, and parent instruction
- Observing and participating with neonatal therapist in NICU Follow-up Clinic

BOX 11-2 ■ DEVELOPMENTAL RISK INDICATORS FOR NEONATAL THERAPY REFERRAL

BIOLOGICAL RISK

Birth weight of 1500 g or less
 Gestational age of 32 weeks or less
 Small for gestational age (less than 10th percentile for weight)
 Prenatal exposure to drugs or alcohol
 Ventilator requirement for 36 hours or more
 Intracranial hemorrhage: grades 3 or 4
 Periventricular leukomalacia
 Muscle tone abnormalities (hypotonia, hypertonia, asymmetry of tone or movement)
 Recurrent neonatal seizures (three or more)
 Feeding dysfunction
 Symptomatic TORCH infections (*toxoplasmosis, rubella, cytomegalovirus infection, herpesvirus type 2 infection*)
 Meningitis
 Asphyxia with Apgar score less than 4 at 5 minutes
 Multiple birth

ESTABLISHED RISK

Hydrocephalus
 Microcephaly
 Chromosomal abnormalities
 Musculoskeletal abnormalities (congenitally dislocated hips, limb deficiencies, arthrogryposis, joint contractures, congenital torticollis)
 Brachial plexus injuries (Erb palsy, Klumpke paralysis)
 Myelodysplasia
 Congenital myopathies and myotonic dystrophy
 Inborn errors of metabolism
 Human immunodeficiency virus infection
 Down syndrome

ENVIRONMENTAL AND SOCIAL RISK

High social risk (single parent, parental age younger than 17 years, poor-quality infant-parent attachment)
 Maternal drug or alcohol abuse
 Behavioral state abnormalities (lethargy, excessive irritability, behavioral state lability)

reduced the incidence and severity of respiratory disease in very low–birth-weight infants but has not been associated with a decline in neurodevelopmental disability.⁸⁵

Established Risk

Established risk is the risk for neurodevelopmental deficits associated with a diagnosis that is clearly established in the neonatal period. Included in this category are congenital malformations, chromosomal abnormalities, central nervous system disorders, and metabolic diseases with known developmental sequelae.

Environmental and Social Risk

Environmental and social risk involves developmental risk related to competency in parenting roles and factors in family dynamics. Such risk may be heightened by prolonged hospitalization of infants with the following characteristics: (1) suboptimal levels of stimulation and interaction (overstimulation or deprivation) in the NICU environment, (2) inadequate infant-parent attachment, (3) insufficient educational preparation of parents for caregiving roles, (4) meager financial resources of parents, and (5) limited or absent family support to assist in taking care of and nurturing the infant in the home environment.

It is common for neonates born preterm to have a combination of risk factors from more than one major category. For example, an infant born prematurely to a single mother in a drug treatment program for heroin use during pregnancy is considered to be at both biological and environmental risk.

Pain, Gestational Age, and Neurological Examination

Multiple neonatal neurological and neurobehavioral examinations have been developed to assess the integrity and maturation of the nervous system⁸⁸⁻⁹¹ and to describe newborn behavior.^{9,89} Most of these tests offer information on the quality of motor performance, attention, and interaction. Because these assessments are based on gestational age, an accurate calculation of gestational age is necessary at the time of the testing.^{92,93}

TABLE 11-5 ■ FACTORS CONTRIBUTING TO PULMONARY DYSFUNCTION IN PRETERM NEONATES

Anatomical	<ul style="list-style-type: none"> Capillary beds not well developed before 26 weeks of gestation Type II alveolar cells and surfactant production not mature until 35 weeks of gestation Elastic properties of lung not well developed Lung space decreased by relative size of the heart and abdominal distention Type I, high-oxidative fibers compose only 10% to 20% of diaphragm muscle Highly vascular subependymal germinal matrix not resorbed until 35 weeks of gestation, increasing infant's vulnerability to hemorrhage Lack of fatty insulation and high surface area/body weight ratio
Physiological	<ul style="list-style-type: none"> Increased pulmonary vascular resistance leading to right-to-left shunting Decreased lung compliance Diaphragmatic fatigue; respiratory failure Decreased or absent cough and gag reflexes; apnea Hypothermia and increased oxygen consumption

Modified from Crane L: Physical therapy for the neonate with respiratory disease. In Irwin S, Tecklin JS, editors: *Cardiopulmonary physical therapy*, ed 2, St Louis, 1990, Mosby.

Pain Assessment

Despite immature myelination, premature infants *definitely* perceive pain and retain the memory of painful experiences. Skin receptors are developed by 14 to 16 weeks' gestation. In addition, the density of pain receptors in the skin of neonates at 28 weeks of gestation is considered similar to and even exceeds adult density during maturation from birth to 2 years of age.⁹⁴⁻⁹⁶ Blackburn⁹⁷ explained that although pain transmission in neonates occurs mainly through the slower, unmyelinated C fibers, the shorter distance in neonates that impulses travel to reach the brain compensates for the slower rate of transmission and creates substantial pain reception. Early pain experiences may create later increased sensitivity to pain and vulnerability to stress disorders.⁹⁸⁻¹⁰⁰ If neonatal therapy assessment or intervention procedures immediately follow a noxious procedure in the NICU, handling techniques may need to be modified or therapy session rescheduled to avoid contributing to a cascade of aversive experiences for the infant.

Psychometric data and clinical use of the pain tools are described for infants as early as 28 weeks of gestation. Many elements in the pain assessments¹⁰¹ have been identified by AIs (the Neonatal Individualized Developmental Care and Assessment Program [NIDCAP]) as signs of excessive stimulation and stress in the preterm infant. Specific extremity movements, such as hand to face, elevated leg extension, salute, lateral extension of arms, finger splay, and fisting, have been proposed as indicators of stress and/or pain.¹⁰²

In addition to practice guidelines on pain assessment developed primarily by neonatal nurses, numerous instruments are available to assess pain in infants. Pain scale data are integrated into NICU nursing assessments and can be a valuable adjunct to the neonatal therapist's baseline and posttherapy observations.

- The Premature Infant Pain Profile (PIPP)¹⁰³ assigns points for changes in three facial expressions (brow bulge, eye squeeze, and nasolabial fold), heart rate, and oxygen saturation. Gestational age and pre-procedural behavioral state are included in the assessment. The maximal PIPP score is 21; the higher the score, the greater the pain. A score of 0 to 6 points indicates minimal or no pain, whereas a score of 12 or more indicates moderate to severe pain.¹⁰³
- The Face, Legs, Activity, Cry, and Consolability Behavioral tool (FLACC) uses grades of 0 to 2 for facial expression, leg activity, general activity, cry nature, and ability to be consoled and has been used in pediatric and adult settings. This test is capable of assessing pain in normal as well as cognitively impaired children, thus giving it a high degree of versatility and usefulness.¹⁰⁴ Change in FLACC score has been used to demonstrate that the use of sucrose and a pacifier during venipuncture is more effective in consoling infants younger than 3 months of age than infants older than 3 months of age.¹⁰⁵
- The Neonatal Pain, Agitation, and Sedation Scale (N-PASS) uses five indicators: (1) cry and irritability, (2) behavioral state, (3) facial expression, (4) extremity movement and tone, and (5) vital signs. As with the PIPP scale, additional points are added for decreasing gestational age.¹⁰⁶ There was good correlation

between the N-PASS and the PIPP assessments during routine heelstick in infants younger than 1 month old born at 23 to 42 weeks' gestation.¹⁰⁷

Indicators of pain summarized across the instruments include the following categories: (1) physiological (heart rate, oxygen saturation, breathing pattern), (2) behavioral (eye squeeze, brow bulge, facial grimace, behavioral state including crying, sleeplessness), and (3) motor (tone and movement in extremities).

Clinical Assessment of Gestational Age in the Newborn Infant

A method for clinical assessment of gestational age in the newborn infant was developed by Dubowitz and colleagues⁹² from data derived from a total of 167 preterm and term infants (28 to 42 weeks' gestation) tested within 5 days of birth. The tool focuses on criteria for calculation of gestational age from a composite of 10 neurological and 11 external (physical) characteristics.

This test rates criteria on a 4-point scale; it is commonly administered by nurses or physicians in the newborn nursery. The accuracy (95% confidence limit) of the gestational age score is determined within a variation of ± 2 weeks on any single examination. This measurement error can be decreased to approximately ± 1.4 weeks when two separate examinations are performed. From the analyses of multiple tests on 70 of the 167 infants, the age score was equally reliable in the first 24 hours of age as during the next 4 days of life. The behavioral state of the infant during the examination is not considered a significant variable in testing.

Calculation of gestational age is an important adjunct to all other neonatal assessment tools. It guides practitioners in interpreting neurological and behavioral findings relative to the expected performance of neonates at various gestational ages. Additional guidelines on gestational differences in neurological, physical, and neuromuscular maturation can be found in the work of French pediatric neurologist Amiel-Tison.^{88,89,108}

Newborn Maturity Rating—Ballard Score

Ballard and colleagues¹⁰⁹⁻¹¹¹ designed a simplified modification of the Dubowitz gestational age tool. It has been widely adopted because of the time efficiency (3 to 4 minutes versus 10 to 15 minutes) and the elimination of active tone items, which are difficult to evaluate reliably in physiologically unstable newborns. The Ballard instrument involves only six physical and six neurological criteria, with a 0 to 5 scale and a maturity rating. It is designed to be used for neonates (20 to 44 weeks gestation) from birth through 3 days of age and has demonstrated concurrent validity with the Dubowitz gestational age calculation tool. The gestational age of the infant is based on the obstetrical dating criteria unless the clinical assessment of the infant deviates more than 2 weeks from the obstetrical calculation.

Neurological Examination of the Full-Term Infant

The Neurological Examination of the Full-Term Infant was designed by Prechtl¹¹² to identify abnormal neurological signs in the newborn period. The examination was developed from an investigation of more than 1350 newborns and was standardized on infants born at the gestational age of 38 to 42 weeks. If the test is used in premature infants who

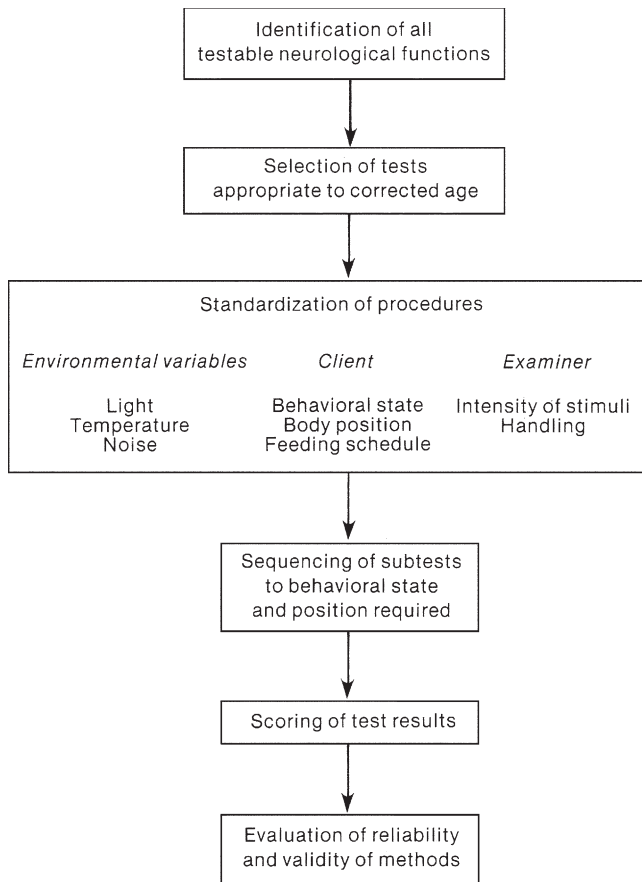

Figure 11-9 ■ Flow diagram illustrating decision steps in the neurological examination process.

have reached an age of 38 to 42 weeks of gestation, lower resistance to passive movements (lower tone) may be expected. Delay of testing until a minimum of 3 days of age is advised to maximize the stability of behavioral states and neuromotor responses for improved reliability and validity of results.

The pattern of examination includes periods of both observation and examination. A 10-minute screening test is offered to determine if the full 30-minute examination of posture, tone, reflexes, and spontaneous movement is required. Although specific requirements for examiner training are not addressed, Prechtl offers a flow diagram (Figure 11-9) to assist clinicians with organizing the neurological examination process. Significant findings from the examination are summarized in the following categories: (1) quality of posture, spontaneous movement, and muscle tone (consistency and resistance to passive movement); (2) presence of involuntary or pathological movements (clonus, tremor, athetoid postures or movements); (3) behavioral state changes and quality of cry; and (4) threshold or intensity of responses to stimulation. (Because of the transient pattern of neurological signs and rapid changes in the developing nervous system, Prechtl advised repeated examinations to monitor neurological status.)

Neonatal Behavioral Assessment Scale

To document individual behavioral and motor differences in infants at term gestation to 2 months of age, Brazelton and Nugent¹¹³ developed a neonatal behavior scale to assess

neuromotor responses within a behavioral state context. The 30- to 45-minute examination consists of observing, eliciting, and scoring 28 biobehavioral items on a 9-point scale and 18 reflex items on a 4-point scale. This is an interactive test and assesses the infant's ability to recover from stimuli and return to an alert state. The reflex items are derived from the neurological examination protocol of Prechtl and Beintema.¹¹⁴

The scale was designed to assess newborn behavior in healthy 3-day-old term (40 weeks of gestation) white infants whose mothers had minimal sedative medication during an uncomplicated labor and delivery. Use of this examination with infants born preterm requires modification of the examination procedure to the environmental constraints of an intensive care nursery and interpretation of findings relative to the gestational age and medical condition of the infant. For preterm infants approaching term gestation (minimum of 36 weeks of gestation), nine supplementary behavioral items are offered. Many of these items were developed by Als⁹ for use with preterm and physiologically stressed infants (see discussion of the APiB, later). In the manual,¹¹³ methods of adapting the Neonatal Behavioral Assessment Scale (NBAS) for preterm neonates with accompanying case scenarios are described to illustrate use of the findings to enhance parent-infant interaction and guide developmental interventions.

Six behavioral state categories are outlined in the NBAS: deep sleep, light sleep, drowsiness or semidozing, quiet alert, active alert, and crying. Behavioral state prerequisites are provided for each biobehavioral and reflex item to reduce the state-related variables in testing. During the assessment the examiner systematically maneuvers the infant from the sleep states to crying and back to the alert states to evaluate physiological, organizational, motor, and interactive capabilities during stimulation and physical handling. The scoring is based on the infant's best performance, with flexibility allowed in the order of testing, repetition of items encouraged, and scheduling of the assessment midway between feedings to give the infant every advantage to demonstrate the best possible responses.

Four dimensions of newborn behavior are analyzed in Brazelton's NBAS: interactive ability, motor behavior, behavioral state organization, and physiological organization. *Interactive ability* describes the infant's response to visual and auditory stimuli, consolability from the crying state with intervention by the examiner, and ability to maintain alertness and respond to social or environmental stimuli.

Motor behavior refers to the ability to modulate muscle tone and motor control for the performance of integrated motor skills, such as the hand-to-mouth maneuver, pull-to-sit maneuver, and defensive reaction (e.g., removal of cloth from face). In the assessment of *behavioral state organization*, the infant's ability to organize behavioral states when stimulated and the ability to shut out irritating environmental stimuli when sleeping are analyzed. *Physiological organization* is evaluated by observing the infant's ability to manage physiological stress (changes of skin color, frequency of tremulous movement in the chin and extremities, number of startle reactions during the assessment). For analysis, the information is divided into seven clusters: habituation, orientation, motor, range of state, regulation of state, autonomic stability, and reflexes. The cluster systems

are highly useful for clinical interpretation and for data analysis in clinical research. Performance profiles of worrisome or deficient interactive-motor and organizational behavior are identified by clusters of behavior associated with potential developmental risk.¹¹⁵

Definite strengths of the NBAS are the well-defined indicators of autonomic stress, analysis of coping abilities of high-risk infants experiencing external stimuli and handling, and quality of infant-examiner interaction. These features generate specific findings to assist therapists in grading the intensity of assessment and treatment within each infant's physiological and behavioral tolerance and in guiding the development of parental teaching strategies to address the individual behavioral styles of infants. The NBAS has proved to be more sensitive to the detection of mild neurological dysfunction in the newborn period than have classic neurological examinations that omit the behavioral dimensions. This assessment is not predictive but gives a good analysis of the infant's strengths and weaknesses. Improved performance from repeat examinations over time is a better predictor of the infant's ability and potential.

Participation of the parent in the newborn assessment may yield long-term positive effects on infant-parent interaction and later on cognitive and fine motor development. Widmayer and Field¹¹⁶ reported significantly better face-to-face interaction and fine motor-adaptive skills at 4 months of age and higher mental development scores at 12 months of age when teenage mothers of preterm infants (mean gestational age at birth, 35.1 weeks) were given demonstrations of the NBAS. These demonstrations were scheduled when the premature infants had reached an age equivalence of 37 weeks of gestation.

Nugent^{117,118} developed parental teaching guidelines for using the NBAS as an intervention for infants and their families. Published by the March of Dimes birth defects foundation, the guidelines offer strategies for interpreting each item according to its adaptive and developmental significance, descriptions of the expected developmental course of the behavior (item) over several months, and recommendations for caregiving according to the infant's response to the items.

A three-step examiner training involving self-study, practice, and certification phases is coordinated through the Brazelton Institute, Children's Hospital, Boston, Massachusetts.^{119,120} Wilhelm¹¹⁵ recommended NBAS training for clinicians beginning to develop competence in examining at-risk infants. She explained that it provides a system for developing basic handling skills with healthy, term infants without concerns of stressing medically fragile preterm infants during the training period. Learning the NBAS in term infants before entering NICU practice provides familiarity with similar testing and scoring procedures for preterm infants.¹¹⁵

Newborn Behavioral Observations System

The Newborn Behavioral Observations (NBO) system, developed from the pioneering work and philosophy of Brazelton, is an interactive, observational tool for use with infants and parents in hospital, clinic, and home settings.¹²¹ The focus is on prematurely born infants and at-risk infants, with emphasis on cultural competence, family-centered care, and infant development. The NBO system helps determine

the behavioral profile of the infant and allows the practitioner to provide parents with individualized and unique information about their infant. This behavioral information promotes positive parent-infant interaction and also a positive partnership between parents and practitioners.

Certification in administering, interpreting, and scoring the 18-item NBO assessment is arranged through the Brazelton Institute in a 2-consecutive-day format. The training encompasses the following observation categories: (1) habituation to external light and sound; (2) muscle tone and motor activity level; (3) behavioral self-regulation (crying and consolability); and (4) visual, auditory, and social-interactive abilities.^{119,120}

Neurological Assessment of the Preterm and Full-Term Newborn Infant

The Neurological Assessment of the Preterm and Full-Term Newborn Infant is a streamlined neurological and neurobehavioral assessment designed by Dubowitz and colleagues¹²² to provide both a systematic, quickly administered newborn examination applicable to infants born preterm or at term gestation and a longer infant examination for children to 24 months of age. A distinct advantage of this tool is the minimal training or experience required by the examiner and the ease of adapting it to the infant and the environment. The adaptability of the test and use of the scoring form with stick figure diagrams have made it useful for implementation in developing countries where English is not widely spoken.

The test includes the six behavioral state categories of the NBAS and seven orientation and behavior items scored on a 5-point grading scale and sequenced according to the intensity of response. The orientation and behavior items consist of the following categories: (1) auditory and visual orientation responses; (2) quality and duration of alertness; (3) irritability (the frequency of crying to aversive stimuli during reflex testing and handling throughout the examination); (4) consolability (the ability after crying to reach a calm state independently or with intervention by the examiner); (5) cry (quality and pitch variations); and (6) eye appearance (absent, transient, or persistent appearance of sunset sign, strabismus, nystagmus, or roving eye movements).

The 15 items that assess movement and tone and the six reflex items evolved from clinical trials on 50 term infants using the clinical assessment of gestational age by Dubowitz and colleagues,⁹² the neurological examination of the newborn by Parmelee and Michaelis,¹²³ and the neurological examination of the full-term newborn infant by Prechtl.¹¹² The examination format was then used during a 2-year period on more than 500 infants of varying gestational ages. After 15 years the authors revised the assessment in the second edition by eliminating seven items, expanding the tone pattern section, and developing an optimality score. Reliability data are not reported, but modification of examination procedures occurred during the pilot phase that promoted objectivity in scoring and a high interrater reliability among examiners, regardless of experience level.

The examination protocol is available in two formats: (1) Hammersmith Short Neonatal Neurological Examination and (2) Hammersmith Infant Neurological Examination (age range, 2 to 24 months). The examination forms are illustrated with stick figures and can accommodate both baseline and repeat assessments. For neonatal therapy examinations the

forms can be effectively combined with a narrative impression, treatment goals, and plan of care. A numerical score for each item and a summary score are provided in the revised edition of the test. The authors advised that the scoring system was primarily intended for the purpose of research and for numerical charting of progress with sequential examinations. Because of the continued clinical emphasis on patterns of responses, selected parts of the protocol (without summary scoring) are appropriate for examining premature or acutely ill infants on ventilators, in incubators, or attached to monitoring or infusion equipment. Scheduling of examinations is recommended two thirds of the way between infant feeding sessions.

Evolution of neurological patterns in infants with IVH, PVL, and HIE is described in the test manual and correlated with brain imaging. Abnormal neonatal clinical signs associated with long-term neurological sequelae were persistent asymmetry, decreased lower-extremity movement, and increased tone. Infants with IVH had significantly higher incidence of abnormally tight popliteal angles, reduced mobility, decreased visual fixing and following, and roving eye movements. The authors cautioned that early signs of motor asymmetry in neonates with cerebral infarction may be associated with normal outcome, but normal neonatal neurological examinations after cerebral infarction do not exclude the possibility of later hemiplegia.¹²⁴

Long-term follow-up data beyond 1 year have not been reported with this examination. Dubowitz and colleagues¹²⁵ reassessed 116 infants (27 to 34 weeks of gestation) at 1 year of age. Of 62 infants assessed as neurologically normal in the newborn period, 91% were also normal at 1 year of age. Of 39 infants assessed as neurologically abnormal in the newborn period, 35% were found to be normal at 1 year of age. According to Wilhelm,¹¹⁵ the predictive value of a negative test result with this instrument was 92%, but the predictive value of a positive test result was only 64%.

Interpretations of evaluative findings from the Neurological Assessment for Preterm and Full-Term Newborn Infants for neonatal therapy practice are comprehensively described in a case study format by Heriza¹²⁶ and Campbell.¹²⁷ Dubowitz¹²⁸ discussed the clinical significance of neurological variations in infants and offered decision guidelines to clinicians on when to worry, reassure, or intervene with developmental referrals.

Assessment of Preterm Infants' Behavior

Als⁹ designed the APIB to structure a comprehensive observation of a preterm infant's autonomic, adaptive, and interactive responses to graded handling and environmental stimuli. It involves six maneuvers with increasing challenging and complex interactions with a highly structured format. As previously described in the theoretical framework section of this chapter, this assessment is derived from synactive theory and is focused on assessing the organization and balance of the infant's physiological, motor, behavioral state, attention and interaction, and self-regulation subsystems. The APIB has testing sequences and a scoring format similar to those used in Brazelton's NBAS, with increased complexity and expansion for premature infants.

Administration and scoring of the APIB may require 2 to 3 hours per infant and often two or more sessions with the

infant depending on examiner experience and infant stability. Although the APIB may be an instrument of choice for the clinical researcher, it is not usually practical (time efficient) for many neonatal clinicians with heavy caseloads in managed-care environments. Extensive training and reliability certification are required to safely administer and accurately score and interpret the test for clinical practice or research.

Neonatal Individualized Developmental Care and Assessment Program

Als¹¹ and Als and colleagues^{11,129} developed NIDCAP to document the effects of the caregiving environment on the neurobehavioral stability of neonates. This naturalistic observation protocol includes continuous observation and documentation at 2-minute intervals of an infant's behavioral state and autonomic, motor, and attention signals, with simultaneous recording of vital signs and oxygen saturation. Documentation occurs before, during, and after routine caregiving procedures. The infant's strengths, weaknesses, and coping skills are identified. A narrative description of the infant's responses to the stress of handling by the primary nurse and to auditory and visual stimuli in the NICU environment is provided to assist caregivers and parents in identifying the infant's behavioral cues and providing appropriate interaction. Options are described in the care plans for reducing aversive environmental stimuli and modifying physical handling procedures. This clinical tool allows neonatal therapists to determine the infant's readiness for assessment and intervention by observing the baseline tolerance of the infant to routine nursing care before superimposing neonatal therapy procedures.¹³⁰ Sequential observations occur weekly or biweekly. Parental involvement is strongly encouraged and instrumental in facilitating a smooth transition to home. Examiner training in the NIDCAP may be coordinated through the National Training Center at Children's Hospital Boston, Massachusetts, where priority is now given to training NICU teams rather than individuals.¹⁰

NICU Network Neurobehavioral Scale

Lester and Tronick¹³¹ developed a tool for preterm and drug-exposed infants from 30 weeks of gestation to 6 weeks post-term. The test includes items from the NBAS, APIB, Finnegan abstinence scale, and other neurological assessments and consists of 115 items in general categories of neurological and neuromotor integrity (tone, reflexes, and posture), behavioral state and interaction (self-regulatory competence), and physiological stress abstinence signs (drug-exposed infants). This test is state dependent and gives a comprehensive and integrated picture of the infant that is not divided into clusters. More than half¹¹⁸ of the test items are infant observations, and 45 items require physical handling of the infant. Test-retest reliability of preterm infants indicated correlations of 0.30 to 0.44 at 34, 40, and 44 weeks of gestation. This test is useful for management of drug-exposed infants but may have limited predictive value. Training and certification in administration and scoring of the test are coordinated through Brookes Publishing Company and available in the United States and internationally with use of videoconferencing for lectures and demonstrations.

Test of Infant Motor Performance

Developed by Campbell and colleagues,¹³² the 42-item Test of Infant Motor Performance (TIMP) is focused on evaluating postural control, spontaneous movement, and head control for neonates at 32 weeks of gestation to 16 weeks postterm. Functional motor performance is assessed through observation of infant movement and through responses to various body positions and to visual or auditory stimuli. Psychometric qualities of the test include (1) construct validity¹³³ and ecological validity,¹³⁴ (2) concurrent validity at 3 months of age with the Alberta Infant Motor Scale (AIMS),¹³⁵ and (3) predictive validity at 5 to 6 years of age with the Bruininks-Oseretsky Test of Motor Proficiency¹³⁶ and at 4 to 5 years of age with the Peabody Developmental Motor Scales and Home Observation for Measurement of the Environment: Early Childhood.¹³⁷ Training on test procedures is available through 2-day workshops or through a self-guided training method with a CD-ROM from the test developer.¹³⁸

Neurobehavioral Assessment of the Preterm Infant

The Neurobehavioral Assessment of the Preterm Infant (NAPI) was developed by Korner as a developmental test to assess medically stable infants from 32 weeks to term gestation using a sequence of specific movements. This test focuses on tone, reflexes, movement, response to visual and auditory stimulation, and observation of cry and state. This tool does not require a specific preassessment state as is required by the previously mentioned tests, but starts with the infant asleep. It does not take as long to administer (less than ½ hour) than the previously described tests and is easy to analyze. The data are categorized into seven clusters and compared with standardized scores. With repeated examinations over time, persistent deviations from the normative scores indicate that the infant is at risk for developmental delays and is in need of close follow-up. In addition, the NAPI has been shown to be predictive of short-term and long-term neurodevelopmental outcomes.¹³⁹

Qualitative Assessment of General Movements

The assessment tools reviewed so far in this chapter require direct handling of the infant. Infants born preterm are particularly vulnerable to developing physiological stress during the maneuvers required by most tools available for infant assessment. Instead, noninvasive, repeated longitudinal observation and assessment are needed to accommodate the concurrent motor variability, immature nervous system, and physiological vulnerability of the young, preterm infant.¹⁴⁰ Based on the pioneering work of Prechtl examining the continuity of prenatal to postnatal fetal movement,¹⁴¹ this criterion-referenced test focuses on evaluating the quality of spontaneously generated movements in preterm, term, and young infants until 16 weeks postterm. A wide repertoire of endogenously generated spontaneous motility in the fetus including isolated limb movements, stretches, hiccups, yawning, and breathing movements can be identified as early as 9 weeks.¹⁴¹⁻¹⁴³

General movements (GMs) are spontaneously generated complex movements involving the trunk, limbs, and neck. They vary in speed and intensity with a gradual onset, increase in speed and intensity, and a gradual end. These movements are among the number of movement patterns

that emerge during fetal life and continue until approximately 16 weeks postterm, when goal-oriented and voluntary movements appear.¹⁴⁴ The quality of movement is assessed through observation and scoring of videotaped spontaneous movement of an infant in supine position without stimulation or handling.¹⁴⁴ A distinct difference occurs between the GMs in the preterm infant and those in the term and postterm infant. GMs in the term infant, and for the first 8 weeks, change in amplitude and speed, taking on a writhing quality. The writhing movements gradually give way to the fidgety movements, which are present in awake infants between 9 and 16 to 20 weeks postterm. Fidgety movements are small, circular movements of small amplitude and varying speed involving the neck, trunk, and extremities.¹⁴⁰ Other approaches to neurological assessment can be found in additional references.^{140,144,145}

This neonatal and young infant assessment instrument has gained substantial attention in the past 20 years for its high reliability, sensitivity, and predictive validity. In a comprehensive review of the psychometric qualities of neuro-motor assessments for infants, the GM assessment was rated among the tools with the highest reliability, averaging inter-rater and intrarater correlation coefficient, or *k*, greater than 0.85.¹⁴⁶ Multiple studies have corroborated the predictive validity and sensitivity of this method. The sensitivity is lower during the preterm period and during the writhing movements, improving during the fidgety movement period. Sensitivity as high as 95% has been reported.^{140,147}

Testing Variables

Neuromuscular and behavioral findings in the newborn period may be influenced by several variables. Increased reliability in examination results and in clinical impressions may occur when these variables are recognized. Medication may produce side effects of low muscle tone, drowsiness, and lethargy. Such medications include anticonvulsants, sedatives for diagnostic procedures (CT scan, electroencephalography, electromyography), and medication for postsurgical pain management. Intermittent subtle seizures may produce changes in muscle tension and in the level of responsiveness. Mild, ongoing seizures may occur in the neonate as lip smacking or sucking, staring or horizontal gaze, apnea, and bradycardia. Stiffening of the extremities occurs in neonatal seizures more frequently than clonic movement. Fatigue from medical and nursing procedures can result in decreased tolerance to handling, decreased interaction, and magnified muscle tone abnormalities. Fatigue may also result when neurodevelopmental assessment is scheduled immediately after laboratory (hematologic) procedures, suctioning, ultrasonography, or respiratory (chest percussion) therapy. Tremulous movement in the extremities may be linked to conditions of metabolic imbalance (hypomagnesemia, hypocalcemia, hypoglycemia), and low muscle tone may be associated with hyperbilirubinemia, hypoglycemia, hypoxemia, and hypothermia.^{148,149}

Summary

Practitioners must be aware of the normative and validation data and of the predictive characteristics of the test(s) administered to allow appropriate interpretation of the results. Specific clinical training with a preceptor is essential to administer, score, and interpret neonatal assessment

instruments accurately; to establish interrater reliability; and to plan treatment based on the evaluative findings. Even low-risk, healthy preterm infants are vulnerable to becoming physiologically and behaviorally destabilized during neurological assessment procedures.¹⁵⁰⁻¹⁵² This risk is reduced with precepted, competency-based clinical training in the NICU.

Intervention Planning

Level of Stimulation

The issue of safe and therapeutic levels of sensory and neuromotor intervention is a high priority in the design of developmental intervention programs for infants who have been medically unstable. The concept of “infant stimulation,” introduced by early childhood educators in the 1980s to describe general developmental stimulation programs for healthy infants, is highly inappropriate in an approach based on concepts of dynamic systems, infant behavioral organization, and individualized developmental care.

For intervention to be therapeutic in a special care nursery setting, the amount and type of touch and kinesthetic stimulation must be customized to each infant’s physiological tolerance, movement patterns, unique temperament, and level of responsiveness. Rather than needing more stimulation, many infants, especially those with hypertonus or those with tremulous, disorganized movement, have difficulty adapting to the routine levels of noise, light, position changes, and handling in the nursery environment. General, nonindividualized stimulation can quickly magnify abnormal postural tone and movement, increase behavioral state lability and irritability, and stress fragile physiological homeostasis in preterm or chronically ill infants. Implementation of careful physiological monitoring and graded handling techniques are essential to prevent compromise in patient safety and to facilitate development. Infant modulation, rather than stimulation, is the aim of intervention. Techniques of sensory and neuromotor facilitation and inhibition developed for caseloads of healthy infants and children are inappropriate for the developmental needs and expectations of an infant with physiological fragility or premature birth history (less than 37 weeks of gestation).

Physiological and Musculoskeletal Risk Management

Many maturation-related anatomical and physiological factors predispose preterm infants to respiratory dysfunction (see Table 11-5). For this reason many preterm neonates require the use of a wide range of respiratory equipment and physiological monitors (Table 11-6). Pediatric therapists preparing to work in the NICU and those involved with designing risk management plans are referred to the neonatal nursing literature for evidence and perspectives on assessing and managing neonatal stressors during interventions in the NICU.¹⁵³⁻¹⁵⁵ Because infants born prematurely or experiencing critical illness communicate via subtle behavioral cues, their understated language is “not easily interpreted unless caregivers understand how infants’ ability to respond to stress reflects their maturation and neurodevelopment.”¹⁵⁶ Their behavioral cues are considered more subtle and more likely to be disregarded than those of infants born at term gestation.

In this subspecialty area of pediatric practice, neonatal therapists are responsible for the prevention of physiological jeopardy in LBW infants while providing developmental services in the NICU. Before examination, discussion with the supervising neonatologist and clinical nurse are advised regarding specific precautions and the safe range of vital signs for each infant. Medical update and identification of new precautions before each intervention session are recommended because new events in the last few hours may not have been recorded or fully analyzed at the time therapy is scheduled. The nurse should be invited to maintain ongoing surveillance of the infant’s medical stability and provide assistance in interpreting physiological and behavioral cues during neonatal therapy activities in case physiological complications occur. If medical complications develop during or after therapy, immediate, comprehensive co-documentation of the incident with the clinical nurse and discussion with the neonatology staff are essential to analyze the events, outline related clinical teaching issues, and minimize legal jeopardy.

Areas of particular concern during neonatal therapy activities include potential incidence of fracture, dislocation, or joint effusion during the management of limited joint motion; skin breakdown or vascular compromise during splinting or taping to reduce deformity; apnea or bradycardia during therapeutic neuromotor handling with potential deterioration to respiratory arrest; oxygen desaturation or regurgitation and aspiration during feeding assessment or oral-motor therapy; hypothermia from prolonged handling of the infant away from the neutral thermal environment of the incubator or overhead radiant warmer; and propagation of infection from inadequate compliance with infection control procedures in the nursery. Signs of overstimulation may include labored breathing with chest retractions, grunting, nostril flaring, color changes (skin mottling, paleness, gray-blue cyanotic appearance), frequent startles, irritability or drowsiness, sneezing, gaze aversion, bowel movement, and hiccups. Signals of overstimulation expressed through infants’ motor systems are finger splay (extension and abduction posturing), arm salute (shoulder flexion with elbow extension), and trunk arching away from stimulation.¹¹ Harrison and colleagues¹⁵⁴ found that motor activity cues of preterm infants were correlated with low oxygen saturation and should be carefully monitored during caregiving procedures to minimize physiological instability.

Even a baseline neurological examination, usually presumed to be a benign clinical procedure, may be destabilizing to the newborn infant’s cardiovascular and behavioral organization systems. The physiological and behavioral tolerance of low-risk preterm and term neonates to evaluative handling by a neonatal physical therapist was studied in 72 newborn subjects.¹⁵¹ During and after administration of the Neurological Assessment of the Preterm and Full-Term Newborn Infant, preterm subjects (30 to 35 weeks of gestation) had significantly higher heart rates; greater increases in blood pressure; decreased peripheral oxygenation inferred from mottled skin color; and higher frequencies of finger splay, arm salute, hiccups, and yawns than in term subjects. Neonatal practitioners must examine the safety of even a neurological examination and weigh the risks and anticipated benefit of the procedure given the expected physiological and behavioral changes in low-risk, medically stable neonates.^{150,151}

TABLE 11-6 ■ EQUIPMENT COMMONLY ENCOUNTERED IN THE NEONATAL INTENSIVE CARE UNIT (NICU)

EQUIPMENT	DESCRIPTION
Thermoregulation radiant warmer	
	Unit composed of mattress on an adjustable tabletop covered by a radiant heat source controlled manually and by servocontrol mode. Unit has adjustable side panels. <i>Advantage:</i> provides ready access to infant and increases area for equipment. <i>Disadvantage:</i> leads to convective heat loss, increases insensible fluid loss, and encourages stimulation (excessive).
Double-walled Isolette	Enclosed unit of transparent material providing a heated and humidified environment with a servocontrol incubator system of temperature monitoring. Access to infant through side portholes or opening side of unit. <i>Advantage:</i> barrier to tactile stimulation, decreased convective losses. <i>Disadvantage:</i> more difficult to get to infant, does not decrease noise from NICU, radiant heat loss if Isolette is single walled.
Thermal shield	Clear acrylic dome or plastic wrap placed over the trunk and legs of an infant in an Isolette to reduce radiant heat loss.
Respiratory assistance	
Conventional pressure	Delivers positive-pressure ventilation; pressure limited, with volume delivered dependent on the stiffness of the lung.
Volume ventilator	Delivers positive-pressure ventilation; volume limited, delivering same tidal volume with each breath, potentially decreasing barotraumas, as most use minimal pressure required to deliver a set tidal volume; common ventilator in use.
High frequency ventilator	Ventilator that delivers short bursts of air at high rates of flow (240-600 breaths/min).
Jet	Active inhalation with passive exhalation; requires conventional ventilator, noisy.
Oscillatory	Piston driven; active inhalation and exhalation.
Continuous positive airway pressure (CPAP) device	Nasal prongs of varying lengths provide CPAP and controlled oxygen delivery. Using <i>bubble</i> CPAP, positive pressure is adjusted by altering the depth of the expiratory tubing, which is under liquid. CPAP prongs can also be connected to a mechanical <i>ventilator</i> to deliver adjustable pressure and a breath rate if required.
Nasal cannula	Specific concentration of oxygen is delivered via soft nasal cannula, usually less than 1 L/min. <i>High-flow nasal cannula</i> delivers humidified oxygen at flows up to 6 L/min and a variable amount of distending pressure to help with alveolar inflation.
Oxyhood	Clear acrylic plastic hood fitting over the infant's head to provide an environment for delivering controlled oxygen and humidification delivery.
Monitors	
Cardiac, respiratory	One unit will display heart rate, respiratory rate, and blood pressure. High and low alarm limits can be set.
Oxygen saturation	Measures peripheral oxygen saturation and pulse from a light sensor secured to the infant's skin. Values can be displayed on the monitor.
Transcutaneous	Noninvasive method of monitoring partial pressure of O ₂ and CO ₂ from arterialized capillaries through the skin through the use of a heated sensor.
Cerebral oxygenation	Noninvasive method to measure regional oxygen saturation, usually cerebral and somatic, to ensure adequate oxygen delivery.
Amplitude-integrated electroencephalography (aEEG)	Continuous recording of cerebral electrical activity used to evaluate presence of seizures, baseline brain activity, and brain maturation.
Intravenous catheter	Used to deliver intravenous fluids, intralipids, and medications at a specific rate and to assist in obtaining blood for analysis. Specific catheters include arterial and venous umbilical lines, peripherally inserted central catheters (PICCs), surgically placed central catheter (Broviac, Cook), and peripheral intravenous catheter.
Extracorporeal membrane oxygenation (ECMO)	Heart-lung-kidney machine used for term infants with severe respiratory or cardiac failure.

High-Risk Profiles

Three general high-risk profiles are observed from a dynamic systems perspective. In these profiles movement abnormalities, related temperament or behavioral characteristics, and interactional styles associated with motor status are identified.

The first high-risk profile involves the irritable, hypertonic infant. These infants classically have a low tolerance level to handling and may frequently reach a state of overstimulation from routine nursing care, laboratory procedures, and the presence of respiratory and infusion equipment. They may express discomfort when given quick changes in body

position by caregivers and when placed in any position for a prolonged time. Predominant extension patterns of posture and movement are associated with this category of infants. Quality of movement may appear tremulous or disorganized, with poor midline orientation and limited antigravity movement into flexion as a result of the imbalance of increased proximal extensor tone. Visual tracking and feeding may be difficult because of extension posturing or the presence of distracting, disorganized upper-extremity movement. In addition, increased tone with related decreased mobility in oral musculature may complicate feeding behavior. Hypertonic infants frequently demonstrate poor self-quieting abilities and may require consistent intervention by caregivers to tolerate movement and position changes. These temperament characteristics and the signs of neurological impairment previously discussed may place infants at considerable risk for child abuse or neglect as the stress and fatigue levels of parents rise and as coping strategies wear thin during the demanding care required by irritable, hypertonic infants.^{7,157} Hypertonic, irritable infants constituted large percentages of neonatal therapy caseloads in the 1970s through the 1990s, but advances in neonatal pulmonary management have now decreased the numbers of infants matching this neurobehavioral profile.

Conversely, the lethargic, hypotonic infant excessively accommodates to the stimulation of the nursery environment and can be difficult to arouse to the awake states, even for feeding. The crying state is reached infrequently, even with vigorous stimulation. The cry is characteristically weak, with low volume and short duration, and related to hypotonic trunk, intercostal, and neck accessory musculature and decreased respiratory capacity. These infants are exceedingly comfortable in any position, and when held they easily mold themselves to the arms of the caregiver. Depression of normal neonatal movement patterns is common. To compensate for low muscle tone when in the supine position, some preterm infants appear to push into extension against the surface of the mattress in search of stability. Although potentially successful in generating a temporary increase in neck and trunk tone, the extension posturing from stabilizing against a surface in supine lying interferes with midline and antigravity movement of the extremities. Such infants dramatically respond to containment positioning in side-lying and prone positions. Drowsy behavior limits these infants' spontaneous approach to the environment and decreases their accessibility to selected interaction by caregivers. Feeding behavior is commonly marked by fatigue, difficulty remaining awake, weak sucking, and incoordination or inadequate rhythm in the suck-swallow process, with the need for supplementation of caloric intake by gavage (oral or nasogastric tube) feeding. The risk for sensory deprivation and failure to thrive is high for hypotonic infants because they infrequently seek interaction, place few if any demands on caregivers, and remain somnolent.

The third high-risk profile is the disorganized infant with fluctuating tone and movement who is easily overstimulated with routine handling but remains relatively passive when left alone. Disorganized infants usually respond well to swaddling or containment when handled. When calm, these infants frequently demonstrate high-quality social interaction and efficient feeding with coordinated suck-swallow sequence. When distracted and overstimulated, however, these infants appear

hypertonic and irritable. Caregiving for intermittently hypertonic, disorganized, irritable infants can be frustrating for parents unskilled in reading the infant's cues, in implementing consolation and containment strategies, and in using pacing techniques during feeding. This profile of infant motor and behavioral disorganization represents a large proportion of infants in a typical neonatal therapy caseload.

Although these profiles address the extremes in motor and behavioral interaction, they suggest a need for identifying different tolerance levels of handling for neonates with abnormal tone and movement even though long-term developmental goals may be similar. Few neonates will demonstrate all behaviors described in the high-risk profile, but outpatient surveillance of neonates with worrisome or mildly abnormal motor and interactive behavior is advised to monitor the course of those behaviors and the developing styles of parenting.

Timing

The timing of neurodevelopmental examination and treatment for infants with high-risk histories or diagnoses is based on the medical stability of the infant and, in some centers, gestational age. All therapy activities need to be synchronized with the intensive care nursery schedule so that nursing care and medical procedures are not interrupted.

Neonatal therapists should not interrupt infants in a quiet, deep sleep state but instead wait approximately 15 minutes until the infant cycles into a light, active sleep or semiawake state. Higher peripheral oxygen saturation has been correlated with quiet rather than with active sleep in neonates. Preterm infants reportedly have a higher percentage of active sleep periods in contrast to the higher percentage of quiet sleep observed in term infants.¹⁵⁸ Allowing the preterm infant to maintain a deep, quiet sleep by not interrupting is a therapeutic strategy for enhancing physiological stability.

Timing of parental teaching sessions is most effective when readiness to participate in the care of the infant is expressed. Some parents need time and support to work through the acute grief process related to the birth of an imperfect child before participation in developmental activities is accepted. Other parents find the neonatal therapy program to be a way of contributing to the care of their infant that also helps them cope with overwhelming fears, stresses, and grief.

Treatment Strategies

This section addresses components of treatment for enhancing movement, minimizing contractures and deformity, promoting feeding behaviors appropriate to corrected age, developing social interaction behaviors, and fostering attachment to primary caregivers. Management approaches to body positioning, extremity taping, graded sensory and neuromotor intervention, neonatal hydrotherapy, and oral-motor and feeding therapy are presented; parental teaching is discussed here. Evidence-based practice recommendations for neonatal therapy are outlined in [Table 11-7](#) and [Box 11-3](#). In managing an intensive care unit caseload, the constant physiological monitoring; modification of techniques to adapt to the constraints of varying amounts of medical equipment; scheduling of interventions to coincide with visits of the parents and peak responsiveness of the infants; and ongoing coordination and reevaluation of goals, plans, and follow-up recommendations with the nursery staff create many interesting challenges and demand a high degree of adaptability and creativity from the

TABLE 11-7 ■ EVIDENCE-BASED RECOMMENDATIONS FOR NEONATAL PHYSICAL THERAPY

TYPE	RECOMMENDATIONS	LEVEL OF EVIDENCE	REFERENCES
Prevention	Collaborate with caregivers to reduce risk of skull deformity, torticollis, and extremity malalignment through diligent positioning for symmetry and neutral alignment	Level II	Van Vlimmeren et al, 2007 ²⁴⁴
		Level II	Vaivre-Douret et al, 2004 ³⁰³
Examination	Conduct baseline observation to determine physiological and behavioral stability (readiness) for evaluative handling	Level II	Monterosso et al, 2003 ¹⁶⁹
	Provide continuous physiological and behavioral monitoring during and after evaluative handling to determine adaptation to evaluative handling and to signal the need for modification of pace and sequence, given expected physiological changes, particularly during neuromotor test procedures	Level II	Sweeney, 1986 ¹⁵⁰
Intervention	Collaborate with caregivers to create a developmentally supportive environment with modulated stimulation from light, noise, and handling	Level I	Symington and Pinelli, 2006 ³⁰⁴
	Support body position and extremity movement—(1) supine: semiflexed, midline alignment using blanket for swaddling containment or “nest” of positioning rolls; (2) prone: vertical roll under thorax; horizontal roll under hips	Level II	Westrup et al, 2004 ³⁰⁵
		Level II	Peters et al, 2009 ³⁰⁶
	In selected neonates with movement impairment or disorganization consider therapeutic handling carefully graded in intensity and paced to facilitate head and trunk control, antigravity movement, and midline orientation	Level II	Vaivre-Douret et al, 2004 ³⁰³
		Level II	Monterosso et al, 2003 ¹⁶⁹
	Consider gradual exposure to multimodal stimuli for stable neonates approaching hospital discharge	Level II	Short et al, 1996 ³⁰⁷
		Level II	Ferrari et al, 2007 ¹⁶⁶
	Provide opportunities for independent oral exploration through positioning with hands to face, and for nonnutritive sucking to improve state organization and readiness to feed	Level II	Girolami and Campbell, 1994 ³⁰⁸
	Determine readiness for and advancement of oral feeding trials using infant behavioral cues	Level I	Symington and Pinelli, 2006 ³⁰⁴
	Encourage parental involvement with feeding while providing interventions for physiological stability (pacing and slowed flow rate)	Level I	Pinelli and Symington, 2005 ¹⁹⁷
Level II		Kirk, Alder, and King, 2007 ¹⁹⁸	
Consider hydrotherapy before feeding for stable infants with movement impairment	Level II	McGrath and Medoff-Cooper, 2002 ³⁰⁹	
Education	Educate parents on behavioral cues and developmental status to mitigate parental stress and improve parental mental health outcomes	Level III	Law-Morstatt et al, 2003 ²⁰⁶
		Level II	Chang et al, 2007 ²⁰⁷
	Implement multiple methods of instruction for parents and caregivers (demonstration, discussion, video, and written materials)	Level IV	Sweeney, 2003 ¹⁹¹

clinician. Willingness to change an established assessment plan, treatment strategy, or therapy schedule to meet the immediate needs of the infant, parents, or nursery staff is paramount. For some infants with prolonged periods of only borderline stability with handling, a discharge examination with recommendations for follow-up care may be the best practice. Productivity standards of billable hours used for other caseloads of stable pediatric or adult clients in the hospital are not appropriate for the NICU setting and necessitate negotiation and reinterpretation with rehabilitation or therapy department managers to protect both the infant and the neonatal therapist. Tolley¹⁵⁹ reported an expected mean productivity of 5.0 billable hours (range 4 to 6.5 hours) for hospital-based pediatric physical therapists among hospitals surveyed across 32 states and the District of Columbia.⁹³

Positioning

A diligently administered positioning program can greatly assist infants on mechanical ventilators, receiving hood oxygen, or in incubators to simulate the flexed, midline postures of the neurologically intact term newborn swaddled in a bassinet. Preterm infants characteristically demonstrate low postural tone, with the amount of hypotonia varying with gestational age. Infants born prematurely do not have the neurological maturity or the prolonged positional advantage of the intrauterine environment to assist in the development of flexion. They are instead placed unexpectedly against gravity and presented with a dual challenge of compensating for maturation-related hypotonia and adapting to ventilatory and infusion equipment that frequently reinforces extension of the neck, trunk, and extremities.

Imbalance of excessive extension may occur in preterm infants with prolonged mechanical ventilation who appear to gain postural stability in the nonfluid extrauterine environment by leaning into or stabilizing against a firm mattress while in the supine position. De Groot¹⁶⁰ explained the postural behavior of preterm infants as an imbalance between low passive muscle tone and active muscle power. She theorized that because preterm neonates have prolonged periods of immobility (often in the supine position), exaggerated active muscle power may be observed in the extensor musculature, particularly in the trunk and hips. This imbalance of extension is viewed as nonoptimal muscle power regulation that may negatively influence postural stability, coordinated movement, and later hand and perceptual skills.¹⁶⁰

Some neonates, especially those born at less than 30 weeks of gestation, may attempt to posturally stabilize by hyperextending the neck in supine or side-lying positions to compensate for maturation-related hypotonia.¹⁶¹ Neck hyperextension posturing, without a balance of movement into flexion, may trigger later development of a host of related abnormal postural and mobility patterns to compensate for inadequate proximal stability.¹⁶⁰ In some infants, excessive postural stabilizing into neck hyperextension may contribute to sequential blocking of mobility in the shoulder, pelvis, and hip regions. The potential components of this high-risk, hypertonic postural profile appear in [Box 11-4](#).

BOX 11-4 ■ POTENTIAL COMPONENTS OF HYPERTONIC POSTURAL PROFILE

Hyperextended neck
Elevated shoulders with adducted scapulae
Decreased midline arm movement (hand to mouth)
Excessively extended trunk
Immobile pelvis (anterior tilt)
Infrequent antigravity movement of legs
Weight bearing on toes in supported standing

Shaping of the musculoskeletal system occurs during each body position experienced by neonates in the NICU. A variety of positional deformities in the extremities and skull can result from inattention to alignment. In [Table 11-8](#), common neonatal positional deformities, musculoskeletal consequences, and functional limitations are outlined. Supporting the skeletal integrity of infants born prematurely is challenging in the midst of numerous equipment obstacles, restricted physical handling because of physiological instability, and limited spontaneous movement. Infants with gastroesophageal reflux are frequently positioned on wedges that make symmetrical, midline postures difficult to maintain. Skull flattening may continue to evolve after NICU discharge from overuse of infant seats, reflux wedges, and limited prone play experiences. Plagiocephaly (asymmetrical occipital flattening) and a secondary torticollis may emerge when a strong head turn preference remains and parents do not vary the direction of head turn for sleeping and infant seat use.

Retracted shoulder posture (scapular adduction with shoulder elevation and external rotation) may accompany excessive neck and trunk extension posture in preterm infants. This abnormal posture can interfere with later reaching, shoulder stability in the prone position, and rolling during the first 18 months of life.^{162,163} Excessive tibial torsion and out-toeing gait were reported in preterm infants at 3 to 8 years of age and traced to prolonged “frog leg” (excessive abduction and external rotation with foot eversion) in the NICU.^{164,165}

Goals of neonatal positioning procedures include the following:

- Optimize alignment toward neutral neck-trunk position, semiflexed, midline extremity posture, and neutral foot position
- Support posture and alignment within “containment boundaries” of rolls, swaddling blanket, or other positioning aids; avoid creating a barrier to spontaneous movement, and allow space for controlled extremity movement
- Create positions that promote alert states for enhanced short-duration interaction and sleep states that promote comfort and physiological stability
- Offer positions that allow controlled, individualized exposure to proprioceptive, tactile, visual, or auditory stimuli while monitoring signs of behavioral and physiological stress from potential overstimulation

The use of blanket or cloth diaper rolls or customized foam inserts in a neonatal positioning program may modify increasing imbalance of extension in selected preterm or chronically ill infants and promote movement and postural stability from positions of flexion. After the infant is facilitated into a flexed posture in the side-lying position, posterior rolls behind the head, trunk, and thighs provide a surface against which the infant can posturally stabilize while a flexed midline posture is maintained ([Figure 11-10](#)). An additional anterior roll between the extremities and the use of a pacifier may promote further midline stabilization in flexion ([Figure 11-11](#)). Small neonates can be maintained in a flexed, symmetrical posture in a circular nest formed from a long blanket roll. Cloth buntings with circumferential body straps and a foot roll ([Figure 11-12](#)) provide positioning support and containment of extremity movement. Ferrari

TABLE 11-8 ■ MUSCULOSKELETAL MALALIGNMENT AND FUNCTIONAL LIMITATIONS IN NEONATES

POSITIONAL DEFORMITY	CONSEQUENCES	FUNCTIONAL LIMITATIONS
Plagiocephaly	Unilateral, flat occipital region; head turn preference; high risk for torticollis	Limited visual orientation from asymmetrical head position; delayed midline head control
Scaphocephaly	Bilateral, flat parietal and temporal regions	Difficulty developing active midline head control in supine position from narrowing of occipital region
Hyperextended neck and retracted shoulders “Frog” legs	Shortened neck extensor muscles; overstretched neck flexor muscles; excessive cervical lordosis; shortened scapular adductor muscles Shortened hip abductor muscles and iliotibial bands; increased external tibial torsion	Interferes with head centering and midline arm movement in supine position; interferes with head control in prone and sitting positions; limits downward visual gaze Interferes with movement transitions into and out of sitting and prone positions; interferes with hip stability in four-point crawling; prolonged wide-based gait with excessive out-toeing
Everted feet	Overstretched ankle invertor muscles; altered foot alignment from muscle imbalance	Pronated foot position on standing; retained, immature foot-flat gait with potential delay in development of heel-to-toe gait pattern from excessive pronation

and colleagues¹⁶⁶ found increased frequency of extremity movements across midline and fewer stiff postures when neonates (25 to 31 weeks of gestation) were positioned in supine position in a circular nest compared with supine position without a nest.

Endotracheal tube placement frequently contributes to the neck hyperextension posture in infants who require mechanical ventilation (Figure 11-13). This iatrogenic component can be avoided by repositioning the ventilator hoses to allow enough mobility for slightly tucked chin and partially flexed trunk posture. For neurologically impaired infants with severe pulmonary disease necessitating prolonged ventilatory support, inattention to the alignment of the neck and shoulders may lead to the development of a contracture in the neck extensor muscles (Figure 11-14).

During the hospital stay, infants on ventilators (Figure 11-15) are now routinely positioned prone to enhance extremity and trunk flexion in the prone position, improve oxygenation, and decrease irritability.^{167,168} Monterosso and

Figure 11-13 ■ Neck hyperextension posture magnified by the position of the endotracheal tube.

Figure 11-14 ■ Clinical presentation of contracture in neck extensor muscles related to hyperextension posture during prolonged mechanical ventilation.

colleagues¹⁶⁹ reported that using a small vertical roll along the torso (sternum to pubis) decreased scapular retraction in the prone position. Although placing infants on a sheepskin surface (see Figure 11-12) offers increased tactile input and has been correlated with increased weight gain in LBW infants compared with a matched group of infants on standard

Figure 11-15 ■ Infant with endotracheal tube and ventilator positioned prone in nest with straps. (Reprinted from Hunter JG: Neonatal intensive care unit. In Case-Smith J, O'Brien JC: *Occupational therapy for children*, ed 6, St Louis, 2010, Mosby.)

cotton sheets,¹⁷⁰ concern regarding the inhalation of microfibers from sheepskin has limited widespread use unless the sheepskin is covered by a thin blanket and used only to midchest level.¹⁷¹

After the infant has been moved from intensive care to intermediate care, transition to a standard mattress without positioning aids is recommended to allow time for adaptation to the type of mattress likely to be used at home. Infants are also transitioned to the supine sleeping position during the week before hospital discharge to reduce the risk of sudden infant death associated with the prone sleeping position and other factors.¹⁷¹

The neonatal therapist provides consultation on body alignment of infants in car seats when the LBW infant has not passed the peripheral oxygen saturation test in the car seat, which is usually conducted by the neonatal nurse before discharge. Some infants require the use of a car bed with body harness when they are unable to tolerate the semiupright position of a car seat without oxygen desaturation.

Preliminary evidence has been reported to support neonatal positioning programs emphasizing postures of extremities in flexion and head in midline.^{166,172} Clinicians are referred to the work of Hunter^{173,174} for detailed positioning techniques in the NICU. Continued research efforts are needed to measure effects of positioning and the risk-benefit effects of other neonatal therapy interventions to guide future directions of neonatal practice.

Extremity Taping

The presence of perinatal elasticity encourages early management of congenital musculoskeletal deformities in the neonatal period (birth to 28 days of age). A temporary ligamentous laxity is presumed to be present in the neonate because of transplacental transfer of relaxin and estrogen from the mother. In addition to the influence of maternal hormones, the rapid growth of the neonate can foster correction

Figure 11-16 ■ Infant with lumbar meningomyelocele demonstrating marked varus foot deformities before taping.

of malalignment if the deforming forces are expeditiously managed. This peak period of hyperelasticity offers pediatric therapists with advanced orthopedic expertise many opportunities to manage congenital joint deformities.¹⁷⁵

Intermittent taping of foot deformities (Figure 11-16) has been more adaptable to the nursery setting than either casts or splints and is more effective in achieving mobility than range-of-motion exercises. Access to the heel for drawing blood, inspection of skin and determination of vascular status, and placement of intravenous lines can be accomplished with the tape in place or by temporary removal of the tape as needed. Therapists without a sound knowledge of arthrokinematic principles and techniques should not attempt the taping procedure, which involves articulation of the joint(s) into a corrected position before taping. Other components of the taping process include application of an external skin protection solution under the tape, application of an adhesive removal solution when removing the tape, observance of skin condition and vascular tolerance, development of a taping schedule beginning with 1 hour and increasing by 1-hour intervals as tolerated, and clinical teaching with selected neonatal nurses for continuation of the taping if needed on night shifts and weekends. Infants with congenital foot deformities required shorter periods of casting in the outpatient period after taping of the extremity (Figure 11-17) was implemented during the inpatient phase. Taping is not appropriate for medically fragile infants on minimal handling protocols or for infants younger than 30 to 32 weeks of gestation because of potential epidermal stripping from tape removal or vascular compromise from inadvertent, excessive compression by either the tape or the underwrap layer.

The availability of thin, self-adherent foam material now allows taping on an underwrap (bandage) layer rather than on the infant's skin (Figure 11-18). Although this method creates a definite advantage in skin protection, it may cover the calcaneal region for blood drawing. Compromise in alignment may occur if the underwrap layer is applied loosely; conversely, restriction in circulation may be observed by edema or purple-blue color changes in the toes if the underwrap is excessively tight around the foot or ankle.

Infants with wrist drop from radial nerve compression related to intravenous line infiltration also benefit from the use of taping (Figure 11-19). The wrist is supported in a

Figure 11-17 ■ Significant correction in alignment of varus foot deformities in neonate with a lumbar meningomyelocele. **A**, Lateral stirrup with open heel taping procedure. **B**, Moderate correction.

functional position of slight extension. As muscle function returns, the taping is used intermittently to reduce fatigue and overstretching of the emerging, but still weak, wrist extensor musculature.

Soft Hand-Wrist Splint

Instead of using rigid, thermoplastic materials or taping, soft foam straps with Velcro closures provide an alternative method of support for wrist drop or hand-wrist malalignment (Figure 11-20). The splinting material is illustrated in Figure 11-21 with a small notch for the thumb on the longer strap placed across the palm and the shorter strap for the wrist band (longer strap attaches to posterior wrist band by Velcro). The wearing time is increased by 1-hour intervals to a 3-hour total wearing time and is often synchronized with nurse caregiving schedules (approximately 3-hour intervals) for alternate on-off application. Collaboration with neonatal nurses on wearing schedule, skin and vascular tolerance, alignment, and parental teaching is critical for successful integration of soft splints into the care plan.

Therapeutic Handling

Use of tactile, vestibular, proprioceptive, visual, and auditory stimuli to facilitate infant development has been reported and reviewed by many authors.¹⁷⁶⁻¹⁸⁴ Selection and

application of the sensory or neuromotor treatment options in neonatal therapy must occur with judicious attention to the prevention of sensory overload and related physiological consequences. Decision making on the type, intensity, duration, frequency, and sequencing of intervention within the context of infant physiological and behavioral stability can be learned only in a mentored clinical practicum in the NICU setting. The current general guidance on intervention is more observation, less handling, protection from bright lights and loud conversation, and readiness for handling determined on the basis of behavioral and physiological cues of the infant.^{11,177,183,184}

Primary aims of therapeutic handling include assisting the newborn to achieve maximal interaction with parents and caregivers and facilitating the experience of postural and movement patterns appropriate to the infant's adjusted gestational age. Helping infants reach and maintain the quiet, alert behavioral state and age-appropriate postural tone appears to enhance opportunities for visual and auditory interaction and for antigravity movement experiences.

The typical early movement experiences include hand-to-mouth movement, scapular abduction and adduction, anterior and posterior pelvic tilt, free movement of the extremities against gravity, and momentary holding of the head in midline.^{127,185}

Behavioral state and some movement abnormalities can be modified by creative swaddling and gentle weight shifts and nesting in the caregiver's lap. Swaddling the infant in a blanket with flexed, midline extremity position appears to promote flexor tone, increase hand-to-mouth awareness, inhibit jittery or disorganized movement, and elicit quiet, alert behavior. These effects can also be accomplished in skin-to-skin holding of infants against the parent's chest, a procedure now commonly adopted in NICUs in North America.^{186,187} Application of neonatal therapy techniques must be contingent on both the infant's readiness for interaction and the need for a recovery break in interaction because of sensory overload. Teaching parents and caregivers to read and respond to the infant's motor cues for interaction, feeding, change of body position, and rest breaks is a critical quality-of-life component of the infant's NICU therapy program.

A semi-inverted supine flexion position (Figure 11-22) with preterm neonates should be used with caution. This position may be used with older infants (6 months old) to facilitate elongation of neck extensor muscles and decrease the neck hyperextension posture, but with neonates the position may compromise breathing from positional compression of the chest and from potential airway occlusion associated with maximal flexion of the neck. The use of cardiorespiratory and oxygen saturation monitors during therapeutic handling activities is recommended for objective measurement of physiological tolerance. Although the peripheral oxygen saturation values from monitors may be intermittently unreliable because of motion artifacts from either the infant's spontaneous movement or the therapist's handling of the infant, reliable readings of oxygen saturation may be taken approximately 1 minute after the infant's body is not moved.

Easily overstimulated preterm infants may not tolerate multimodal sensory stimulation but may instead respond to a single sensory stimulus.^{79,181} Implementation of a positioning program, oral-motor therapy, and environmental modifications and reinforcement of developmental activities with

Figure 11-22 ■ Potential respiratory compromise to the infant from neck extensor muscle elongation in excessively flexed position while supine.

parents can be instituted only in collaboration with the shifts of bedside nurses who are in charge of the infant's 24-hour day in the NICU. Collaboration with nurses is a major component of precepted neonatal therapy training and requires integration into and valuing of the unique culture of the NICU.¹³⁰ Part of NICU culture is the unique ecology of environmental light and sound modifications, medical procedures, equipment, and caregiving patterns. Observing and analyzing the effects of the environment on an infant's behavior, physiological stability, postural control, and feeding function are critical elements to establish a prehandling baseline status before each neonatal therapy contact.¹³⁰

Neonatal Hydrotherapy

Modified for use in an intensive care nursery setting, the traditional physical therapy modality of hydrotherapy has been adapted and implemented into neonatal therapy programs in some NICUs. Neonatal hydrotherapy was conceptualized in 1980 at Madigan Army Medical Center in Tacoma, Washington, and results of a pilot study of physiological effects were first reported in 1983.¹⁸⁸

Indications for referral of medically stable infants to the hydrotherapy component of the neonatal therapy program include (1) muscle tone abnormalities (hypertonus or hypotonus) affecting the quality and quantity of spontaneous movement and contributing to the imbalance of extension in posture and movement (Figure 11-23); (2) limitation of motion in the extremities related to muscular or connective tissue factors; and (3) behavioral state abnormalities of marked irritability during graded neuromotor handling or, conversely, excessive drowsiness during handling that limits social interaction with caregivers and lethargy that contributes to feeding dysfunction.

Infants are considered medically stable for aquatic intervention when ventilatory equipment and intravenous lines are discontinued and when temperature instability and apnea or bradycardia are resolved. A standard plastic bassinet serves as the hydrotherapy tub, and the water temperature is prepared at 37.8° C to 38.3° C (100° F to 101° F). An overhead radiant heater is used to decrease temperature loss and enhance thermoregulation in the undressed infant. Agitation of the water is not included in the hydrotherapy protocol in the NICU.

Figure 11-23 ■ Adjustment to water immersion before introduction of guided movement during neonatal hydrotherapy.

After medical clearance and individualized criteria for the maximum acceptable limits of heart rate, blood pressure, and color changes during hydrotherapy have been received from the neonatal staff, the baseline heart rate and blood pressure values are recorded and pretreatment posture and behavioral states are observed. The undressed infant is swaddled and moved into a semiflexed, supine position. The blood pressure cuff is placed around the distal tibial region to continuously measure heart rate and blood pressure at 2-minute intervals during the 10-minute water immersion period. After being lifted into the water, the swaddled infant is given a short period of quiet holding in the water without body movement or auditory stimulation to allow behavioral adaptation to the fluid environment (Figure 11-24). A second caregiver (e.g., nurse or parent) is recruited to stabilize the infant's head and shoulder girdle region while the neonatal therapist provides support at the pelvis (Figure 11-25).

Within the loosened boundaries of the swaddling blanket, the movement techniques involve midline positioning of the head and slow, graded movement incorporating slight flexion and rotation of the trunk, followed (if tolerated) by progression distally to the pelvic girdle region and finally to the shoulder girdle region. After guided trunk extensor flexion with partially dissociated movement at the shoulder or pelvic girdle, most infants will demonstrate active extremity movement in the water and the swaddling blanket is adjusted (or removed) to allow more movement or more stability depending on the response of the infant. The improved range and smoothness of spontaneous extremity movement is facilitated by the buoyancy and surface tension of the water. Movement experiences in the supine, side-lying, and prone positions are offered as tolerated. If the movement therapy becomes stressful, with agitation or crying by the infant, body movement is stopped immediately, and the infant is either consoled or removed from the water and held with warmed towels. Compromise in hemodynamic stability (increased heart rate, increased blood

Figure 11-24 ■ Swaddled infant is supported in neonatal hydrotherapy tub by neonatal physical therapist and neonatal nurse. The blanket is gradually loosened to encourage spontaneous, midrange movement of the extremities.

Figure 11-25 ■ Parents being trained in hydrotherapy techniques for later therapeutic bathing at home.

pressure, decreased respiratory rate) and decrease in arterial oxygen tension during crying have been well documented in neonates.¹⁸⁹ Careful monitoring of behavioral tolerance to hydrotherapy (with avoidance of crying) is considered critical for reducing physiological risk with hydrotherapy.

Multiple therapeutic benefits have been observed from the selective use of 10-minute aquatic intervention sessions. Improved postural tone with semiflexed posture is obtained with less time and effort by the therapist and with higher behavioral tolerance by the infant than when a similar therapeutic handling approach is used without the medium of water. Postural tone changes are frequently maintained for 2 to 3 hours when aquatic intervention is followed by flexed, midline body positioning in the side-lying or prone position on a water mattress or supported against rolls. Mild flexion contractures of knees and elbows and dynamic hip adduction contractures can be safely and quickly reduced by gentle muscle elongation techniques in warm water. Enhancement of visual and auditory orientation responses (e.g., visual fixing and tracking, auditory alerting, and localization to human voices), prolonged high-quality alertness, and longer periods of social interaction with caregivers are clinically observed during and after hydrotherapy sessions.

Improved sleep quality and behavioral organization were documented in 12 preterm infants (less than 36 weeks of gestation) after a 10-minute hydrotherapy session in a NICU in Brazil.¹⁹⁰ In this study the infants were used as their own controls, and responses were measured by a Neonatal Facial Coding System scale and by sleep-wake cycles from an adapted NBAS.

Feeding performance may improve when hydrotherapy is scheduled 30 minutes before feeding to prepare the infant for arousal to the quiet, alert state and for flexed, midline postural changes for optimal feeding. A sample of 31 preterm infants received both a 10-minute hydrotherapy session and a 10-minute rest period control condition (crossover design) before bottle feeding by a nurse blinded to the order of the treatment phase. Mean duration of feeding was significantly decreased ($P < .004$) after

hydrotherapy compared with the rest condition. Mean daily weight gain after hydrotherapy was significantly higher ($P < .026$) than after the rest condition. All infants consumed 100% of the required feeding volume after the 10-minute hydrotherapy session, indicating that potential overstimulation or fatigue did not occur. On a short-term basis, weight gain was enhanced.¹⁹¹

Therapeutic bathing techniques are incorporated into the parental teaching program to foster early parental participation in child care and in specific neonatal therapy activities during the inpatient period to prepare for carryover into the home environment. This early pleasurable involvement of parent and child in hydrotherapy and therapeutic bathing may provide a strong base for future participation in aquatics as a family leisure sports activity and, if needed, as an adjunct to an outpatient therapy program.

When oriented to treatment goals and trained in specific hydrotherapy techniques for individual infants, the nursing staff can effectively carry on the hydrotherapy program established by the neonatal therapist. This release of the neonatal therapist's role to nurses allows additional use of hydrotherapy on evening and night shifts and continued teaching and supervision of parents during evening and weekend visits (see Figure 11-25).

An additional advantage of neonatal hydrotherapy is cost-effectiveness, with the use of equipment readily available in the newborn nursery and the short time (10 minutes) required for therapeutic bathing. Hydrotherapy becomes labor efficient for the neonatal therapist when it is incorporated into nursing care plans and conducted by nurses and parents, with the therapist assuming a supervisory role.

Although many clinical benefits may be obtained by judicious use of hydrotherapy in the newborn nursery, pilot study data obtained on physiological changes in high-risk infants during hydrotherapy clearly indicate a physiological risk.¹⁸⁸ This risk (7% increase in blood pressure and heart rate in the pilot sample) must be carefully evaluated relative to each infant's general medical stability and baseline heart rate and blood pressure status before hydrotherapy can be included safely in a neonatal therapy program. In collaboration with the neonatology and nursing staff, the therapist must use established criteria for general medical stability and the maximal limits during hydrotherapy for blood pressure, heart rate, and acceptable color changes; this step is essential for risk management. Physiological monitoring of mean blood pressure and heart rate with a neonatal vital signs monitor during aquatic intervention is recommended. The blood pressure cuff is a pneumatically driven device that is not electronically connected to the infant and can be safely immersed in water. Because hypothermia is a recognized risk with hydrotherapy, body temperature should be routinely measured before and after the hydrotherapy session by using a thermometer with a digital display. A risk-benefit analysis of the potential physiological risk to each infant and the expected therapeutic benefits is strongly advised before hydrotherapy techniques are incorporated into a neonatal therapy program.

Oral-Motor Therapy

Feeding difficulties in preterm neonates may be related to neurological immaturity, depressed oral reflexes, prolonged use of an endotracheal tube for mechanical ventilation and

subsequent oral tactile hypersensitivity, or insufficient postural tone. Because behavioral state affects the quality of feeding behavior, feeding performance may be significantly improved by specific arousal or calming procedures before feeding. Other variables influencing feeding may include decreased tongue mobility, presence of tongue thrusting, decreased lip seal on nipple, nasal regurgitation, tactile hypersensitivity in the mouth, inefficient and uncoordinated respiratory patterns, insufficient proximal stability from hypotonic neck and trunk musculature, and hypertonic posturing of the neck and trunk in extension.^{192,193}

Three instruments for assessing oral-motor and feeding behaviors in the nursery are the Neonatal Oral-Motor Assessment Scale (NOMAS),¹⁹⁴ the Nursing Child Assessment of Feeding Scale (NCAFS),¹⁹⁵ and the Early Feeding Skills (EFS) Assessment for preterm infants.¹⁹⁶ The NOMAS is used to evaluate the following oral-motor components during sucking: rate, rhythmicity, jaw excursion, tongue configuration, and tongue movement (timing, direction, and range). Tongue and jaw components are analyzed during nutritive and nonnutritive sucking activity. Cutoff scores were derived from a pilot study with the instrument: a combined score of 43 to 47 indicated “some oral-motor disorganization”; a score of 42 or less indicated oral-motor dysfunction.¹⁹⁴ The absence of a category to evaluate breathing pattern, work of breathing or respiratory exertion, and physiological variables during feeding limits the use of this instrument to low-risk, healthy neonates.

The NCAFS is used to analyze parent-infant interaction during feeding. It provides a method for evaluating the responsiveness of parents to infant cues, signs of distress, and social interaction opportunities during the feeding process. In concurrent validity studies, NCAFS scores were positively correlated with findings of the Home Observation for Measurement of the Environment inventory at 8 months ($r = 0.72$) and at 12 months ($r = 0.79$).¹⁹⁵

The EFS Assessment is a 36-item observational measure of oral feeding readiness, feeding skill, and feeding recovery. The assessment tool includes examination of physiological and behavioral stability, behavioral feeding readiness cues, oral-motor coordination and endurance, coordination of breathing and swallowing, and postfeeding alertness, energy level, and physiological state. Preliminary content validity and intrarater and interrater reliability procedures were described as “stable and acceptable” (correlation data not reported) with predictive, concurrent, and construct validity testing in process.¹⁹⁶ This tool is specifically designed for feeding examinations in the NICU environment and with expanded psychometric testing will be a relevant instrument in managing neonates with feeding impairment.

General strategies during feeding may include semiflexed, upright positioning with light support under the chin (Figure 11-26). Techniques such as tactile facilitation of the facial muscles, use of a pacifier during gavage feedings, light manual support to the jaw or lip, and thickening of formula are frequent components of oral-motor therapy programs.^{193,197} Scheduling of feeding based on the infant’s readiness (behavioral cues of hunger and alertness) is usually implemented by neonatal nurses and shown to be effective in helping infants advance the frequency of oral (rather than gavage) feedings.^{198,199}

Figure 11-26 ■ Swaddled preterm infant fed in semiupright position with light support under chin.

For some infants, oral intake by bottle may be improved by individualizing nipple selection according to contour, length, hole size, texture, and compression resistance. Wolf and Glass^{193,200} advised evaluation of the flow rate of liquid from various types of nipples and analysis of the effects of nipple size, shape, and consistency on an infant’s sucking proficiency. Feeding infants in the side-lying position may improve tongue position, particularly if marked tongue retraction is present (Figure 11-27). The timing of movement therapy or neonatal hydrotherapy 30 minutes before feeding may improve performance by preparing postural tone, facilitating oral musculature, and enhancing alertness.

Infants with orofacial anomalies (e.g., cleft palate, hypoplastic mandible) often respond to bottle feeding with a Haberman feeding system (Medela, McHenry, Illinois), which allows control of the flow rate through a valve in the bottle and manual compression of the nipple. The Haberman feeder is an ideal option for infants with large bilateral cleft lip and palate because of the long, flexible nipple, which allows formula to be released from manual compression of the nipple by caregivers instead of requiring negative pressure for suction by the baby (Figure 11-28). Placement of the nipple on the middle of the tongue is advised regardless

Figure 11-27 ■ Infant fed in side-lying position to improve tongue position.

Figure 11-28 ■ Infant with cleft palate fed with specialized nipple (Haberman Feeding System).

of the location of the palate or lip defect.²⁰¹ The feeding performance of infants with severe cleft palate deformities may be improved by a dental obturator. This custom-fabricated prosthesis is inserted before feeding to cover the defect in the palate.

The increasing popularity of breast feeding has encouraged the development of breast-feeding aids (e.g., Lact-Aid, JJ Avery, Denver, Colorado). These devices allow supplementation of oral intake during breast feeding through a small tube that goes to the mouth from a sterilized bag containing infant formula.

Expected outcomes of oral-motor intervention supported by clinical research include (1) increased number of nutritive sucks after perioral stimulation,^{202,203} (2) increased volume of fluid ingested during nipple feedings,²⁰⁴ (3) decreased number of gavage feedings and earlier bottle feeding,^{203,205} (4) accelerated weight gain,²⁰⁵ and (5) earlier hospital discharge.²⁰⁵ Research evidence has emerged on the benefits of interventions to assist pacing to allow breathing pauses²⁰⁶ and to provide slower flow rate with specialized nipples²⁰⁷ for preterm infants during the process of learning to bottle feed.

Monitoring the infant's physiological tolerance, breathing pattern, and work of breathing is critical during oral-motor examination, intervention, and feeding trials.¹⁹³ Heart rate values may be monitored from either the cardiorespirograph or with peripheral oxygen saturation from a pulse oximeter. Color changes, diminished tone in facial muscles, and behavioral stress cues (e.g., restlessness, trunk arching) must be carefully monitored to allow appropriate response to early signs of fatigue, overexertion, and potential airway difficulty. Regurgitation with aspiration of milk or formula into the lungs may occur during feeding trials, with complications of pneumonia, cardiopulmonary arrest, and associated asphyxia. Because of these risks, feeding trials should not be attempted by neonatal therapists untrained in managing the respiratory and general physiological monitoring components of neonatal feeding.²⁰⁰

Success during feeding activities enhances parent-infant interaction and perceived competency in parenting. Parents of infants with feeding dysfunction describe higher stress

than that reported by parents of infants who are gaining weight and feeding satisfactorily. Oral-motor dysfunction has been reported as an early functional deficit in infants at high risk for later neuromotor sequelae²⁰⁸; early support for parents coping with a challenging feeding situation builds competence in caregiving and also commitment to continuity in outpatient developmental monitoring.

Parental Support

Grief Process

Strong, continuous support is essential to help parents through perhaps the most frightening crisis in their adult lives—the potential death or disability of their infant.^{209,210} Although touching and holding infants contribute to infant-parent attachment,²¹¹ parents may initially establish emotional and physical distance from the infant “s” as they cope with the knowledge that the infant may die. During this time of anticipatory grief, peer group support from other parents of prematurely born children can be of immeasurable value. Actively listening to the parents' feelings and concerns and providing support without judgment through their episodes of detachment and anger are critical. Although long-range plans include participation of parents in all aspects of the developmental program, the timing and amount of initial teaching must be individualized to the levels of stress and acute grief present.

When an infant dies, the neonatal therapist begins the important work of closure. This work includes attending memorial or funeral services to support the family, writing a note expressing sympathy to the family, and initiating a personal closure process. Neonatal therapists are advised to find a senior nurse mentor to guide them through the closure process of identifying and dealing with feelings of loss regarding the infant and family. Finding meaning and value in the process of caregiving rather than solely in functional outcomes is an important task in the work of closure and in preventing professional burnout.

Parent/Caregiver Teaching

Components of the parental/caregiver teaching process may include (1) discussion of the program goals and services in the NICU; (2) orientation to the interdisciplinary follow-up plan after discharge; (3) guidelines for recognizing and understanding the infant's temperament, stress, and stability cues; (4) methods of creating a calm environment with protection from aversive light and sound; and (5) specific instructions on selected corrected-age-appropriate developmental activities or therapeutic handling techniques. When used in conjunction with verbal instructions and demonstrations, a packet of written guidelines and pictures individualized to the infant's needs may improve parents' overall skills and understanding of the program.

Occasionally, when geographical distance prevents participation by parents in the neonatal therapy program, the infant's individualized developmental plan may be mailed and later reviewed at discharge or during outpatient follow-up. During times of separation, telephone contact with parents helps foster attachment to the infant and explain the purpose and content of the home developmental intervention program as well as providing opportunity to discuss the critical need for follow-up. Parents need this ongoing dialogue to make the infant seem real to them and to allow

communication of their fears and concerns during the separation.

Teaching strategies are most effective when they are adapted to the learning style of the parents. This adaptation may involve more demonstrations and an increased opportunity for supervised practice for some parents, particularly those with reading or language difficulties that limit use of a written instructional packet. Parents have shown preference for combined educational methods including demonstration, video, and written materials rather than one single method.^{212,213} Cultural caregiving practices of the family may necessitate elimination of common procedures such as use of pacifiers for nonnutritive sucking or hand-to-mouth engagement.

With consultation from and in collaboration with the neonatal therapist, neonatal nurses can incorporate recommendations to support skeletal and motor development into their routine discharge teaching activities. General considerations for discharge teaching by nurses may include the following²¹⁴:

- Varying the direction of head turn for sleeping in the supine position to prevent plagiocephaly
- Placing the head in midline with lateral rolls extending along the side of the head and trunk for car seats and swings
- Limiting the use of infant seats and encouraging the use of prone play on the floor with a roll under the arms and upper chest to assist in head lifting and weight bearing on the arms
- Highlighting the importance of the prone play position for strengthening the neck, trunk, and arm musculature to prepare for sitting and rolling
- Reinforcing the value of interdisciplinary follow-up for musculoskeletal and neurodevelopmental monitoring
- Recommending expedient follow-up if parents notice signs of head flattening, persistent lateral head tilt, strong asymmetrical head turn preference, or asymmetrical arm use

In the neonatal period, the quality of infant-parent attachment and comfort level and proficiency in routine caregiving and therapeutic handling set the stage for later parenting styles. Helping parents find and appreciate a positive aspect of the neonate's motor or other developmental behaviors gives them a spark of hope from which emotional energy can be generated to help them through the marathon of the NICU experience. Empowering parents early in their parenting experience with the infant is crucial. In the life of the child, the effects of parent empowerment will last far longer than neonatal movement therapy and positioning strategies.

CLINICAL MANAGEMENT: OUTPATIENT FOLLOW-UP PERIOD

Purpose of Outpatient Follow-up for the at-Risk Infant

Systematic follow-up of the at-risk infant after discharge from the NICU is an essential component of the clinical management of high-risk infants. The purpose of this follow-up is threefold: (1) monitor and manage ongoing medical issues, such as respiratory problems and feeding difficulties; (2) provide support and guidance to parents and

caregivers in care and nurturing of at-risk infants; and (3) assess the developmental progress of infants to ensure that neuromotor impairments and delays in motor development can be identified and intervention initiated as early as possible. Issues of assessment, intervention, and developmental profiles of the high-risk infant after discharge from the NICU are discussed in this section.

Medical Management

The routine medical care of preterm infants after discharge may be provided by a pediatrician, family practitioner, or health professional. Infants at neurodevelopmental risk are frequently followed by a number of additional professionals, including neurologists, ophthalmologists, cardiac or pulmonary specialists, nutritionists, public health nurses, physical and occupational therapists, and infant educators. Communication among these specialists is often minimal, especially when they are located at different facilities, and access to providers may be restricted by policies of varied hospital or managed-care systems. The parent or caregiver is often confronted with conflicting opinions, demands, and expectations of the family and the infant. The follow-up clinic can play a valuable role in this situation by providing case management to assist caregivers in coordinating necessary services, verify that all needs of the infant are being met, and help parents set realistic goals and priorities for themselves and their child.

Family Support

The stress that a vulnerable, premature, or at-risk infant brings to a family is well documented. Grief, anger, and depression are common reactions to the trauma and anxiety of an unanticipated premature birth.^{209,215-217} The caregivers of high-risk infants are required to become knowledgeable about complex medical terminology and equipment. At discharge, they often become responsible for the administration of multiple medications of varying dosages, cardiopulmonary resuscitation procedures and equipment, and complicated feeding schedules requiring daily measurement and recording of nutritional intake and output. In addition, families are often faced with an unexpected, large financial obligation to the hospital and the confusion of dealing with different billing agencies and funding sources.

These stresses and demands are even more overwhelming for parents who are young, are single, or do not speak English. In contrast to the 1980s, a greater proportion of at-risk infants now seen in follow-up clinics are living with caregivers other than their biological mothers. These caregivers may include other relatives, such as single fathers, grandparents, aunts and uncles, foster care providers, or preadoptive parents. At the same time the changing demographics of American society are reflected in the increasing ethnic diversity of preterm infants. Whether they are recent immigrants to the United States, seasonal workers, or residents of an ethnic neighborhood, parents from minority ethnic groups are frequently overwhelmed by the complexities and procedures of a large medical institution. To serve this population adequately, a follow-up clinic team should have access to interpreters and include social workers who are knowledgeable about community resources outside the predominant culture. Cultural competence, defined as performing "one's professional work in a way that is congruent

with the behavior and expectations that members of a distinctive culture recognize as appropriate among themselves,” is an essential prerequisite for professionals working in a high-risk infant follow-up clinic.²¹⁸ For the physical therapist conducting an evaluation, cultural competence includes familiarity with differing cultural norms regarding personal interaction, child-rearing practices, and family dynamics.

Preterm or at-risk infants may be irritable, hypersensitive to stimulation, less responsive to the affective interactions of adults, and more irregular in sleeping and feeding schedules compared with the term infant.²¹⁹ The demands that such an infant place on caregivers can be extremely stressful, especially when other siblings in the home, financial concerns, and sleep deprivation are present. Although these stresses may resolve as the infant’s schedule and temperament become more stable, some studies raise concerns about their long-term impact on the parent-infant relationship and the infant’s social and affective development.^{220,221}

The pediatric therapist in the follow-up clinic must be sensitive to these parent or caregiver stresses and concerns. Because social work and nursing services may not be routinely available, the therapist, within the context of the examination, needs to be alert to cues in the behavior of the infant or caregiver that may indicate problems in the home. Thoughtful questions regarding daily routines, feeding patterns, the sleep schedule of the caregiver as well as the infant, the caregiver’s impression of the infant’s temperament, and the availability of supportive resources can prompt a discussion of concerns that may not be readily communicated to a pediatrician or other professionals involved in the child’s care.

Examination of Neurodevelopmental Status

Because preterm infants are at increased risk for neurodevelopmental disabilities, close follow-up is necessary during the first 6 to 8 years of life. Compared with term infants, the incidence of CP is greater in infants born preterm, and the rate of CP increases with decreasing birth weight levels.^{82,222-225} CP is one of several major neurological conditions that are sequelae of prematurity; others include mental retardation, hydrocephalus, sensorineural hearing loss, visual impairment, and seizure disorder. When examined as a group, these major disabling conditions occur more frequently in LBW infants, and the incidence increases as the birth weight and gestational age of the infant decrease.^{222,226-228}

Preterm infants are also at increased risk for more subtle neurodevelopmental disabilities, including visual-motor dysfunction, speech and language deficits, reading and math problems, balance and coordination impairment, and behavioral disorders such as attention deficit and hyperactivity.^{83,228-232} Longitudinal studies indicate that by school age approximately half of all infants with LBW will have educational and learning deficits compared with a reported rate of 24% in the general population.^{227,228} Overall 10% to 30% of preterm infants are estimated to eventually have “major” disabilities and another 40% to have “minor” disabilities.^{227,228}

A primary objective of developmental follow-up in at-risk infants is the early identification of neurodevelopmental disabilities and the expedient referral to therapeutic intervention services. Preterm infants who participate in a

follow-up clinic program have been shown to have advanced performance on cognitive measures and to receive more intervention services compared with unmonitored infants.^{233,234} A confirmed or tentative diagnosis can direct the family toward intervention services, financial resources, and social supports. Systematic follow-up and recognition of developmental problems in a high-risk infant play a major role in supporting the relationship between an infant and the caregiver. The behavioral interaction of an infant with a developmental disability is often different from that of a typically developing infant, evoking negative maternal responses of anxiety, frustration, or withdrawal.^{24,235} Diagnosis of a neurodevelopmental disability often facilitates dialogue about parental concerns and can assist caregivers in their process of accepting the disability and adjusting their expectations for the infant.

Follow-up Clinic Examination and Evaluation Processes

It is widely recognized that preterm infants are at risk for neurodevelopmental and musculoskeletal impairments that may lead to functional limitations.^{6,236,237} Early assessment plays an important role for discharge teaching, follow-up planning, and identifying infants at the highest risk for developmental impairments so they can be appropriately referred for early intervention.

Although developmental assessment in the neonatal period is useful, it has been shown to have low predictive value for later outcome. The neonatal period and the first 2 to 3 months of life are characterized by variability in infant behavior and motor skills as well as instability of postural organization and control.^{9,10} Longitudinal studies with sequential examinations indicate that neonatal examinations are less accurate in long-term prediction of neurodevelopmental outcome than examinations administered to older infants.³⁻⁵ Ongoing repeated assessments to monitor developmental outcome are necessary to ensure early identification of potential functional activity limitations in infants.^{6,146,238} Pediatric therapists are in a unique position as consultants to the multidisciplinary team to become involved in the process of identification of infants at risk, care coordination, and follow-up planning.²³⁹ Critical examination periods and signs of neuromotor or musculoskeletal abnormality indicating a need for comprehensive examination by a pediatric physical therapist are described in the next sections.

Months 2 to 4

The American Academy of Pediatrics has established guidelines for the follow-up of high-risk infants⁸⁰ and has defined indicators for follow-up care.²⁴⁰ No specific timelines or recommended schedules for follow-up visits are available, but general agreement exists that the lower the gestational age, the higher the risk for neurodevelopmental impairments. Although most early neonatal assessments have poor predictive value, it is recommended that infants at highest risk be followed closely to ensure early identification and referral.⁶

Important changes in postural control, movement, and behavioral organization occur at 2 to 4 months. Head control and balance reactions are emerging, and functional skills are present with orientation around the midline.²⁴¹ This is also the time when the transition from GMs

to goal-directed movement begins to take place (Figure 11-29).²⁴² The pediatric therapist can perform an early developmental follow-up evaluation to monitor changes in posture and movement, development of head control, midline orientation, visual skills and provide parental education. A marked increase in the prevalence of positional plagiocephaly (also known in the literature as *nonsynostotic plagiocephaly*, *plagiocephaly without synostosis*, or *flat head syndrome*)^{243,244} has occurred since 1992 when the American Academy of Pediatrics released a position paper recommending that all infants be positioned for sleeping on the back or side to minimize risk of SIDS.^{245,246} Two to 4 months postterm is a critical window of time for identifying positional preferences in infants and providing parental education to prevent plagiocephaly.

Months 6 to 8

For most LBW infants, medical concerns have resolved at this age and caregivers are raising questions about developmental expectations. This is a period of great variability in the development of goal-directed behaviors and attainment of motor milestones that are dependent on postural control. General agreement exists that most typically developing infants achieve independent sitting in this time frame.²⁴¹ Definitive predictions on long-term prognosis are difficult for a preterm infant at this age. Tools measuring specific milestones have low clinical value owing to variability in the acquisition of motor skills and postural control.²⁴² A developmental assessment with emphasis on postural control at 6 to 8 months' adjusted age (e.g., Alberta Infant Motor Scale) can document an infant's current level of performance and provide a baseline for subsequent evaluations.

Months 10 to 14

During the first year of life, infants gain increasing levels of postural control and express neurological integrity and capabilities through movement and exploration. Lack of variability and variety in movement strategies may be an

Figure 11-29 ■ Goal-directed reaching and symmetrical lower-extremity alignment in 4-month-old born at term gestation.

early indicator of atypical development. Learning to transition out of supine position and crawling are typically achieved at 10 to 12 months and by 12 to 14 months most infants have achieved the ability to walk independently.^{241,242} By 12 months corrected or chronological age, infants demonstrate a wide repertoire of behaviors in other domains including cognitive and language intertwined with motor development. Multidisciplinary evaluation at 12 months is recommended for infants at risk, to create a more comprehensive developmental profile.⁸⁰

Months 18 to 24

With the foundation for gross motor skills well established by 18 months, identifying deficits in the fine motor, cognitive, social adaptive, and language domains that might interfere with school performance becomes the main focus of assessment during this period. High prevalence of positive screening for autism in infants born preterm has been described in the recent literature.²⁴⁷ These data suggest that while the focus of most follow-up programs for high-risk infants is on motor and cognitive abilities, evidence now supports the inclusion of screening tools to identify early signs of social and behavioral dysfunction. Recent evidence also points to a high prevalence of cerebellar damage or dysgenesis in preterm infants. Cerebellar hemorrhage represents a high risk for cognitive and motor delays in these infants.^{42,248} D'Amore and colleagues reported findings that assessment at 2 years of age can reliably identify developmental impairments.²⁴⁹

Comprehensive assessment at 24 months is recommended, including language, fine motor, adaptive, and cognitive skills. Most multidisciplinary follow-up programs stop at this time owing to cost and high rate of attrition.⁸⁰ Growing evidence is reported of higher rates of educational and behavioral challenges becoming apparent at school age among children with ELBW. Therefore, ongoing follow-up beyond 24 months is desirable.²⁴⁹

Age Correction

Premature infants are scheduled for evaluations in the follow-up clinic according to their corrected age (age adjusted for weeks of prematurity). The issue of whether to adjust for prematurity when assessing cognitive or motor development is an ongoing question. Several researchers have demonstrated that if chronological or unadjusted age is used for standardized testing, the premature infant who is developing appropriately will have a low developmental quotient and test scores indicative of motor delay.²⁵⁰⁻²⁵⁴ If age is adjusted for prematurity, the performance of the premature infants is comparable to that of term infants at 1 year. Although some investigators caution that adjustment for prematurity tends to result in overcorrection, particularly for infants born at less than 33 weeks' gestation,²⁵⁵ the general consensus is that infants born prematurely should be evaluated according to their corrected age.^{255,256}

The decision regarding correction for gestational age in a follow-up clinic should be based on the objectives and testing protocol for that clinic. Consideration should be given to the following factors: (1) the testing instruments used, with attention to the competencies evaluated by the tool and the number of preterm infants in the normative sample, and (2) the overall purpose of the evaluation and whether the emphasis is on screening or diagnosis

Neuromotor Assessment of the at-Risk Infant

Neuromotor Assessment Tools: Purpose and Clinical Use

Evaluation of the at-risk infant with a quantitative, standard assessment tool serves two major purposes in a follow-up clinic:

1. Documentation of the infant's motor status relative to developmental norms or relative to the infant's performance on previous examinations. The information is used to determine the child's developmental progress, rate of change, or extent of motor delay. Achievement of this objective is determined by the scope and focus of the assessment tools used in the evaluation.
2. Identification of a neuromotor impairment to initiate appropriate intervention services. Early identification is not simply a task of detecting signs of neuromotor deviation. The challenge is to identify those infants who are most likely to have an abnormal neurodevelopmental outcome. Achievement of this objective is determined by the predictive validity of the assessment tools that are used.

Evaluation of Predictive Validity of Infant Assessment Tools

A primary goal of the neuromotor evaluation is prediction of the long-term developmental outcome of the child on the basis of a clinical examination of the infant. The ability to achieve this goal accurately depends on the clinical experience and expertise of the therapist as well as the predictive accuracy or validity of the assessment tool used. The predictive validity of a test is defined by sensitivity and specificity and positive and negative predictive values (Table 11-9).²⁵⁷

The *sensitivity* of a test evaluates how sensitive the test is in its ability to identify a defined developmental problem, such as CP. In the testing situation described here, sensitivity is calculated as the proportion of children with abnormal neurodevelopmental outcome who were correctly identified as "abnormal" when examined as infants. *Specificity* refers to how specific the test is in identifying *only* the defined developmental problem and not overdiagnosing by identifying children who do not have the problem. Specificity is calculated as the proportion of children with normal developmental

outcome who were correctly identified as "normal" when examined as infants. The children with normal developmental outcome who were inaccurately classified as "abnormal" by the infant test are referred to as *false positives*; that is, they were falsely determined by the test to be positive for the developmental problem. On the other hand, children who were classified as "normal" when tested as infants but subsequently are diagnosed with CP are described as *false negatives* because the test falsely indicated that they were negative for the developmental problem.

The *positive predictive value* of a test refers to the accuracy of the infant test in its classification of infants as "abnormal." For example, of the infants who were identified as "abnormal" or "suspect" by the infant test, the proportion of infants who are actually diagnosed with CP represents the *positive predictive value*. The *negative predictive value* refers to the accuracy of the infant test in its classification of infants as "normal." It is calculated as the proportion of infants categorized as "normal" who actually have normal developmental outcome. To the therapist in a follow-up clinic, it may appear that the positive and negative predictive values of a given test would be most useful because they indicate the probability of a given outcome for an infant being tested. However, predictive value is not a stable measure of the predictive validity of a test because the predictive values vary according to the prevalence of the developmental problem within a group or population of infants. When a condition is common, the positive predictive value will be relatively high. When the outcome of interest is rare, the positive predictive value will be relatively low. Further discussion about test evaluation and measurement can be found in a number of excellent resources available to pediatric therapists.^{257,258}

Examples of Infant Assessment Tools

In addition to the tools previously described for the assessment of the neonate, a number of testing instruments have been designed for evaluation of the infant. The choice of instrument for a particular clinical situation depends on the emphasis and purpose of the clinic as well as on the professional disciplines that are represented in the follow-up team. Neurological findings may be the most useful indicator of impairment in the neonate or young infant because this is a

TABLE 11-9 ■ PREDICTIVE VALIDITY OF AN INFANT ASSESSMENT TOOL

INFANT TEST	OUTCOME (AT SPECIFIED AGE IN CHILDHOOD)		
	NORMAL	ABNORMAL	
No risk	a Correct nonreferrals	b Incorrect nonreferrals (false negatives)	a + b = Total nonreferrals
	c Incorrect referrals (false-positives)	d Correct referrals	c + d = Total referrals

a + c = Total normal at outcome.

b + d = Total abnormal at outcome.

Sensitivity = d/b , $d \times 100$ = Percentage of abnormal children who were correctly identified as "no-risk" by the infant test.

Specificity = a/a , $c \times 100$ = Percentage of normal children who were correctly identified as "risk" by the infant test.

Positive predictive value* = d/c , $d \times 100$ = Percentage of infants identified as "risk" by the infant test who had abnormal outcome.

Negative predictive value* = a/a , $b \times 100$ = Percentage of infants identified as "no risk" by the infant test who had normal outcome.

*Positive and negative predictive values will vary according to the prevalence of the abnormal outcome within the study population.

time when behavioral responses are influenced by the infant's affective state and when motor skills are rudimentary. As the infant matures, neuromotor integrity manifests with the acquisition of motor skills. For infants older than 3 months, longitudinal researchers indicated that observed neuromotor abnormalities were predictive of later CP only when accompanied by delay in one or more developmental milestones.^{3,259} A brief review of the infant assessment tools commonly used in follow-up clinics is presented in the following sections.

Bayley Scales of Infant Development. The Bayley Scales of Infant Development (BSID) were first published in 1969 in a format used extensively in clinical and research settings throughout the United States. The BSID-II,²⁶⁰ a revised version of the BSID, was published in 1993. The goals of the revision process included updating the normative data, extending the upper age level of the test from 30 to 42 months, and adding more relevant test items and materials. The revised test was standardized on 1700 young children representing a distribution of race, gender, geographical region, and level of parental education as an indicator of socioeconomic status. In addition, approximately 370 children with various clinical diagnoses, including autism, Down syndrome, developmental delay, preterm birth, and prenatal exposure to drugs, were tested with the BSID-II. Test scores from these children were not included in the normative data and are intended to provide a baseline of performance for children with these diagnostic conditions.²⁶⁰

The expanded age range and updated normative data offered by the BSID-II enhanced its overall use as an assessment tool. However, several areas of weakness have been identified in using the BSID-II, particularly with preterm infants.²⁶¹⁻²⁶³ Unlike the protocol of the original test, the administration of items and the scoring procedures for the BSID-II are based on item sets. The appropriate item set for an individual child is usually determined according to the child's chronological age, but the examiner is told to "select the item set that you feel is closest to the child's current level of functioning based on other information you might have."²⁶⁰ The option to begin testing at different item sets, which can yield different raw scores for the same infant, introduces a level of variability in administration procedures and test results that is inconsistent with the purpose of a standardized test.²⁶³ This problem is magnified for preterm infants because it places even greater importance on the decision of whether to test the infant according to chronological or corrected age.²⁶⁰

The third edition of the BSID (BSID-III), published in 2006, is the most recent update.²⁶⁴ The goals for developing the current edition included updating the normative data, fulfilling the requirements set by the Individuals with Disabilities Education Improvement Act of 2004, strengthening psychometric measures, updating testing materials, simplifying test administration, and improving the test's clinical utility.^{238,265} The BSID-III is a comprehensive assessment for children aged 1 to 42 months to be administered by experienced and trained professionals. This edition comprises five different subscales—cognitive, expressive, and receptive communication; gross and fine motor development; and parental report scales to assess social-emotional development and adaptive behaviors.

The cognitive scale of the BSID-III assesses sensorimotor development, object manipulation and relatedness, concept formation, memory, and simple problem solving. The expressive and receptive language subscales examine verbal comprehension, vocabulary, babbling, utterances, and gesturing. The fine motor subscale examines grasping, motor planning, speed, and visual motor activities, and the gross motor subscale includes sitting, locomotion, standing, and balance. Social-emotional and adaptive behaviors are tested using the parental report scales. Administration times vary depending on the age of the child but can range from approximately 50 minutes for children aged 12 months or younger to 90 minutes for children aged 13 months and older. The child's chronological age (adjusted for prematurity as needed) gives the examiner a starting point, designated by a letter A through Q. The rules for establishing basal and ceiling levels are the same for the cognitive, language, and motor scales. The child must pass three consecutive items in order to establish a ceiling, and the test is discontinued once the child fails five consecutive items. The BSID-III has expanded basal and ceiling levels with standardized scores ranging from 40 to 160. The mean for the standardized composite score for the cognitive, language, and motor skills is 100 with standard deviation of 15. The language and motor skills also yield scaled scores with a mean of 10 and standard deviation of 3. In addition, percentile rank, age equivalents, and growth scores can be derived.^{264,265}

The BSID-III was standardized on a normative sample of 1700 children from the ages of 16 days to 43 months 15 days living in the United States in 2004. Stratification was based on age, gender, parental education level, ethnic background, and geographical area. Norms for the social-emotional and adaptive behavior scales were derived from smaller groups (456 and 1350 children, respectively) but the same stratification pattern was followed.²⁶⁴ There are a total of 91 items in the new cognitive scale including 72 items from the BSID-II. Many items from the former cognitive scale were removed, modified, or moved to other subscales such as language and fine motor scales. The fine and gross motor scales contain a total of 66 items including 18 new items. The parental report scales are a new addition to assess social-emotional and adaptive behaviors.^{264,266}

The psychometric attributes of the BSID-III are as strong as those of the earlier editions and are thoroughly described in the technical manual.^{266,267} Reliability coefficients for the subscales and composite scores range from 0.86 to 0.93, with similar or higher coefficients obtained when the reliability was examined testing special groups. Test-retest reliability was examined in a sample of 197 children tested on two separate occasions with an average interval of 6 days. Reliability coefficients ranged from .67 to .94, with an average correlation score of .80. The technical manual describes in great detail the convergent and divergent validity, illustrating the correlation between the BSID-III and other relevant testing tools.^{264,266}

The BSID-III is still relatively new, and many questions remain regarding its potential limitations and utility for clinical application. Administration of the full test is a lengthy procedure, and the composite scores are reported to be higher than those of the BSID-II.²⁶⁷ Anderson and colleagues²⁶⁸ recently examined the ability of the BSID-III

to detect developmental delay in 2-year-old extremely preterm children and those born at term with normal birth weights. The study participants were former preterm infants born at less than 28 weeks or weighting less than 1000 g ($n = 221$). Two hundred and twenty healthy full-term infants with normal birth weight were randomly selected as a control group. Developmental assessment was conducted at 2 years (age corrected for prematurity) using the cognitive, language, and motor scales of the BSID-III. The social-emotional and adaptive behavior scales were not used. The authors observed a serious overestimation in the developmental progress of this sample. Questions were raised regarding the sensitivity of this test to detect developmental delay in children. More research is needed to examine this test's sensitivity and the interpretation of test results, especially for high-risk or premature infants. Continued use of the BSID-III should be conducted with caution in the absence of more data to establish the sensitivity of this tool.²⁶⁶

Alberta Infant Motor Scale. The AIMS²⁶⁹ was designed to evaluate gross motor function in infants from birth to independent walking, or birth through 18 months. The stated purposes of the AIMS are (1) to identify infants who are delayed or deviant in motor development and (2) to evaluate motor maturation over time. The AIMS is described as an "observational assessment" that requires minimal handling of the infant by the examiner. The test includes 58 items, organized by the infant's position, designed to evaluate three aspects of motor performance: weight bearing, posture, and antigravity movements. The normative sample consisted of 2200 infants born in Alberta, Canada.

Raw scores obtained on the AIMS can be converted to percentile ranks for comparison with motor performance of the normative sample. Test-retest and interrater reliabilities, established on normally developing infants, ranged from 0.95 to 0.98 depending on the age of the child. The AIMS reportedly had high agreement with the Motor Scale of the BSID and the Gross Motor Scale of the Peabody Developmental Motor Scales (PDGMS) ($r = 0.93$ and $r = 0.98$, respectively).⁵ An evaluation of concurrent validity between the AIMS and the Movement Assessment of Infants (MAI) at 4 and 8 months demonstrated acceptable agreement ($r = 0.70$ and $r = 0.84$, respectively).²⁷⁰

The Movement Assessment of Children. The Movement Assessment of Children (MAC) assesses functional gross motor and fine motor skills of children from age 2 months to 24 months.²⁷¹ The motor assessment is composed of three sections including head control, upper extremities and hands, and pelvis and lower extremities. In addition, there are four assessment sections (general observations, special senses, primitive reactions, and muscle tone) that contribute to the interpretation of MAC findings for any one child. These four sections assist therapists in making a therapy diagnosis, thus focusing the therapist's selection of treatment modalities. The MAC, on average, has five functional test items per month over 23 months of development. It is anticipated that this number of items will allow for accuracy in evaluative and discriminative measures, leading to effective clinical judgments. The MAC can be completed in less than 30 minutes (20 minutes for some children), and it takes 5 minutes to update during reevaluation.

Four hundred and seven assessments were completed on typically developing children aged 2 to 24 months in the greater Denver, Colorado area. The gestational ages of the children at birth were 37 to 42 weeks, and the majority were Caucasian (77%).

Construct validity of the MAC was established using Rasch analysis with the 407 assessments. In brief, 34 of the 37 super items fit the model based on fit statistics (infit and outfit mean square error values of 0.5 to 1.7). Unidimensionality of the MAC was also achieved: Rasch principal component analysis showed that the model explained 90.4 % of the variance. The Rasch analysis also indicated that the MAC has excellent person and item reliabilities. The person reliability index was .98, indicating that the person ability ordering would be stable if these children were assessed on another evaluation tool with the same construct as "the motor super items" of the MAC. Cronbach's alpha was .97, implying that the MAC super items were internally consistent with little redundancy. The item reliability index was 1.00, indicating that the difficulty hierarchy of these motor super items would be stable if another group of children with the same traits and sample size were tested.²⁷²

High-Risk Clinical Signs

Longitudinal studies of LBW infants have been used to identify specific clinical signs or conditions that are most predictive of abnormal neurodevelopmental outcome, such as CP. The conclusions among studies are inconsistent because of the lack of standard criteria for the risk variables, demographic and clinical variation in the study samples, and use of different outcome measures. Results from these studies are summarized in Table 11-10.

Neonatal Period

During the neonatal period through 1 to 2 months after term (40 weeks of gestation), clinical signs suggestive of neuro-motor abnormality include stiff, jerky movements or a paucity of movement. Prechtl and colleagues¹¹² developed an assessment technique based on the recognition of GMs that occur at specific times during maturation. Abnormal GMs are characterized as movements with "reduced complexity and a reduced variation. They lack fluency and frequently have an abrupt onset with all parts of the body moving synchronously."¹¹⁴ Persistence of these movements is considered to be predictive of CP or cognitive impairment.²⁷³

Infancy

At 4 months of age, hypertonicity of the trunk or extremities is recognized as a high-risk clinical sign.^{89,259,274} Neck extensor hypertonicity has been reported to be highly predictive of CP.³ This finding correlates with neck hyperextension and shoulder retraction associated with the tonic labyrinthine reflex in the supine position, which has been identified in other studies as a high-risk sign.²⁷⁵ Although neck hypertonicity was the single item most predictive of CP in one study, the majority of infants (60%) who exhibited this clinical sign did not subsequently develop CP.³

The predictive value of primitive reflexes has been extensively debated. Reflexes and neurological signs, such as the asymmetrical tonic neck reflex (ATNR) and tremulousness, have been correlated with CP in some studies^{3,276} but not in others.²⁷⁵ Of the four sections in the MAI, primitive reflexes

TABLE 11-10 ■ MOTOR IMPAIRMENT “RED FLAGS” DURING NEONATAL INTENSIVE CARE UNIT FOLLOW-UP

2 months*	Persistent asymmetrical head position; risk for plagiocephaly and torticollis Absent midline orientation even when visual stimulation is present Jerky or stiff movements of extremities
4 months*	Excessive neck or trunk hyperextension in supine position Poor midline head control in supine position Difficulty engaging hands at midline and in reaching for dangling toy Persistent fisting of hands Difficulty lifting head and supporting weight on arms in prone position Trunk hypertonicity or hypotonicity Resistance to passive movement in extremities Persistent, dominant asymmetrical tonic neck reflex (“fencing” position of arms) Stiffly extended or “scissored” legs with weight bearing on toes in supported standing
8 months*	Inability to sit and roll independently Inability to transfer objects between hands Persistent asymmetry of extremities with differences in muscle tone and motor skill Hypertonicity of trunk or extremities
12 months*	Inability to pull to stand, four-point crawl, walk around furniture Movement between basic positions Persistent asymmetry of control in extremities

*Ages corrected for prematurity.

were found to be the least predictive of later outcome.^{259,277} The positive support reflex, characterized by stiff extension of the lower extremities when the infant is held in supported standing, is frequently cited as a high-risk sign, but this posture is seen in both term and LBW infants and has not been consistently associated with adverse sequelae.^{254,259,275} Persistent primitive reflex activity and asymmetry have been identified as early signs of athetoid CP, more common in infants born at term.²⁷⁸ In **Figure 11-30** a dominant ATNR posture is demonstrated by a 4-month-old infant with athetoid CP. Immature automatic reactions of balance and equilibrium at 4 months, including head righting and the Landau reaction, have been found to be a significant predictor of abnormal neurological outcome.²⁷⁵

Comparing an infant’s spontaneous, active movements with reflex or passive responses is important in determining risk for neurodevelopmental disability. Systematic observation of kicking activity in LBW infants indicated that infants with neurological impairment demonstrated less alternate

Figure 11-30 ■ Dominant asymmetrical tonic neck reflex in 4-month-old infant with athetoid cerebral palsy.

kicking movement compared with typically developing LBW infants.²⁷⁹ Abnormal patterns of kicking, including simultaneous flexion and extension of the hips and knees, were associated with subsequent CP.²⁸⁰ Abnormalities of kicking described by Prechtl as “cramped-synchronized,” that is, limited in variety and characterized by “rigid movement with all limbs and the trunk contracting and relaxing almost simultaneously,” were observed in 3-month-old infants who were subsequently diagnosed with CP.²⁸¹

In addition to qualitative differences in motor function, delayed acquisition of motor milestones is an important indicator of neuromotor impairment. Several investigations of the predictive validity of the MAI found volitional movement (gross and fine motor skills) to be the most predictive MAI category at 4 and 8 months.^{259,277} This finding is supported by other studies in which delayed developmental milestones were significant predictors of later CP (**Figure 11-31**).^{3,282} In particular, delay in achieving upright, gross motor milestones, such as sitting without support, creeping on hands to knees, and pulling to stand, was found to be useful in identifying infants with neuromotor impairment.²⁸²

Challenges to Prediction of Neurodevelopmental Outcome

Accurate prediction of neurodevelopmental outcome of LBW infants on the basis of standard neuromotor tests is particularly challenging because of several complicating factors.

Impact of Medical Status on Test Performance

Infants with LBW often exhibit motor delay or neuromotor deviations because of their health or medical status, not because of neurological impairment. Two primary examples are residual influences from habitual positioning in the NICU and chronic medical conditions.

Figure 11-31 ■ **A**, Typically developing term infant at 4 months of age demonstrating ability to bring hands to midline and elevate legs with flexion and abduction of hips and dorsiflexion of ankles. **B**, Infant diagnosed with cerebral palsy at 5 months of age; note inability to bring hands to midline because of shoulder retraction, extension and adduction of hips with limited movement into flexion, and plantarflexion of ankles.

Variations in Posture and Movement Caused by Residual Influences from Time in the Neonatal Intensive Care Unit. Although current NICU positioning and handling procedures are increasingly sensitive to the developmental needs of the neonate, the application of life-sustaining interventions (e.g., mechanical ventilation) assumes priority in clinical management. On follow-up evaluation, these infants are typically delayed in reaching skills and in achieving antigravity postures.

LBW infants frequently exhibit asymmetry that may be related to intrauterine position or prolonged positioning in the NICU necessitated by surgical or medical intervention. On outpatient follow-up examinations, this asymmetry may appear as visual orientation to one side of the body, more mature upper-extremity skill on the same side, and asymmetry of primitive reflex activity. Physical deviations, such as tightness of neck musculature on the preferred side and relative weakness of the opposing muscles, or skull deformities (plagiocephaly) may also be present.^{251,283} Asymmetrical motor function resulting from intrauterine or NICU positioning can usually be distinguished from early spastic hemiplegia or other hemisyndromes by clinical examination and by review of the infant's medical history.^{251,259} Positional asymmetry is generally not associated with differences in muscle tone between the two sides of the body or with neuromotor abnormalities, such as fisting of the hand on the less-active side. Caregivers are advised to promote symmetrical posture through their physical handling of the infant, placement of the infant in relation to toys, social activity in the room, and use of cushions or rolls to maintain midline positioning for the infant's head and proximal musculature.

Prolonged Motor Delay from Chronic Medical Conditions. Infants with chronic lung disease typically exhibit low muscle tone, delayed gross motor function, and immature balance reactions. Motor skills are often delayed as long as the infant's pulmonary capacity is compromised, but the rate of developmental progress typically accelerates when the respiratory condition resolves.^{233,284} Intervention for infants with persistent respiratory disease includes providing reassurance and support to the caregivers who are dealing with the demands and stresses of parenting a medically fragile child. Caregivers are advised to avoid aggressive physical activity and excessive sensory stimulation that could cause fatigue or tax the infant's limited respiratory capacity. At the same time, the child should be given opportunities to develop skills in nonmotor tasks. Adaptive positioning techniques reduce energy expenditure and fatigue while enabling the infant to be supported in age-appropriate postures (e.g., prone or upright sitting) for developing hand function, vestibular responses, and social skills.

Transient Dystonia

During the first year of life up to 60% of all LBW infants, as well as a number of term infants, exhibit abnormal neurological signs that subsequently resolve without evidence of major neurodevelopmental sequelae.²⁸⁵⁻²⁹⁰ This phenomenon is referred to as "transient dystonia." The clinical characteristics of transient dystonia described most frequently are summarized in Table 11-11.

The presence of these findings on clinical examination poses a challenge to the physical therapist because they are often indistinguishable from clinical signs considered to represent early CP. From longitudinal studies researchers have suggested that infants with transient neuromotor abnormalities may be at increased risk for long-term neurodevelopmental problems. Infants who demonstrated abnormal neurological findings during the first 12 months, although considered to be developmentally normal at 1 year of age, reportedly had a higher incidence of mental, motor, and behavioral deficits in preschool and at school age.^{88,287-289} However, a definite relationship between transient abnormalities in infancy and long-term developmental outcome has not been confirmed in other studies.^{287,290,291}

TABLE 11-11 ■ **CLINICAL CHARACTERISTICS OF TRANSIENT DYSTONIA**

PERIOD	CLINICAL CHARACTERISTICS
Neonatal period	Neck extensor hypertonia Hypotonia Irritability; lethargy
Age 4 months	Increased muscle tone in extremities Truncal hypotonia Scapular adduction, shoulder retraction Persistent reflexes: asymmetrical tonic neck reflex; positive support reflex Asymmetry
Age 6-8 months	Increased muscle tone in lower extremities Truncal hypotonia; minimal trunk rotation Immature postural reactions Immaturity of fine motor skills

Abnormal neuromotor signs, even if they appear to be transient, should not be considered as clinically insignificant. These signs may indicate a child who is at risk for subtle neuromotor problems that will not be functionally evident until school age. Furthermore, neuromotor deviations, although transient, may interfere with the infant's ability to form attachments with caregivers. The infant who arches back into extension instead of cuddling, has poor head control and difficulty establishing eye contact, or stiffens when held may contribute to feelings of frustration, inadequacy, or resentment in caregivers. Instructing in handling techniques to minimize these postures, as well as informing caregivers that these behaviors reflect neurological instability commonly seen in LBW infants, are often valuable interventions during this transient period.

Differences between Preterm and Term Infant Neuromotor Function

Even when not compromised by chronic illness or neurological impairment, the motor development of preterm LBW infants differs from that of typical term infants. Compared with term infants, healthy preterm infants demonstrate variations in passive and active muscle tone and initially have greater joint mobility, such as increased popliteal angles and low muscle tone in the trunk.^{283,292} In the older infant, increased extremity tone is often present, particularly in the hips and ankles.^{253,283} Comparison studies have frequently noted that preterm infants tend to exhibit more neck hyperextension and scapular adduction and fewer antigravity movements in the supine position (Figure 11-32).*

Primitive reflexes such as the ATNR, Moro reflex, and positive support reflex persist longer in preterm infants, even when assessed at corrected age.^{160,254,294} Gross and fine motor skills are frequently delayed in preterm infants, especially activities requiring active flexion, such as (1) bringing hands to midline and feet to hands, (2) trunk stability required for head control and upright sitting, and (3) trunk rotation for rolling and transitional movements.^{283,293}

Preterm infants exhibit more asymmetry in active movement compared with infants born at term gestation, but

*References 163, 254, 274, 283, 289, 293.

Figure 11-32 ■ Healthy preterm infant at 4 months of corrected age demonstrating neck hyperextension, scapular adduction and shoulder retraction, and limited antigravity movement into flexion.

asymmetry is usually not observed in passive tone or reflex activity.^{251,283} One group of investigators concluded that “these findings convey an important clinical message: if motor asymmetries are only restricted to the facet of active muscle power, then they are unlikely to be of central origin and as such should not be seen as a sign of neurological impairment. In short, they constitute a typical feature of the post-term development of relatively healthy preterm infants.”²⁵¹ For most premature infants, these early variations in movement and posture eventually resolve. However, in the first months of life neuromotor deviations may influence the infant's performance on a standard assessment of motor function or neurological status.

NEUROMOTOR INTERVENTION

Levels of Intervention

Therapeutic intervention for the high-risk infant in the outpatient phase after discharge from the NICU occurs at multiple levels. Type and intensity of intervention depend on (1) the needs of the infant and family, (2) the structure and organization of the follow-up clinic, and (3) the availability of resources in a particular clinical and geographical setting.

Assessment as Intervention

The clinical assessment of an infant is a unique opportunity for intervention on behalf of the infant and family. For the full potential of this interaction to be realized, parents or caregivers must be informed and involved participants in the assessment process, not passive observers. The focus of intervention in this context is on parent or caregiver support with two primary components: education and positive reinforcement for parenting skills.

Education

The educational component of intervention includes enabling the parents of an at-risk infant to recognize their child's unique capabilities and strengths as well as his or her ability to respond to and influence the surrounding environment. Caregivers learn about their infant's individual responses to stimuli—for example, what causes their child to attend to a stimulus and what elicits stress reactions. Education of parents includes describing typical characteristics and common developmental patterns of the LBW or medically fragile infant that may differ from expectations that are based on observations or published descriptions of healthy, full-term infants. Parents of at-risk infants are informed about the appropriate sequence and pace of development for their child so they will be realistic in their expectations and interpretation of the child's progress. This anticipatory guidance enables parents to prepare for and maximize learning opportunities.

Reinforcement for Parenting Skills

During the follow-up examination, opportunities to provide positive reinforcement to caregivers need to be emphasized. Parents of a high-risk infant who responds inconsistently to affective cues should particularly be given positive feedback and affirmation for their investment of emotion and energy.²⁹⁵ They should be reassured that they are providing appropriate and beneficial parenting and reminded that the infant's behavioral responses reflect neurobehavioral immaturity or instability

rather than an unpleasant personality or negative affective feelings toward the caregiver.

Instruction in Home Management

A critical component of intervention is instruction in specific activities and handling techniques for home management. The recommendations are made on the basis of the therapist's knowledge of the infant's medical and neurological history, current health status, and findings from the neurodevelopmental assessment. The overall purpose may be to maximize a healthy child's growth potential or to promote developmental progress in an infant who demonstrates delay or neuromotor abnormality. In either case, the parent or caregiver must have a clear understanding of the purpose of the activity, what motor behavior it is intended to facilitate or counteract, the underlying neurodevelopmental process that the activity will support, and the desired response on the part of the infant. This enables the parent to participate more creatively in the process of intervention by adapting and modifying the recommendations according to the infant's responses and progress of the infant at home.

Although neuromotor handling recommendations are specific to the individual child, some intervention activities are applicable to many preterm infants.

Activities to Counteract Shoulder Retraction

Up to 50% of LBW infants reportedly demonstrate shoulder retraction.¹⁶³ This posture may inhibit the infant's ability to bring hands to midline and often results in delayed achievement of upper-extremity skills and rolling. To overcome shoulder retraction, play activities and carrying techniques that bring shoulders forward and hands to midline are encouraged.

Reaching

Most premature infants are immature in reaching skills, reducing their ability to interact with the environment. Activities to counteract shoulder retraction will promote reaching, but the infants should also be provided with other opportunities to practice this skill. Infants who are ready to initiate reaching at 3 to 4 months of age often have only a visually stimulating mobile suspended beyond their reach in the crib. Caregivers are advised to hang toys *within the child's reach* in the crib, playpen, infant seat, or other suitable places. Objects that are suspended, rather than handed to or placed in front of the infant, are preferred to promote the development of directed reach and grasp as well as shoulder stability (Figure 11-33). Commercially available, relatively inexpensive activity gyms that stand upright on the floor are highly recommended for infants at neurodevelopmental risk.

Head Centering and Symmetrical Orientation

Midline positioning of the head with symmetrical alignment of the trunk and extremities is encouraged to counteract the residual effects of asymmetrical positioning in utero or during hospitalization. Midline orientation will reduce the influence of the ATNR and promote symmetrical function of the right and left sides of the body. Asymmetry that is not caused by neurological dysfunction tends to resolve when positioning and environmental influences are modified.

Figure 11-33 ■ Toys suspended directly in front of infant to encourage symmetrical reaching and midline orientation of head.

Prone Positioning

Active play time in the prone position with weight bearing on the arms is beneficial for the development of neck and trunk postural and shoulder girdle stability. The prone position also counteracts extension posturing tendencies because the influence of the tonic labyrinthine reflex in the prone position contributes to extremity flexion. However, parents of vulnerable premature infants are often hesitant to place their infants in the prone position for play. Many preterm infants demonstrate a low tolerance for prone positioning, particularly if they have relatively large heads and are visually attentive. Duration of the prone play position can be gradually increased; visually stimulating objects, including mirrors, musical toys, and the faces of siblings or caregivers, can be placed on the floor in front of the infant to encourage acceptance of the prone position. A roll or wedge positioned under the infant's axillae and upper chest will facilitate the ability to push up in prone, particularly for the infant with low muscle tone. An infant who is apprehensive or stressed when placed on the stomach may tolerate prone lying on the caregiver's chest, where reassuring eye contact can be maintained.

Head Balance

Balance activities to develop active head control are frequently recommended for preterm infants. Tilting responses are usually achieved most effectively with the infant in the parent's lap. Instruction to the caregivers often includes demonstration and practice using a doll before attempts with the infant. Emphasis is placed on the importance of (1) adequate trunk support; (2) movement through small ranges; (3) slow, graded motion; (4) desired head-righting response; and (5) sensitivity to indications of stress or fatigue.

Limited Use of Infant Jumper or Baby Walker

For infants with increased lower-extremity tone or a tendency for toe-standing, the use of baby walkers and jumpers is discouraged because of potential increased stiffness and extension posturing of the legs.²⁹⁶ Mobile baby walkers are associated with a high risk of injury, including serious

trauma such as burns, drowning, and severe head injuries resulting from falls down stairs.²⁹⁷⁻³⁰⁰ However, baby walkers are usually enjoyable for infants and may provide caregivers with some needed moments of respite in stressed households. When recommending that time in a baby walker or jumper be restricted, the therapist should help the caregivers find alternative methods of positioning and amusement for the infant. Parents are often reluctant to discard a baby walker, believing that it promotes early ambulation and is beneficial for infants. Informing caregivers of the hazards of infant walkers and research findings indicating walker use may delay the acquisition of gross and fine motor skills enhances the likelihood of their cooperation to eliminate walkers and jumpers.^{297,298,301,302} The lower-extremity tone and movement effects of semisitting activity centers that allow supported standing and some lateral steps have not been documented.

SUMMARY

This chapter on the NICU management and follow-up of at-risk neonates and infants has presented three theoretical models for NICU practice, reviewed neonatal neuropathological conditions related to movement disorders, and described expanded professional services for at-risk neonates and infants in a relatively new subspecialty within pediatric practice. Pediatric therapists participating in intensive care nursery and follow-up teams in the care of high-risk neonates and their parents are involved in an advanced-level practice area that requires heightened responsibility for accountability and for precepted clinical training (beyond general pediatric specialization) in neonatology and infant therapy techniques. Practice guidelines for the NICU from national task forces representing the American Physical Therapy Association and American Occupational Therapy Association indicate roles, proficiencies, and knowledge for neonatal therapy and designate the NICU as a restricted area of practice to therapy assistants, aides, and entry-level students on affiliation.

Inherent to this subspecialty practice is the challenge to design comprehensive neonatal therapy protocols and

clinical paths that include standardized examination instruments, comprehensive risk-management plans, long-term follow-up strategies, and systematic documentation of outcome. Ongoing analyses of the physiological risk-therapeutic benefit relationship of neuromotor and neurobehavioral treatment for chronically ill and preterm infants must guide the NICU intervention process. The quality of collaboration between therapists and neonatal nurses largely determines the success of neonatal therapy implementation in the 24-hour care environment of the nursery.

Pediatric therapists working in neonatal units are encouraged to participate in follow-up clinics for NICU graduates to identify and analyze the development of movement dysfunction and behavioral sequelae that may, in the future, be minimized or prevented with creative neonatal treatment approaches. The important preventive aspect of neonatal treatment must be guided by careful analyses of neurodevelopmental and functional outcomes in the first year of life.

The preterm or medically fragile infant is at increased risk for major and minor neurodevelopmental problems that may manifest in infancy or not become evident until childhood. Prenatal and perinatal risk factors may identify infants who have a greater likelihood of neurological complications, but the relation between single factors and outcome is neither direct nor consistent. Abnormal neurological signs in the first year are also not reliably predictive of abnormal outcome. Attempts to identify factors that definitively indicate significant brain injury are complicated by changing NICU technology, management procedures, environmental variables, and variability among and within individual infants.

In deciding whether and when an infant requires regular intervention, consideration must be given both to the potential for abnormalities to resolve during the first year and to the time span that may elapse before definitive evidence of CP emerges. The pediatric therapist's long-term clinical management of the at-risk infant is guided by the developmental course of the individual infant over time, including behavioral and cognitive growth as well as neuromotor progress, considered within the context of the priorities and values of the family.

CASE STUDY 11-1 ■ HIGH-RISK INFANT A

Infant A was born prematurely at 29 weeks of gestation with a birth weight of 940 g. Her neonatal course was complicated by idiopathic respiratory distress syndrome, which was treated with surfactant.

She was first evaluated in the high-risk infant follow-up clinic at 4 months' corrected age (6 months' chronological age). Her mother stated that the infant had several respiratory illnesses after discharge from the NICU. She reported that her infant felt "tense" compared with her older child born at term and seemed to be "a little behind" in overall development. Performance on the BSID-II generated a Mental Development Index (MDI) of 94 and a Psychomotor Development Index (PDI) of 82. On the MAI this infant had a total risk score of 7. She had mildly increased lower-extremity muscle tone evident in mild resistance to passive range of motion of her hips and ankles. She demonstrated persistent primitive reflexes,

including the ATNR, Moro reflex, and tonic labyrinthine reflex influence in the supine position. Head balance was immature, but emerging righting reactions were noted. When the infant was observed in the supine position her posture was extended, but she was beginning to bring her hands to midline. In prone, she had started to push up on elbows but posture was immature and unstable. Her parents were given recommendations for handling to include holding and carrying positions with shoulders forward to inhibit retraction, frequent play in the prone position, and increased opportunities for reaching in supine.

When the infant returned at 8 months' corrected age, her mother reported that progress had been made in the areas of rolling, talking, and sitting. She indicated that the body "stiffness" was less evident, but the infant still did not like to play on her "tummy" and instead preferred to use the baby walker. BSID-II scores at this time were MDI of 101 and PDI

CASE STUDY 11-1 ■ HIGH-RISK INFANT A—cont'd

of 81. The MAI total risk score was 9. Increased muscle tone observed previously was less evident and she had full hip mobility but some resistance to passive ankle movement. Muscle tone of the trunk was mildly hypotonic, but age-appropriate antigravity movements were demonstrated in all positions. Primitive reflexes were no longer evident except for the positive support reflex, characterized by toe-standing tendency during weight bearing. Balance reactions were present but immature in some areas, including head righting into flexion and protective extension reactions. In volitional skills, the infant was now sitting independently for up to 30 seconds, could roll from supine to prone, and could pivot sideways in the prone position. She could pick up a block with either hand and transfer objects. Immaturity was observed in sitting balance, inability to move out of sitting, and failure to move forward on the floor (i.e., low two-point crawl). She attempted to pick up a pellet but was unable to do so. Her parents were advised to discontinue using the baby walker and to maximize play time on the floor. Because the infant reportedly enjoyed watching her 4-year-old sibling, the therapist recommended that he play on the floor beside her. Her mother was also advised to provide the infant with tiny bits of food (e.g., Cheerios) to practice fine motor dexterity.

When seen at 12 months' corrected age, the infant had an MDI of 108 and a PDI of 88. Although not yet walking independently, she was cruising with good weight shift and balance. She was able to creep reciprocally on hands and knees and pulled to stand. She picked up a pellet with an inferior pincer grasp. No deviations of muscle tone or reflex development were observed during examination by the developmental pediatrician. The infant was developing normally and will return for follow-up at 2 years of age. Her parents were advised to call if she was not walking within 2 months or if they had any concerns regarding her pattern of independent walking.

In the management of this child who demonstrated abnormal signs, the primary responsibilities of the pediatric therapist were ongoing assessment and parental guidance and teaching. Although initial concerns about this infant's muscle tone and reflex deviations were present, diagnosing her with a particular condition would have been inappropriate. When followed up over time, the abnormalities resolved and proved to be transient. This child should continue to be followed up in the high-risk infant clinic because she remains at risk for other neurodevelopmental problems that may not become evident until school age.

CASE STUDY 11-2 ■ HIGH-RISK INFANT B

Infant B was born prematurely at 29 weeks of gestation with a birth weight of 1200 g. The neonatal course was complicated by idiopathic respiratory distress syndrome and persistent apnea and bradycardia. Cranial ultrasonography revealed a left subependymal hemorrhage with ventriculomegaly and left-sided PVL.

She was first seen in the high-risk infant follow-up clinic at 4 months' corrected age (6 months and 17 days' chronological age). The parents stated that they had no specific concerns regarding their daughter's development. On the BSID-II the infant received an MDI of 96 and a PDI of 87. On the MAI she received a total risk score of 14. Muscle tone was normal at rest but increased when she was active or agitated. Tone in the lower extremities was mildly increased with restricted passive movement in the hip adductor and gastrosoleus muscles bilaterally. In the supine position she was frequently in an extended posture and brought her hands to midline only once during the examination. In prone she was able to push up and elevate her head while kicking actively. In the prone suspended position, she showed good postural elevation but movements were stiff. Persistent primitive reflexes included the tonic labyrinthine reflex in supine, ATNR, neonatal positive support reflex, and bilateral ankle clonus. Plantar grasp with toe curling was observed on the right. Righting and equilibrium reactions were emerging. She showed a mature Landau reflex with full extension in prone suspension, which is atypical for her age. In volitional movement, mild asymmetry was evident because she had difficulty bringing her right arm forward when prone and brought her left arm to midline more frequently. Her kicking pattern when supine was low (close to the surface), and she did not elevate her

hips. On the right side, hip extension was accompanied by knee extension and plantarflexion of the ankle. She was not yet reaching for objects, and her hands were frequently fistled, particularly on the right. Her parents were assisted with handling skills to reduce shoulder retraction and extension posturing and to facilitate symmetry in movements and posture.

When the family returned for a follow-up visit at 6 months they reported that their daughter was making good progress, but she continued to prefer use of her left hand in spite of their efforts to encourage use of the right hand. At this evaluation, Bayley Scale scores were an MDI of 94 and a PDI of 83; the MAI total risk score was 13. The infant had made the following developmental progress: (1) rolling from supine to prone (over the right side only), (2) beginning sitting balance, and (3) reaching out and grasping objects. She showed a preference for and greater skill and dexterity with her left hand. Occasional fistling was still observed on the right hand. She transferred objects only from right to left. Muscle tone continued to be increased in the lower extremities, with restricted passive mobility of the gastrosoleus muscles bilaterally. Toe clawing was observed on the right with minimal spontaneous dorsiflexion observed on this side. Primitive reflexes were integrated except for persistent neonatal positive support and ATNR to the right. Automatic reactions were improved, but balance responses were asymmetrical, with equilibrium reactions and protective extension reactions delayed on the right. Although the developmental progress was encouraging, the persistent asymmetry remained a major concern. The infant was referred to a developmental intervention program with the recommendation that she receive consistent pediatric therapy in her home at least once a week.

Continued

CASE STUDY 11-2 ■ HIGH-RISK INFANT B—cont'd

The infant was seen in the follow-up clinic at 12 months' corrected age (14 months' chronological age). On the BSID the MDI was 95 and the PDI was 82. She now was creeping reciprocally on hands and knees. When she pulled to stand she consistently brought the left foot up first. She cruised holding onto furniture with a tendency to stand on her toes on the right. She picked up cubes with either hand but showed partial palmar grasp on the right. She picked up a pellet with an inferior pincer grasp on the left but scooped it into the palm of the right hand. Muscle tone continued to be mildly increased in the lower extremities with Achilles tendon tightness, particularly on the right. She sat independently with a mildly flexed thoracic spine. When moving into and out of sitting, she lacked full trunk rotation, and weight was predominately over the left hip. Language development was considered appropriate for her age. The infant was diagnosed

with mild right hemiplegic CP. It was recommended that she continue in the intervention therapy program and return for reevaluation at 2 years of age.

In the management of this child, the role of the pediatric therapist was assessment of neurodevelopmental status and referral to therapy when it became evident that the abnormalities of muscle tone were persisting and interfering with developmental progress. Of note, this child's MDI scores were in the normal range at both the 4- and 8-month examinations. Because the BSID-II does not require infants to perform tasks with both hands, a normal score can be obtained by using just one side of the body. This child should continue to be followed up in the high-risk infant clinic after 2 years of age to provide periodic reassessment and guidance to the family as they confront questions of school placement and program planning for their child.

CHAPTER 12 Management of Clinical Problems of Children with Cerebral Palsy*

CLAUDIA R. SENESAC, PT, PhD, PCS

KEY TERMS

cerebral palsy
direct intervention
family
indirect intervention
postural and movement compensation
research
spasticity
treatment strategies

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify the parameters of the diagnosis of cerebral palsy including motor, family, and psychosocial components.
2. Analyze the multifaceted aspects of the clinical problem and appreciate a multifaceted approach to evaluation and treatment.
3. Analyze treatment strategies and their application to clinical problems.
4. Identify and critique current research for the pediatric client with cerebral palsy.
5. Identify the therapist's role in the treatment of the child with cerebral palsy, with family involvement, in different settings, and with other health professionals.

OVERVIEW

Historical Perspective

Cerebral palsy is a misnomer at best. Little¹ suggested the name in the mid-1800s, but there is still no established direct relationship between the identifiable state of the brain and the distortions in posture and movement control that we are able to observe in the individual.^{2,3} The condition is not always evident at birth, although the work of Precht⁴ statistically supports the possibility of a link between the quality of spontaneous movements in the first months of life and later difficulties in coordinated movement expression. In only a small number of children has a specific lesion been identified that corresponds to the observed motor responses of the child, and this elite group includes children with porencephaly and other early developmental malformations of the brain. Whether there is a biochemical element in the brain of a child that distorts the actual motor learning process has not been established. There is a shocking variability in the age at which intervention is initiated for individual children and a wide variety of programs that do not necessarily take into account the current information available from clinical studies on efficient motor development and brain function. This confusion has led us astray in understanding the process of movement and postural distortion that characterizes children who carry the label of “cerebral palsy.”

Historically, the evolution of diagnosis and treatment intervention or management is clear and relates to the recognition of the special needs of this minority of society. The

British physician Little identified the condition on the basis of observable characteristics of movement and posture, or—in other words—the external features of the condition, so the initial efforts at remediation fell to orthopedists such as Deaver and Phelps.^{3,5,6} Deaver placed importance on external bracing that was periodically reduced in the hope that the child would take over control of increasing parts of his or her own body.⁵ Phelps used bracing and surgery and was a significant force in obtaining schooling for these children in the United States.⁶ He pointed out that they did not belong in academic classes with children diagnosed as retarded or mentally handicapped and that children with cerebral palsy should be exposed to a traditional academic curriculum. In his Children's Rehabilitation Institute in Reisterstown, Maryland, he also advocated restriction of a more functional limb to encourage use of the one less used, particularly in work with the upper extremities.

In the 1950s and 1960s there simultaneously emerged new theories of neuromotor behavior that redefined the clinical characteristics of cerebral palsy and permitted clinicians to orient their intervention strategies to the principles of motor development and motor learning. Kabat in conjunction with Knott introduced proprioceptive neuromuscular facilitation (PNF), which was applied to children with movement disorders and to adults with a history of trauma.⁷ The use of diagonal patterns of movement in this approach changed the customary postures of the child and introduced more functional movement patterns in logical learning sequences. Physical and occupational therapist Margaret Rood added the more specific sensory components of ice and light quick brushing of the skin surface to guide the desired motor response.⁸ She spoke of the need to focus attention on both “heavy work” and “light work” during the early development of movement skills. These terms referred to the central body moving over limb support and limb movement with central stability. Bobath was working

*This chapter is dedicated to Christine Nelson—master clinician, true friend, and mentor. Her gifts as a clinician and artistic eclectic approach to the treatment of children were unmatched and often seemed beyond what one could comprehend. She ever changed those she touched and enlightened all those she taught. Christine will be forever missed and yet her *gift of touch* will be everlasting and live on in her patients, students, and friends.

in London at this same time and observed the need to have a dynamic interaction between stability and mobility, after finding that inhibition of the reflexive movements was not sufficient to change the functional outcome of the child with cerebral palsy.⁹ They pointed out that the areas of the child's body that appeared to be spastic changed when the body was placed in a different relationship to gravity. This observation held up for reexamination the prevailing view of the time, namely, that spasticity existed in a tendon or muscle, a specific structure.

Cerebral palsy was identified in the mid-1900s as an incident that occurred shortly before, during, or shortly after the birth of the infant. Early intervention was recommended. This time line was extended to cover the first 2 years of life, which included early cases of meningitis, encephalitis, near-drowning accidents, and so forth. Although the clinicians mentioned tried to define cerebral palsy as a "disorder of posture and movement control," many of the children also had learning problems and inadequate general brain development. There was a general agreement on categories according to movement characteristics that included spasticity, athetosis, flaccidity, ataxia, and rigidity. Categorization according to the part of the body affected was added to identify hemiplegia, quadriplegia, diplegia, and even monoplegia, affecting one limb, and triplegia, affecting three limbs. It was noted that some children moved from one category to another as they matured, and therapists began to be aware that a child with high tone could have some low tone underneath when spasticity was inhibited. Fluctuating tone could be confused with ataxia, and the precise intervention strategy might be elusive.

The birth process is complex at many different levels. Sequential hormonal changes alert both the fetus and the mother that it is time for a separation. The infant moves into position for exiting the uterus through the birth canal while the mother's body prepares to participate in the work (labor) of the expulsion. When all goes smoothly, the head of the infant is molded by the passage through the birth canal, and the membranous-like cranial plates return to their balanced alignment and functional motion.

When the birth process is prolonged for any of many reasons, the physiological timing of these changes is interrupted. Unique combinations of pressure may make it difficult for the membranous structures to maintain their structural alignment. That lack of structural alignment may persist long after birth and affect future movement and development. Rapid changes of pressure, with minor misalignments of the head and body during the birth process, result in sufficient trauma to affect the nervous system and the delicate fascia and in a small percentage of infants to affect the expression of spontaneous movements. In the majority of healthy infants born at term the spontaneous movements seem to assist in the activation of the central body and the limbs so that physiological changes in the fascia are sufficient to permit a typical expression of developmental movement responses after birth. Body movement and respiration are coordinated with the infant's physiological rhythms in this initial adaptation to the world of gravity. With complications of the pregnancy or the birth process, these spontaneous movements that are so easily made by the healthy infant become laborious and sometimes impossible, affecting motor actions, postural mechanisms, and the basic physiological rhythms. Cerebral

palsy is a heterogeneous collection of clinical syndromes, not a disease or pathological or etiological entity.¹⁰ Little described cerebral palsy as "a persistent disorder of movement and posture appearing early in life and due to a developmental nonprogressive disorder of the brain."³ Current definitions have reiterated that atypical execution of movement and interference with postural mechanisms are the key characteristics of this nonprogressive disorder affecting the developing brain.^{10,11}

Cerebral palsy affects the total development of the child. The primary disorder is of motor execution, but common associated dysfunctions include sensory deficits (hearing or vision); epilepsy; learning disabilities; cognitive deficits; emotional, social, and behavioral problems; and speech and language disorders. The degree of severity varies greatly from mild to moderate to severe.¹⁰⁻¹²

Diagnostic Categorization of the Characteristics of Cerebral Palsy

In general, a diagnosis of cerebral palsy suggests that the individual has a lesion within the motor control system with a residual disorder of posture and movement control. Varying degrees of associated components are seen with this disorder that further define the category that a child may fall into: severity of motor abnormalities, anatomical and magnetic resonance imaging findings, extent of associated impairments, and the timing of the neurological injury. In addition, the labeling process often identifies the parts of the body that are primarily involved. Diplegia, hemiplegia, and quadriplegia, respectively, indicate that the lower extremities, one side of the body, or all four extremities are affected. This can be misleading to the therapist who is working with infants because these children often change their clinical signs and symptoms and their respective disabilities. The disorder is not progressive, but the presentation of involvement of body segments may manifest itself differently as the child grows and his or her structure and tonal distribution changes against gravity.

The clinician must be aware that the categorization of cerebral palsy is based on descriptions of observable characteristics; thus, it is a symptomatic description. The hypertonus of spasticity prevents a smooth exchange between mobility and stability of the body. Constriction of respiratory adaptability occurs with poor trunk control. Incrementation of postural tone occurs with an increase in the speed of even passive movement, and clonus may occur in response to sudden passive movement. Although diagnostic terms reflect the distribution of excessive postural tone, the entire body must be considered to be involved. Spasticity, by nature, involves reduced quantity of movement, which makes its distribution easier to identify. Recruitment of the corticomotor neuron pool is affected in the presence of spasticity, and therefore timing issues result in the poor grading of agonists and antagonists.^{13,14} There is also a risk of reduction in the range of limb movements over time when therapy does not include active adaptation in end ranges and organization of postural transitions.¹⁵ This category (spasticity) has the highest occurrence of cases of cerebral palsy.¹⁶ There are several spastic types of cerebral palsy that require clarification. Spastic diplegia implies that the lower extremities are more involved than the upper extremities but could manifest with varying degrees of hand function, and often the involvement

is asymmetrical.¹⁴ Hemiplegia displays involvement of one side of the body and can manifest itself with the arm involved more than the leg or the leg involved as much as or more than the arm.¹⁰ Quadriplegia, as the term implies, involves the entire body.¹⁰

Dyskinetic syndromes, which include athetosis and dystonic types of cerebral palsy, are characterized by involuntary movements. The term *dyskinetic* is commonly used with children who lack posture and axial and trunk coactivation. The excessive peripheral movement of the limbs occurs without central coactivation. Dystonic types of cerebral palsy are dominated by tension, and athetosis usually has a hypotonic base or underlying tone. Dyskinetic syndromes may occur with greater involvement in particular extremities, although the condition most often interferes with postural stability as a whole. When pathological or primitive reflexes are used to accomplish movement, there is a difficulty with midline orientation. Dyskinetic distribution of postural tone is changeable in force and velocity, particularly during attempted movement by the individual. Midrange control is limited if present at all, and frequently end ranges of motion are used to accomplish a motor task.¹⁰ For these reasons, these children have a reduced risk for contractures over time.

Hypotonicity is another category of cerebral palsy, but it may also mask undiagnosed degenerative conditions (see Chapter 13). Recent reports suggest that “pure hypotonia” is not an attribute of cerebral palsy, and further testing to rule out other causation may be indicated.¹⁶

Hypotonia in a young infant may also be a precursor of a dyskinetic syndrome. Often, athetoid movements or spasticity are not noticed until the infant is attempting antigravity postures, although there may be some disorganization apparent to the careful observer. Generalized hypotonia often masks some specific areas of deep muscle tension with accompanying local immobility.

True ataxia is a cerebellar disorder that is seen more frequently as a sequela of tumor removal (see Chapters 21 and 25) than as a problem occurring from birth. Ataxic syndromes are more commonly found in term infants. This type of cerebral palsy is a diagnosis of exclusion. In a small number of patients there is congenital hypoplasia of the cerebellum. Most of these children are hypotonic at birth and display delays in motor acquisition and language skills.¹⁰ Recruitment and timing issues remain problems in this population. Trajectory of the limbs, speed, distance, power, and precision are frequently documented as problems in this category. Midline is often achieved, but control of midrange movements of the extremities and control of trunk postural reactions are affected.

These classifications, even when accurately applied, give the therapist only a general idea of the treatment problem and must be supplemented by a specific analysis of posture and movement control during task performance, an interview for home care information, and assessment of treatment responses (see Chapters 7 and 8). The therapist is then ready to establish treatment priorities for the individual child.

Many of the characteristics described in the preceding paragraphs also apply to children who have had closed head traumas or brain infections. Further information can be obtained in Chapters 24 and 26. Some of the treatment suggestions that

follow may also be applied in such cases. As with cerebral palsy, early positioning and handling after trauma may deter later problems.

EVALUATIVE ANALYSIS OF THE INDIVIDUAL CHILD

Initial Observations and Assessment

Examination of the individual child begins with careful observation of the interaction between parents and the child, including parental handling of the child that occurs spontaneously. Some additional insight can be gained about the relationship between parent and child by observing how the child is handled both physically and emotionally. Does the child receive and respond to verbal reassurance from the parent in the therapy situation? Are immediate bribes offered to the child? Does parent eye contact increase the child's confidence in responding? Does family communication convey the idea of negativity in the therapy situation or a difficult experience that will soon come to an end? The family orientation will affect the response of the child while working with the therapist. Making connections with the child and family is a critical component to a successful relationship that forms with ongoing treatment.

The therapist working as part of a team may have the advantage of a social worker or psychologist who will relate to the problems and motivations of the parents. Parental responses toward the disabled child arise from the parents' uncertainty, fear, concern for the future, disappointment, distress, and other typical reactions to this unforeseeable life experience. The therapist will observe positive changes in parental orientation to the child as the parents are educated as to what can be done to help the child move forward. They may be further assisted by opportunities to interact with well-adjusted parents of older children with a diagnosis of cerebral palsy. Assisting families to make connections with other families and children in the community provides them a supportive network of people who share similar experiences.

A problem-based approach to the assessment and management of the child with cerebral palsy includes the family as key members of the team.¹⁷ While observing the child, the experienced therapist will want to periodically elicit from the parents their view of the problem. By listening carefully, the therapist will also be able to discern the emotional impressions that have surrounded previous experiences with professionals. Sometimes what is not said is more important than what is verbally offered immediately. Listening carefully and clarifying facts are more important than overwhelming the parents with excessive information and suppositions during early contacts. Observation of the family response to information will keep the therapist on track in developing a positive relationship with parents that deepens over time. The therapist's role is often as interpreter of medical information as parents attempt to make some sense of their child's diagnosis.

The next general step is to observe, in as much detail as possible, the spontaneous movement of the child when separated from the parent (Figure 12-1). Is the child very passive? Does he or she react to the supporting surface (Figure 12-2)? Are there atypical patterns of movement to

Figure 12-1 ■ Typical infants accumulate a multitude of experiences as they move smoothly in their environments.

Figure 12-2 ■ Lack of support surface contact demonstrates difficulty conforming to and activating off of the supporting surface.

reach a toy? Are clearly typical responses occurring with specific interference by reflexive synergies or total patterns of movement? Does the child rely heavily on visual communication? Do the eyes focus on a presented object, or does the postural abnormality increase with an effort to focus the eyes? Does the child lead or follow hand activity? Does an effort to move result only in an increase of postural tone with abnormal distribution? Does respiration adapt to new postural adaptations (Figure 12-3)? Is the child able to speak as well while standing as while sitting?

This type of observation is valuable because movement patterns directly reflect the state of the central nervous system and can generally be seen while the parent is still handling the child.¹⁸ Once the child is on the mat or treatment table, outer clothing can be removed to observe interactions of limbs and trunk. Movement responses of the child can gradually be influenced directly by the therapist. Many disabled children associate immediate undressing in a new

Figure 12-3 ■ Emotional reactions are also translated into stronger spastic reactions influencing respiratory adaptation (see Chapter 5 on the limbic system).

environment with a doctor's office, and the chance to establish rapport is lost. In some instances it is preferable to have the parent gently remove some of the child's clothing or even to leave the child dressed during the first therapy session. Gaining the trust of the child and parent is crucial during the first few sessions.

Examination of the child's status is more likely to be adequate if the therapist follows the child's lead when possible. Notes can be organized later to conform to a specific format. It is often possible to jot down essential information while observing the child moving spontaneously or while the parent is holding the child. Reactions to the supporting surface will differ in these circumstances. After the session, the therapist may dictate the salient information into a tape recorder, or a videotape or digital tape can be made to capture the interactions and movement patterns. Attention should be given to the typical movements of the child and to those postures that the child spontaneously attempts to control. Building a treatment plan will be based on the strengths of the child noted in these first encounters. Eye alignment is important; the correspondence between visual and postural activity relates directly to the quality of movement control. It is important to note the interaction between the two sides of the body. In noting atypical reactions and compensatory movement patterns, the therapist must also indicate the position of the body with respect to the supporting surface. There is a tendency to compile more pertinent data by learning to cluster observations and relating one to the other. Children are vibrant beings. Their choices of position tell us something about their habits and how comfortable they are in this situation. To be the slave of a preformulated sequence destroys the decision-making initiative appropriate to the situation at hand. This is true for the therapist as well as for the child. Although it is important to see the child in every position, making smooth transitions from one to another will ensure that the child is secure and give the therapist a more accurate assessment of the child's abilities. Noting the "preferred" position or movement strategy can provide information about the ability to conform to a support surface,

initiation of movement, muscle tightness, muscle tone distribution, and movement variety in the child's repertoire.

Standardized assessments are often used by facilities to document the developmental level of the functioning of a child with disability and to justify treatment. The Gross Motor Function Measure (GMFM) was developed to assess children with cerebral palsy and has good reliability and validity for children aged 5 months to 16 years.^{19,20} The Gross Motor Function Classification System (GMFCS), developed in 1997, is often used in conjunction with the GMFM.^{21,22} The GMFCS has five levels of classification for gross motor function, emphasizing movement initiation related to sitting, walking, and mode of mobility. Descriptors of motor function span an age range of 2 to 18 years, reflecting environmental and personal factors. The Pediatric Evaluation and Disability Inventory (PEDI) assesses children aged 6 months to 7.5 years in three domains: social, self-care, and mobility.²³ The Functional Independence Measure for Children was developed as a test of disability in children aged 6 months to 12 years. This assessment covers self-care, sphincter control, mobility, locomotion, communication, and social cognition.²⁴⁻²⁶ This tool has been used to track outcomes over time. Although several instruments have been developed that meet psychometric criteria to document function in children with disabilities, the GMFM and the PEDI are thought to be the most responsive to change in this population of children because of their good reliability and validity.^{27,28} Often the decision to use an instrument to assess development will be left up to the clinician or facility. To date, there is no one tool that will cover all the categories necessary to document change in a child with cerebral palsy, so the clinician will need to rely on observational skills to describe quality of movement and response to changes in position in space and handling.

Each child will differ in the ability to separate from her or his parents. Spontaneity of movement, interest in toys, general activity level, and communication skills will also vary from child to child.²⁹ Responding to the specific needs of the child enables the therapist to set priorities more effectively. If fatigue is likely to be a factor, it is important first to evaluate those reactions that present themselves spontaneously, followed by direct handling to determine the child's response and potential for more typical movements. Movements or abilities for which there is a major interference from spasticity, reflexive responses, or poor balance may be better checked at the termination of the assessment so that the child remains in a cooperative mood as long as possible. Information regarding favorite sleeping positions, self-care independence, and chair supports used at home can be requested as the session comes to a close.

Clinical reasoning involves taking information from the assessment, including observations, results from standardized tools, family input, and the therapist's handling of the child to formulate a treatment plan. Placing this information into a framework that makes sense to the therapist, the physician, other health professionals, and the family will assist in goal writing. The International Classification of Functioning, Disability and Health (ICF)³⁰ is well known in the field of health care and allows one to see the overall interaction of the person with his or her environment and activities in the presence of the health condition.³⁰

Reactions to Placement in a Position

If the child totally avoids certain postures during spontaneous activity, these are likely to be the more important positions for the therapist to evaluate. Observing how the child conforms to the support surface and how much contact there is with the surface will provide information about the ability to initiate movement from the surface. Support surface contact is essential for weight bearing and weight shifting to occur; both are critical for movement. Placement of the child in the previously avoided position will permit the therapist to feel the resistance that prevents successful control by the child.²⁹ As mentioned previously, this may be held for the end of the assessment. The parent should play an active role in the assessment whenever possible. Continued dialog with the parents reveals factors such as the frequency of a poor sitting alignment at home or a habitual aversion to the prone position. Sitting close to the television set or tilting the head when looking at books should also be noted so that functional vision skills can be related to other therapy interventions.³¹ These contributions by the parents establish the importance of good observation and the need for parents and the therapist to work cooperatively. Therapists of different specialties need to initiate continuing communication to coordinate therapy objectives.

According to the guide for typical development, infants should be able to maintain the posture in which they are placed before they acquire the ability to move into that position alone.^{32,33} The problems presented by cerebral palsy occur to some extent as a reaction to the field of gravity in which the child moves.³² Visual perceptions of spatial relationships motivate and determine movement patterns while the child must react at a somatic level to the support surface. It is helpful, therefore, to attempt placement of the infant or child into developmentally or functionally appropriate postures that are not assumed spontaneously (Figure 12-4). Resistance to placement indicates an increase in tone, a structural problem, or an inability to adapt to the constellation of sensory inputs for that alignment. A movement that resists control by the therapist will be even less possible for the child. What appears to be a passive posture may hide rapid increases in hypertonicity when movement is initiated or instability of a proximal joint when weight bearing is

Figure 12-4 ■ Baby treatment must be dynamic and precisely oriented to individual needs.

initiated. A child may have learned to avoid excitation of the unwanted reactions and may fix the body position to avoid the alignment that cannot be controlled. Another child may enjoy the sensory experience of accelerated changes in postural tone and deliberately set them off as a means of receiving the resulting stimulation to his or her system.

VISUAL-MOTOR ASSESSMENT

It is the visual-motor aspect of performance function that is of primary concern to the therapist because spatial judgments are needed to control movement of the body in an upright alignment. The infant who is able to stand and walk along a support and then seems unable to let go of the support is often found to have functional vision interferences. The child with cerebral palsy most often demonstrates significant neuromotor delay in the developmental process, which often results in the inadequate establishment of matching of inputs from the postural and visual systems (Figure 12-5). Visual-motor learning experiences are filled with compensatory responses from both systems. Vision plays an important role in early motor development for learning about, manipulating, and exploring the environment. Therefore vision requires attention during the assessment of motor abilities. (Refer to Chapter 28.)

The visual system in its development has many parallels with the postural system.³⁴ Binocular control and freedom of movement are necessary for the system to function properly. Ambient visual processing must be integrated with central visual processing to take in information that relates to position in space and to focus on a particular target. A simple screening examination may check acuity at 20 feet on the E chart and declare vision to be normal. An ophthalmological examination is needed to determine the health of the eye structures, particularly in the case of infants born preterm. Equally important is a functional vision examination given by a behavioral or developmental optometrist to reveal the level of efficiency that the two eyes have achieved in working together and whether the ability to focus in far and near ranges is

Figure 12-5 ■ Touching the target integrates the new visual perception with the motor response.

smoothly established. Strabismus dysfunctions commonly coexist with cerebral palsy and may cause the child to receive a double image of environmental objects. Judgments about space are related to a three-dimensional perception of the surrounding environment, which requires coordinated use of the two eyes. Conservative management of eye alignment problems is done with the use of lenses and prisms by the experienced optometrist, which permits the therapist to work for basic head control by the child before any irreversible changes are made to the eye muscles. Eye movement differentiates from head movement in much the same way that the hand differentiates from general arm movement, corresponding to general maturation of the central system.

Because the visual system is first a motor system, children with cerebral palsy most often have difficulty separating eye movement from head movement and controlled convergence for focal changes. When their posture is supported, eye movement can proceed to evolve in accuracy and complexity. With inadequate alignment of the head in relation to the base of support, the visual system accumulates distortions and inconsistent input, which leads to the formation of an inadequate perceptual base for later motor learning (see Chapters 4 and 28). Even after improvement in the control of posture and movement, the visual system continues to adapt to the previous faulty visual-motor learning, resulting in perceptual confusion and inefficient organization of body movement in space. The therapist who is working for improved motor control may notice that such a child reacts with adequate postural adaptations when facing the therapist or a support and that the movement quality seems to disintegrate when the child faces an open space. This immediately jeopardizes the ability of the child to use her or his new responses after leaving the therapy environment. Visual orientation to the environment will dictate alignment against gravity, and the reverse is also true; poor alignment against gravity will affect visual orientation to the environment. Movement, postural stability, and muscle activation are closely related to vision.³⁵

Padula, a behavioral optometrist specializing in neuro-optometric rehabilitation, has described a posttrauma vision syndrome in adults with acquired central dysfunction and has applied this information to children with cerebral palsy.³⁶ A perceptual distortion in the perceived midline of the body, known as *visual midline shift syndrome*, is corrected with the use of prescribed prism lenses, which then permits the child to step into the perceived space with more confidence (Figure 12-6). The observant therapist will begin to notice that the sudden increase in neuromuscular tension in a child taking steps in a walker is often accompanied by closing of the eyes. This seems to be a momentary inability of the central processing system to integrate the information arriving from different sources. With the use of prism correction, the child experiences the body as more coherent with visual-spatial perceptions. By incorporating an understanding of visual observations into intervention strategies, physical and occupational therapists are able to note compensatory adaptations by the complementary systems and use them to their advantage in effective treatment intervention.

Some children who walk on their forefeet or even on their toes and who have made little if any permanent gait change after the use of inhibitory casting or orthotics also fall into the population described previously. With prisms that

Figure 12-6 ■ This 3-year-old girl with diplegia takes her weight evenly over two feet with the help of prism lenses to shift her perception of space while engaged in a motor task.

correct the perception of forward space, the child places the entire foot in contact with the support. Such prism lenses are used during therapy handling as a perceptual learning experience for the child, with the optometrist and the therapist coordinating their efforts. Hand-coordination activities also require timing of reach and grasp that is based on feed-forward input from the visual system.³⁵ In some cases the therapist observes the visual system to overfocus in the moment that the child loses control of his or her postural stability. This suggests that the visual system may be attempting to compensate for the inadequacy of the postural control, much in the same way that we all adjust our head position to see better. Understanding the nature of the continuing dynamic interaction between these two functional subsystems of the central nervous system and attending to the needs of visual-postural orientation will increase the successful evolution of clients with cerebral palsy.

POSTURE AND MOVEMENT COMPENSATIONS

Compensatory patterns of movement arise from the motivation of the child to move in spite of various restrictions on the expression of that movement. Components in the developmental process that drive a person to right the head with the horizon and the body against gravity are met with interference from the central nervous system. Visual impressions of the environment motivate movement, and the infant attempts to influence nearby objects or confirm visual impressions by reaching into the environment and touching. As visual awareness enlarges to include more distant targets, the infant is motivated to move toward the object or person seen. With poor balance between flexion and extension and poor grading of agonist with antagonist, the resultant movements are

influenced. When the child's body does not respond in a smooth way, the child begins to learn and perfect the uncoordinated reaction. Repetition of inadequate ranges of movement and limited variability of movement patterns begin to establish the atypical appearance of posture in the child with cerebral palsy.

The quality of a body posture or position in space determines the quality of the movement that is expressed. Lack of head control, poor midline organization, and deficient trunk strength begin the process of compensation. From a distorted starting position the movement initiated is one that is restricted (Figure 12-7). The lack of central "core" stability in the body restricts the full mobility of a limb. This limitation over time is increased by fascial and muscular restrictions on smooth coordinated muscle action. The child continues to learn the atypical responses because the movement patterns tend to be reinforced by either accomplishment or reinforcement of some kind from the environment. Compensatory movement patterns evolve because of necessity rather than any feedback as to efficiency or functional smoothness.

Habitual movement patterns are established on the basis of frequency of use, so the child with cerebral palsy tends to repeat the atypical responses that have been learned. In the therapy situation the child has the opportunity to learn new combinations of input to create the basis for a more stable postural control. Careful analysis of the postural adjustments and movement patterns of the child with cerebral palsy is crucial to initiate effective intervention strategies. There are many factors to be considered in the context of the continuing developmental changes in the child, which makes a simple solution impossible.

Active therapy intervention allows the sensorimotor learning of the child to be modified so that some part of the compensatory response becomes unnecessary and the movement becomes more typical (Figure 12-8). This relative

Figure 12-7 ■ Compensatory postures restrict movement initiation.

Figure 12-8 ■ The experience of coming to stand over the more affected side activates diagonal patterns of postural adjustment.

approximation of what is expected in a typical response may occur in the area of initiation, timing, strength, or ability to sustain an antigravity alignment. As movement expression and postural stability are better established, the compensatory patterns are used less often, and new motor learning occurs on a base of closer-to-normal experience.

Compensatory processes have their positive aspects.³⁷ The independence finally achieved by the older child reflects her or his intelligence and motivation and the family's attitude toward the child and the disability. The most debilitating handicap of cerebral palsy in an intelligent child may be social or psychological when the child is not accepted by the family and therefore cannot develop a positive self-image. Compensatory movement patterns may permit greater independence, if and when they do not limit or block the active learning of new motor strategies.

OTHER ASSESSMENT CONSIDERATIONS

Nutritional Aspects of Neuromotor Function

Nutrition is viewed as providing an important biochemical base for enhanced human performance. Williams,³⁸ author of the classic reference *Biochemical Individuality*, was one of the first to point out the existence of significant variability in the need for specific individualized nutrients because of differences in assimilation and other factors. Physicians Crook and Stevens,³⁹ Smith,⁴⁰ Pfeiffer,⁴¹ and Cott⁴² are a few of the leaders who have analyzed the link between nutrient intake and behavioral differences in children and adults. Many of these references address issues of attention and learning. To have efficient function of the transmitters at the myoneural junction and good health for the myelinated neurons of the nervous system, a variety of trace elements must be present.⁴¹ Lack of dendritic proliferation is associated with malnutrition regardless of the cause.⁴³ The ambulatory child with cerebral palsy will need to be considered for a new level of energy expenditure to avoid short stature and poor nutritional status.⁴⁴

Another body of work explains more about the direct link between food intake and muscle efficiency for high performance and normal function. The need for water is paramount for healthy fascia. In children with cerebral palsy and related disorders there is often from the beginning a difficulty in the smooth automatic sucking needed for nutritive intake. Uncoordinated patterns of mandibular and tongue motion persist when not addressed in early and precise intervention strategies. Even the digestive process is affected negatively by inadequate chewing, a higher-than-typical percentage of food allergies, and less-than-efficient physiological functions.⁴⁵

It is likely that brain dysfunction in some of these children extends to the hypothalamus, thus influencing the entire digestive process. Duncan and colleagues⁴⁶ have documented the risk of osteopenia in nonambulatory children with cerebral palsy. This retrospective study showed that fewer than 75% of the calories needed were administered to 95% of the children with gastrostomy tubes. Nutrients were also deficient. This may explain part of the poor physical response level of such children. Sonis and colleagues⁴⁷ looked specifically at energy expenditure in children and adolescents with spastic quadriplegia in relation to food intake. They found dietary intake to be markedly overreported for this population and determined that nutrition-related growth failure was likely related to inadequate energy intake. Reflux is also common in infants with developmental problems. In some infants reflux subsides as the physical stress is reduced in the tissues bordering the upper thoracic and cervical spine, but it can be related to milk sensitivity or even susceptibility to environmental contaminants.

To supplement nutritional intake in the child with cerebral palsy, the individual child must be considered with regard to age, size, activity level, and growth factors.⁴⁸ Ideally, blood, urine, or hair analyses would be done to determine nutrient imbalances, and supplementation with specific nutrients would be guided by a specialist. Environmental medicine has taken the lead in this type of work. The rehabilitative process places increased demands on the entire system and requires fuel to set the stage for improved muscle function. Protein, carbohydrates, and adequate hydration are sources that build muscle and provide a foundation for strengthening and the advancement of motor skills in populations without disability.^{49,50} A well-balanced diet will provide the requisite energy for exercise. However, little research has been done specifically on children with cerebral palsy and appropriate levels of protein during exercise. Therefore it is necessary to discuss these issues with the family using caution unless specifically trained to do so. A nutritional consultation is warranted when concerns arise in this area.

Consideration of Supplemental Oxygen

Oxygenation of muscle tissue is considered essential for smooth movement control, and it is generally accepted that respiratory support increases automatically to permit faster or stronger movement patterns in a typical subject. Therapists often note that children with cerebral palsy resist moving into new ranges of movement and that respiratory adaptation does not occur automatically. Supporting the child in the novel posture until a respiratory adaptation is noted results in

acceptance of the new experience. Oxygen needs increase in children during growth spurts or when mastering more vertical postural alignments. Increased oxygen is also required for sustained activity such as continuous walking.

Shintani and colleagues⁵¹ performed a careful study of 233 children with cerebral palsy to determine the presence of obstructive sleep apnea. In 10 children with cerebral palsy who were received at the hospital for treatment of severe obstructive sleep apnea, these authors determined that adenoidal or tonsillar hypertrophy were noted in only four children and that the main cause of sleep apnea in the other six children was pharyngeal collapse at the lingual base. Fukumizu and Kohyama⁵² looked at central respiratory pauses, sighs, and gross body movement during sleep in 19 healthy children, ages 3 months to 7 years. Central pauses occurred more often during non-rapid-eye-movement sleep and increased with age. Developmental differences need further study.

Decreased oxygen levels have been associated with impaired cognitive and physical performance in the literature.⁵³ In the presence of inadequate peripheral oxygen saturation, low levels of oxygen can be administered during the night. This practice has been used with selected low-tone and athetoid children for improved energy during the day during growth changes, but formal study is needed on a larger group of children with cerebral palsy. Better oxygenation of the tissues can also result in increased food intake and consequently improved energy levels.

ROLES OF THE THERAPIST

Role of the Therapist in Direct Intervention

The primary role of the therapist is in direct treatment or physical handling of the child in situations that offer opportunities for new motor learning. This should precede and accompany the making of recommendations to parents, teachers, and others handling the child. Positioning for home and home handling recommendations should always be tried first by the therapist during a treatment session. As noted for the initial assessment, many interventions will cause a reaction unique to the particular youngster.^{29,54} It is the role of the therapist to analyze the nature of the response that is accompanied by adaptation inadequacies, to analyze the movement problems, and to choose the most effective intervention (Figure 12-9). It will then be possible for other persons to manage play activities and supervise independent functioning that reinforce treatment goals.⁵⁵

The therapist working with these children becomes an important and trusted resource to the family. At times the therapist who has had the more consistent contact with the child becomes the facilitator of better communication between the parents and medical or health care professionals. The child who starts early and continues with the same therapist may make of this person a confidant and share concerns that are difficult or uncomfortable for the child to explain to parents. It is a challenge for the therapist who follows the same child for an extended time to come up with appropriate goals and new activities to continue positive change. Part of direct intervention is to recognize when the amount of therapy can be reduced and replaced with recreational activities with peers.

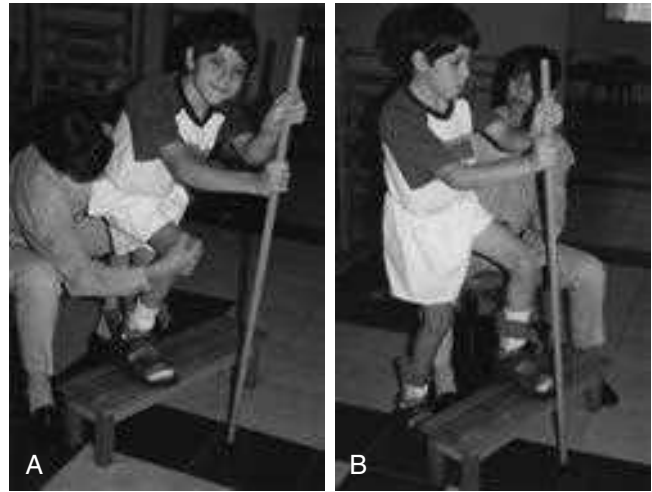

Figure 12-9 ■ The two sides of the body (A and B) often respond very differently to the same task, and therapy must be adapted accordingly.

Case Management and Direct Intervention

Simple documentation of observed changes in a child over a series of regular clinic visits is still too common for many children with cerebral palsy. Regular appointments, with periodic assignment of a new piece of apparatus, do not constitute active treatment. Although physical intervention in the form of direct handling of the child is considered a conservative treatment by most physicians, relatively few children receive sufficient physical treatment at an early age.^{56,57} Therapists need to demonstrate their unique preparation and describe their interventions in ordinary language so that families as well as other health care professionals understand the importance of specific treatment versus general programs of early stimulation that are designed for neurologically intact infants.

The prognosis for change in cerebral palsy is too often based on records of case management rather than on the effect of direct and dynamic treatment by a well-prepared therapist. Bobath^{32,58} documented accurately the developmental sequence expected in the presence of spasticity or athetosis. Her book consolidates some observations of older clients that help professionals understand the uninterrupted effects of the cerebral palsy condition. In any institution one can observe the tightly adducted and internally rotated legs, the shoulder retraction with flexion of the arms, and the chronic shortening of the neck so common as the long-term effects of cerebral palsy. The long-term influence of athetosis results in compensatory stiffness or limited movement patterns to create a semblance of the missing postural stability while a limited number of movement patterns with limited degrees of freedom are used to function (Figure 12-10).

Within the clinical community there is increasing evidence that soft tissue restrictions further limit spontaneous movement in children with cerebral palsy. The fact that these fascial restrictions are often found in infants suggests that they originate early rather than as a gradual result of limited ranges in movement. Because of the tendency of fascial tissue to change in response to any physical trauma or strong biochemical change, some of these characteristics might be originating with traumatic birth experiences, and they would

Figure 12-10 ■ Attempted movement activates atypical patterns and restrictions; restrictions are revealed with limited degrees of freedom available for function.

be exacerbated by daily use of limited patterns of movement. Tissue restrictions can also occur with immobilization or general infectious processes.⁵⁹⁻⁶¹ Soft tissue begins to change its physiological structure with the application of gentle sustained pressure, so it serves as documentation that there are changes caused by the therapist's simple hand contact. Some of the sensory information in the form of tapping or holding or application of pressure affects fascial meridians and muscle alignments.⁶² A therapist must be prepared to defend his or her approach with a solid foundation, theory, and objective outcomes. Objective documentation is important when dealing with any population but essential for demonstrating therapeutic change.

Applying specific soft tissue treatment techniques to any person with a neuromotor disorder creates the need for immediate follow-up with practice of new skills using this improved range of motion. Creating excessive tissue mobility in a given area of the body can destroy the delicate patterns of coordination that permit synergic function in the person with cerebral palsy, so functional activation of the body after each specific mobilization is strongly recommended to integrate the tissue change. Well documented in the literature on current motor control and motor learning is the need to practice, practice, practice.⁶³ Practice time is related to skill performance; the amount and type of practice are determined by the stage of learning that an individual is in and the type of task to be learned⁶³⁻⁶⁵ (see Chapter 4 on motor control and learning). Interestingly, most of what we know about motor control and motor learning is based on individuals who are "typicals," and it is yet to be determined

whether the same principles that are considered important in healthy individuals apply to people with disability. However, it makes sense that practice would influence the use of any new or relearned skill.

An occupational therapist, Josephine Moore, stressed Bach-y-Rita's⁶⁶ works to emphasize some important points for therapists regarding the concept of increasing functional demands on the central system and the importance of the neck structures in developmental movement sequences. Children with spasticity often have a lack of developmental elongation of the neck, whereas children with athetoid or dystonic movement lack neck stability and consistent postural activation. Tone changes often originate with changes in the delicate postural interrelationship between head and body or with ambient visual processing.

By appreciating the abundance of polysynaptic neurons and parallel processing in the central nervous system, the therapist will become more optimistic regarding his or her role as facilitator and feedback organizer to guide new movement. Restak,⁶⁷ in his book *The New Brain*, confirms the continual reorganization of the brain in response to new input. Several animal and human studies on neuroplasticity have confirmed that the brain reorganizes after an injury and that this reorganization is shaped by rehabilitation and motor skill learning.⁶⁸⁻⁷¹ In the child with cerebral palsy, the therapist looks for subtle changes in the child's response to determine newly integrated sensorimotor learning. For example, excessive emphasis on extensor responses in the prone posture for the older child can jeopardize the quality of neck elongation in sitting, so it is essential to work on the components necessary for control of the new posture desired.

Therapy intervention is far from innocuous when it is responsibly applied. A truly eclectic treatment approach comes with clinical experience and personal consideration of observations of the functional problems presented by the complex issue of cerebral palsy at different ages. Priorities in intervention strategies have a practical aspect, and new developments in our knowledge lead us forward in clinical applications. The intricacies of typical development offer many new clues for new effective interventions. With high-quality treatment intervention the need for direct therapy service as a crucial aspect of case management for these children is confirmed. Clinical findings in individual case studies need to become part of the professional literature to strengthen the efficacy of intervention in this population.

Special Needs of Infants

The direct treatment of infants deserves special mention because there are significant differences in intervention strategies for the infant and the older child. Aside from the delicate situation of the new parents, the infant is less likely to have a diagnosis and presents a mixture of typical and atypical characteristics. It is essential that the clinician have a strong foundation in the nuances of typical developmental movement and early postural control.^{4,72} Soft tissue issues must be addressed in detail. Direct intervention can be offered as a means of enhancing development and overcoming the effects of a difficult or preterm birth. It will be important, however, to pursue a diagnosis for the infant who reaches 8 or 9 months of age and continues to need therapy

because third-party payers often require a diagnosis beyond developmental delay or prematurity.

Infants with early restrictions in motor control should be followed until they are walking independently, even if they no longer need weekly therapy. Infant responses can change rapidly as the therapist organizes the components of movement control. Soft tissue restrictions should be treated initially to have more success with facilitated movement responses. Careful observation is essential because all but the severely involved infant will change considerably between visits. The therapist should invest some time in training the parents to become skilled observers while appreciating the small gains made by their infant. Physiotherapist Mary Quinton⁷³ has written specific intervention strategies for babies (Figure 12-11). Infant massage is important to improve the bonding of mother and child and to improve physiological measures.^{74,75}

Referral to other health care professionals is essential in the presence of possible allergies, new neurological signs, visual or auditory alterations, and persistent reflux or nutritional issues. There is always the possibility of convulsions when some brain dysfunction is present, and neurological evaluation should be recommended if this is a concern.

ORIENTATION TO TREATMENT STRATEGIES

The child whose movement is bound within the limitations of hypertonicity suffers first of all from a paucity of movement experience. Because early attempts to move have resulted in the expression of limited synergistic postural patterns, the child often experiences the body as heavy or awkward and loses incentive to attempt movement. The therapist will want to focus on the child's ability to sustain postural control in the trunk. Central "core" stability to support directed arm movement or weight shifts for stepping have not developed, so they need to be addressed during therapy intervention. Improved upper extremity control opens the possibility for new learning of more coordinated tasks. Specific work on hand preparation for reach and grasp follows use of the arm for directed movement and

Figure 12-11 ■ Mary Quinton, British physiotherapist, is widely recognized as the originator of effective infant intervention.

often results in improved balance in standing. Any freedom gained in upper body control results in more efficient balance in the upright posture.

Inhibiting or stopping the movement of one part of a movement range or even one limb must be done in a way that permits the child to activate the body in a functional way. The child who lies in the supine position with extreme pushing back against the surface is rarely seen when therapy intervention has started early. The therapist initially eliminates the supine position entirely but would incorporate into the treatment plan the activation of balanced flexion and extension in sitting with the ability to vary pelvic tilt for functional play and reaching (Figure 12-12). The child might later be reintroduced to a supine position with postural transitions that support balanced control of the body with more differentiated movement.

One of the primary considerations for the child with spasticity is adequate respiratory support for movement. Mobility of the thoracic cage and the midtrunk must be combined with trunk rotation during basic postural transitions (Figure 12-13). Consideration of age-appropriate movement velocity will guide the therapist in choosing activities that challenge better respiratory adaptability and prepare for speech breathing to support vocalization. The therapist will find it helpful to hum or sing or even make silly sounds that encourage sound production by the child during therapy. Movement of the child's body changes respiratory demands and frequently results in spontaneous sound production during therapy. Assessing the ability to sustain a breath to speak is easily done during a therapy session by counting the letters in the alphabet that can be said with one breath. This should be done with the child supine and in an upright position because trunk control required while sustaining a breath changes with the posture attained against gravity. Describing the chest shape and movement of the thorax observed can serve to assist the therapist in problem solving and prioritizing the treatment plan.

In some children respiratory patterns remain immature and superficial, which may be related to the causative factors of the impairment. A lack of postural control limits even the physiological shaping of the rib cage itself because the ribs do not have an opportunity to change their angle at the spine.

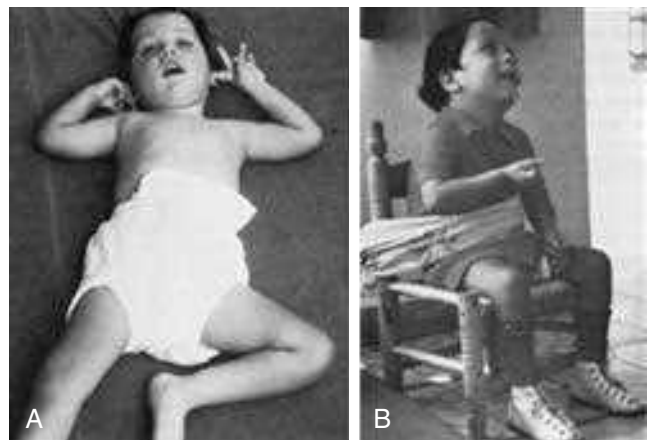

Figure 12-12 ■ **A**, Strong asymmetry and atypical tone in the supine position. **B**, Simple seating can inhibit strong asymmetry and make function a possibility.

Figure 12-13 ■ Rotational patterns combined with transitional movements can be used to mobilize the thoracic cage.

The therapist must give careful support to sustain the transitional posture of the older child during transient respiratory change. An active respiratory adaptation will increase the variability of postural adaptation. Improved respiratory adaptation will improve trunk tone, just as dynamic trunk alignment facilitates better respiration.

Weight bearing changes postural tone. The trunk can be helped to experience weight bearing in a variety of alignments by using inflated balls or rolls that offer a contoured surface. The threshold of the original response is gradually altered so that the child begins to learn the new sensations and can follow guided postural transitions. When there are distinct differences between the two sides of the body, attention must be given to lateral weight shifts in sitting and standing. Changes near the vertical midline of the body seem to represent the more difficult input for the compromised system to integrate. It may be necessary to assist sustained weight over one side and then the other to initiate the change. It is important to assist the shoulders to align with the hips and that the visual orientation of the individual brings the head to a correct alignment. Young children need special help with segmental rotation of the trunk in the vertical alignment so that the weight-bearing side is relatively forward with dynamic balance of flexion and extension influences.

Children and adolescents with cerebral palsy often require a more intense or prolonged sensory cue for a desired movement response to be obtained. Weight bearing against the surface may need to be sustained for a prolonged period of

time and a range of movement prepared beyond the essential range for the functional goal. The therapist is addressing a system that is deficient in its ability to receive, perceive, and use the available input. This makes careful analysis and functional orientation of the sensory input essential. If the microcosm of experience given the child during a therapy session is no more intense than an equal amount of time in her or his living environment, the therapist has failed to use this unique opportunity to deliver a meaningful message to encourage the learning of new motor behavior. Although therapists cannot provide during a treatment session every experience necessary for all movement scenarios, the therapist should provide the component parts necessary for motor skills to be transferred or generalized to other activities.

The therapist working with the child with cerebral palsy constantly monitors the quality of the child's motor response. These continuing observations guide the manipulation of the environment and the assistance given the child to move toward a functional goal. Is the body tolerating the position? Does the child adapt to the supporting surface and use the supporting surface contact for movement initiation (Figure 12-14)? Is the movement of a limb graded and without unwanted associated reactions in other parts of the body? By analyzing the answers to such questions, the therapist is guided to an appropriate sequence of the therapy session and is enabled to set functional treatment goals and realistically change prognoses.

The therapist makes constant judgments as to the child's responses during therapy, challenging the child's system while ensuring success and moving toward improved control. By using specific intervention strategies, the therapist works to introduce new somatosensory and motor learning. The therapist may introduce a slight modification of the child's response, such as an elongation of a limb as it is being moved. At other times the therapist augments sensory information that helps direct a movement. Weight bearing over the feet may be simulated with the young child's foot against the therapist's hand and pressure given through the knee. Visual-motor experiences can be altered with the child's use of prism lenses, prescribed by an optometrist for use during therapy.

To be meaningful, sensory input must be contextual and meaningful to the individual who is receiving it. Multiple sensory systems are simultaneously activated by most therapeutic input, and a variety of sights and sounds may be available in the immediate environment. Memory, previous

Figure 12-14 ■ This child has little contact with the supporting surface, resulting in poor movement initiation.

learning, and cognition are activated during the therapy interaction. The therapist makes a continuous reassessment of the child's experiential needs compared with the current input provided. When the therapist works with the child in a more upright alignment during at least part of the session, the central nervous system is alert and more receptive to the incoming information.

The developmental meaning attached to the sensation of typical movement is complex and starts with the ability to process contrasting stimuli. While several parts of the body are stable, another is moving. Stability of the proximal body permits a limb to extend forcefully or to be maintained in space. Each new level of developmental dissociation of movement increases the complexity of central nervous system processing. The process of self-feeding illustrates how internal and external stimuli impinge simultaneously on the central nervous system. The process of guiding a full spoon toward the mouth initially engages the child's attention. The arm is lifted at the shoulder to bring the fragrant food odor to the level of the mouth before elbow flexion takes the spoon to the face (Figure 12-15). Between 2 and 6 years of age the self-feeding pattern is modified and the elbow moves down beside the body. Now the motor aspect of the task has become procedural and more efficient, permitting the child to participate in social exchanges with the family at the same time that she or he manages independent self-feeding. The complexity of the task increases with the secondary task of social exchange.

A solid understanding of typical developmental sequences is essential for the clinician providing direct treatment intervention.^{18,76} Early responses of the typical infant change from a self-orientation to an environmental orientation as new developmental competence emerges. More sophisticated balance in independent sitting occurs as the ability to pull to standing at a support begins to develop. Such knowledge of developmental details supports the therapist in introducing postural activities at a higher developmental

Figure 12-15 ■ Maintaining the child's elbow in this high position initially permits forearm pronation and activates the shoulder in the typical developmental pattern for improved motor learning.

level to integrate more basic abilities. The assisted self-dressing process is an effective way to introduce and integrate new movement and sensorimotor learning while using established movement skills. To sit well, the child needs practice moving over the base of support and coming in and out of sitting, and control of coming to stand from sitting. To walk well, the child may need to practice running to allow practice in changing rate, direction, range, and balance. Sitting is made more dynamic by using a gymnastic ball as a seat. Transitional adaptations of posture may be elaborated during therapy sessions to include more complex alignments. Specific techniques are reviewed in Chapter 9.

With the child dominated by athetoid movement, the therapist's role relates primarily to organization and grading of seemingly erratic movement responses and establishing function around midline. These children have the ability to balance, but their balance reactions are often extreme in range and velocity. Their movements are rarely in the midline, asymmetrical, and frequently dominated by primitive reflexes, with poor midrange control of the trunk and extremities. Cognitively they are eager to participate and usually are responsive to working on specific goals that relate to functional success. By working to improve central control, the therapist gradually introduces taking of body weight over the limbs, with assistance to grade the postural control of the central body. By working closely with a behavioral optometrist the therapist can use visual input to improve the child's balance reactions. In these children the therapist may note that disruption of eye alignment or focusing results in a momentary disorganization of postural control (see Chapter 28).

Movement control must become procedural so that it is not interrupted by every environmental distraction. This is more likely to happen when balanced activity of the visual, vestibular, and proprioceptive systems has been achieved. Independent ambulation becomes practical when the individual is able to think of something else at the same time. The therapist begins this process by carrying on a conversation with the child to engage the cognitive attention so that the motor act becomes more automatic. The concept of graded stress is discussed in Chapters 5 and 6.

Direct intervention for the hemiplegic child takes into account the obvious difference in postural tone between one side of the body and the other. Treatment for children that addresses itself only to the more affected side of the body will not prove to be effective. The critical therapeutic experience seems to be that of integration of the two sides of the body and the establishment of midline (Figure 12-16). The child with hemiplegia differs from the adult stroke patient in that the adult had a clearly established midline and integration of both sides of the body by learning to cross midline before the stroke episode. The child with hemiplegia has not had that experience and will need emphasis on this during intervention. The integration of both sides of the body begins early for the typical infant, with lateral weight shifts in a variety of developmental patterns, and leads to postural organization that permits later reaching for a toy while the body weight is supported with the opposite side of the body. The child with a contrast in the sensorimotor function of the two sides of the body needs to experience developmental patterns that include rotation within the longitudinal body

Figure 12-16 ■ This boy with hemiplegia tries to move a chair by orienting only his more active side to the task and bearing weight only briefly on the more affected side.

axis and lateral flexion of the trunk, the more affected side forward. The more affected side needs the experience of supporting the body and the experience of initiating movement.

Development of hand use first focuses on bilateral arm activity while keeping the affected hand well within the functional visual field (Figure 12-17). The infant or young child works primarily in sitting until dynamic trunk flexion is activated. Pelvic mobility is essential to activate the necessary trunk responses. The therapist may find that true lateral flexion of the more affected side of the body is fully as difficult for some children as the initial active elongation of that side. There tends to be a high incidence of soft tissue restrictions in the shoulder and neck of the affected side. Children with hemiplegia have difficulty in sustaining a balanced posture against the influence of gravity, and some begin to struggle to do everything with the less affected side. This characteristic contrast in function may contribute to the development of seemingly hyperactive behavior that is related to the inability of the central nervous system to resolve contrasting incoming information. Hyperkinetic responses in one side of the body may compensate for relative inactivity in the opposite side. Leg length discrepancy, scoliosis, pelvic obliquity, and shortening between the ribs and pelvis may develop. One goal of treatment is to bring these divergent response levels closer together so that the child can experience more comfortable postural change and adapt to later school demands.

The limbs of the hemiplegic child will change in postural tone as the trunk reactions are brought under active control and lateral weight shifts more clearly to the more affected side. The two hands need the experience of sustaining the

Figure 12-17 ■ Bilateral arm activity with visual regard that corresponds to hand motion incorporated into therapy.

body weight simultaneously, as do the two feet. Although the more affected hand may not develop sensation adequate for skilled activity, an important treatment goal is sufficient shoulder mobility to move the arm across the body midline and to assume a relaxed alignment during ambulation. Early treatment increases the possibility that the more affected hand will be used as an assisting or helping hand. There are some children who have such severe sensory loss that active use is minimal, although considerable relaxation can be achieved.

The greater the discrepancy between the sensorimotor experience of the one side of the body and the other, the more tendency the system seems to have to reject one of the messages. This can lead to distortions in verticality and is a major interference in bilateral integration. Functional vision evaluation is important to avoid the midline shift problem that will distort postural control. As body weight is shifted to the more intact side, flexor withdrawal patterns of the limbs increase in frequency and strength in some children. These postural reactions are often associated with lack of full weight bearing on the more affected side. The presence of a lateral visual midline shift or some visual field loss may increase the avoidance of bearing weight on the more affected side.⁷² One important therapy goal is the achievement of graded weight shift through the pelvis during ambulation (Figure 12-18).

Treatment strategies must incorporate a wide variety of more basic developmental alignments in which pelvic weight shift is a factor. The choice of prone, moving from sitting to four-point support, or a simple weight shift while sitting on a bench will depend on the movement characteristics observed by the therapist during the evaluative session. Diagonal adaptations are useful in the redistribution of tone for upright function. Careful attention must be given to pelvic alignment and mobility because the pelvis has a tendency to be rotated posteriorly on the more affected side in

Figure 12-18 ■ The use of poles was introduced by the Bobaths as a way to achieve graded weight shift for increasingly complex postural adjustments in standing and walking.

children who have not had good early therapy. This can cause increased hip flexion and incomplete hip extension at terminal stance later if the child begins to walk with the more affected side held posteriorly, a characteristic that may be observed during analysis of leg position in gait. Dynamic foot supports will facilitate a more functional weight shift when the child is not in the treatment session. The goal of functional movement is best reached through a wide variety of weight-bearing postures, from the obvious developmental alignments to horizontal protective responses or reaching above the shoulders in sitting and standing to incorporate practical and commonly used adaptations.

The child with low muscle tone is perhaps the greatest challenge for both therapist and parent. Adequate developmental stimulation is difficult unless positioning can be varied. Placing the child in a more upright alignment, although it is achieved with complete support initially, seems to aid the incrementation of postural control. To prepare the low-tone body for function, it is helpful to review the articulations for possible soft tissue restrictions. However, equally important is not to take away muscle tightness that is providing a form of stability for the child without the ability to give him or her another form of stability for functional use. The neck and shoulder girdle are particularly vulnerable. Strong proprioceptive input while accurate postural alignment is ensured is an important part of the treatment session. A direct push-pull motion of the limbs, which is gentle traction alternated with approximation as described by Bobath,⁷⁷ also assists in maintaining antigravity positions and creates postural variance in the practice of antigravity postural reactions. Positioning at home may include a high table that supports the arms, allows for increased trunk extension in good alignment, and permits voluntary horizontal arm motion. The therapist must be cautious of the tendency to fixate in response to trunk instability and initial hypotonicity. This seemingly hypertonic response, which can be distributed in the deeper musculature, contributes to limited adaptability rather than differentiated postural control. It is difficult to ramp up the corticomotor neuron pool even though the

child's motor output may remain limited; changes in positioning and opportunities for the child to have other sensory and visual experiences will often serve to motivate the child and contribute to motor learning. Home handling needs to include a variety of positions during each day for seating and play. Consistency in these practices is essential for the child with low tone to progress.

The process of undressing and dressing can be a dynamic part of the treatment program for any child (Figure 12-19).

Figure 12-19 ■ With assistance, this boy with right hemiplegia is helped to improve his self-esteem by exploring dressing.

Diagonal patterns of movement that are incorporated into the removal of socks and shoes assist in the organization of midline orientation. Weight shifts and changes in stability-mobility distribution occur throughout the dressing process. Concepts of direction and spatial orientation are applied to the relationship of body parts and clothing. Directional vocabulary terms and names of clothing and body parts are learned with this experience. A bench is useful because it permits the adult to sit behind the child who is just beginning to participate actively. The older child with difficult balance reactions can use the bench in a straddle-sit alignment (Figure 12-20). Aside from the physical and perceptual benefits, this achievement of dressing independently is one that offers the child a feeling of pride and independence. It is also a very practical preparation for the future when it is introduced in keeping with individual developmental and emotional needs (Figure 12-21).

Figure 12-20 ■ Straddle-sitting on a bench gives this diplegic boy postural stability while he concentrates on the buttoning process.

Figure 12-21 ■ Organization of clothing within reach is essential for success in independent dressing.

RESEARCH

Pediatric clinicians are faced with selecting treatments that are efficacious for children with cerebral palsy. Increasing pressure on clinicians to establish that treatments are effective in improving functional abilities is often dictated by third-party payers. In the past there was little research on pediatric treatment approaches and protocols that withstood the rigors of scientific investigation. Today, several methods that warrant mentioning are beginning to undergo systematic investigation.

Constraint-induced movement therapy (CIMT) was developed from basic science experiments on deafferented monkeys to overcome learned nonuse of the upper extremity.^{78,79} This forced use approach was adapted for adult patients after a stroke; the affected upper extremity is forced to participate in activities and the less involved upper extremity is constrained. Practice is intense, with 6 hours of mass practice for a 2-week period.⁸⁰⁻⁸² This protocol has been quite successful, with significant improvement in upper extremity movement and use of the affected limb. CIMT is very popular and is now beginning to appear in the clinical setting. The pediatric client has also demonstrated a favorable response to this treatment protocol in several single-case studies.⁸³⁻⁸⁷ In a clinical randomized trial by Taub and colleagues,⁸⁸ children with hemiplegia or brain injury receiving CIMT for 21 consecutive days, 6 hours a day, demonstrated significant improvement in the amount of use, quality of movement, and spontaneous use of the affected upper extremity. These results were sustained at 6-month follow-up. Several studies from around the world are beginning to show up in the literature with varied methods. Most of these studies are promising; however, further investigation is necessary to establish the critical threshold, adequate dosage, and selection process for subjects who will benefit the most.⁸⁹⁻⁹³ Clinicians are beginning to adapt these studies to their therapeutic settings and modify the protocols for clinical use and reimbursement potential.

Treadmill training has also been used in children with cerebral palsy.⁹⁴⁻¹⁰¹ The treadmill has been instrumental in rehabilitation for many years with a variety of purposes. This treatment began with animal studies on spinalized cats and rats and their responses to training on a treadmill in the recovery of a walking pattern.¹⁰²⁻¹⁰⁵ Today this treatment is used in many populations, including those with spinal cord injury, traumatic brain injury, Parkinson disease, stroke, and cerebral palsy.¹⁰⁶ The use of the treadmill in children with cerebral palsy has shown promising results: improvement in gait pattern, increased walking speed, decreased coactivation in lower extremity musculature, overall gross motor skill improvement, and improved and stabilized energy expenditure.⁹⁴⁻¹⁰¹ Treadmill training interventions have taken on many different faces, including use of a regular treadmill, commercial equipment, and high-tech body-weight support systems (Figures 12-22 and 12-23). Commercial equipment is now available to assist with supporting the body weight of individuals who otherwise would not be candidates for such a treatment. Clinical adaptations have also been incorporated to accommodate smaller bodies on a treadmill, which allows the therapist to assist from behind or from the side. Setting goals for this treatment must be precise, with an understanding of the purpose intended for its use: improving endurance, changing the parameters of the gait pattern, strengthening, and gait training. Each goal must be based on a sound theoretical foundation, which is now available from the literature.

Figure 12-22 ■ This young girl is practicing walking on the treadmill without holding on and incorporating arm swing to improve her stride length.

Strength training was never thought possible in the presence of spasticity in children with cerebral palsy. Several studies have now shown that strength can improve in children with spastic cerebral palsy.¹⁰⁷⁻¹¹⁰ Circuit training was used in an afterschool training program for 4 weeks, two times a week for 1 hour of intense group training, resulting in improved strength and functional performance.¹⁰⁷ Strength was maintained in this group of individuals at an 8-week follow-up posttest. Dodd and colleagues¹⁰⁸ set up a home-based lower extremity strengthening program in a randomized clinical trial with 21 individuals with cerebral palsy. All subjects in the treatment group had improved lower extremity strength that was maintained at follow-up periods of 6 and 12 weeks. In a study focused on biofeedback and strength training to improve dorsiflexion and range of motion, Toner and co-workers¹¹⁰ demonstrated significant changes in active range of motion and dorsiflexion strength.¹¹⁰ Strength training in the presence of spasticity is also documented in adults as beneficial not only for conditioning, improved range of motion, and psychological well-being, but in some cases reduction of spasticity.¹¹¹⁻¹¹⁴ Strength training in children and adolescents with cerebral palsy has continued with investigations into the intensity, type of contractions to practice, and dosage.^{115,116} Interestingly, a systematic review of common physical therapy interventions in school-aged children found that strength training demonstrated significant improvements in selected muscle groups but no meaningful change in function. Martin and

Figure 12-23 ■ This young girl, who is an independent ambulator with a rollator walker, is participating in partial body weight-supported locomotor training to improve her gait pattern.

colleagues¹¹⁷ and Moreau and colleagues¹¹⁸ studied muscle architecture as a predictor of maximum strength and its relationship to activity levels in cerebral palsy.¹¹⁸ They found that ultrasound measures of the vastus lateralis muscle thickness adjusted for age and the GMFCS level were correlated and predictive of maximum torque in children with and without cerebral palsy. A variety of methods for strength training can be incorporated into a clinical treatment setting or home exercise program with anticipated improvement in muscle strength, which may also result in improved functional status for children with cerebral palsy. Strength training encompasses free weights, aerobic workouts, stretch bands or tubing, and machines that address resistive exercise (Figure 12-24).

Many adjuvant therapies that are popular in combination with other treatments are available to individuals with cerebral palsy. Electrical stimulation (ES) has been used in a variety of ways with children with cerebral palsy. In several case reports by Carmick,¹¹⁹⁻¹²¹ neuromuscular ES used in conjunction with task-oriented practice was found to improve sensory awareness, strength, gait parameters, and passive and active range of motion. Neuromuscular ES was used as an adjunct therapy with upper and lower extremity practice protocols.¹¹⁹⁻¹²² ES has been used in conjunction with 6 weeks of intensive therapy to improve sitting posture and trunk control for children with spastic cerebral palsy.

Figure 12-24 ■ Using free weights to strengthen the upper extremities while stabilizing the trunk while seated on an incline bolster.

Radiographic studies confirmed the statistical significance in decreasing the kyphotic angle of the spine and sitting score on the GMFM.¹²³ Two recent studies documented an improved gait pattern and reduced spasticity in 27 children with spastic diplegic cerebral palsy after use of transcutaneous electrical nerve stimulation on selected lower extremity musculature for 15 minutes, three times a day, for 1 week.^{124,125} Neuromuscular ES was used successfully in combination with dynamic splinting to improve upper extremity range of motion at the elbow and wrist in 6 children with cerebral palsy.¹²⁶ ES has been in the therapy arena for many years, and its selective use with children who have cerebral palsy may supplement regular therapy sessions with enhanced results. (Therapeutic subthreshold ES at meridian points is discussed in the section on electroacupuncture treatments and in Chapter 39.)

Botulinum toxin A (BtxA) has been used to assist in decreasing spasticity because it provides a permissive condition that improves and increases range of motion and practice of new motor patterns without interference from increased muscle tone. Gait velocity, stride length, range of motion, and decreased spasticity were noted to be significant in 33 subjects with cerebral palsy after local injections of BtxA.¹²⁷ Several studies have shown a decrease in spasticity, successful treatment of foot deformities, and improved gait parameters with BtxA.¹²⁸⁻¹³¹ In a study by Galli and colleagues,¹³² dynamic dorsiflexion improved during stance and swing phases of gait, with significant improvement in foot placement at initial contact. BtxA has been used with varying results as an adjunct treatment for the management of upper extremity spasticity.¹³³ Lukban and colleagues¹³⁴ reviewed six randomized clinical trials with a total of 115 children receiving BtxA in the upper extremities. Five of the six trials demonstrated a reduction in spasticity that was time limited, and four of the six trials documented improved hand function. Four systematic reviews concluded that there simply was not enough evidence to support or refute the effectiveness of BtxA for upper extremity use. It allows for the reduction of muscle tone and opens a window of practice opportunity, in combination with other

treatments, to learn new movement possibilities. BtxA has a temporary effect, so the critical element is its combination with other treatment modalities. Park demonstrated improved range of motion and decreased spasticity in ambulatory children with cerebral palsy when BtxA was used in combination with serial casting.¹³⁵ It has also been used as an alternative to control the progression of hip dislocation and hip pain in children with cerebral palsy.¹³⁶

Joint and trunk taping and strapping have been used to provide sensory input and alignment for posture, balance, and strengthening. To date, there is no evidence that these adjunctive treatments actually provide these benefits, but there is also no evidence that they do not. Further objective investigation will be necessary to address the issues presented by these additives to therapy. Both are considered noninvasive with few side effects other than those associated with adhesive allergy to tape and autonomic nervous system responses such as sweating and overheating. Several different types of tape (athletic, Leukotape P Patella Tape [Notoden, The Netherlands]; Kinesio Tape [Kinesio USA Corporation]) and strapping devices are available commercially.

Soft tissue mobilization is a method of stretching tight structures that have become restricted from overuse, spasticity, deformities, muscle shortening, surgeries, trauma, and poor nutrition. This type of stretching has strong roots in osteopathic medicine but is not limited to that area of expertise. Over the years, research investigating the cellular and tissue changes that occur with immobilization has revealed some interesting and shocking alterations in the muscle and collagen fibers. With immobilization, slow muscle fibers show greater atrophy than fast fibers do.⁵⁹ There is atrophy, a decrease in peak torque, an increase in fatigue resistance, loss of strength, and reduced central activation when the plantar flexors of the ankle are immobilized.^{137,138} In a recent study of children with severe spasticity, muscle biopsies were performed on the vastus lateralis to determine collagen accumulation in the spastic muscle. An increased accumulation of collagen I fibers in the endomysium of the muscle was noted, with thickening and decreased muscle fiber content in the more severe cases.¹³⁹ This study, in combination with what we understand about healthy muscle, reinforces the need to keep the muscles flexible and active to help prevent this accumulation of collagen. Soft tissue mobilization and deep tissue stretching are methods that can improve the ability of the tissue to lengthen and fold, allowing for a more efficient activation of the muscle fibers, thus optimizing the formation of typical synergies during practice of motor skills.

As mentioned earlier, children with cerebral palsy often have visual difficulties that are not acuity problems and that are not correctable with a standard lens. Vision therapy has demonstrated good results when emphasis is placed on ocular motility and accommodation.¹⁴⁰ When children were given intense visuo-oculomotor training, improvement was noted in visuo-oculomotor control.¹⁴¹ Improvement in the child's ability to execute smooth pursuit precision and maximum velocity, improvement of saccadic movement precision and stability, and shortening of the saccadic reaction time were significant after training.¹⁴¹ Although many clinicians are not experts in the area of vision, vision is an important part of every therapy session. Incorporating vision as an integral part of a therapy session will not only improve the child's

orientation in space but will address his or her ability to scan the environment while learning to move through space.

Many therapies become popular by purporting to be a “fix” for a particular problem associated with cerebral palsy. The clinician accepts responsibility for making sound judgments concerning treatment and outcomes for children with cerebral palsy. Not all the treatments used in therapy will be investigated rigorously in a scientific manner. However, when a treatment approach is presented as advantageous for many diagnoses and conditions, with claims of success beyond what is reasonable for those conditions, it is your duty to proceed with caution. Always stop and think what theory and frame of reference the approach will fit best. Does this “new” therapy make sense with the knowledge you have of anatomy, physiology, neurology, and motor learning? As clinicians we will always be tempted to try new approaches before the scientific community has investigated them thoroughly. Clinicians, because they are creative and innovative, have advanced our professions. It is essential to advance patient care with treatments that are safe and do no harm. Every environment affords research opportunities that contribute to the treatment of children with cerebral palsy. Single-case reports and single-case studies are the beginning of this process and, although descriptive in nature and with limited generalization, provide evidence for new therapeutic approaches and further systematic investigation.

MEDICAL INFLUENCES ON TREATMENT

Because the problems of cerebral palsy are so varied, the condition lends itself to diverse interventions, some of which have a longer life than others. Management of spasticity has always been an area of great concern and interest, and over the years several treatments have been offered to control this positive sign. Various medications have been used to control spasticity; baclofen, diazepam, and dantrolene remain the three most commonly used pharmacological agents in the treatment of spastic hypertonia.¹⁴² (See Chapter 36 for additional information.) The baclofen pump has been used in children with excessive spasticity. This pump is implanted in the lower abdomen with a catheter leading to the intrathecal space for the administration of the drug. This treatment for spasticity has been effective for some types of cerebral palsy but led to complications in some patients with mixed cerebral palsy, low body weight, younger age, gastrostomy tubes, and nonambulatory status.¹⁴³⁻¹⁴⁵

The cerebellar implant so popular in the late 1970s offered the possibility of regulating tone by supplementing cerebellar inhibition.¹⁴⁶⁻¹⁴⁹ As time passed, the procedure was used less often, and patients had difficulty getting repairs or replacement parts for the implant. The procedure that largely replaced the cerebellar implant was the placement of four electrodes in the cervical area to offer more control over postural tone.¹⁵⁰ These had the advantage of being adjustable so that the individual or a family member could make daily choices as to the optimal tone distribution. In some cases early success gave way to disappointment as the system adapted to the inputs. In some cases the child or adolescent had to make a decision whether movement or speech was more important on a given day. Therapy was always recommended after the procedure, although the nature of the specific program was left to the family to decide. The success of the cerebellar stimulator is consid-

ered moderate when used on a select group of individuals with cerebral palsy.¹⁴⁶⁻¹⁴⁹ Other, more recent spasticity management programs are less invasive and are often considered before use of this invasive procedure.

In 1968 a posterior rhizotomy surgical intervention was developed, with some success reported in reducing spasticity.^{151,152} It remained for Peacock and Arens¹⁵³ to apply the procedure more selectively and functionally and to bring it to the United States from South Africa. On the basis of their experience, Peacock and colleagues insisted on daily neurodevelopmental (Bobath) treatment for at least 1 year after the surgical intervention. Electromyographic testing before and during the surgery is used to determine which posterior nerve rootlets are creating the spasticity in the lower extremities.¹⁵⁴ The foundations for success are accurate selection of the child, an experienced surgeon, and careful analysis of therapy goals.

A more recent improvement in the selective dorsal rhizotomy (SDR) procedure was developed by Lazareff and colleagues,¹⁵⁵ who enter a limited number of levels rather than five levels of the spinal column and prefer to work close to the cauda equina, according to the technique of Fasano.¹⁵⁶ Several studies have documented improvement in function and strength and reduction of spasticity outcomes as far out as 3 to 5 years.^{151,157} In a more recent longitudinal study by Nordmark and co-workers,¹⁵⁸ it was found that SDR was safe and effective in reducing spasticity without major complications. When combined with physical therapy and careful selection of candidates for the procedure, the functional outcomes over a period of 5 years were lasting. Trost and colleagues¹⁵⁹ reported on differences between preoperative and postoperative measures: the Ashworth scale for spasticity, the Gillette Gait Index, oxygen cost for gait efficiency, and the Gillette Functional Assessment Questionnaire for functional mobility. All outcome measures demonstrated improvement for the 136 subjects as a whole. Careful selection of the appropriate candidate for this surgery followed by intense therapy intervention is essential for the success of the procedure and for optimizing motor outcomes.

A new approach to controlling spasticity is percutaneous radiofrequency lesions of dorsal root ganglion (RF-DRG), a noninvasive procedure that has been reported in the literature recently. Vles and colleagues¹⁶⁰ performed a pilot study of 17 patients with a diagnosis of cerebral palsy. They reported that this new treatment is promising for reducing spasticity and improving function in children with cerebral palsy. Further investigation into this treatment is necessary to assess its effectiveness.

Alcohol (phenol) blocks and the use of botoxin (botulinum toxin) (BtxA) have been used locally to affect a change in the individual muscle or motor point injected.^{142,161-167} Both orthopedists and neurologists have taken an interest in the use of botoxin to block selected muscle responses for a temporary period. BtxA has been reported to have fewer side effects than the phenol blocks and is now considered the drug of choice for this type of procedure.¹³⁰ These conservative interventions serve to delay surgery until the child is more capable of responding to postsurgical therapy programs. Botulinum toxin injection combined with serial casting has been shown to improve range of motion, muscle tone, and dynamic spasticity in ambulatory children with cerebral palsy.¹³⁵ Therapists

should be involved in the decision-making process of determining interventions for reduction of spasticity because they often are the most familiar with the child's movement strategies and the postural changes that occur in muscle tone as the child moves against gravity.

Orthopedic surgical intervention continues to be effective in cerebral palsy when there are tendon contractures or specific structural limitations that are not accompanied by excessive levels of spasticity.^{168,169} In any surgery the outcome is much improved by close coordination between therapist and surgeon, with a functional orientation toward goal setting for the child. Early standing after surgery and use of dynamic footplates inside the casts and orthotics after cast removal will generally improve functional outcomes. Bony surgeries that offer better joint stability are usually planned for the termination of growth. The orthopedist is also able to guide conservative positioning measures to prevent hip problems resulting from spasticity while direct treatment intervention continues. Bracing of the trunk, which is sometimes warranted for scoliosis or kyphosis, is prescribed by the orthopedist. Surgical intervention for spinal deformities is determined by the physician, with consideration of the child's age, condition, and health and the degree of curvature.

Children with cerebral palsy differ in their ability to relax completely during sleep, and a small number of these children can benefit from inhibitive casting or night bracing. More often this type of positioning is used during therapy sessions and independent ambulation to combine control with weight bearing.¹⁷⁰ The orthopedist should participate in any plan for prolonged immobilization or temporary casting that will be used on a 24-hour schedule, such as serial casting to improve range of motion.^{171,172} A variety of lower-extremity bracing is available, and its selection is dependent on the segment to control and the outcomes sought in positioning or dynamic action, as in ambulation (Figure 12-25).

Figure 12-25 ■ A supportive shoe with footplates inside for this low-tone child facilitates more typical trunk reactions and permits use of the hands for play.

EQUIPMENT

Equipment recommendations must take into account the physical space in the home and the amount of direct treatment available to the child (Figure 12-26). Young children in particular can often use normal seating with slight adaptations. This not only is more socially and financially acceptable but also permits changes as required by the child's developmental progress. The portability of supportive seats or standers encourages the family to take the apparatus along for weekend outings or visits to relatives. Chair designs should place children at an age-appropriate level in their environments. This permits a better quality of visual exploration and facilitates social exchange with siblings and visiting peers. When planning the amount of physical support needed by the child, the therapist considers varying the structural control in relation to activity (Figure 12-27). The child who is merely watching the play of others or a television presentation may successfully control trunk and head balance independently with minimal support. However, concentration on hand skills or self-feeding may necessitate trunk control assistance via a chair insert to avoid the child's use of compensatory reactions. As postural reactions become more integrated and hence more automatic, support should be diminished. There are now several options available to the consumer on the internet. Families and therapists alike can search online for commercially available products and alternatives to commercially available products.

For the more severely disabled child, equipment should be easily and completely washable. Mothers should be able

Figure 12-26 ■ An upright stander is easily incorporated into the home environment, providing the child with an upright position, stimulation, and an opportunity to participate in activities.

Figure 12-27 ■ Use of a simple cut-out space in 3-inch foam gives this 1-year-old child security while requiring more active trunk adaptation during play.

to place special seating inserts into wheelchairs or travel chairs with one hand while holding the child. Wheelchairs should be ordered with consideration for family needs and the child's environment. The most costly does not always offer the best solution. Control straps and seating should be adaptable and allow for future change on the basis of growth and improved function. The severely limited child needs seating changes at least once every hour during the day to prevent pressure and provide environment changes as in typical development. Pleasing color, good-quality upholstery, and professional finishing are important not only for the child but also for family members, who are accepting the equipment as part of their personal living environment.

As prices rise and the applicability of insurance changes, the therapist must consider cost-effectiveness more carefully. Parents are often desperate to do everything possible for the child and tend to be very susceptible to high-powered advertising and reassuring sales personnel. By providing a list of essential equipment features, the therapist will aid the parents in becoming informed consumers. Perusal of several catalogs permits some comparison of quality and prices. Adaptive equipment fairs are often open to parents and therapists and are great opportunities to actually try the equipment without the burden of the cost. Therapists can forge a relationship with a representative of a medical supply company and then access equipment on loan to try with their patients for short periods of time. Once the appropriate equipment has been purchased, periodic review of equipment used by the child can serve to encourage the family to pass along to someone else equipment items that are no longer needed. Investment in expensive equipment also has the hidden effect of influencing both parent and therapist to continue its use well beyond its effectiveness as a dynamic supplement to treatment. For this reason more than any other, large investments must be thoroughly researched with regard to their long-term applicability for the child.

Adaptive equipment is not the only type of equipment that the therapist must consider for clients. Conditioning and strengthening, now recognized as beneficial to children and adults with cerebral palsy, open the door for equipment that lends itself to these parameters.¹⁰⁷⁻¹¹⁴ Exercise bikes, treadmills (see Figure 12-22), light weights (see Figure 12-24), and balance equipment (Figure 12-28) are all valuable

Figure 12-28 ■ Balance equipment allows for increased complexity in the therapy program with the refinement of balance reactions.

adjuncts to a home exercise program and should be considered, when appropriate, for a particular individual. Many of the commercially available items found at a sporting goods store can be well adapted to fit the needs of the higher functioning person with cerebral palsy. With more emphasis on working out, sports equipment can even be found in discount stores. Offering to adapt equipment for your clients can encourage and increase compliance with exercises given for home exercise programs.

ALTERNATIVE THERAPIES

Hyperbaric oxygen treatment is gaining popularity as a treatment for cerebral palsy in children. Clinics are beginning to spring up worldwide for this type of therapy. Research on this treatment has been inconclusive, and scientific evidence for its efficacy is lacking.^{173,174} Clinicians should keep abreast of the latest developments in the treatment of cerebral palsy and inform families about the pros and cons of designer treatments. Currently the Undersea and Hyperbaric Medicine Society (UHM) states that there is not enough evidence to recommend the use of hyperbaric oxygen therapy for cerebral palsy.^{175,176} A systematic review by McDonagh and colleagues¹⁷⁷ found that there was no significant difference between pressurized air versus room air pressure and that the subjects in both groups made gains. This topic remains controversial even within the UHM. Several articles and editorials have been written with the overwhelming conclusion that randomized clinical trials should be carried out to determine the effectiveness of this treatment.

The Adeli suit is a compression garment with bungee cord–like elastic cords attached to the suit, along the trunk and extremities. This suit, once referred to as the *therapeutic space suit* or *treatment-loading suit*, was developed for Russian cosmonauts to counteract the adverse effect of long-term zero gravity on the skeletal muscles.¹⁷⁸ There are a few studies that suggest that there are benefits for children with cerebral palsy when they receive therapy in the suit.^{175,178-181} The suit allows for controlled practice of activities with resistance, and assistance when necessary; the cords are attached in a variety of ways to give different types of practice repetitions. As is prescribed by the proponents of this approach, intense practice is warranted to reap the benefits. This therapy is expensive, and the suit, if bought to use at home, is also very expensive. Rosenbaum¹⁷⁵ has suggested that the benefits of this therapy vary with the type and severity of the involvement, the child's ability to participate in controlled movement, and the tolerance to wearing the suit for extended periods of time. In Australia the Upsuit, described by Blair et al as being made of a stretchy material, has been investigated for use with children with cerebral palsy.¹⁸² Similar results have been noted by Chauvel et al that the type of cerebral palsy and the person's ability to participate in movement forecast the potential outcomes.¹⁸³ The Upsuit was also noted to compromise lung capacity, which interfered with the child's ability to participate.¹⁸² As clinicians, it is important for us to stay abreast of the latest developments and to provide families with reasonable alternatives. Although intense practice is well known in the literature as being beneficial for motor learning, the addition of the suit brings in a component that "appears" to provide stability and graded control during practice. Caution when describing this approach to families is warranted because some evidence suggests that it may not be appropriate for every child with cerebral palsy. The long-term effects and measurable outcomes after the use of the Adeli suit and the Upsuit are not documented in the literature.^{175,184,185} The following questions must be asked: What happens to the motor abilities of the child when the suit is removed? Has the suit actually prevented the development of postural antigravity coactivation of the trunk and proximal axial joints?

In the mid-1980s Pape¹⁸⁶ published a case series involving five children with cerebral palsy receiving therapeutic (subthreshold) ES. Reported from this case series was that overnight use of low-intensity ES in combination with standard therapy demonstrated significant improvement in gross motor, balance, and locomotor skills as measured by the Peabody Developmental Motor Scales in children with mild cerebral palsy.¹⁸⁶ Results reported were based on observations by individuals who were not blinded to the purpose of the study, and therefore the research design was biased. In a follow-up study Steinbok and colleagues¹⁸⁷ followed children who had undergone selected dorsal rhizotomy and received therapeutic ES for 1 year. Although this study reported improvement in gross motor function, no other measures were changed: range of motion, spasticity, or strength. Two well-controlled clinical trials investigating this method of threshold electrical stimulation (TES) delivery concluded that no objective effects on motor or ambulatory function or clinical benefit for children and youths with cerebral palsy were detected.^{188,189} In two separate randomized placebo-controlled clinical trials using TES, the results indicated no significant clinical benefit observed when compared with neuromuscular ES.^{188,190} (Refer to Chapter 9 for additional discussion.) Parents often report changes with this therapy, but the objective measures do not demonstrate significant results. Clinicians in the field have reported that overnight use of subthreshold ES builds muscle bulk, but unless combined with active participation of the musculature, overall improvement in movement may not be seen. This therapy, for children with cerebral palsy, requires a special stimulation unit that is subthreshold and capable of being used at night and has a shutoff setting that is activated if the electrodes become disconnected from the child. The unit is costly and further requires a clinician who is specially trained in its use to evaluate and periodically update the treatment protocol. Significant benefits for this type of ES have not been documented.

The Peto method or "conductive education" (CE), developed by Andres Peto in Budapest after World War II, has been used in children with disabilities.¹⁹¹ This approach is an educational versus medical model, as the name implies, and the focus is on the many aspects of child development.¹⁹² It is based on practice and repetition combined with verbal guidance of a trainer (conductor) and self-verbalization by the child as he or she performs the task or activity.¹⁷⁵ Most of the claims that promote its value have come from the Peto Institute in Budapest, Hungary. The institute has been very selective in choosing candidates for this approach on the basis of the child's potential for independent mobility and function with a good overall prognosis.^{175,191,193} Research into this method of delivery of services to children with cerebral palsy has been sparse outside the Peto Institute's studies. In two studies in Australia, CE was found to have encouraging results in developmental changes.^{194,195} In a randomized controlled study with children assigned to a CE group or a neurodevelopmental intervention group, no significant differences were noted in the two groups.¹⁹⁸ This approach advocates intense practice of all skills, motor and educational, with emphasis on self-doing regardless of whether a compensatory pattern is used. Various pieces of equipment are used to facilitate independent skills: wooden slatted beds to allow the child to pull and maneuver, and

wooden ladders mounted on the wall to assist with dressing and transitions. The literature on CE does stress the concept of intense practice for motor learning. Similarly, promoting practice in the CE environment must transfer to home and community for carryover to everyday life situations.⁶³ To fully optimize the outcomes of CE, a commitment from the family is essential, as is the case in most therapeutic approaches. Further investigation into this approach is warranted before this philosophy is fully supported. For a selected group of individuals, CE research results seem hopeful, although transfer to unpracticed tasks and different environments may be minimal.¹⁹⁷⁻¹⁹⁹

The Feldenkrais method was developed by an Israeli engineer, Moshe Feldenkrais, while looking for a solution to his own knee problem. (Refer to Chapter 39 for additional discussion.) He started analyzing body alignment for more efficient movement.^{200,201} This form of body work has been used to help dancers, gymnasts, and other skilled persons improve their performance. Some therapists have undertaken the long training necessary to understand typical movement in more detail and to improve the movement coordination of their clients with neuromotor challenges. There is no published research on this method, but several books and training courses exist that promote its use. In a review article by Liptak¹⁸⁴ on alternative interventions, the Feldenkrais method is described; however, no articles have been published examining its use with children who have cerebral palsy.

Ida Rolf, trained in physics, had a son with some postural disorganization.²⁰² She developed a structural approach, called the Rolfing technique, to improve body alignment; the technique uses specific release of deep soft tissue to restore effortless postural control against gravity.²⁰³ She was able to make positive changes in the movement patterns of many children with cerebral palsy, but she never claimed to treat the disorder itself. This approach requires special training in the Rolfing technique, which is a type of deep tissue massage.

Dr. William Sutherland,²⁰⁴ an osteopathic physician, developed direct treatment of the cranium, which is referred to commercially as *cranial therapy* or *cranial sacral treatment*. (Refer to Chapter 39 for additional information.) This type of therapy is believed to have wide application to many disabilities and conditions.²⁰⁵ Today, there are persons trained at many different levels, so the family of a child with cerebral palsy seeking this treatment will need to be certain that the practitioner is a professional and that she or he has experience with small children.²⁰⁶ Cranial treatment is purported to restore the physiological motion of the craniosacral system, improving circulation of fluids to the brain as well as respiratory function, to which it is believed to be closely linked. Research has been encouraged in this area to substantiate the claims of this approach.

DEVELOPING A PERSONAL PHILOSOPHY OF TREATMENT

The practicing therapist continues to learn much about the nuances of typical human development (see Chapter 3).²⁰⁷ The dynamic interaction of developmental movement components becomes more significant as the therapist acquires greater clinical experience and recognizes developmental change as a reflection of central nervous system maturation. Increasing knowledge of the functional nature of sensory

systems and central nervous system processing will influence the choice of treatment techniques. Direct intervention will have more depth and specificity to improve the child's control of posture and movement while the therapist appreciates the complex interaction of developmental factors in cerebral palsy. On the basis of individual experience, each therapist develops a personal philosophy of treatment that incorporates new research findings and evolving perceptions of the problem of central nervous system dysfunction. Without a philosophical or theoretical orientation for decision making, the therapist may succumb to following each promising treatment idea that is learned without having a clear image of the potential benefits for the specific client. "Commercial" programs may benefit the child whose needs match the program objectives. An "individualized" program adapts to the needs of the particular child and is shaped by the response of that child during therapy. Without an internalized treatment goal toward which independent techniques are applied, the result may remain ineffective and unconvincing. The therapist in a direct treatment situation must develop a concise visualization of what is to be achieved in each session with the individual child based on a sound foundation. The repetition and practice that are so critical for learning must often be carried out at home, and the therapist becomes responsible for family instruction. Home exercise programs must be tailored for both the child and the family situation and must be in alignment with the goals and expectations of the family. These programs need to be practical, fun ideas for practice that can be incorporated into the child's home life with reasonable assurance that the activities can and will be carried out regularly. Creative therapeutic ideas for playtime, dressing, grooming, mealtime, and relaxation time are best addressed in the home exercise program because these are everyday tasks that every family encounters and the family is likely to be compliant.²⁰⁸ The time spent in therapy throughout the week cannot substitute for all the hours spent at home and school.

Specialized therapy, like typical development, is potentially a preparation for functional performance. Training in specific coordination skills may be necessary for the older child or adolescent and must begin with a thorough analysis of the whole person who happens to demonstrate the effects of cerebral palsy. Some children have learned self-care along with brothers and sisters. Others have needed therapy guidance for each achievement. Intelligent children with strong motivation may only need some assistance in avoiding use of atypical reactions, whereas others have poor spatial orientation and minimal motivation to achieve independence. The therapist most often needs to create a dialog with the individual who has the problem because parents are often fatigued and without energy to solve the issue of adolescent life skills. Perseverance is key to success with these individuals.

INVOLVING THE FAMILY

To be successful, therapy for the child with cerebral palsy includes active family participation. Variability of practice in different environments tends to promote more effective motor learning, and parents who learn to help their child early begin to understand the importance of their participation as well as the nature of their child's disability. Parents are in the process of healing their own self-image, which was so injured when they learned of their child's disability. They should not be expected to become therapists per se but should learn to

observe small gains in treatment sessions that offer insight into the child's current strengths and weaknesses.¹⁷

Parents need to adapt their expectations in keeping with the child's continuing change and emotional maturity. Parenting a child with cerebral palsy is no easy task, and the therapist will do well to develop respect for this demanding role. No one provides more for the child with cerebral palsy than the nurturing parent who guides the child to self-acceptance of limitations without destroying personal initiative. This is the child who most often becomes an independent working adult (Figure 12-29).

The therapist must give serious thought to priorities in home recommendations. Therapists must consider the size of the family and whether there are siblings, outside employment of the mother and father, physical capabilities of the child, general health status of the child, and psychological acceptance of the problem within the family. The emotional needs of some parents demand a period of less, rather than more, direct involvement with the child. Other parents must be cautioned that repetition of an activity more times than recommended will not result in faster improvement. This impression is sometimes gained from wide advertising of commercial programs that offer the same activity sequence for every child and demand a large number of daily repetitions. Both parent and therapist must appreciate the need for the central nervous system to have some time to integrate new sensorimotor experiences and to perfect emerging control of postural adjustments. Excessive control of movement patterns and overprotection by an adult tends to reduce the child's initiation of postural change and decrease active sensorimotor learning. Health needs for good nutrition and adequate rest must also be considered by parents and professionals. The attitude of teachers in the first years is extremely important for the child with cerebral palsy. Advocating for a positive environment across the settings is advantageous for the child's achievement.

ROLE OF THE THERAPIST IN INDIRECT INTERVENTION

For many children with cerebral palsy, active treatment is not available. Geographical isolation, socioeconomic

Figure 12-29 ■ Therapy goals must incorporate functional activities that lead to personal independence if they are to be pertinent for the older child and adolescent.

factors, poor or lack of insurance coverage, and lack of qualified therapists may interfere with the delivery of direct service. The therapist must then assume the role of teacher, counselor, or consultant. More often the new role emerges as one in which the therapist tries to meet a combination of needs and is frequently frustrated by lack of time, energy, and community resources. The therapist may be a member of a community team that includes a psychologist, a social worker, and a public health nurse. This sometimes creates more of a behavioral than a traditional medical orientation. Therapists can also be primarily responsible to the public school systems, introducing therapeutic positioning to classroom teachers. For these types of situations the clinician will find videotape a valuable adjunct to direct instruction. The individual child may be filmed with equipment, adequate positions, or therapeutic procedures. Useful topic-oriented videotapes are also available for professionals and families. Instruction of key personnel in these settings is critical to the success of the therapist's recommendations.

When children have no access to direct treatment, positioning is of paramount importance. The selected support is used to avoid contractures, scoliosis, and permanent limitations in range of movement. Even the most severely limited child should have a minimum of three positions that can be alternated during the day. In addition, the position selected should be as functional as possible for the individual child to allow access to the child's environment. In some cases this may mean encouraging eye contact. For another child, hand use becomes a possibility with proper trunk support. Each program should be individualized to maximize potential for the child in that environment.

Communication for the nonverbal client with cerebral palsy must be an integral part of the therapy or school program.²⁰⁹ A simple start may be made with pictures to permit choices in food, clothing, and therapy activities. The parents need encouragement to begin the process of letting the child make some simple choices in food, clothing, or preferred activities. Although computers have their place, the child should have the communication device with him or her at all times. Language development in the young child is enhanced by having this type of alternative communication device available while articulation is still difficult. Use of head movement is a powerful influence on muscle tone changes that may cause negative regression in postural or visual control. Care and consideration should be taken when evaluating the body part to access the device. Postural and visual control is essential toward the goal of better function and communication. A solution that was successful with one 9-year-old athetoid girl was moving the elbow back to a switch mounted on the vertical bar of the wheelchair backrest to access her communication device. Any activity that is repeated on a daily basis should be examined in light of possible interference by atypical patterns.

Affordable electronic systems with voice recording, portability, and growth features are available. Communication, which can be achieved by coordinating efforts with the speech pathologist, can make the difference between passivity and active participation in the environment.²⁰⁹ Play can be encouraged with the use of switch toys and touch-screen computers. Many new programs are being developed for computers and electronic interactive books.

THERAPY IN THE COMMUNITY

Therapists are often concerned with body functions and structure and neglect to address participation in real-life activities such as school attendance, sports, employment, and involvement in the community.²¹⁰ Children with mild dysfunction as a result of cerebral palsy may be successfully incorporated into physical education (PE) classes if the teacher is prepared to make some small adaptations. Teachers generally appreciate the opportunity to discuss with the therapist specific limitations of the child and those movements that should be encouraged. Taking the opportunity to meet with the PE coach to establish adaptations and modifications or appropriate participation in activities is time well spent for the child's integration into the class. PE class is often rewarding for the child and important in establishing peer relationships. For better success the child with functional limitations can be incorporated into a class that follows the British form of movement education, which places much less emphasis on intragroup competition and encourages each child to progress at her or his own rate.

Classroom teachers who lack experience with children who have special needs are understandably reluctant to incorporate a child with movement limitations into the classroom until they know the child. A meeting with the therapist might be used to help the child demonstrate his or her strengths, physical independence, and ability to participate in classroom activities. The child may often play an active role in the problem-solving process necessary for a successful classroom experience. Children often have developed their own ways of managing the water fountain, the locker door, or personal care needs. Demonstrating these abilities reinforces strengths rather than limitations and empowers the child to receive positive responses from curious peers.

As programs that hire therapists move into the fields of prevention and early intervention, the therapist is dealing directly with a population that is not familiar with therapy per se nor aware of the need for this intervention. The therapist may discover a need to reorient previously accepted concepts of general rehabilitation. Clarification of one's own ideas is essential to establish effective communication with others. In some instances, active intervention to help the child will precede the labeling or diagnostic process, and referral to other specialists becomes part of the therapist's responsibility. Philosophically, early therapy becomes an enhancement of typical development rather than a remedial process, and it is advocated in the natural environment by federal funding agencies for children 0 to 3 years of age. This implies introducing new concepts of quality in early child development to the public. Day care programs are an example of new early childhood settings that incorporate children with impairments.

It is important to keep direct, active treatment available for older children, adolescents, and adults who are motivated to change. Now that more effective procedures are available for changing some of the basic neurophysiological movement characteristics observed in children with cerebral palsy, it is possible to achieve change with direct treatment of the older client. The adolescent often responds best to short-term, goal-oriented therapy programs that are patient centered. Motor learning concepts are better understood by both the therapist and the client and can be incorporated in

activities after mobilizing tissues that have been unused for so many years (see Chapters 4 and 9). With current program directions, many older clients may not have had the opportunity for direct treatment over time by a qualified therapist. For the minimally involved teenager, young adult, and adult with cerebral palsy the local gym offers an alternative to direct therapy. General conditioning is very popular in community programs including weight training, endurance training, water exercises, yoga, and walking programs. A therapist can be consulted to establish an appropriate program for the individual who wants to work out at the gym on equipment, attend special classes that are offered, or work out in the pool. When asked, it is the therapist's area of expertise to help identify and make recommendations regarding functional movement and activity participation for adults with developmental disabilities such as cerebral palsy. (See the section in Chapter 35 on adults with developmental disabilities.) The movement toward a health orientation as opposed to crisis intervention for illness will also affect services for children and adults with cerebral palsy. This population does not have an illness or an active disease process, and they strive to lead as normal a life as possible. Many adults with neuromotor disabilities express their preference to participate in the decisions that are made for them regarding their ultimate lifestyle and participation in the community. The therapist who works with this population should familiarize himself or herself with the patient's living situation—family home, group home, or independent living—as well as the support system and work environment if applicable. These factors should be considered when establishing a viable program. Many opportunities for employment and volunteerism exist in communities for individuals with disabilities. This may require that the therapist venture into the workplace to assess accessibility and modifications that can be done in that environment to make for successful integration of the individual into the community. Optimal health for the adult with cerebral palsy has yet to be described, and much more data must be collected. However, it is an exciting time as our society moves forward in its views and acknowledgment of disability (see Chapter 35).

PSYCHOSOCIAL FACTORS IN CEREBRAL PALSY

We have defined cerebral palsy as a condition existing from the time of birth or infancy. The developing child has no memory of life in a different body. Movement limitations circumscribe the horizon of the child's world unless the family is able to provide enriching experiences. The development of both intelligence and personality relies heavily on developmental experiences and the opportunity for self-expression.

The child with spastic diplegia or spastic quadriplegia may be hesitant in making decisions or reaching out for a new opportunity because the world may seem overwhelming and threatening. The child may find it easier to withdraw toward social isolation. Parents and professionals can help children, adolescents, and adults with cerebral palsy avoid these reactions by encouraging independence in thought and in physical tasks. Early choices can be made by the child regarding which clothes to wear or which task to do first. Understanding the child's limitations helps build successes rather than failures. To function in spite of the constraints of

spasticity or other movement problems demands considerable effort on the part of the child.

Athetoid children, in contrast, have adapted to failures as a transient part of life. However disorganized their movements, they repeatedly attempt tasks and eventually succeed. Their social interactions reflect this life experience. Most people will sooner or later succumb to the positive smiling approach without analyzing the deeper communication offered by the child. These children are difficult for parents to discipline and structure during their early years. Early treatment with concomitant guidance for young parents ameliorates some of the problems by making the developmental expectations for the child more appropriate. The words of professionals who are in contact with the parents at the time of the diagnosis echo through time to influence future decision making for the child.

Intelligent children with low tone demand that the world be brought to them. Mentally limited children may fail to receive sufficient stimulation for optimal development at their functional levels. Many of these children need visual or auditory evaluations and intervention, and some of them need a special educational approach. Whatever the learning potential of the child with cerebral palsy, it is not always evident early in the child's life. Parents find it difficult to know how to guide a child when they are not certain that an assigned task or calm explanation is understood by the child.

Parental guidance of the child with functional limitations is also influenced by the adults' adaptation to their offspring's problem. Parents need to resolve in their own way the emotional impact of the child's disability. Parents need time to grieve the loss of dreams they had for their child, and each person will approach this in his or her own way and time. Each major milestone anticipated in a typical child's life may bring on the grieving process again. Most parents feel inadequate, ignorant, and relatively helpless at being unable to remedy the situation for their child. They need help in feeling good about themselves before they can effectively guide the child toward self-acceptance as an adequate human being. Parents need guidance to provide themselves with opportunities to rest and renew their energies. Therapists can be instrumental during this process by remaining nonjudgmental. (Refer to Chapter 6 for additional information.)

The therapist plays an important role in the psychosocial development of children who receive regular treatment. The child may perceive the therapist as a confidant, disciplinarian, counselor, or friend at various stages of development. Some children accept the therapist as a member of their extended family. This is natural, considering the extent to which therapists influence clients' own self-awareness through changes in their physical bodies. However, it also places a personal responsibility on the therapist to be aware of the continuing interaction and its effect on the maturational process of the child. Long-term relationships with patients and their families must remain professional for the therapist to be effective.

Any evaluation of personality characteristics in a disabled child must take into account the unnatural lifestyle that is imposed by the need for therapy, medical appointments, limited environmental exploration, and hospitalization. The child is expected to separate from parents earlier than the average child and usually confronts many more novel situations. There is little time or physical opportunity

for free play. Continuous demands are placed on children to prove their intellectual potential in evaluations of various types. Adults most often monitor their social interaction while they assume a dependent role. Nonetheless, these children's social acceptance frequently rests on their skill in interacting with persons in their environments. It is not fair to the child to evaluate the evolution of personality without considering these experiential factors.

DOCUMENTATION

Developing a plan of care (POC) with objective measurable goals is required for documentation of progress in intervention and reimbursement from third-party payers. (Refer to Chapter 10 for additional recommendations.) Carefully extracting a child's strengths and weaknesses from the assessment should drive the POC. Using timed measures, distance, number of repetitions, standardized tools, and other measurable outcomes provides a source of encouragement for families and justification for continued intervention.

Data collection is an important task in the treatment of cerebral palsy. Change occurs at variable rates, but it is important to document the cause and effect of change whenever possible. Slides or videotapes are useful in recording functional comparisons over time. Digital video now allows a specific analysis of movement sequences. A motor drive unit or automatic advance on a 35-mm single-lens reflex camera can record a sample of movement five or more times per second. Placing the subject against a spaced grid in a specific alignment to perform a movement task allows for measurement of efficiency of movement. These ideas may be applied to documentation of treatment effectiveness or analyzed for an understanding of similar movement problems in other clients. When attempting to document using photographs or filming, consistency in the environment is critical to the outcome and analysis. Reliable comparisons made between one time point and another require the same testing environment, time of day, and conditions.

Methods of intervention or treatment are measurable for research and applicable to the functional problems presented by a diagnosis of cerebral palsy. Once a specific research question has been formulated, systematic recordings of appropriate data can be gathered over time to accumulate data for a viable study. There is value in longitudinal reporting of a single case or a small group of individuals who have some characteristics in common because this aids our understanding of what we need to prevent in the young child to permit optimal function later. (See Chapters 8 and 10 for suggestions of impairment and disability measurements to be used as objective measures for functional outcome studies and record keeping.) Clinicians have a difficult time putting into words exactly what takes place during intervention, which further complicates research investigation into the efficacy of treatment. Descriptive analysis of treatment is essential to document and begin to understand what a therapist does during a therapy session. Understanding what takes place in therapy will help identify questions that could be investigated more closely.

The way in which therapists learn to view a problem determines, to a large extent, the potential range of solutions available to them. Cerebral palsy is a complex of motor and movement inabilities that cluster about the inadequacy of central nervous system control, visual and soft tissue

restrictions, and the amazing ability of the human body to compensate. Therapists need to look critically at developmental processes, qualities of movement, postural adjustments, timing and limitations of movements, and the range of dynamic functional movement. New areas of motor learning and systems and chaos theories offer the researcher novel approaches to the challenge of cerebral palsy and the resultant disorder of posture control and movement learning. Environmental factors may have as much influence as specific central nervous system limitations. Early intervention should be analytical, specific, and based on a theoretical foundation. Posture and movement control begins to change with direct treatment. Analysis of the postural components and movement characteristics of children with cerebral palsy will lead to meaningful research more quickly than will professional reliance on the traditional definitions of the medical condition. Thorough documentation of therapy progress using objective measures is critical for development of more effective intervention strategies in the future (see Chapter 10).

CASE STUDY 12-1

A young woman was pregnant with her first child. She was middle class, was well nourished, and had no identified risk factors. In the seventh month of pregnancy, her older sister died, causing considerable emotional upheaval. The much-anticipated infant was born, small for gestational age, at the correct date.

It was theorized that there had been inadequate intrauterine nourishment during the first 6 to 7 months. The child, L. P., weighed 3 pounds, 8 ounces (1587 g) and was fed initially by nasogastric tube. Her movements were quick, and eye movement was very active for a newborn infant. She was seen for therapy at 17 days of age, immediately after hospital discharge.

The initial therapy focus was on the practical task of adequate nutritional intake so that the nasogastric tube could be removed before scarring occurred from repeated passage of the tube. Swaddling was suggested to calm the infant and assist her organization of body movement. Simple handling was oriented toward moving the trunk over midline to let the head follow and assisting the infant to assume age-appropriate antigravity postures.

CASE STUDIES

To understand the problems of children with cerebral palsy, it is essential to follow some children over time to capture the evolution of family problems. Functional treatment must change according to the developmental level, chronological age, and neuromotor responses of the child. Intervention must be specific to the presenting problem of the moment while the missing aspects of complete motor development are considered. The case study comparison of two boys illustrates the typical lack of clinical correlation between history and manifested characteristics of cerebral palsy.

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 210 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

At 3 years of age L. P. continued to have difficulty with control of her head position in space and was unable to initiate postural changes with her head. The clinical picture was one of low tone with athetoid movement. She could not speak, communicated with looks and a few word approximations, and hitched along the floor in a seated position with one supporting hand.

By 5 years of age L. P. was still receiving therapy three times per week and could walk in a hesitating way with her hands held. At this stage she was evaluated by a behavioral optometrist and started vision therapy to prepare her to participate in preschool activities. As a secondary benefit her balance in walking improved markedly. L. P. began walking up and down 27 steps daily in her new home.

Now, at 7 years of age, L. P. can walk independently on level surfaces. She has physical therapy once a week and vision therapy once a week to maintain her control of posture and movement. Her school performance is adequate to keep her with her age peers and she attends a regular school.

CASE STUDY 12-2

D. D. and E. D. were born within 6 months of each other at 6 months 1 week of gestation. Both were first-born infants for their respective mothers. D. D.'s mother was discovered to have a double uterus when she had a miscarriage early in the pregnancy. E. D. had malnutrition during his intrauterine development. D. D. started therapy just before he was 5 months old, and E. D. began therapy at almost 7 months old.

At 6 years of age D. D. walks alone with very mild athetotic "overflow." He wears corrective lenses that were fit at 2 years of age, and he returns for follow-up examinations with the behavioral optometrist once a year. Vision therapy was an important adjunct to physical handling because it introduced changes in spatial perception on the basis of specific sessions

with prism lenses. At age 4 years D. D. was discovered to have a mild to moderate hearing loss; he still uses a hearing aid in one ear. He speaks English and Spanish, as do his parents, and he understands the French spoken to him by his grandparents. He functions in a regular school with his age peers and is a well-adapted, active child.

At 6 years of age E. D. has moderately severe diplegia, with some immaturity of hand use and trunk control. He speaks English and Spanish well, although he demonstrates some emotional instability and difficulty in dealing with his disability. He is creative in storytelling and offers to tell original stories for other children in therapy. He is just beginning to walk with a walker within interior environments and with low resistance.

evaluation
 functional skills
 genetic disorders
 natural environments
 occupational therapist
 physical therapist

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe the main types of genetic disorders and give examples of each type.
2. Differentiate between genetic disorders diagnosed with clinical versus laboratory methods.
3. Describe three modes of inheritance for single-gene disorders.
4. Recognize key impairments that are common to many genetic conditions in pediatric clients.
5. Explain the physical or occupational therapist's role in the recognition, referral, and multidisciplinary management of genetic conditions in pediatric clients.
6. Identify resources and strategies for accessing information and increasing knowledge about genetic disorders for use in clinical decision making.
7. Explain why it is important to include family members in the planning and development of therapy programs for children with genetic disorders.
8. Describe and give examples of three types of assessment tools, and state the intended purpose of each.
9. Describe the importance of developing therapy programs for children that are outcome focused on functional skills in natural environments.

Genetic disorders in children can result in a wide variety of movement impairments and disabilities. The resultant impact of certain genetic conditions on the child may be evident before or immediately after birth, whereas other conditions may not be diagnosed until later in life when problems manifest. In this chapter we discuss disorders of known genetic origin that physical and occupational therapists are most likely to encounter in therapy programs for children.

The Human Genome Project, completed in 2003,¹ expanded knowledge about the genetic basis for disease and congenital malformations. The impact of this project is just being realized, with new research into diagnostic techniques and treatment options for genetic disorders. Pediatric health care professionals will be faced with questions from families who, in seeking diagnostic and prognostic information, are accessing the wealth of information both in the lay scientific press and on the World Wide Web (Box 13-1 and Table 13-1).

An accurate diagnosis of a specific genetic disorder (syndrome or disease) is necessary for a prognosis to be provided, for eligibility for therapy and education services to be determined, and as a basis for genetic counseling for the child's family.² The diagnostic process for genetic disorders includes a combination of clinical assessments by the physician who collects the child's medical history and a clinical geneticist who may construct a family history or "pedigree" to recognize disorders with familiar inheritance patterns. Molecular studies may confirm a clinical diagnosis, differentiate between diagnoses with similar clinical presentation, and identify the genetic cause of the disorder. Some genetic disorders are not easily identified, and laboratory testing can

be extensive, prolonged, and often inconclusive; therefore pediatricians may refer children to occupational and physical therapy before the nature of their condition is fully known.^{2,3} Although sometimes far removed from the hospitals and specialized centers that perform genetic testing and diagnosis, the pediatric therapist is often able to contribute clinical evidence that will assist the diagnostic process.⁴⁻⁶ Furthermore, many genetic diseases and syndromes are increasingly survivable into adulthood; thus it is vital that physical and occupational therapists achieve competence in genetics and genomics in order to deliver care throughout the patient's life span.^{6,7} An overview of the general categories and subtypes of genetic disorders is presented first. Specific examples of each type are given, along with a brief description of key diagnostic features and issues commonly addressed with medical and therapeutic intervention. A summary of impairments common to many pediatric genetic disorders is presented in the second section. The third section includes a discussion of the medical management of genetic disorders, genetic counseling, and the ethical implications of genetic screening and testing. The final section focuses on the physical or occupational therapist's role in the clinical management of children with genetic disorders. The therapist's role and responsibilities in developing competence in recognition, referral, and clinical practice when working with patients and families affected by a genetic disorder are discussed. Evaluation procedures, treatment goals and objectives, and general treatment principles and strategies are discussed from a family-centered perspective. A list of educational resources for clinicians and families is provided.

AN OVERVIEW: CLINICAL DIAGNOSIS AND TYPES OF GENETIC DISORDERS WITH REPRESENTATIVE CLINICAL EXAMPLES

Genetic disorders are typically divided into four categories: chromosomal, single-gene, mitochondrial, and multifactorial. Chromosomal disorders arise when there is an alteration in either the number or structure of chromosomes that exist in either autosomal or sex (X, Y) chromosomes.⁸ Numerical or large structural chromosomal abnormalities can be seen through a microscope; therefore a sample of the patient's peripheral blood can be used in detection of disorders such as Down syndrome. When there is a suspicion of a clinical spectrum associated with some of the known chromosomal microdeletions, translocations, or inversions, direct deoxyribonucleic acid (DNA) analysis techniques such as fluorescence in situ hybridization (FISH) with use of specific sequence DNA probes can confirm a specific suspected diagnosis. Indirect DNA analysis techniques such as linkage analysis can be performed to confirm single-gene disorders when the gene or genomic region associated with the disorder is unknown.⁹

Of our 20,000 to 25,000 protein-coding genes,¹ a single gene may be responsible for approximately 6000 known genetic traits. Approximately 4000 of these known traits are diseases or disorders.¹⁰ Single-gene disorders may be transmitted through three different patterns: autosomal dominant, autosomal recessive, and sex linked. *Dominant* refers to the case in which a mutated gene from one parent is sufficient to produce the disorder in offspring. *Recessive* refers to the case in which the disorder will not be expressed unless offspring inherited a mutated copy of that gene from both parents. It is incorrect to say that a *gene* is recessive or dominant; rather the *trait*, or disorder, is dominant or recessive.⁷

Inheritance is usually a term reserved for the transmission of a previously recognized family trait to subsequent offspring. However, many genetic disorders arise from new, spontaneous mutations in a *gamete*, the single egg cell from the mother or a sperm cell from the father. The remainder of the gametes from either parent are most likely normal. In this case their offspring will be the first in the family to display the *sporadic* disorder, and the faulty gene can then be passed onto subsequent generations. A disorder that results from a single copy of a mutated gene is referred to as a *dominant* disorder, even if it is acquired by a spontaneous mutation. Not all literature sources will include spontaneous mutations in the description of *inherited* disorders.

It is important to understand how a disorder was acquired, because the relative risks to other offspring for the disorder vary according to mode of transmission. For example, the risk of having another child with the same genetic disorder that occurred as a result of a spontaneous mutation is low. However, when one parent is affected by an inherited dominant mutation, the risk of passing that faulty gene onto each child is 50%.⁸

Most congenital malformations and many serious diseases that have an onset in childhood or adulthood are not caused by single genes or chromosomal defects; these are called *multifactorial disorders*.^{7,8}

Mitochondrial disorders are caused by alterations in maternally inherited cytoplasmic mitochondrial DNA (mtDNA). The clinical manifestations of mtDNA-related disorders are extremely variable,¹¹ and the occurrence is reportedly rare

(5.0 per 100,000)^{8,12}; however, collectively as a group of neuromuscular disorders, they account for substantial use of health care resources.¹²

Currently there are over 1000 genetic tests available in the United States.¹ Specific DNA testing may soon be able to identify nearly all human genetic disorders. This not only allows for accurate and more complete diagnosis but should pave the way for the development of mechanisms for treatment, cure, and prevention of certain genetic conditions.^{4,5,8,9} Table 13-2 lists examples of specific disorders in categories of the most common pattern of inheritance by which each occurs.

Chromosomal Disorders

Cytogenetics is the study of chromosomal abnormalities. A karyotype is prepared that displays the 46 chromosomes—22 pairs of autosomes arranged according to length, and then the two sex chromosomes that determine male or female sex. Modern methods of staining karyotypes enable analysis of the various numerical and structural abnormalities that can occur. Most chromosomal abnormalities appear as numerical abnormalities (aneuploidy) such as one missing chromosome (monosomy) or an additional chromosome, as in trisomy 21 (Down syndrome).⁸ Structural abnormalities occur in many forms. They include a missing or “extra portion” of a chromosome or a translocation error, which is an interchange of genetic material between nonhomologous chromosomes. The incidence of chromosomal abnormalities among spontaneously aborted fetuses may be as high as 60%.^{8,13} About one in 150 live-born infants have a detectable chromosomal abnormality; and in about half of these cases the chromosomal abnormality is accompanied by

congenital anomalies, intellectual disability, or phenotypical changes that manifest later in life.⁸ Of the fetuses with abnormal chromosomes that survive to term, about half have sex chromosome abnormalities and the other half have autosomal trisomies.⁸

The following section provides a brief overview of common genetic disorders seen by physical and occupational therapists working with children.

Autosomal Trisomies

Trisomy is the condition of a single extranuclear chromosome. Trisomies occur frequently among live births, usually as a result of the failure of the parental chromosomes to disjoin normally during meiosis. Trisomy can occur in autosomal or sex cells. Trisomies 21, 18, and 13 are the most frequently occurring trisomies; however, few children with trisomy 18 and 13 survive beyond 1 year of age.¹

Trisomy 21 (Down Syndrome). Trisomy 21 occurs in approximately one in every 740 live births,¹⁴ and its incidence is distributed equally between the sexes.¹⁰ The pathophysiological features of Down syndrome are caused by an overexpression of genes on human chromosome 21. Ninety-five percent of individuals have an extra copy in all of their body's cells. The remaining 5% have the mosaic and translocation forms.¹⁵ In the United States the incidence of Down syndrome increases with advanced maternal age.¹⁰ Detection of Down syndrome is possible with various prenatal tests, and the diagnosis is confirmed by the presence of characteristic physical features present in the infant at birth.¹⁶ Down syndrome is the most common chromosomal cause of moderate to severe intellectual disability.¹⁵ The typical phenotypical features observable from birth are hypotonia,

TABLE 13-2 ■ PARTIAL LISTING OF PEDIATRIC GENETIC CONDITIONS

SYNDROME OR DISEASE	APPROXIMATE INCIDENCE (UNITED STATES)
CHROMOSOMAL ABNORMALITIES	
Autosomal Trisomy	
Trisomy 21	1:740
Trisomy 18	1:5000
Trisomy 13	1:16,000
Sex Chromosome Aneuploidy	
Turner syndrome	1:2500 females
Klinefelter syndrome	1:500-1000 males
Partial Deletion	
Prader-Willi syndrome	1:10,000-30,000
Angelman Syndrome	1:12,000-20,000
Cri-du-chat syndrome	1:20,000-50,000
SINGLE-GENE ABNORMALITIES	
Autosomal Dominant	
Neurofibromatosis type 1	1:3500
Tuberous sclerosis	1:5800
Osteogenesis imperfecta	6-7:100,000
Autosomal Recessive	
Cystic fibrosis	1:2500-3500 Caucasians (highest ethnic incidence)
Spinal muscle atrophy	1:6000-10,000
Phenylketonuria	1:10,000-15,000
Hurler syndrome	1:100,000
Sex-Linked	
Duchenne muscular dystrophy	1:3500
Fragile X syndrome	1:4000 males, 1:8000 females
Hemophilia A	1:4000-5000 males
Rett syndrome	1:10,000-22,000 females
MULTIFACTORIAL ABNORMALITIES	
Cleft lip with or without cleft palate	1:1000
Clubfoot (talipes equinovarus)	1:1000
Spina bifida	7:10,000
MITOCHONDRIAL ABNORMALITIES	
Mitochondrial myopathy	Rare
Kearns-Sayre disease	Rare

epicanthic folds, flat nasal bridge, upward slanting palpebral fissures, small mouth, excessive skin at the nape of the neck, and a single transverse palmar crease (Figure 13-1).

Information compiled by the Centers for Disease Control and Prevention for years 1968 through 1997 indicates that the median survival age of individuals with Down syndrome is 49 years, compared with 1 year in 1968. Improvements in the median survival age were less in races other than white, although the reasons for this remain unclear.¹⁴ Half of all children with Down syndrome have congenital heart defects.¹⁶ Congenital heart problems, respiratory infection, and leukemia are the most common factors associated with morbidity and mortality in childhood,¹⁷ whereas a possible increased tendency for premature cellular aging and

Figure 13-1 ■ Ten-month-old girl with Down syndrome.

Alzheimer disease may account for higher mortality rates later in life.¹⁸

Impairments of visual and sensory systems are also common in individuals with Down syndrome. As many as 77% of children with Down syndrome have a refractive error (myopia, hyperopia), astigmatism, or problems in accommodation.¹⁹ Hearing losses that interfere with language development are reportedly present in 80% of children with Down syndrome. In most cases the hearing loss is conductive; in up to 20% of cases the loss is sensorineural or mixed.^{16,20} Obstructive sleep apnea has been reported to exist frequently in young children^{21,22} and adults with Down syndrome.²³ Craniofacial impairments such as a shortened palate and midface hypoplasia, along with oral hypotonia, tongue thrusting, and poor lip closure, frequently result in feeding difficulties at birth.²⁴ Bell and colleagues studied the prevalence of obesity in adults with Down syndrome and reported it in 70% of male subjects and 95% of female subjects.²⁵ Children with Down syndrome also appear to have a higher risk of being overweight or obese,²⁶⁻²⁸ which may be, in part, a result of the retarded growth and endocrine and metabolic disorders associated with trisomy 21.²⁸ In a small population study of children with Down syndrome, Dyken and co-workers²⁹ reported that there was a high prevalence of obstructive sleep apnea associated with a higher body mass index.

Children with Down syndrome may have musculoskeletal anomalies such as metatarsus primus varus, pes planus, thoracolumbar scoliosis, and patellar instability and have an increased risk for atlantoaxial dislocation,³⁰⁻³² which has been observed through radiography in up to 10% to 30% of individuals with this syndrome^{30,31} with and without neurological compromise.³³ There is some controversy in the medical community as to the necessity and efficacy of

radiographic screening for the instability.^{31,32} Proponents of radiographic screening argue that neurological symptoms of atlantoaxial instability may often go undetected in this population because symptoms are often masked by the wide-based gait and motor dysfunction already associated with the disorder. If the child is unable to verbalize complaints or the child is uncooperative with physical and neurological examinations, symptoms may be missed. There is particular concern about cervical instability if these children undergo surgical procedures requiring general anesthesia³² and participate in recreational sports such as the Special Olympics.³¹ Symptomatic instability can result in spinal cord compression leading to myelopathy with leg weakness, decreased walking ability,³³ spasticity, or incontinence. Although reportedly rare, there have been cases where atlantoaxial dislocation has resulted in quadriplegia.³⁰

Several researchers have explored the neuropathology associated with Down syndrome. Changes in brain shape, size, weight, and function occur during prenatal and infant development of babies with Down syndrome, with important differences apparent by 6 months of age.³⁴ The relatively small size of the cerebellum and brain stem was reported by Crome and Stern in the 1970s.³⁵ Marin-Padilla³⁶ studied the neuronal organization of the motor cortex of a 19-month-old child with Down syndrome and found various structural abnormalities in the dendritic spines of the pyramidal neurons of the motor cortex. He suggested that these structural differences may underlie the motor incoordination and intellectual disability characteristic of individuals with Down syndrome. Loesch-Mdzewska³⁷ also found neurological abnormalities of the corticospinal system (in addition to reduced brain weight) in his neuropathological study of 123 individuals with Down syndrome aged 3 to 62 years. Crome³⁸ reported lesser brain weight in comparison with normal persons. Finally, Benda³⁹ noted a lack of myelination of the nerve fibers in the precentral area, frontal lobe, and cerebellum of infants with Down syndrome. As McGraw⁴⁰ has pointed out, the amount of myelin in the brain reflects the stage of developmental maturation. The delayed myelination characteristic of neonates and infants with Down syndrome is thought to be a contributing factor to the generalized hypotonicity and persistence of primitive reflexes characteristic of this syndrome.⁴¹

Trisomy 18. Trisomy 18, or Edwards syndrome, is the second most common of the trisomic syndromes to occur in term deliveries, although it is far less prevalent than Down syndrome. It occurs in one in 5000 newborns, and approximately 80% of affected infants are female.⁴² As with Down syndrome, advanced maternal age is positively correlated with trisomy 18. Most cases of Edwards syndrome occur as random events during the formation of reproductive cells; fewer cases occur as errors in cell division during early fetal development; and inherited, translocation forms rarely occur.⁴² Only 10% of infants born with trisomy 18 survive past the first year of life; female and non-Caucasian children survive longest.⁴³ The survival of girls averages 7 months; the survival of boys averages 2 months.⁴³ Individuals surviving past infancy most often have the mosaic form, and there is high variance in phenotype (Figure 13-2).⁴⁴

Individuals with trisomy 18 generally have far more serious organic malformations than seen in those with Down

Figure 13-2 ■ Twenty-one-month-old male with mosaic form of trisomy 18. (Reprinted with permission of Tucker ME, Garringer HJ, Weaver DD: Phenotypic spectrum of mosaic trisomy 18: two new patients, a literature review, and counseling issues. *Am J Med Genet A* 143:505–517, 2007.)

syndrome.⁴⁵ Typical malformations affect the cardiovascular, gastrointestinal, urogenital, and skeletal systems. Infants with trisomy 18 have low birth weight and small stature, with a long narrow skull, low-set ears, flexion deformities of the fingers, and rocker-bottom feet. Muscle tone is initially hypotonic, but it becomes hypertonic in children with longer than typical life span.⁴⁵ The period of hypertonicity in the early years may change to low tone and joint hyperextensibility by preschool and school age. Microcephaly, abnormal gyri, cerebellar anomalies, myelomeningocele, hydrocephaly, and corpus callosum defects have been reported in individuals with trisomy 18.⁴⁶

Common skeletal malformations that may warrant attention from the developmental physical or occupational therapist include scoliosis,⁴⁶ limited hip abduction, flexion contractures of the fingers, rocker-bottom feet, and talipes equinovarus.⁴⁵ Infants with trisomy 18 may also have feeding difficulties as a result of a poor suck.⁴⁷ Profound intellectual disability is another clinical factor that will affect the developmental therapy programs for children with trisomy 18.^{46,47}

Trisomy 13. Trisomy 13, also commonly called *Patau syndrome*, is the least common of the three major autosomal trisomies, with an incidence of one in 10,000 to 20,000 live births.^{8,42} As in the other trisomic syndromes, advanced

maternal age is correlated with the incidence of trisomy 13.⁴⁸ Fewer than 10% of individuals with trisomy 13 survive past the first year of life^{42,43}; girls and non-Caucasian infants appear to survive longer.^{42,43} Individuals surviving past infancy most often have the mosaic form, and there is high variance in phenotype.⁴³ As with Edwards syndrome, most cases of Patau syndrome occur as random events during the formation of eggs and sperm, such as nondisjunction errors during cell division.⁴⁸

Trisomy 13 is characterized by microcephaly, deafness, anophthalmia or micropthalmia, coloboma, and cleft lip and palate.⁴⁸ As in trisomy 18, infants with trisomy 13 frequently have serious cardiovascular and urogenital malformations and typically have severe to profound intellectual disability.⁴⁹ Skeletal deformities and anomalies include flexion contractures of the fingers and polydactyly of the hands and feet.¹⁰ Rocker-bottom feet also have been reported, although less frequently than in individuals with trisomy 18. Reported central nervous system (CNS) malformations include arhinencephalia, cerebellar anomalies, defects of the corpus callosum, and hydrocephaly.⁵⁰

Sex Chromosome Aneuploidy

The human X chromosome is large, containing approximately 5% of a human's nuclear DNA. The Y chromosome, much smaller, contains few known genes.⁸ Females, with genotype XX, are mosaic for the X chromosome, meaning that one copy of their X chromosome is inactive in a given cell; some cell types will have a paternally derived active chromosome, and others a maternally derived X chromosome. Males, genotype XY, have only one copy of the X chromosome; therefore diseases caused by genes on the X chromosome, called *X-linked diseases* (see section on sex-linked disorders), can be devastating to males and less severe in females.⁸ In the presence of abnormal numbers of sex chromosomes, neither male nor female individuals will be phenotypically normal.⁸ Two of the most prevalent sex chromosome anomalies are Turner syndrome and Klinefelter syndrome.

Turner Syndrome. Turner syndrome affects females with monosomy of the X chromosome. The syndrome, also known as *gonadal dysgenesis*, occurs in one in 2500 live female births.^{51,52} Turner syndrome is the most common chromosomal anomaly among spontaneous abortions.^{53,54} Most infants who survive to term have the mosaic form of this syndrome, with a mix of cell karyotypes, 45,X and 46,XX. The *SHOX* gene, found on both the X and Y chromosomes, codes for proteins essential to skeletal development. Deficiency of the *SHOX* gene in females accounts for most of the characteristic abnormalities of this disorder.^{52,55} Three characteristic impairments of the syndrome are sexual infantilism, a congenital webbed neck, and cubitus valgus.⁵⁶ Other clinical characteristics noted at birth include dorsal edema of hands and feet, hypertelorism, epicanthal folds, ptosis of the upper eyelids, elongated ears, and shortening of all the hand bones.^{51,57} Growth retardation is particularly noticeable after the age of 5 or 6 years, and sexual infantilism, characterized by primary amenorrhea, lack of breast development, and scanty pubic and axillary hair, is apparent during the pubertal years. Ovarian development is severely deficient, as is estrogen production.^{10,58} Congenital heart disease is present in 20% to 30% of individuals with Turner

syndrome,⁵⁷ with a fewer number of cardiovascular malformations in individuals with the mosaic form⁵⁹; 33% to 60% of individuals with Turner syndrome have kidney malformations.⁵¹ Hypertension is common even in the absence of cardiac or renal malformations.^{57,60}

There are numerous incidences of skeletal anomalies, some of which may be significant enough to require the attention of a pediatric therapist. Included among these are hip dislocation, pes planus and pes equinovarus, dislocated patella,⁵¹ deformity of the medial tibial condyles,⁴⁶ idiopathic scoliosis,⁵⁷ and deformities resulting from osteoporosis.^{10,57}

Sensory impairments include decrease in gustatory and olfactory sensitivity^{61,62} and deficits in spatial perception and orientation,⁶¹ and up to 90% of adult females have moderate sensorineural hearing loss. Recurrent ear infections are common and may result in future conductive hearing loss.⁶⁰ Although the average intellect of individuals with Turner syndrome is within normal limits, the incidence of intellectual disability is higher than in the general population.⁴⁵ Noonan syndrome, once thought to be a variant of Turner syndrome, has several common clinical characteristics; however, advancements in genetics research have shown that the syndromes have different genetic causes.^{63,64}

Klinefelter Syndrome. Klinefelter syndrome is an example of aneuploidy with an excessive number of chromosomes that occurs in males. The most common type, 47,XXY, is usually not clinically apparent until puberty, when the testes fail to enlarge and gynecomastia occurs.⁶⁵ Nearly 90% of males with Klinefelter syndrome possess a karyotype of 47,XXY, and the other 10% of patients are variants.⁶⁶ The incidence of Klinefelter syndrome (XXY) is about one in 500 to 1000 males, and an estimated half of 47,XXY conceptions are spontaneously aborted.⁸ The extra X chromosome(s) can be derived from either the mother or the father, with nearly equal occurrence.⁶⁷ Advanced maternal age is widely accepted as a causal factor.^{8,66} FISH analysis of spermatozoa from fathers of boys with Klinefelter syndrome suggests that advanced paternal age increases the frequency of aneuploid offspring.⁶⁸⁻⁷⁰

Most individuals with karyotype XXY have normal intelligence, a somewhat passive personality, and a reduced libido. Eighty-five percent of individuals having the nonmosaic karyotype are sterile. Individuals with the karyotypes 48,XXXXY and 49,XXXXXY tend to display a more severe clinical picture. Individuals with 48,XXXXY usually have severe intellectual disability, with multiple congenital anomalies, including microcephaly, hypertelorism, strabismus, and cleft palate.^{10,65} Skeletal anomalies include radioulnar synostosis, genu valgum, malformed cervical vertebrae, and pes planus.¹⁰ A 2010 systematic review of literature⁷¹ on neurocognitive outcomes of persons with Klinefelter syndrome concluded that problems of delayed walking in children and persistent deficits in fine and gross motor development, and problems in motor planning.^{71,72} Giedd and co-workers published the results of a case-control study examining brain magnetic resonance imaging (MRI) scans of 42 males with Klinefelter syndrome and reported cortical thinning in the motor strip associated with impaired control of the upper trunk, shoulders, and muscles involved in speech production.⁷³

Partial Deletion Disorders

Deletions are one example of mutations that cause changes in the sequence of DNA in human cells. A sequence change that affects a gene's function can cause the final protein product to be altered or not produced at all.

Cri-du-Chat Syndrome. Cri-du-chat syndrome, also referred to as *cat-cry syndrome*, and *5p minus syndrome* results from a partial deletion of the short arm of chromosome 5. Example nomenclature for a female with this syndrome is (46,XX,del[5p]). The incidence of the syndrome is estimated to be one case per 20,000 to 50,000 live births.^{10,74} Although approximately 70% of individuals with cri-du-chat syndrome are female, there is an unexplained higher prevalence of older males with this disorder.⁷⁵ Advanced parental age is not a causal factor. A study completed in 1978 indicated that life expectancy was 1 year for 90% of infants born with this disorder,⁷⁶ but now life expectancy is nearly normal with routine medical care.⁷⁷

Primary identifying characteristics at birth include a definitive high-pitched catlike cry, microcephaly, evidence of intrauterine growth retardation, and subsequent low birth weight.^{10,76,78} Abnormal laryngeal development accounts for the characteristic cry, which is present in most individuals and disappears in the first few years of life.⁷⁶ Other features of individuals with this syndrome include hypertelorism, strabismus, “moon face,” and low-set ears.^{10,76,78} Associated musculoskeletal deformities include scoliosis, hip dislocations, clubfeet, and hyperextensibility of fingers and toes. Muscular hypotonicity is associated with this syndrome, although cases with hypertonicity have also been noted.⁷⁹ Severe respiratory and feeding problems have also been reported.⁷⁷ Postnatal growth retardation has been documented, with the median near the 5th percentile of the normal growth curve.⁸⁰

Although intellectual disability and physical deformities are more severe with larger deletions,⁷⁴ there is evidence that with early developmental intervention these children can develop language, functional ambulation, and self-care skills.^{81,82}

Prader-Willi Syndrome and Angelman Syndrome. Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are discussed together because they result from a structural or functional loss of the PWS and AS region of chromosome 15 (15q11-13), which can occur by one of several genetic mechanisms.^{83,84} PWS has an incidence of one in 15,000 to 30,000⁸³ and AS has an incidence of one in 12,000 to 20,000.^{83,84} These two syndromes illustrate the effect of *genomic imprinting*, which is the differential activation of genes of the same chromosome and location, depending on the sex of the parent of origin (Figure 13-3).⁸

PWS results from a failure of expression of paternally inherited genes in the PWS region of chromosome 15.⁸³ Conversely, AS results when the maternal contribution in the 15q11.2-q13 region is lost.⁸⁴ *OCA2* is a gene located within the PWS and AS region of chromosome 15 that codes for the protein involved in melanin production. With loss of one copy of this gene, individuals with PWS or AS will have light hair and fair skin. In the rare case that both copies of the gene are lost, these individuals may have a condition called *oculocutaneous albinism*, type 2, which causes severe vision problems.⁸⁴

Figure 13-3 ■ Illustration of the effect of imprinting on chromosome 15 deletions. **A**, Inheritance of the deletion from the father produces Prader-Willi syndrome. **B**, Inheritance of the deletion from the mother produces Angelman syndrome. (From Jorde L, Carey J, Bamshad M, White R: *Medical genetics*, ed 3, St Louis, 2005, Mosby.)

Characteristics of PWS in infancy include hypotonia, poor feeding, lethargy, and hypogonadism.^{85,86} Developmental milestones in the first 2 years of life are not acquired until approximately twice the normal age.^{87,88} Between 1 and 4 years of age, hyperphagia is apparent and if uncontrolled will lead to morbid obesity and its associated health complications.^{86,87,89} Most individuals with PWS have mild to moderate intellectual disability, although some individuals have IQ scores within normal limits.⁹⁰ Maladaptive behaviors such as temper tantrums, aggression, self-abuse, and emotional lability have been reported.⁹¹ As a result of extreme obesity, many individuals with PWS have impaired breathing that can produce sleepiness, cyanosis, cor pulmonale, and heart failure.⁹¹ Scoliosis is common but does not appear to be related to obesity.⁹²

Clinical diagnosis is confirmed by laboratory genetic testing techniques including DNA-based methylation testing, FISH probe, and pyrosequencing assays.^{86,93} Most cases of PWS are caused by random mutations in parental reproductive cells.⁸⁷ Other cases may result from translocation errors.^{86,94} Parental studies are important in translocation cases because 20% of cases cited in the literature involved familial rearrangements, which may significantly increase the risk of recurrence.⁹⁵

Angelman syndrome, named after Dr. Harry Angelman, who first described children with AS in 1965, is characterized by developmental delay or intellectual disability, seizures, ataxia, progressive microcephaly, and severe speech impairments. Tongue thrusting, drooling, and sucking and swallowing disorders occur in 20% to 80% of children. Individuals often display spontaneous bouts of laughter

accompanied by hand-flapping movements and a characteristic walking posture of arms overhead and flexed elbows.^{8,84,96} Infants appear normal at birth, but severe developmental delay becomes apparent by 6 to 12 months of age. More unique features of the disorder do not appear until after 1 year of age. Children with AS typically have structurally normal brains on MRI and computed tomography (CT) scans, but electroencephalogram (EEG) findings are often abnormal, showing a characteristic pattern that may assist with diagnosis before other clinical symptoms emerge,^{84,97} and molecular studies can also confirm the disorder before all of the clinical criteria for this diagnosis are met.⁸⁴

Most cases of AS occur as a result of mutations involving deletion or deficient function of the maternally inherited *UBE3A* gene. This gene codes for an enzyme, ubiquitin protein ligase, involved in the normal process of removing damaged or unnecessary proteins in healthy cells. In most of the body's tissues except the brain, both copies (maternal and paternal) of the *UBE3A* gene are active. Only the maternal copy of the gene is normally active in the brain, so if this copy is absent or deficient, the normal cellular housekeeping process breaks down.⁸⁴ The risk of having another child with AS can vary from 1% to 50% depending on which of the six known genetic mechanisms is responsible for the disorder.

Translocation Disorders

Translocation errors have been identified in many childhood hematologic cancers and sarcomas.^{98,99} Translocation errors are also commonly seen in couples with infertility.¹⁰⁰ Translocation abnormalities occur when genetic material is exchanged and rearranged between two nonhomologous chromosomes (those not in the same numbered pair). The structural abnormality can result in the loss or gain of chromosomal material (an unbalanced arrangement) or no loss or gain of material (a balanced arrangement). Unbalanced arrangements can produce serious disease or deformity in individuals or their offspring. Carriers of balanced arrangements—estimated at one in 500 individuals—often have a normal phenotype, but their offspring may have an abnormal phenotype.⁸ There are two basic types of translocations: reciprocal translocation and robertsonian translocation. Reciprocal translocations occur when two different chromosomes break and the genetic material is mutually exchanged. A robertsonian translocation occurs when there is a break in a portion of two different chromosomes, with the longest remaining portions of both chromosomes forming a single chromosome. The shorter portions that broke away usually do not contain vital genetic information; therefore the individual may be phenotypically normal.⁸ An example notation of a reciprocal translocation is 46,XY,t(7;9)(q36;q34). This individual is male with a normal number of chromosomes but with a translocation of genetic material on chromosomes 7 and 9; “q” refers to the short arm of these chromosomes, and the numbers “36” and “34” refer to the location.

Translocations occur in children seen in therapy settings, including about 3% to 5% of children with Down syndrome,¹⁰ and translocations are found in 40% of all cases of acute lymphoblastic leukemia (ALL).¹⁰¹

Acute Lymphoblastic Leukemia. ALL accounts for one fourth of all childhood cancers, and it is the most common type of childhood cancer.¹⁰²⁻¹⁰⁴ ALL occurs when the

DNA of immature lymphoblasts is altered and they reproduce in abnormal numbers, crowding out the formation of normal cells in the bone marrow.^{102,105} Sixty percent of cases of ALL occur in children, with the peak incidence in the first 5 years of life. A rise in the incidence of ALL has been reported during major periods of industrialization worldwide^{105,106} and is hypothesized to be associated with exposure to radiation¹⁰⁷ and other environmental teratogens^{108,109} in the preconception, gestational, and postpregnancy periods.^{103,106}

With advancements in medical treatment protocols for pediatric patients, 5-year survival rates have improved to 80%.¹⁰⁴ Children aged 1 to 9 years at diagnosis have a better prognosis than infants, adolescents, or adults diagnosed with ALL.¹⁰³ There are numerous forms of translocation mutations associated with ALL. Some translocation forms of ALL do not respond well to combination chemotherapy treatment; an example is the translocation that occurs between chromosomes 9 and 22, known as the “Philadelphia chromosome.”^{104,110} Other translocations that result in hyperdiploidy (more than 50 chromosomes), in particular within chromosomes 4, 10, and 17, may confer a more favorable outcome.¹¹¹

Frequently, diagnosis is made when a physician relates the child's history of a persistent viral respiratory infection with other characteristic clinical signs and symptoms consistent with hematopoietic leukemia. The key symptoms of ALL are pallor, poor appetite, lethargy, easy fatigue and bruising, fever, mucosal bleeding, and bone pain.⁹⁹ A complete blood count will show a shortage of all types of blood cells, including red, white, and platelets. Diagnosis is confirmed by the presence of lymphoblasts in bone marrow. Radiographs may be necessary to determine metastases, and cerebrospinal fluid will be examined because early involvement of the CNS has important prognostic implications.¹⁰⁶ Cytogenetic studies will be performed to aid in selection of treatment protocols and prognosis.¹⁰⁴

Referral to physical and occupational therapists is made for other common problems such as muscle cramps, muscle weakness, impaired gross and fine motor performance, decreased energy expenditure, osteopenia, and osteoporosis.¹¹²

Single-Gene Disorders

The previous section described genetic disorders that occur because of chromosomal abnormalities involving more than one specific gene. Other genetic disorders commonly seen among children in a therapy setting include those that result from specific gene defects. The inheritance patterns of single-gene traits were described by Gregor Mendel in the nineteenth century. These patterns, autosomal dominant, autosomal recessive, and sex linked, are discussed separately, and specific examples of syndromes or disorders associated with each type are presented.

Autosomal Dominant Disorders

Mutations on one of the 22 numbered pairs of autosomes may result in isolated anomalies that occur in otherwise normal individuals, such as extra digits or short fingers. Each child of a parent with an autosomal dominant trait has a 50:50 chance of inheriting that trait.⁸ Other autosomal dominant disorders include syndromes characterized by profound musculoskeletal and neurological impairments

that may require intervention from a physical or an occupational therapist. Three examples of autosomal dominant disorders are osteogenesis imperfecta (OI), tuberous sclerosis, and neurofibromatosis (NFM).

Osteogenesis Imperfecta. OI is a spectrum of diseases that results from deficits in collagen synthesis associated with single-gene defects, most commonly of *COL1A1* and *COL1A2*, located on chromosomes 17 and 7, respectively.^{10,113} OI is characterized by brittle bones resulting from impaired quality, quantity, and geometry of bone material and hyperextensible ligaments.^{114,115} Deafness, resulting from otosclerosis, is found in 35% of individuals by the third decade of life.⁴⁵ New knowledge about this disease from molecular genetic studies and bone histomorphometry has expanded the classification subtypes of OI into types I through VII.^{113,116} These classifications are helpful in determining prognosis and management, although there is a continuum of severity of clinical features and much overlap in the features among the different classifications.¹¹⁶ Types I, IV, V, and VI occur in the autosomal dominant pattern; whereas type VII occurs as a recessive trait, and types II and III can occur as either dominant or recessive traits.¹¹³ OI types V and VI account for only 5% of cases, and type VII has been found to date only in a Native Canadian population.¹¹⁶ This section will compare and contrast only types I through IV.

The overall incidence of OI is one in 10,000 live births in the United States, with types I and IV accounting for almost 95% of all patients with OI.¹¹³ Ninety percent of dominant forms of OI can be confirmed by DNA analysis.¹¹⁷ Type I is the least severe form, followed by types IV and III, with type II being the most severe.

Type I is characterized by blue sclera, mild to moderate bone fragility, joint hyperextensibility, and hearing loss in young adulthood.¹¹⁷ There are no significant deformities; individuals with this type may not sustain fracture until ambulatory, and incidence of fractures decreases with age.¹¹⁷ Type IV OI is characterized by more severe bone fragility and joint hyperextensibility than is type I. Bowing of long bones, scoliosis, dentinogenesis imperfecta, and short stature are common.^{114,116,118}

Children with type IV OI are often ambulatory but may require splinting or crutches.¹¹⁴

Children with type III OI have severe bone fragility and osteoporosis; often there are fractures in utero. Type III occurs primarily in autosomal dominant inheritance in North Americans and Europeans.¹¹⁶ The less frequent, autosomal recessive form of OI, type III is characterized by progressive skeletal deformity, scoliosis, triangular facies, large skull, normal cognitive ability, short stature, and limited ambulatory ability.^{114,116,119} The long bones of the lower extremities are most susceptible to fractures, particularly between the ages of 2 to 3 years and 10 to 15 years,⁴⁵ with the frequency of fractures diminishing with age. Intramedullary rods inserted in the tibia or femur may minimize recurrent fractures.³⁶

Type II, the most severe form, is most often lethal before or shortly after birth, although there are a few cases of children living to 3 years.^{116,119} Infants with type II OI have multiple fractures, often in utero, and underdeveloped lungs and thorax; therefore many die from respiratory complications after birth. Most type II cases are the result of spontaneous mutations; because only one copy of the gene

is sufficient to cause the disorder, it is still commonly classified as an autosomal dominant condition. There are fewer cases of autosomal recessive inheritance.⁸

Prevention of fractures is an important goal in working with individuals with OI, but fear of handling and overprotection by caregivers may limit a child's optimal functional independence. Caregiver education in careful handling and positioning should begin in the patient's early infancy, and training in the use of protective orthoses and assistive devices is appropriate from the period of crawling through ambulation.^{115,120,121} Aquatic therapy can be a valuable treatment strategy for children with OI.^{120,121}

Tuberous Sclerosis Complex. Tuberous sclerosis complex (TSC) is characterized by a triad of impairments: seizures, intellectual disability, and sebaceous adenomas; however, there is wide variability in expression, with some individuals displaying skin lesions only.¹²² Infants are frequently normal in appearance at birth, but 70% of those who go on to show the complete triad of symptoms display seizures during the first year of life. Although tuberous sclerosis is inherited as an autosomal dominant trait, 86% of cases occur as spontaneous mutations, with older paternal age a contributing factor. TSC affects both sexes equally, with a frequency of one in 5800 births.¹²³ Mutations in the *TSC1* and *TSC2* genes are known to cause tuberous sclerosis.¹⁰ The normal function of these genes is to regulate cell growth; if these genes are defective, cellular overgrowth and noncancerous tumor formation can occur.¹²³ Tumor formation in the CNS is responsible for most of the morbidity and mortality with TSC,¹²³ followed by renal disease associated with formation of benign angiomyolipomas.¹²² Diagnostic criteria for TSC have been established, and the determination can be made clinically; results of genetic testing are currently viewed as corroborative.¹²² Hypopigmented macules are often the initial finding. These lesions vary in number and are small and ovoid. Larger lesions, known as *leaf spots*, may have jagged edges.¹²³ Sebaceous adenomas first appear at age 4 to 5 years, with early individual brown, yellow, or red lesions of firm consistency in the nose and upper lips. These isolated lesions may later coalesce to form a characteristic butterfly pattern on the cheeks. Known also as hamartomas (tumor-like nodules of superfluous tissue), the skin lesions are present in 83% of individuals with tuberous sclerosis.⁴⁵

Delayed development is another characteristic during infancy,¹²⁴ particularly in the achievement of motor and speech milestones. Cerebral cortical tubers are present in over 80% of patients and account for cognitive disability including autism.¹²² Ultimately, 93% of individuals who are severely affected will have seizures, usually of the myoclonic type, in early life, progressing in later life to grand mal seizures. Seizure development is the result of formation of nodular lesions in the cerebral cortex and white matter.⁴⁵ Tumors are also found in the walls of the ventricles. Neurocytological examination reveals a decreased number of neurons and an increased number of glial cells and enlarged nerve cells with abnormally shaped cell bodies.¹⁰ Surgical excision of seizure-producing tumors has been successful in some cases.¹²²

Other associated impairments include retinal tumors and hemorrhages, glaucoma, and corneal opacities.¹²³ Cyst formation in the long bones and in the bones of the fingers and

toes contributes to osteoporosis. Cardiac and lung tissues are also affected by TSC, and these effects are included in the major diagnostic criteria.¹²²

Neurofibromatosis. There are two recognized forms of NFM: neurofibromatosis 1 (NFM1) and neurofibromatosis 2 (NFM2).¹²⁵⁻¹²⁷ Neurofibromas, or connective tissue tumors of the nerve fiber fasciculus, impede the development and growth of neural cell tissues^{126,127} and are the hallmark feature of NFM1. Neurofibromas are noncancerous, and malignant changes are rare in children¹²⁸ but an increased risk of malignancy has been observed in adult patients with NFM1 and is a major contributor to decreased life expectancy by approximately 15 years.¹²⁹ Tumors typically increase in number with increasing age. About half of all cases of NFM are caused by sporadic mutation in parental germ cells or during fetal development.¹²⁵⁻¹²⁷ Schwannomas are the main tumor type of NFM2 and classically appear bilaterally on the vestibular nerves.^{127,130} NFM1 is also known as *von Recklinghausen disease*. Compared with type II, type I is more common (one per 3000 births)^{10,126} and usually identified in younger children. It is associated with mutations in the *NF1* gene, which produces a protein, neurofibromin, the complete function of which is not yet understood but which is suspected to be a tumor suppressor. Diagnostic criteria for NFM1 include the presence of two of the following features: six or more café-au-lait spots, two or more fibromas, freckling in the axillary or inguinal region, optic pathway glioma, two or more Lisch nodules, specific osseous lesions, and a first-degree relative with NFM1.¹²⁶ Infants usually appear normal at birth, but initial café-au-lait spots appear by age 3 years in 95% of individuals (Figure 13-4).¹³¹ Cognitive impairment is the most common neurological complication of NFM1¹³¹ and is postulated to

Figure 13-4 ■ Four-year-old boy with neurofibromatosis and characteristic café-au-lait spots on trunk.

be caused by altered expression of neurofibromin in the brain and/or hyperintense lesions in the brain seen on MRI.¹³¹ These focal areas of high signal intensity on T2-weighted MRI, known as *unidentified bright objects* (UBOs), are seen in 60% of children and young adults with NFM1. The lesions, commonly found in the basal ganglia, internal capsule, thalamus, cerebellum, and brain stem,^{128,132} tend to disappear in adulthood and often do not cause other overt neurological symptoms.¹²⁸ Fewer than 10% of individuals are mentally retarded, but about 30% to 60% of affected children have learning disabilities that are mild and nonprogressive.^{128,133} Poorer social skills and differences in personality, behavior, and quality-of-life perception have been reported in children with NFM1 compared with children without the disorder.¹²⁶

In older children and adolescents, pain, itching, and stinging can occur from cutaneous neurofibromas, and in approximately half of all patients, neurological motor deficits occur from plexiform neurofibromas when the growth puts pressure on peripheral nerves, spinal nerve roots, and the spinal cord.¹³¹ One percent to 5% of children aged 0 to 6 years develop symptoms associated with optic pathway glioma.^{126,128} Neurofibromatous vasculopathy interferes with arterial and venous circulation in the brain.^{126,131,134} Hydrocephalus occurs in some individuals.^{126,128} Hypertension is common and may develop at any age,¹²⁶ and cardiovascular disease is a major cause of premature death.^{129,131,135} Headaches are a commonly reported symptom in children, adolescents, and adults.^{126,128,136,137}

Scoliosis may develop in 10% of patients and is rapidly progressive from ages 6 to 10 years, or it may manifest in a milder form without vertebral anomalies during adolescence.¹²⁶ Other skeletal deformities include pseudarthrosis of the tibia and fibula, tibial bowing, craniofacial and vertebral dysplasia, rib fusion, and dislocation of the radius and ulna.¹²⁶ Differences in leg length¹²⁶ also have been noted and may contribute to scoliosis. NFM2 occurs less frequently than type I (one in 25,000 to 40,000 births)¹⁰ and is caused by a mutation in the gene encoding the protein neurofibromin 2, also called *Merlin*.¹⁰ Merlin is produced in the nervous system, particularly in Schwann cells that surround and insulate the nerve cells of the brain and spinal cord. Although type II shares characteristics with type I, it is commonly characterized by tumors of the eighth cranial nerve (usually bilateral), meningiomas of the brain, and schwannomas of the dorsal roots of the spinal cord.¹⁰ Contrary to first descriptions of NFM1 and NFM2, café-au-lait spots are seldom a singular feature of NFM2¹²⁷; rather, signs and symptoms of tinnitus, hearing loss, and balance dysfunction usually appear during adolescence or in the person's early 20s.^{125,127} Problems with visual acuity caused by strabismus and refractive errors are common in young children.¹³⁸ NFM2 may be underrecognized in children up to 10 years old because early hearing loss and tinnitus are present in only 20% of cases and otherwise only singular features of the condition are observed. Infants may have cataracts, and children may demonstrate unilateral facial paralysis, eye squinting, mononeuropathy (foot or hand drop), meningioma, spinal tumor, or cutaneous tumor. It is recommended that children of parents with NFM2 should be considered to be at 50% risk for NFM2 and screened from birth.¹³⁰

Autosomal Recessive Disorders

An unaffected carrier of a disease-causing trait is *heterozygous* for the abnormal gene (possessing one normal and one mutated copy of the gene). If both parents are unaffected carriers of the gene, each of their offspring has a 25% risk of exhibiting the disorder.⁸ Consanguinity involving close relatives increases the chance of passing on autosomal recessive traits.⁸ Certain types of limb defects, familial microcephaly, and a variety of syndromes are passed on through autosomal recessive genes. Four examples of autosomal recessive disorders affecting children in therapy settings are presented in this section: cystic fibrosis (CF), Hurler syndrome, phenylketonuria (PKU), and spinal muscle atrophy (SMA).

Cystic Fibrosis. CF is one of the most common autosomal recessive disorders and is more common in Caucasians, affecting one in 2000 to 4000.¹⁰ The CF gene has been mapped to chromosome 7, and its protein product, CF transmembrane regulator (CFTR).⁸ CFTR is involved in the regulation of chloride channels of the bowel and lung, which is dysfunctional in patients with CF. Although CF has markedly variable expression, the overall median survival time has improved from about 6 years of age in the 1940s to an average of 36 years of age in 2006.¹³⁹ In addition to the phenotypical features of CF, diagnosis of CF is made when two or more disease-causing mutations exist on the CFTR gene.¹³⁹ Newborn screening tests for CF are required in all states in the United States.¹⁴⁰

Fibrotic lesions of the pancreas cause pancreatic insufficiency in the majority of patients, which leads to chronic malnutrition. Ten percent to 20% of newborn infants with CF also have intestinal tract involvement with a meconium ileus. The sweat glands are commonly affected; high levels of chloride found in the sweat is the basis for the sweat chloride test used in diagnosis. The most serious impairment in CF is the obstruction of the lungs by thick mucus, which leads to chronic pulmonary obstruction, infection that destroys lung tissue, and eventual death from pulmonary disease in 90% of individuals.⁸

Improved survival rate in recent decades is a result of improved antibiotic management, aggressive chest physical therapy, and pancreatic replacement therapy. Postural drainage, percussion, vibration, and breathing exercises are key components of the management program provided by the therapist and caregivers.¹⁴¹ Modern and less labor-intensive devices such as those that provide positive expiratory pressure may not be as effective at clearing secretions as conventional chest physiotherapy,¹⁴¹ but patient and caregiver compliance with a regular program may be improved with them.¹⁴² Attention to diet is important, and every attempt should be made to maintain a routine exercise program with a goal of helping the children be more active to improve their respiratory status and to prevent secondary impairments of adolescence and adulthood such as stress incontinence in young women caused by excessive coughing,^{143,144} chronic back pain, and osteopenia and osteoporosis.¹⁴⁵

Massery¹⁴³ describes the relationship among respiration, postural control, and secondary impairments that develop in individuals with CF in the musculoskeletal and neuromuscular systems. She addresses the threefold problem faced by individuals with CF: (1) lung dysfunction leading to

increased respiratory demand; (2) increased workload of respiration as a deforming force on the immature musculoskeletal frame; and (3) resultant impaired motor strategies for postural control during physical activity. Patients were once widely cautioned to avoid overexertion and fatigue with exercise, but as patients are living longer, more evidence supports the benefits of regular, even vigorous exercise for children and adults with CF. Guidelines for exercise frequency and intensity have been published by the Association of Chartered Physiotherapists in Cystic Fibrosis.¹⁴⁶

Hurler Syndrome (Mucopolysaccharidosis I, Severe Type). Hurler syndrome is an inborn error of metabolism that results in abnormal storage of mucopolysaccharides in many different tissues of the body.⁹⁷ The incidence is estimated to be one in 100,000 live births for the severe forms¹⁰ and one in 500,000 for milder forms.¹⁴⁷ *IDUA* is the only gene currently known to be associated with this multisystem disorder.¹⁴⁷

Infants born with Hurler syndrome are usually normal in appearance at birth, may have inguinal or umbilical hernias,¹⁴⁷ and may have higher birth weights than their siblings. Symptoms of this progressively deteriorating disease usually appear during the latter half of the first year of life,¹⁴⁷ with the full disease picture apparent by 2 to 3 years of age.^{10,147} Diagnosis is made by identification of deficiency in lysosomal enzymes.^{147,148} Premature death, usually from cardiorespiratory failure, occurs within the first 10 years of life.¹⁴⁷

Characteristic physical features are caused by storage of glycosaminoglycans (GAGs)¹⁴⁷ and include a large skull with frontal bossing, heavy eyebrows, edematous eyelids, corneal clouding, a small upturned nose with a flat nasal bridge, thick lips, low-set ears, hirsutism, and gargoyle-like facial features. Growth retardation results in characteristic dwarfism.¹⁴⁷ Some individuals with the physical characteristics of Hurler syndrome have normal intelligence, but most have progressive and profound intellectual disability.^{10,147}

Spastic paraparesis or paraplegia and ataxia have been observed in individuals with Hurler syndrome.⁸ Commonly reported orthopedic deformities include flexion contractures of the extremities, thoracolumbar kyphosis, genu valgum, pes cavus, hip dislocation, and claw hands as a result of joint deformities.⁴⁵ Defective ossification centers of the vertebral bodies results in spinal deformity, complications of nerve entrapment, atlanto-occipital instability, and restricted cervical range of motion.¹⁴⁷ Conductive and sensorineural hearing loss is common.¹⁴⁷ Delayed motor milestones have been noted as early as 10 months of age,¹⁴⁸ with severe disabilities occurring with increasing age. Adaptive equipment often is needed, and most children with Hurler syndrome become wheelchair users in their later years.¹⁴⁸

Phenylketonuria. PKU is the result of one of the more common inborn errors of metabolism. Mutations of the *PAH* gene located on chromosome 12 cause a deficiency in the production of phenylalanine hydroxylase.¹⁴⁹ Without this enzyme, there is no conversion of phenylalanine to tyrosine, resulting in an abnormally excessive accumulation of phenylalanine in the blood and other body fluids.^{149,150} If untreated, this metabolic error results in mental and growth retardation, seizures, and pigment deficiency of hair and skin.¹⁵¹ PKU is most prevalent among individuals of northern European ancestry, with a frequency of one in 10,000 to

15,000 births in the United States.¹⁴⁹ It is estimated that one of every 50 individuals is heterozygous for PKU.⁸

Children born with PKU are usually normal in appearance, with microcephaly and delayed development becoming apparent toward the end of the first year. Parents usually become concerned with the child's slow development during the preschool years.¹⁵¹ If PKU is untreated, the affected child may go on to develop hypertonicity (75%), hyperactive reflexes (66%), hyperkinesia (50%), or tremors (30%),¹⁵² in addition to intellectual disability. IQ levels generally fall between 10 and 50, although there have been reported rare cases of untreated individuals with normal intelligence.¹⁵¹

A simple blood plasma analysis, which is mandatory for newborn infants in all 50 U.S. states,¹⁴⁰ can detect the presence of elevated phenylalanine levels in nearly 100% of cases.¹⁵⁰ This test is ideally performed when the infant is at least 72 hours old. If elevated phenylalanine levels are found, the test is repeated, and further diagnostic procedures are performed. Placing the infant on a low phenylalanine diet (low protein) can prevent the intellectual disability and other neurological sequelae characteristic of this disorder.¹⁵¹ Follow-up management by an interdisciplinary team consisting of a nutritionist, psychologist, and appropriate medical personnel is advised in addition to the special diet. Individuals with poor compliance with the recommended diet have a greater risk of osteopenia in adulthood.¹⁵⁰

Spinal Muscle Atrophy. SMA (5q SMA) is characterized by progressive muscle weakness because of degeneration and loss of the anterior horn cells in the spinal cord and brain stem nuclei.^{153,154} Diagnosis of SMA is based on molecular genetic testing for deletion of the *SMN1* gene (named for "survival of motor neuron 1"), location 5q13. Another gene, *SMA2*, can modify the course of SMA. Individuals with multiple copies of *SMA2* can have less severe symptoms or symptoms that appear later in life as the number of copies of the *SMN2* gene increases.¹⁵⁵ The overall disease incidence of SMA is five in 100,000 live births.¹⁵⁵

The clinical classifications of SMA are still evolving.^{153,154,156} At present, four subtypes (types I to IV) are well accepted, and a fifth, type 0, is being explored. The subtypes are based on age at symptom onset and expectations for maximum physical function, the latter being more closely related to life expectancy.¹⁵⁶

SMA type 0 is characterized by extreme muscle weakness apparent before 6 months of age that likely had a prenatal onset.^{153,154} Some infants have a prenatal history of decreased fetal movements during the third trimester.¹⁵³

SMA I, otherwise known as *Werdnig-Hoffmann disease* or *acute infantile SMA*,¹⁰ has an onset before 6 months of age.^{153,156} Incidence is estimated to be one in 20,000 live births.¹⁰ It is characterized clinically by severe hypotonicity, generalized symmetrical muscle weakness, absent deep tendon reflexes, and markedly delayed motor development. Intellect, sensation, and sphincter functioning, however, are normal.¹⁵³ Children usually cannot sit without support and have poor head control.¹⁵⁶ They have a weak cry and cough and problems with swallowing, feeding, and handling oral secretions.¹⁵⁴ The diaphragm is spared, but combined with weakness in intercostal muscles, infants exhibit paradoxical breathing, abdominal protrusion, and a bell-shaped trunk with chest wall collapse.¹⁵⁴ Overall, this pattern of chest wall weakness and poor respiratory function contributes

to the greatly increased susceptibility to pulmonary infection, which usually results in death before the age of 2 years.^{10,154,155}

SMA II, otherwise known as *intermediate* or *chronic infantile SMA*, has an onset at age 6 to 18 months and is associated with delayed motor milestones.¹⁵⁶ Seventy percent of children diagnosed with SMA II are alive at 25 years of age.¹⁵³

Children with SMA II can usually sit independently if placed but never stand unsupported.¹⁵⁴ Bulbar weakness with swallowing difficulties, poor weight gain, and diaphragmatic breathing are common.¹⁵⁵ Finger trembling is almost always present.^{153,154} Joint contractures are present in most individuals. Kyphoscoliosis of severity to require bracing and/or surgery often develops, but patients are at risk of postanesthesia complications.¹⁵⁴ Respiratory failure is the major cause of morbidity and mortality. Nocturnal oxygen desaturation and hypoventilation occur before daytime hypercarbia and are early indications of need for ventilator support.¹⁵⁴

SMA III is characterized by onset of symptoms in childhood after 18 months.¹⁵³ It is also known as *juvenile SMA* or *Kugelberg-Welander syndrome*.¹⁰ These individuals have a normal life span and usually attain independent ambulation and maintain it until the third or fourth decade of life.¹⁵³ Lower extremities are often more severely affected than the arms. Strength is often not sufficient for stair climbing, and balance problems are common.¹⁵³ Muscle aches and joint overuse symptoms are frequently reported.¹⁵⁴

SMA IV typically has an onset at older than 10 years of age and is associated with a normal life expectancy and no respiratory complications.^{154,156} Individuals maintain ambulation during the adult years.¹⁵⁴

Variants of SMA occur in individuals with similar phenotypes and clinical diagnostic features of electromyography (EMG) that are not associated with deletion of *SMN1*.¹⁵⁶ Genetic testing for *SMN* gene deletion achieves up to 95% sensitivity and nearly 100% specificity.¹⁵⁴ For cases that remain unclear, a clinical diagnosis may be accomplished through EMG and muscle biopsy, which reveal neurogenic atrophy. Key physical signs are common: symmetrical weakness in the more proximal musculature versus distal, and lower extremity weakness that is greater than in the arms.¹⁵⁴ Traditional strength measurements are not practical for children with SMA. The Gross Motor Function Measure¹⁵⁷ has excellent reliability in studies of gross motor evaluation in this population.^{154,158} Consensus guidelines on pulmonary care including assessment, monitoring, and treatment; feeding and swallowing, gastrointestinal dysfunction and nutrition; and orthopedic management have been published by the Standard of Care Committee for Spinal Muscle Atrophy.¹⁵⁴ Currently there are no efficacious drugs to effectively treat the symptoms of SMA.^{160,161}

Sex-Linked Disorders

The third mechanism for transmission of specific gene defects is through sex-linked inheritance. In most sex-linked disorders, the abnormal gene is carried on the X chromosome. Female individuals carrying one abnormal gene usually do not display the trait because of the presence of a normal copy on the other X chromosome. Each son born to a carrier mother, however, has a 50:50 chance of inheriting

the abnormal gene and thus exhibiting the disorder. Each daughter of a carrier mother has a 50:50 chance of becoming a carrier of the trait.⁸ Four syndromes that result in disability are discussed in this section: hemophilia, fragile X syndrome (FXS), Lesch-Nyhan syndrome (LNS), and Rett syndrome (RS).

Hemophilia. Hemophilia is a bleeding disorder caused by a deficient clotting process. Affected individuals will have hemorrhage into joints and muscles, easy bruising, and prolonged bleeding from wounds. The term *hemophilia* refers to hemophilia A (coagulation factor VIII deficiency) and hemophilia B or Christmas disease (coagulation factor IX deficiency). There are numerous other clotting diseases, and some that were once referred to as hemophilia are now genomically distinguished. For example, von Willebrand disease has a distinctly different genetic basis from hemophilia; it follows an autosomal recessive or autosomal dominant pattern and involves mutation of the von Willebrand factor (VWF) gene, located on chromosome 12. VWF plays a role in stabilizing blood coagulation factor VIII.¹⁶² Hemophilia A and B occur as X-linked recessive traits owing to mutations of genes *F8* and *F9*, respectively, both of which are located on the X chromosome.^{163,164}

Hemophilia A is reported to affect one in 4000 to 5000 males worldwide.¹⁶³ Hemophilia B is less common, affecting one in 20,000 males worldwide.¹⁶⁴ Hemophilia can affect females, though in milder form. The severity and frequency of bleeding in hemophilia A are inversely related to the amount of residual factor VIII (less than 1%, severe; 2% to 5%, moderate; and 6% to 35%, mild).¹⁶³ The proportions of cases that are severe, moderate, and mild are about 50%, 10%, and 40%, respectively.¹⁶⁵ The joints (ankles, knees, hips, and elbows) are frequently affected, causing swelling, pain, decreased function, and degenerative arthritis. Similarly, muscle hemorrhage can cause necrosis, contractures, and neuropathy by entrapment. Hematuria and intracranial hemorrhage, although uncommon, can occur after even mild trauma. Bleeding from tongue or lip lacerations is often persistent.⁸

Hemophilia is usually diagnosed during childhood, with the most severe cases diagnosed in the first year of life: bleeding from minor mouth injuries and large “goose eggs” from minor head bumps are the most frequent presenting signs in untreated children.¹⁶³ Children are especially vulnerable to bleeding episodes owing to the nature of their physical activity combined with periods of rapid growth.¹⁶³

Treatment includes guarding against trauma and replacement with factor VIII derived from human plasma or recombinant techniques.⁸ In the late 1970s to mid 1980s it was estimated that half of the affected individuals in the United States contracted hepatitis B or C or human immunodeficiency virus (HIV) infection when treated with donor-derived factor VIII. The initiation of donor blood screening and use of heat treatment of donor-derived factor VIII has almost completely eliminated the threat of infection.⁸ Although replacement therapy is effective in most cases, 30% of treated individuals with hemophilia A and 3% of individuals with hemophilia B have neutralizing antibodies that decrease its effectiveness.^{163,164} Before treatment with clotting factor concentrates was available, the average life expectancy was 11 years¹⁶³; currently, excluding

death from HIV, life expectancy for those with severe hemophilia who receive adequate treatment is 63 years.¹⁶³ Factor replacement therapy is credited for increasing the ease and safety of vigorous exercise and sports participation for individuals.¹⁶⁶ The benefits of regular exercise are the same as for unaffected individuals and outweigh the risks in treated persons.¹⁶⁷ A 2002 pilot study by Tiktinsky and colleagues¹⁶⁷ found decreased episodes of bleeding in a population of young adults with a long-term history of resistance training that began in adolescence.

Fragile X Syndrome. FXS is the most common sex-linked inherited cause of intellectual disability, affecting one in 4000 males and one in 8000 females.¹⁶⁸ Males manifest a more severe form than females. A fragile site on the long arm of an X chromosome is present, with breaks or gaps shown on chromosome analysis. A region of the X chromosome, named *FMRI*, normally codes for proteins that may play a role in the development of synapses in the brain. Mutations of this region are errors of trinucleotide repeats, in which the number of CGG triplets at this region is expanded, thereby making the gene segment unable to produce the necessary protein.¹⁶⁸

Developmental milestones are slightly delayed in affected males.¹⁶⁸ Eighty percent of males are reported to have intellectual disability, with IQs of 30 to 50 being common but ranging up to the mildly retarded to borderline range.¹⁶⁸ *Penetrance* (the proportion of individuals with a mutation that actually exhibit clinical symptoms) in the female is reported to be only 30%.⁸ Other impairments include epilepsy, emotional lability, attention-deficit/hyperactivity disorder (ADHD), and clinical autistic disorder in 30% of males.^{168,169} Life span is normal for individuals with this condition.¹⁶⁸

Lesch-Nyhan Syndrome. Also known as *hereditary choreoathetosis*,¹⁷⁰ LNS leads to profound neurological deterioration. First described in 1964 by Lesch and Nyhan,¹⁷¹ it is associated with a mutation in the *HPRT1* gene on the X chromosome. This gene codes for an enzyme, hypoxanthine guanine phosphoribosyltransferase, which allows cells to recycle purines, some of the building blocks of DNA and ribonucleic acid (RNA).¹⁷² Without this gene's normal function, there is an overproduction of uric acid (hyperuricemia),¹⁷² which accumulates in the body. High uric acid levels are thought to cause neurological damage.^{170,172}

The prevalence of LNS is one in 380,000 individuals.¹⁷² Females born to carrier mothers have a 25% chance of inheriting the mutation. There are rare reports of females demonstrating this syndrome as a result of X chromosome inactivation. Most female carriers are considered to be asymptomatic, but some may have symptoms of hyperuricemia in adulthood.¹⁷²

LNS is detectable through amniocentesis, and genetic counseling is advisable for parents who have already given birth to an affected son.¹⁷³

The prenatal and perinatal course is typical for affected individuals. Hypotonia and delayed motor skills are noticeable by age 3 to 6 months.¹⁷² Dystonia, choreoathetosis, and opisthotonus indicative of extrapyramidal involvement emerge during the first few years of life.¹⁷² Many children are initially diagnosed with athetoid cerebral palsy when pyramidal signs such as spasticity, hyperreflexia, and abnormal plantar reflexes emerge.¹⁷² Most children never walk. A hallmark of the disease is severe and frequent self-injurious

behaviors such as lip and finger biting, which emerge in almost all affected children by their third birthday.¹⁷² Because of the extreme self-mutilation that characterizes this disorder, it has been questioned whether these children have normal pain perception.¹⁷⁴ Although these children have the abnormal catecholamine metabolism seen in other patients with congenital pain insensitivity,¹⁷⁵ behaviors documented in children with LNS suggest that they do sense pain, demonstrated by their apparent relief when they are restrained from hurting themselves. Children may actually request the restraining device¹⁷⁶ even when the device may be one that would not physically prevent biting, such as a glove or bandaid.¹⁷² A reported survey of parents of children with LNS indicated that parents often find behavioral programming techniques helpful in modifying aggression toward self or others.¹⁷⁶ However, there is no consensus on the best kind of behavioral treatments, as any reward, either positive or negative, may increase the frequency of self-injury.¹⁷⁷ Some parents have reported that they elected tooth extraction as a means to prevent biting. Other impairments in children with LNS include severe dysarthria and dysphagia. Bilateral dislocation of the hips may occur as a result of the spasticity.¹⁷² Growth retardation is also apparent, as well as moderate to severe intellectual disability.¹⁰ Individuals may have gouty arthritis and kidney and bladder stones.

Blood and urine levels of uric acid have been decreased successfully through the administration of allopurinol, with a resultant decrease in kidney damage. With current management techniques, most individuals survive into their second or third decade of life.¹⁷²

Rett Syndrome. RS is inherited in an X-linked pattern and it affects females almost exclusively, as it is most often lethal in boys before age 2 years. Males may inherit RS with an extra X chromosome in many or all of the body's cells.¹⁷⁸⁻¹⁸¹ The estimated incidence is one in 15,000 to 20,000 females.^{10,182} It has been reported that 99% of all cases of RS are the result of sporadic mutations.^{181,183} Most cases of RS, called *classic RS*, are caused by mutations in the *MECP2* gene, which is responsible for directing proteins critical for normal synaptic development; however, it is unclear how these mutations lead to all the signs and symptoms of the syndrome.^{181,184} Several variants of RS exist; they have overlapping features with classic RS but may have a much milder or more severe course.¹⁸¹

Classic RS is characterized by apparently normal development during the first 6 months of life, followed by a short period of developmental plateau, and then rapid deterioration of language and motor skills typically occurring at 6 to 18 months of age.^{181,185} Most girls survive into adulthood.¹⁸¹ The hallmark of the syndrome is that during the period of regression, previously acquired purposeful hand skills are also lost and replaced by stereotypical hand movements. These nonspecific hand movements have been described as hand wringing, clapping, waving, or mouthing. Virtually all language ability is lost, although some children may produce echolalic sounds and learn simple manual signing. Evidence of minimal receptive language skills may be observed. Autistic behaviors, inconsolable crying and screaming, and bruxism are common features of individuals with RS.¹⁸¹ Almost all

individuals with RS function in the range of severe to profound intellectual disabilities.

Head circumference is normal at birth, and its increase may decelerate in early childhood, but microcephaly is not a consistent feature of RS.¹⁸¹ Retarded growth and muscle wasting are observed in most girls, likely associated with poor food intake and gastrointestinal problems.¹⁸¹

Almost one fourth of girls with RS never develop independent ambulation skills; otherwise the onset of walking is usually delayed until about 19 months of age.¹⁸⁶ Initially hypotonia may be evident, but with advancing age, spasticity of the extremities develops.¹⁸⁷ Increased muscle tone is usually observed first in the lower extremities, with continued greater involvement than in the upper extremities. Peripheral vasomotor disturbances, especially in the lower limbs, are often noted.¹⁸¹

Scoliosis, which is often severe enough to require surgical correction, occurs in most girls by adolescence, characterized by a long C-shaped thoracolumbar curve, kyphoscoliosis, and an early onset of posterior pelvic tilt and abducted shoulder girdles.^{186,188-192} Heel cord tightening, and hip instability have also been identified as areas of potential concern.¹⁸⁸ Abnormal EEG and seizures occur in 70% of individuals with RS in the first 5 years of life. Cranial CT results are normal or show mild generalized atrophy. Breathing dysfunction, including wake apnea and intermittent hyperventilation,¹⁸⁶ is also associated with RS. Interventions reported in the literature have focused on splinting,¹⁹³ behavioral modification techniques to teach self-feeding skills,¹⁹⁴ aquatic therapy,¹⁹⁵ occupational therapy,¹⁹⁶ music therapy,¹⁹⁷ physical therapy,^{181,190,191,197} and the first two combined in a dual-intervention approach.¹⁹⁸

Mitochondrial DNA Disorders

In addition to the nuclear genome, humans have another set of genetic information within their mitochondria. Nuclear genes exist in pairs of one maternal and one paternal allele. In contrast, there are hundreds or thousands of copies of mtDNA in every cell. mtDNA is small, circular, and double stranded. It has been well studied and was mapped long before the human nuclear genome. mtDNA contains 37 genes responsible for normal function of the mitochondria in all body cells.^{198a} Humans inherit mtDNA maternally. mtDNA is highly susceptible to mutation, and the molecule has limited ability to repair itself. Tissues that have a high demand for oxidative energy metabolism, such as brain and muscle, appear to be most vulnerable to mtDNA mutations.¹¹ Normal and mutated versions of mtDNA can coexist within a patient's body, but when a certain critical number of mutations exist, the body's tissues will show clinical signs of dysfunction. These disorders affect the metabolic functions of the mitochondria, such as the generation of the body's energy currency, adenosine triphosphate. Many patients with point mutations of mtDNA exhibit symptoms in early childhood; these mutations may be the most frequent cause of metabolic abnormality in children.¹¹ The minimum birth prevalence of childhood mitochondrial respiratory chain disorders is reported to be 6.2 per 100,000.^{12,199-201} Medical intervention for mitochondrial encephalomyopathies cannot treat the underlying disease, but the value of rehabilitative therapies has been reported.^{202,203} An example

of a childhood disorder that can result from an mtDNA mutation is Leigh syndrome.

Leigh Syndrome

Leigh syndrome, or subacute necrotizing encephalomyopathy, may also be transmitted by X-linked recessive and autosomal recessive inheritance. Approximately 20% of all cases of Leigh syndrome are caused by mitochondrial mutations.²⁰⁴ The discussion in this section will focus on characteristics of mtDNA-associated Leigh syndrome.

Leigh syndrome has an onset in infancy, typically at 3 to 12 months of age. Initial features may be nonspecific, such as a failure to thrive and persistent vomiting.^{204,205} It is a progressive disorder caused by lesions that can occur in the brain stem, thalamus, basal ganglia, cerebellum, and spinal cord. Common clinical features include seizures, epilepsy, muscle weakness, peripheral neuropathy, speech and feeding difficulties, gastrointestinal and digestive problems, and heart problems. Most affected children have hypotonia, movement disorders such as chorea, and ataxia. Life expectancy is 2 to 3 years; death most often results from respiratory or cardiac failure.²⁰⁴

Multifactorial Disorders

Multifactorial disorders are believed to be a result of the combined effects of mutations in multiple genes and environmental factors.⁸ Environmental factors may be those that have an impact on a developing fetus, such as prenatal diet, or those that have an impact on humans as we age, such as cigarette smoking. Disorders in this category can result in congenital malformations such as spina bifida and clubfoot. An in-depth discussion of spina bifida can be found in Chapter 15. Management information on clubfoot can be found in pediatric textbooks that include orthopedic information.²⁰⁶⁻²⁰⁹

Many diseases such as cancer can result when the environment interacts with genetic variations that exist in all humans.⁸ Scientists are exploring genetic contributions to premature births.^{210,211} Premature birth is the leading cause of infant mortality and morbidity,^{212,213} and it most likely is a result of multiple genetic and environmental determinants that tend to run in families.^{210,211} Premature infants are at higher risk of neurological, musculoskeletal, and respiratory problems than term infants are. Management of infants with low birth weight is discussed in Chapter 11 of this text.

BODY STRUCTURE AND FUNCTION PROBLEMS COMMON TO MANY PEDIATRIC GENETIC DISORDERS

Specific examples of genetic disorders in children were presented in the foregoing section. Although there are many disorders that physical and occupational therapists may see often, others are rare and may only be suspected based on clustered problems of body structure, function, and activity limitations. Decisions about which interventions to implement and the expected outcomes will be largely influenced by the diagnosis of the specific disorder, once attained. Many genetic conditions share in common a short list of primary problems that will negatively affect the child's physical movement and daily activities and participation, both immediately and in the long term. [Table 13-3](#) summarizes the problems common to many

genetic disorders that are most relevant for physical or occupational therapists.

Hypertonicity

Abnormalities of tone may result from dysgenesis or injury to developing motor pathways. Hypertonia is common to many motor disorders and is defined as “abnormally increased resistance to externally imposed movement about a joint.”²¹⁴ Examples of externally imposed movement are passive movement by the therapist or changes in ankle and knee position resulting from ground reaction forces during ambulation. Children with hypertonus generally display stiff or jerky movements that are limited in variety, speed, and coordination. Controlled, voluntary movements tend to be limited to the middle ranges of a joint. Total patterns of flexion or extension may dominate, with limited ability for selective joint movements. Motor development of children with hypertonicity may be further complicated by the retention of primitive reflexes, which can result in stereotyped movements associated with sensory input.²¹⁴

Sanger and colleagues²¹⁴ proposed a classification system to objectively define and distinguish different types of hypertonicity. Three general types of hypertonicity—spasticity, dystonia, and rigidity—may occur alone or in combination. Spasticity is a velocity-dependent, increased resistance to muscle stretch that may occur above a given threshold of speed and/or joint angle and may depend on the direction of joint movement. Dystonia is also an involuntary alteration in the pattern of muscle activation during voluntary movement or maintenance of posture. The observable disorder is demonstrated by intermittent muscle contractions causing twisting or repetitive movement, postures, or both.²¹⁴ Dystonia may be triggered by attempts at voluntary movement or to prevent the movement of a joint (e.g., to prevent knee buckling in stance). The pattern and magnitude of the abnormal muscle activity may change with the child's arousal, emotional state, and tactile contact.²¹⁴ Rigidity is a form of hypertonus in which the speed of movement and joint angle do not affect the movement quality. Stiffness caused by diminished tissue length and extensibility of muscles and connective tissue is not included in the recent definitions of hypertonus (but may exist alongside hypertonicity).^{214,215}

Children may learn to use stereotypical patterns of movement and hypertonus to achieve functional goals by activating the muscle synergies of a reflex without sensory feedback.²¹⁶ If a goal of therapy is to facilitate functional movement that is not dominated by persistent reflexes, it is critical to practice new motor patterns to accomplish the functional activity for which that reflex is being used. The focus of therapy activities needs to be on active movement of the child and not on passive inhibition techniques of abnormal reflexes for the sake of “normalization” of tone and movement.²¹⁶⁻²¹⁹

Hypotonicity

In contrast to hypertonia, low tone or hypotonia is not clearly defined. The “floppy” infant or child is commonly characterized as having hypermobility of joints that lack resistance to passive movement, with diminished antigravity movement and postural stability. Hypotonia may occur because of central or peripheral nervous system dysfunction,

TABLE 13-3 ■ CHARACTERISTIC FEATURES OF SELECTED GENETIC CONDITIONS

GENETIC CONDITION	TYPICAL AGE AT DIAGNOSIS	CRANIOFACIAL DYSMORPHISM	MUSCULOSKELETAL INVOLVEMENT	NEUROMUSCULAR SYSTEM INVOLVEMENT AND TONE	CARDIO-PULMONARY INVOLVEMENT
Trisomy 21	Prenatal or infancy	Yes	Joint laxity and instability	Hypotonia	Yes
Trisomy 18	Prenatal, neonatal	Yes	Yes	Hypotonia	Yes
Turner syndrome	Infancy, adolescence; girls	Yes	Short stature, hip dislocation, scoliosis		Yes
Klinefelter syndrome	Adolescence; adulthood; males	Yes	Yes	Varies with age	
Cri-du-chat syndrome	Infancy	Yes	Yes	Hypotonia	Yes
Prader-Willi syndrome	Infancy	Yes	Scoliosis	Hypotonia	Secondary to obesity
Angelman syndrome	Infancy	Microcephaly		Hypotonia and seizures, ataxia	
Acute lymphoblastic leukemia	Childhood		Bone pain and muscle cramps		
Osteogenesis imperfecta	Varies with type and severity		Multiple fractures and muscle weakness		Yes
Tuberous sclerosis complex	Infancy, early childhood		Yes, cyst formation	Hypertonia; seizures	Yes, cyst formation
Neurofibromatosis type 1	Infancy, childhood		Yes		
Cystic fibrosis	Infancy		Chest wall deformity, muscle and bone pain		Yes
Hurler syndrome	Infancy	Yes	Yes	Yes	Yes
Spinal muscle atrophy type II	Infancy		Yes	Hypotonia	Yes
Hemophilia type A	Childhood or earlier if severe		Joint pain and hemarthroses		
Fragile X syndrome	Childhood	Yes	Joint laxity		Yes
Lesch-Nyhan syndrome	Infancy		Gouty arthritis	Varies	
Rett syndrome	Late infancy to early childhood		Scoliosis	Hypotonia, ataxia, seizures	

as is the case in newborns with PWS and toddlers with SMA type II, respectively. Many genetic disorders are revealed in newborns based on the common features of severe, global hypotonia and low Apgar scores.²²⁰ Retrospective studies of newborns report key features of absence of antigravity movements and decreased reflexes. The presence of fetal hypokinesia and/or polyhydramnios is reported to be predictive of neonatal hypotonia in many cases.²²¹ In full-term neonates with hypotonia, studies report that 30% to 60% of cases are associated with a genetic disorder. A clinical neurological examination such as described by Dubowitz and the use of dysmorphic data bases can identify the majority

of cases.^{221,222} First-line genetic testing is indicated in neonates with hypotonia plus facial dysmorphism or signs of peripheral hypotonia (e.g., as seen in SMA).²²¹

Martin and colleagues²²³ surveyed physical and occupational pediatric therapists and reported that the majority of therapists do not use formal examination methods to quantify hypotonia directly, but rather use measurements for various expressions of hypotonia, most often muscle strength and developmental milestones. This study also confirmed that most therapists agree that children with hypotonicity have diminished postural control and thus tend to lean on supports to maintain a position. Examples of this behavior

OTHER SYSTEM INVOLVEMENT	OTHER DISEASE PROCESSES	SENSORY DYSFUNCTION	MOTOR DELAY	COGNITIVE DELAY	HALLMARK FEATURE(S)
	Alzheimer disease, sleep apnea, obesity	Vision, hearing	Yes	Yes	Facial features, simian crease
Yes Distal lymphedema; reproductive system		Yes Hearing	Yes	Yes	Life span < 1 year Webbed neck appearance and short stature
Endocrine and reproductive system			Yes	Yes	Intellectual disability; course of gonadal development
Reproductive system	Morbid obesity	Vision Vision	Yes	Yes	“Cat cry” Hypotonia, obesity
			Yes	Yes	Happy demeanor, sleep disorders
	Osteopenia, osteoporosis Dentinogenesis	Hearing (type I)			Lethargy, fever, respiratory infections Multiple fractures
Skin lesions, adenomas; renal disease		Vision	Yes	Yes	Sebaceous adenomas, seizures
Café-au-lait spots and cutaneous neurofibromas; vasculopathy		Vision			Café-au-lait spots, neurofibromas
Gastrointestinal system; urinary stress incontinence in females	Osteoporosis, osteopenia				Lung and digestive dysfunction
Yes		Vision, hearing	Yes	Yes	Progressive craniofacial abnormalities and developmental deterioration
Yes			Yes		Progressive loss of peripheral motor function
Skin bruising					Bleeding, bruising, joint pain, and loss of motion
Urogenital system		Yes Yes	Yes	Yes	Intellectual disability, autism Self-injurious behavior, gouty arthritis
		Yes	Yes	Yes	Regressive developmental delay; stereotypical, purposeless hand movements

are locking out weight-bearing joints and assuming positions that provide a broad base of support to maximize their stability (Figure 13-5). Although retention of primitive reflexes is less likely in children with hypotonia compared with those with hypertonia, delays in the development of postural reactions are a major concern. Limited strength and lack of endurance are often concerns with children who have hypotonicity. Hypotonicity and joint laxity are often associated with motor delay; however, therapists should not assume that hypotonia and joint laxity are absolutely predictive of persistent motor delay.²²⁴ For example, many premature infants, with or without a genetic disorder, have

global hypotonia at birth that resolves and does not cause long-term functional impairment.^{224,225} Hypotonicity is a persistent problem in many children with developmental delay. Therapists may address hypotonia and problems of postural control with a variety of treatment modalities and techniques including aquatic therapy,²²⁶ hippotherapy,²²⁷ and neurodevelopmental therapy.²²⁸

Hyperextensible Joints

Hyperextensible joints are commonly observed in children with hypotonicity and are noted in many children with a variety of genetic disorders, representing different

Figure 13-5 ■ Eight-year-old boy with hypotonia associated with a chromosomal translocation error. Note the broad base of support in this “W” sitting position.

underlying organ structure problems. Activities should be modified to avoid undue stress to these joints and the surrounding ligaments, tendons, and fascia. For example, positions that allow the knee or elbow joints to lock into extension should be modified so that weight bearing occurs through more neutral alignment. Varying the placement of toys and support surfaces, providing physical assistance, and using adaptive equipment can help modify weight-bearing forces to achieve more neutral alignment.²²⁹ For example, if hyperextensibility of ligaments leads to excessive pronation in stance (Figure 13-6), the use of ankle-foot orthoses may provide enough support to the structures to allow functional activities in standing (see the discussion of orthotics in Chapter 34). For a child who stands with knee hyperextension, a vertical stander may allow that child to stand and play at a water table with her or his classmates for extended periods with the knees in a more neutral position. Rather than restricting a child’s repertoire of upright positions, it is preferable to modify an activity or provide external support to enable a child to participate fully (Figure 13-7).²³⁰

Contractures and Musculoskeletal Deformities

Skeletal anomalies and deformities are associated with many genetic disorders. The therapist should be aware of factors that can contribute to the development of deformities to prevent or minimize such problems. The physical or occupational therapist may work with orthopedists, prosthetists, and orthotists to detect and prevent the progression of a variety of conditions.

Conditions that cause hypertonicity or spasticity are well known to place children at risk for joint contracture.²³¹ Children with hemophilia are at great risk of joint contractures associated with hemarthroses and intramuscular hemorrhages.²³² Spinal deformities, such as lumbar lordosis and thoracic kyphosis and scoliosis, are also common concerns in children with hypertonia or hypotonia. Although joint contractures are less likely to occur in a child with

Figure 13-6 ■ Excessive bilateral pronation and flat feet associated with hyperextensibility in 8-year-old boy with global hypotonia.

Figure 13-7 ■ Adapted equipment to promote participation in upright activities for children with trunk weakness and poor postural control. **A**, The corner chair provides this child with Rett syndrome the proper back support, and toys can be placed within her reach on the tray. **B**, This particular gait trainer allows appropriate patterns of weight-shifting to occur while providing her with stability in the pelvis and lower trunk.

hypotonicity, habitual positioning may lead to soft tissue restrictions. For example, children with hypotonia often adopt a constant position of wide abduction, external rotation, and flexion at the hips (“frog” or “reverse W” position)²³³; in these children, soft tissue contractures can develop at the hips and knees. Children whose hips are maintained in a position of adduction, flexion, and internal rotation are at risk for hip subluxation or dislocation.²³³

Deformation of the anterior chest wall and shoulder girdles may result from primary problems in the cardiopulmonary system such as in children with CF. When coupled with hypotonicity and poor postural control, the anterior chest wall muscles tighten as a result of the long-term rounded, internally rotated shoulders and protracted scapulae, in which case therapeutic interventions should target improving chest wall and scapulothoracic mobility as well as strengthening postural muscles (Figure 13-8).²³⁴⁻²³⁶ In general, contractures and deformities are a concern for most children who display a limited variety of postures and

Figure 13-8 ■ Postural changes after therapeutic intervention to improve mobility in chest wall and shoulder girdles and strengthen postural muscles in a child with cystic fibrosis. (Before intervention on left, after intervention on right.)

movements. Therapists should consider the nature of the disorder that places the child at risk for contractures when choosing treatment techniques; disorder-specific techniques can be found in pediatric occupational and physical therapy textbooks.^{206,237}

Respiratory Problems

A genetic risk for respiratory distress in infancy has been suggested by reports of family clusters.²³⁸ Furthermore, comparison of short- and long-term respiratory function in infants with respiratory distress syndrome suggests that if all other factors of nutrition, previous mechanical ventilation, and gestational development are comparable, genetic risk may account for cases of chronic and potentially irreversible respiratory failure.²³⁸

Respiratory problems are often observed in children with limited mobility. If the mobility impairments are the result of hypotonicity or hypertonicity, impaired respiration may be a result of chest and skeletal deformities. Many infants with genetic disorders are born prematurely and are more susceptible to respiratory problems than infants born at full term.^{210,211,233} Prolonged mechanical ventilation and other medical procedures may increase the time neonates spend in the supine position, thus increasing the risk of gravity-induced deformity of the rib cage and inefficiency of the respiratory musculature.^{234,239,240}

Some children may find it difficult to tolerate one position for an extended time owing to respiratory difficulties. For these children, frequent changes of position and use of adapted positioning devices may be necessary. Premature infants in the neonatal intensive care unit may benefit from regular prone positioning to facilitate restorative sleep,²⁴⁰⁻²⁴² improved arterial oxygen saturation,²⁴³ and improved respiratory synchrony.²⁴⁴ Children with respiratory problems may require mobilization techniques, deep breathing, chest expansion exercises, and postural drainage. In the case of children with CF, a comprehensive program of respiratory care is the primary therapy goal.²⁴⁵

Developmental Delay

Genetic disorders that affect neuromuscular, somatosensory, and cognitive function are frequently associated with developmental delays in children. The genetic basis for multisystem syndromes such as Down syndrome or LNS can be identified by cytogenetic and molecular techniques. Congenital malformations, hearing impairment, and mental or growth retardation are examples of common components of developmental delay that often have a genetic basis.

Developmental delay is typified by the failure to meet expected age-related milestones in one or more of five areas: physical, social and emotional, intellectual, speech and language, and adaptive life skills. Developmental milestones that are typically assessed in the first 5 years of life can be found in [Box 13-2](#).

Physical and occupational therapists can observe the interaction among each of the five areas of development in an infant or child. For example, a child with severe hypotonia who has limited movement experiences will not develop a well adapted sensory system. Children with problems processing sensory information often withdraw from social interaction through which they would otherwise find

opportunities to develop speech, language, and social skills. Dynamical systems theory²⁴⁶ explains this relationship among all of the developing components in a child; language does not develop independently of gross motor skills, and the ability to feed or dress oneself is as related to social, emotional, and intellectual development as it is to fine motor skills.

Suspicion of developmental delay often leads to physician referral. An accurate medical diagnosis is important in

that it facilitates knowledgeable surveillance for potentially associated health problems. A delayed diagnosis can preclude timely implementation of beneficial medical, therapeutic, and educational services. Children who are identified to be at risk for developmental delay may be referred to early intervention programs. Examples of assessment techniques and interventions for children with developmental delay can be found in pediatric physical therapy textbooks.^{247,248}

BOX 13-2 ■ DEVELOPMENTAL MILESTONES

BY 1 MONTH

Sucks poorly and feeds slowly
Lower jaw trembles constantly even when infant is not crying or excited
Does not respond to loud sounds or bright light
Does not focus on and follow a nearby object moving side to side
Rarely moves
Extremities seem loose and floppy or very stiff

BY END OF THIRD MONTH

No Moro reflex
Does not notice own hands by 2 months
Does not grasp and hold objects
Eyes cross most of the time or eyes do not track well together
Does not coo or babble

BY END OF FOURTH MONTH

Head flops back when infant is pulled up to sitting by his or her hands
Does not turn head to locate sounds
Does not bring object to mouth
Does not smile spontaneously
Inconsolable at night

BY END OF FIFTH MONTH

Persistent tonic neck reflexes
Cannot maintain head up when placed on stomach or in supported sitting position
Does not reach for objects
Does not roll in both directions

BY END OF SEVENTH MONTH

Reaches with one hand only
Cannot sit with help by 6 months
Does not follow objects at a distance
Does not bear some weight on legs
Does not laugh; does not try to attract attention through actions
Refuses to cuddle; shows no affection for caregiver

BY END OF TWELFTH MONTH

Does not creep on all fours
Cannot stand when supported
Does not search for toy hidden while he or she watches
Says no single words (e.g., “mama” or “dada”)
Does not use gestures such as waving hand or shaking head; does not point to objects or pictures

BY END OF SECOND YEAR

Cannot walk by 18 months
Failure to develop heel-toe walking pattern after several months of walking

Does not speak at least 15 words by 18 months
Does not use two-word sentences by 2 years
Does not know the function of common objects (brush, telephone, spoon) by 15 months
Does not imitate actions or words; does not follow simple instructions

BY END OF THIRD YEAR

Frequent falling and difficulty with stairs
Persistent drooling or unclear speech
Inability to build a tower of more than four blocks
Difficulty manipulating small objects
Cannot copy a circle
Cannot communicate in short phrases
No pretend play
Little interest in other children
Extreme difficulty separating from caregiver

BY END OF FOURTH YEAR

Cannot throw a ball overhand
Cannot jump in place with both feet
Cannot ride a tricycle
Cannot grasp a crayon between thumb and fingers; cannot scribble
Resists dressing, sleeping, using the toilet
Does not use sentences of more than three words; does not use “me” and “you” appropriately
Ignores other children or people outside the family
Does not pretend in play; no interest in interactive games
Persistent poor self-control when angry or upset

BY END OF FIFTH YEAR

Does not engage in a variety of physical activities
Has trouble eating, sleeping, using the toilet
Cannot differentiate between fantasy and reality
Seems unusually passive or aloof with others
Cannot correctly give her or his first and last names
Does not use plurals or past tense when speaking
Does not talk about daily experiences
Does not understand two-part commands
Cannot brush teeth efficiently
Cannot take off clothing
Cannot wash and dry hands
Cannot build a tower of six to eight blocks
Does not express a wide range of emotions
Seems uncomfortable holding a crayon

Behavioral Phenotypes in Genetic Syndromes

Study into the cognitive and behavioral aspects of individuals with certain genetic syndromes has given rise to the term *behavioral phenotype*. Certain clusters of behavior that characterize a given syndrome can aid in the early recognition and diagnosis of a syndrome and can guide intervention choices. Example aspects of behavioral phenotypes include social interaction, sleeping patterns, mood, attention, motivation, adaptive and maladaptive strategies, intellect, and memory.²⁴⁹⁻²⁵³

Down syndrome, PWS, AS, FXS, and LNS are examples of genetic disorders discussed in this chapter with delineated behavioral phenotypes.^{250,251} Compulsive overeating in children with PWS, sleep disturbances in children with AS, and self-injury in children with LNS are behavioral problems that can have significant negative impact on quality of life for children and their families. Although children with Down syndrome have fewer maladaptive behaviors than most children with intellectual disabilities,^{249,251,253} they have been shown to abandon challenging tasks sooner than other children at similar developmental levels in exchange for peer social interaction.²⁵² Furthermore, this strength of sociability in children with Down syndrome contributes to the child's learning through modeling and peer collaboration. A knowledgeable, observant therapist can use peer groups to motivate and model for a child with Down syndrome but should also recognize that the child may be distracted by other children and default to a social strategy and avoid the task at hand.²⁵²

MEDICAL MANAGEMENT AND GENETIC COUNSELING

The physical or occupational therapist should have general knowledge of both medical management of children with genetic disorders and genetic counseling for family members. This information allows the therapist to answer the family's general questions and to refer family members to the appropriate persons for more specific information.

Medical Management

Early detection of genetic disorders has improved the health and survival of individuals with certain genetic disorders such as PKU, hemophilia, and CF. Medical treatment for the other disorders is not curative but rather palliative or directed at specific associated anomalies.

Surgical Intervention

The congenital heart defects present in many individuals with Down syndrome can in most instances be corrected by cardiac surgery.²⁰ Orthopedic surgery in the form of insertion of intramedullary rods in the tibia or femur may minimize the recurrence of repeated fractures associated with OI.^{115,253} Surgical correction of dystrophic scoliosis may be warranted in individuals with NFM,¹³¹ RS,^{186,189,191,192,197} or Werdnig-Hoffmann disease¹⁵⁴ if the deformity is severe and bracing is not successful. Radiographic screening for atlantoaxial instability in children with Down syndrome can be initiated beginning at age 2 years.¹⁶ If atlantoaxial instability is excessive or results in a neurological deficit, a posterior fusion of the cervical vertebrae is recommended.³³ Surgical removal of obstructive or malignant tumors is advisable in certain cases of NFM, as is removal of cerebral nodular

growths for the control of seizures in individuals with tuberous sclerosis.¹²² Surgical interventions such as gastric bypass, small intestinal bypass, and jaw wiring have been attempted for weight control in children with PWS but have had limited success.^{83,90}

Pharmaceutics

Second-generation bisphosphonates can reduce fracture frequency, improve bone quality, and improve outcomes after orthopedic surgery in children and lessen the severity of osteoporosis in adults.¹¹⁵ Antibiotics and pneumo-otachian tubes to lessen the frequency and severity of otitis media can reduce the incidence of hearing loss in individuals with Down syndrome²⁰ and Turner syndrome.⁵⁷ The use of appetite-regulating drugs for individuals with PWS has had equivocal results. Reproductive hormone therapy can promote pubertal development in girls with Turner syndrome^{57,60} and boys with Klinefelter syndrome.^{67,254} Growth hormone has been shown to improve stature in girls with Turner syndrome.⁵⁷ The use of anticonvulsants is an important part of seizure management for individuals with RS^{186,190} and tuberous sclerosis.¹²³ Allopurinol has been used for individuals with LNS to prevent urological complications, although it has no effect on the progressive neurological symptoms.¹⁷² The use of large, potentially toxic amounts of vitamins and minerals (the orthomolecular hypothesis) has been proposed for children with many different types of developmental disabilities. This approach has been rejected for children with Down syndrome on the basis of the results of several investigations. In addition, supplementation of individual metabolites such as 5-hydroxytryptophan or pyridoxine for children with Down syndrome is ineffective.²⁵⁵

Pharmacogenetics is a new field of scientific research that helps provide a biochemical explanation for why some patients respond well to a medication and others with the same condition being treated do not. "Personalized medicine" is the concept in which doctors may make decisions regarding which medications, dosages, and combinations with other drugs to prescribe based on the analysis of selected genes in their patients.¹⁵

Cell Therapy

Hematopoietic stem cell transplantation and enzyme replacement therapy can increase survival in children with Hurler syndrome.¹⁴⁷ Gene therapy could potentially correct defective genes responsible for disease, but there has not yet been much success in clinical trials. The purpose of gene therapy is to replace missing or mutated genes, change gene regulation, or enhance the "visibility" of disease genes to improve the body's immune response. Gene therapy trials have been approved for use in humans only on somatic cells. A vector carries the gene product to the person's cells; vectors may be either an altered virus, stem cells, or liposomes.²⁵⁶ Gene therapy is still only experimental and is moving along cautiously in the United States. In 1999 and again in 2003, individuals died while participating in gene therapy trials.¹

The oversight of gene therapy falls under the U.S. Department of Health and Human Services, which oversees agencies that in turn are responsible for establishing research protocols (National Institutes of Health [NIH]), evaluating investigational gene products (Food and Drug

Administration), monitoring ethics (Recombinant DNA Advisory Committee), and educating human subjects (Office for Human Research Protections).²⁵⁷ The clinical development of a gene product that could be widely dispensed must include four phases: phase 1 consists of regulatory approval of the protocol and then human pharmacology focusing on safety and tolerability and pharmacokinetics; phase 2 examines the effectiveness in terms of dose and regimen and target populations; phase 3 determines a basis for licensure and marketing of the product; and phase 4 establishes therapeutic use in a wider population.²⁵⁷ As of November 2011 the U.S. Food and Drug Administration had not approved any human gene therapy products for sale,²¹² but the United States led all others in the numbers of initiated protocols.^{258,259} Approximately 600 gene therapy protocols have been initiated in the United States, most in the area of cancer research.¹ In the United States about 50 therapy protocols have focused on treating nine different single-gene disorders including CF, Duchenne muscular dystrophy, hemophilia B, and mucopolysaccharidosis.²⁵⁸ To date, a gene therapy protocol is underway for Duchenne muscular dystrophy but not for any of the disorders described in this chapter. The interested reader can obtain an up-to-date listing of current gene therapy protocols from the NIH's Genetic Modification Clinical Research Information System (GeMCRIS) on the World Wide Web at www.gemcris.od.nih.gov/Contents/GC_HOME.asp.

In light of the limited medical treatment strategies available for children with genetic disorders, the physical or occupational therapist must be concerned with maximizing the child's developmental or functional potential within the limitations imposed by the lack of possible cures and the prospect of the shortened life span that characterizes many of these disorders. When deterioration of skills is expected, therapy must be directed at maintaining current functioning levels, minimizing decline, and minimizing caregiver support as much as possible.

Genetic Counseling

Developmental physical or occupational therapists must have an understanding of the modes of inheritance of the various genetic disorders and information about the services that can be offered through genetic counseling. Although the physician has primary responsibility for informing the parents of a child with a genetic disorder about the availability of genetic counseling, the close professional and personal relationships that therapists often develop with families may prompt family members to seek this type of information from the therapist.

Although a physical or occupational therapist cannot fill the role of a qualified genetic counselor, it is important that therapists be aware of the availability and location of genetic counseling services so that they may be assured that parents of a child with a genetic disorder have this information. Most major university-affiliated medical centers provide genetic counseling.

Process of Genetic Counseling

Six steps or procedures in genetic counseling were introduced in the 1970s by Novitski; they included descriptions of various genetic tests and a clinical interview.²⁶⁰ The desired outcome of genetic counseling is to make an accurate

medical diagnosis of the child's disorder. In the case of a suspected chromosome abnormality, this usually involves determining the karyotype of the child and possibly the karyotypes of the parents. Other diagnostic procedures may include a medical examination, FISH, DNA studies, biochemical studies, muscle biopsy, and other laboratory tests.

A pedigree or family tree is constructed of all known relatives and ancestors of both parents.²⁶⁰ Pedigree information includes the age at death and cause of death of ancestors, a history of stillbirths and spontaneous abortions, and a history of appearance of any other genetic defects or unknown causes of intellectual disability. The country of origin of ancestors is also important because certain genetic defects, such as PKU, are far more prevalent in families of a particular ethnic origin. Once the defect has been identified and a pedigree constructed, Novitski²⁶⁰ advises that further information be obtained from one of the comprehensive resource texts on genetic disorders. Informing family members about the characteristics of the disorder and its natural history may diminish fears of the unknown.

The third procedure in genetic counseling is to estimate the risk of recurrence of the disorder.²⁶¹ In specific gene defects, the probability of recurrence is fairly straightforward, with a risk of 25% for autosomal recessive disorders and a 50% risk for each male child in sex-linked disorders. These percentages, however, do not hold true in cases of spontaneous mutations. In cases of chromosomal abnormalities, such as Down syndrome, karyotyping is mandated to determine whether the child has the translocation type of Down syndrome. In that case the risk of recurrence is much greater than with a history of standard trisomy 21 Down syndrome.

Informing parents of the probability of recurrence is the next procedure. Novitski²⁶⁰ points out the common misunderstanding that if a risk is one in four for a child to be affected, as in an autosomal recessive disorder, many parents assume that if they have just given birth to a child with the disorder, the next three children should be normal. It is important to explain that each subsequent child faces a one in four risk of inheriting the disorder regardless of how many siblings with the disorder have already been born. Estimating the risk of multifactorial disorders is a complex process. Although these conditions tend to cluster in families, there is no clear-cut pedigree pattern. The risk of recurrence of a multifactorial disorder is typically low, but if a couple has had two children with the same condition, the recurrence risk is presumed higher, with either a high genetic susceptibility or a chronic environmental insult suspected.

The fifth step in genetic counseling is for the parents to decide on the course of action they will take for future pregnancies once the counselor has presented all available facts to them.²⁶¹ Some parents may choose not to have any more children; others may elect to undergo prenatal diagnostic procedures for subsequent pregnancies. These decisions rest entirely with the parents and may be influenced by their individual religious or ethical preferences.

Follow-up counseling and review of the most recent advances in medical genetics are the final steps in the genetic counseling procedure.²⁶⁰ Genetic counseling can play an important role in opening channels of communication among parents, other family members, and their friends;

connecting parents and siblings to support groups; and helping families to address their grief, sadness, or anger.²⁶² The effect of a child's disability on the family may modify the parents' earlier decision to have or not to have more children. Recent medical advances may allow a more certain prenatal diagnosis of specific genetic disorders.^{263,264}

Early Detection of Genetic Conditions

Diagnosis of many genetic disorders is made clinically, as in observation of a congenital malformation; however, many serious conditions are not immediately apparent after birth. Detection of genetic conditions is performed through various screening procedures, followed by specific diagnostic testing to confirm a suspected disorder. With technological advancements in genetics, these procedures have been expanded for the unborn and the newborn. Couples planning to have children can be tested for specific genetic disorders before conception or embryonic implantation.²⁶⁵ Health care professionals and parents should be informed about both the positive and the negative aspects of using this new knowledge and technology. The American College of Medical Genetics has published lists of the more common reasons for genetics referral as guidelines for health care providers working with infants, children, or couples planning to have children.²⁶⁶

Newborn Screening

Routine newborn screening is required practice in the United States. Screening is performed on whole populations for common disorders. The purpose of screening is the early identification of infants who are affected by a certain condition for which early treatment is warranted and available. Of the 4 million newborn infants screened each year, approximately 3000 have detectable disorders.²⁶⁷ Currently all 50 states require screening for three disorders: PKU, congenital hypothyroidism, and galactosemia.¹⁴⁰ Some populations known to be at higher risk of certain disorders may be screened automatically, or individuals may elect state-specific screening.²⁶⁷ Most states screen for eight or fewer disorders.²⁶⁸ Tandem mass spectrometry (MS/MS) is a laboratory technique that allows for the identification of several metabolic disorders using a single analysis of a small blood sample drawn from the neonate. Many states use MS/MS for newborn screening for various disorders and have expanded their list of those that are mandated and those that are part of limited pilot programs.²⁶⁹ Some genetic screening is performed primarily for research purposes when the disorder is not preventable, for example, type I diabetes. Screening for type I diabetes is available in some states, and early reports are that 90% of parents consent to the test.²⁷⁰

Benefits of newborn screening are earlier definitive diagnosis and medical intervention for the affected child. Concerns about expanded newborn screening include hasty medical decisions before conclusive evidence is available, and parental stress because of a lag time between screening and definitive results. A study by Waisbren and colleagues²⁷¹ conducted on parents of children screened for biochemical genetic disorders recognized that parents generally reported less stress the earlier a diagnosis could be made. However, in the same study, in cases in which the test yielded a false-positive result, parents reported a higher stress index and their children were twice as likely to experience

hospitalization (usually the emergency department) than in mothers of children with normal screening results.²⁷¹ In the case of a positive screening result, infants will typically undergo more definitive genetic testing.

Genetic Testing in Infants and Children

Many genetic disorders can be diagnosed by clinical criteria specific to that disorder. If a diagnosis cannot be made on the basis of the patient's clinical presentation, then genetic testing may be warranted. There are currently about 900 genetic tests that can be offered by diagnostic laboratories; specific information can be found at www.genetests.org. In the United States, the standards and methods of all laboratories performing clinical genetic tests are governed at the federal level.²⁶⁵

Prenatal Testing

Tests to diagnose a genetic disorder in a developing fetus can be placed into two broad categories: invasive and noninvasive procedures. Currently, in contrast to the most common invasive procedures, noninvasive methods typically cannot permit a definitive diagnosis, but they can be performed with less risk to the fetus. Invasive procedures are recommended in cases of high risk for a serious disorder, when definitive diagnosis could lead to treatment, and to allow parents to make decisions about the pregnancy.²⁷² The ethical implications for prenatal testing are many. Parents are often given information that requires a sophisticated understanding of biology and medicine to fully understand the implications and results of a diagnostic procedure. For example, amniocentesis can detect many chromosomal abnormalities, but the functional outcome of some disorders can have great variety.²⁷³

Invasive Procedures. The most common prenatal diagnostic procedure is amniocentesis, which is used to detect early genetic disorders in the fetus at 11 to 20 weeks' gestation.²⁷² This method involves inserting a long, slender needle through the mother's abdominal wall and into the placenta to extract a small amount of amniotic fluid.²⁷⁴ Laboratory tests of amniotic fluid reveal all types of chromosome abnormalities and a number of specific gene defects, including LNS, and some disorders of multifactorial inheritance, such as neural tube defects. This procedure carries a risk of miscarriage of about 0.5% to 1.7%,²⁷⁵ and the risk increases the earlier that it is performed.²⁷²

Chorionic villus sampling involves extracting and examining a portion of the placental tissue. It has nearly a 99% detection rate for chromosomal abnormalities,²⁷² and it can be definitive earlier than amniocentesis; however, the risk of severe limb defects (amniotic band syndrome) increases the earlier that it is performed. The miscarriage rate with this procedure is estimated to be 0.5%.²⁷²

Noninvasive Procedures. Ultrasonographic examination of a fetus has been used to identify congenital malformations since 1956. It is currently offered to most women in the United States. It is currently believed that there is no inherent risk from this procedure. First-semester sonography is performed mainly to confirm the gestational age, to identify multiple pregnancy, and to measure nuchal thickness (NT). NT is a measure of the subcutaneous space between the skin and the cervical spine in the fetus; increased NT is often associated with trisomies. Second-trimester

ultrasonography can detect problems in the quantity of amniotic fluid, large fetal structural defects, and certain smaller defects associated with a genetic disorder. A definitive diagnosis is not made on the basis of the presence of small defects alone, but the findings are considered along with the other risk factors present.²⁷⁶ Again, there are ethical questions about the risk to the parents (emotional stress and uncertainty) versus the benefits of early detection.

Tests of maternal serum screening done at about 15 to 20 weeks' gestation can detect chromosomal abnormalities, but the accuracy depends on many factors, such as gestational age, maternal weight, ethnicity, multiple pregnancy, maternal type I diabetes, and maternal smoking.²⁷² Finally, it is possible to perform cytogenetic analysis of fetal blood cells that can be isolated from a sample of the mother's blood, but this requires expensive equipment and expertise.²⁷²

Assisted Reproductive Technology and Preimplantation Genetic Diagnosis

Couples who want to conceive often seek genetic counseling if one or more parents is aware of a familial genetic condition, if they are having difficulty conceiving, and commonly in cases of advanced maternal or paternal age. More than 1 million babies have been born worldwide as a result of in vitro fertilization (IVF).²⁷⁷ IVF has enabled couples with fertility problems to conceive and more recently is used to diagnose a genetic disease or condition in an embryo when it has differentiated into just eight cells.²⁷⁸ Chromosomal abnormalities are the most common detected abnormality, and approximately 100 single-gene disorders have been diagnosed.²⁷⁸ The ultimate purpose of preimplantation genetic diagnosis is to implant only mutation-free embryos into the mother's uterus; however, infants conceived with assisted reproductive technology (ART) are two to four times more likely to have certain types of birth defects than children conceived naturally.²⁷⁷ The reasons for the increased risk of birth defects is unknown, but it may be that ART results more often in multiple births, which are at higher risk regardless of use of ART.²⁷⁷ Intracytoplasmic sperm injection (ICSI) is another form of ART used often in cases of paternal infertility. Male infertility caused by azoospermia or oligozoospermia is associated with several genetic factors such as paternal sex chromosome aneuploidy in the case of Klinefelter syndrome.^{70,279} Preimplantation genetic testing is optional in the United States but recommended in cases of family history and in men with non-obstructive azoospermia.²⁷⁹

Ethical, Social, and Legal Issues in Genetics

Advancements in genetics have led to important ethical questions about testing and screening for genetic disorders during the course of a couple's family planning and after the birth of the child. Ethical debates about genetic testing are inevitable. The persistent ethical issue in newborn screening surrounds mandatory or voluntary approaches taken by the states.² All states require newborn screening, usually without parental consent for the tests. Thirty-three states have newborn screening statutes or regulations that allow exemptions from screening for religious reasons, and 13 additional states have newborn screening statutes or regulations that allow exemptions for any reason. The majority of states have

statutes that contain confidentiality provisions, but these provisions are often subject to exceptions.²⁶⁸

Traditionally in pediatric medicine, parents are presumed to be best suited to make the decision whether to pursue genetic testing. Organizations such as the American Academy of Pediatrics (AAP) have argued that parental autonomy should not be absolute in cases of life-threatening situations coupled with clear medical treatment benefit, but the AAP supports efforts to make informed parental consent a standard in the United States. Furthermore, the AAP does not support the broad use of carrier screening in children or adolescents or the position that newborn screening should be used to identify carrier status in parents of newborns identified as having disorders through newborn testing.² The American Society of Human Genetics has recommended that family members not be informed of misattributed paternity revealed through testing for the purpose of screening for disorders and that informed consent should include cautions regarding the unexpected finding of a different disease.²⁸⁰

Pediatricians and other health care professionals should be prepared to equip families with the appropriate information to use in the decision-making process about genetic testing. From a medical standpoint, Ross and Moon²⁸¹ propose a decision algorithm that weighs the risks and benefits of genetic testing. A decision to pursue genetic testing would be advised if the child was symptomatic, had a suspected genetic condition, or was from a high-risk family; if early diagnosis would decrease morbidity or mortality; and if the testing method was considered ethical and the testing would lead to a beneficial treatment. Lastly, practitioners and researchers should be prepared to educate families on the protections and limitations of the Genetic Information Nondiscrimination Act of 2008 (GINA). This federal law, which sets a nationwide level of protection for U.S. citizens, does not preempt state law, which usually provides broader safeguards. GINA prohibits health insurers from using the results of *predictive* genetic testing done for an individual to determine policy rates for that individual or for persons in a similar population; this includes information discovered in the course of medical testing and research. However, it does not protect a person's right to insurance for a genetic illness that is diagnosed. GINA prohibits insurers from requesting or requiring that person undergo a genetic test. It prohibits employers from requesting, requiring, or using a person's genetic information in making employment decisions, including information about the employee's family's genetic information. GINA does not apply to decisions about life, disability, or long-term care insurance, nor does it apply to members of the military.²⁸²

INTEGRATING GENETICS INFORMATION FOR PRACTICAL USE IN PEDIATRIC CLINICAL SETTINGS

Therapists in all settings frequently find it challenging to keep up with practice issues and the growing body of knowledge and evidence in rehabilitative medicine. In clinical settings where most of a therapist's day is spent in actual hands-on treatment, the wealth of information that is available may seem burdensome and practically inaccessible. Patients and their families will present the therapist with many questions about medical interventions, diagnostic procedures, and research. Although therapists know that a

working knowledge of all of these areas is important, often time and access to resources are limited.

Pediatric therapists know the importance of collaboration with other professionals, including a type of collective knowledge about the child and his or her diagnosis, impairments, functional limitations, and quality-of-life issues identified by the family. A 1998 survey of individuals from six different health professions, including physical therapists,

revealed that most professionals are not confident in their education and working knowledge in the field of genetics.²⁸³

Additional studies have indicated that there are not enough genetic counselors^{271,281} to meet the growing needs of patients and families and that patients often express the most stress and dissatisfaction because their primary care physician does not appear to be informed about their child's disorder.^{271,284} See Case Study 13-1, Part 1.

CASE STUDY 13-1, PART 1 ■ THERAPISTS' ROLE IN EARLY RECOGNITION AND CLINICAL DIAGNOSIS OF GENETIC DISORDERS

This case study series portrays how basic knowledge and skills competence in genetics are essential for therapists in the delivery of services for pediatric patients with genetic disorders. Two female patients with presenting signs of developmental delay received physical therapy services before and after receiving a definitive diagnosis.

SCREENING FOR GENETIC DISORDERS AT INITIAL VISIT

Developmental delay is a common classification for infants and young children entering into physical therapy services before a definitive diagnosis of a particular genetic disorder has been made. Family history and course of pregnancy are key areas for the physical therapists to consider during ongoing assessment. The sensitive nature of this information requires that appropriate trust and rapport have been established between practitioner and family.

For the female patients discussed in this case, no remarkable information was revealed to indicate that a genetic disorder was suspect: Each of the girls was the first-born child and lived with her biological parents, in whom there was no previous family history of a genetic disorder. This was the first pregnancy for the mothers of both girls. The mothers each became pregnant in their late 20s without the assistance of reproductive technology, and they received the recommended course of prenatal care without specialized prenatal testing. The course of the mothers' pregnancies and deliveries were unremarkable, as was the neonatal period for the children.

Both girls were Caucasian with blond hair, blue eyes, and absence of notable dysmorphism. Figure 13-9, A and B shows 2 females. The first child was 16 months and the second was 14 months before given a medical diagnosis.

MEDICAL RECORDS REVIEW

	DYLEN: CONTRASTING FEATURES	DANIKA: CONTRASTING FEATURES	FEATURES OF BOTH GIRLS
0-6 MONTHS OF AGE			
Parental concerns	Vomiting and abnormal eye movements		Low muscle tone and slow motor development.
Tests and measures	Normal brain MRI scan and EEG at 3 months	No tests	
Development			Normal head control. Purposeful reach, grasp, and object release. Good eye contact and "happy" disposition. Some babbling and one-syllable sounds.
6-8 MONTHS OF AGE			
Parental concerns	Tongue thrusting and episodic nystagmus; parents suspect seizures	Sleep disturbances Visual disturbance suspected	Both girls are slow to achieve independent sitting and crawling.
Tests and measures			
Development	Pivots in prone position at 8 months. Sits without support at 8 months.	Not yet sitting.	Delayed trunk control. Both girls roll over by 7 months.

EEG, Electroencephalogram; MRI, magnetic resonance imaging.

Pediatric therapists should recognize that marked developmental delay and global hypotonia are two features common to many genetic disorders. However, in the case of both girls, the urgency of a genetics referral was lessened by the following

factors: no dysmorphic features, healthy neonatal development, absence of family history of genetic disorders, and no other major presenting risk factors (e.g., no prior loss of pregnancies, young maternal age, and normal course of pregnancy).

Figure 13-9 ■ A, Dylen at 16 months of age. B, Danika at 14 months of age.

Basic Knowledge and Skills Competence for Physical and Occupational Therapists

The National Coalition for Health Professional Education in Genetics (NCHPEG) is an organization of individuals from approximately 120 health professions. They have proposed basic competencies for all health care professionals.⁷ With a working knowledge about genetics, therapists can develop competence in eliciting and accessing genetic information from subjective interviews with proper patient consent, can learn how to protect patient privacy while making appropriate recommendations to genetics professionals, and can understand the social and psychological implications of genetic services.^{283,285}

Professional education for physical therapists³ and occupational therapists²⁸⁶ faces challenges to prepare practitioners who meet the minimum competencies set forth by NCHPEG.⁷ Most physical therapists responding to the survey by Long and colleagues²⁸³ reported that they received most of their information through nonscientific media and that they had limited or no education in genetics. Some of the barriers to implementation of genetics content in professional programs include lack of faculty qualified to teach the content and time limitations within a didactic program.³ Continuing education courses for practicing clinicians are in short supply. Physical therapists have identified needs for continuing education in genetics to include topics such as the role of genetics in common disorders such as cancer and heart disease, an overview of human genetics, what treatments were available, and how to direct clients to information resources. Although occupational therapists were not part of Long's study, it is felt that colleagues would stress similar needs.²⁸³

Service Delivery for Children with Genetic Disorders and Their Families

For therapists to be supportive of families they are working with, they must acknowledge the importance of family priorities, respect the family's cultural values and beliefs,²⁸⁷⁻²⁸⁹ include families as integral team members, and promote and deliver services that build on family and community resources.

This section includes strategies for supporting families of children with genetic disorders, assessment strategies, construction of therapeutic goals and objectives, and guiding principles for pediatric interventions.

Family-Centered Service

Family-centered service is both a philosophy and an approach to service delivery that is considered to be a best practice in early intervention and pediatric rehabilitation.²⁹⁰⁻²⁹² Children with genetic disorders have complex, long-term needs that can be addressed by a family-centered service delivery model. At the core of this model is the manner in which therapists interact with the children and their families—the therapists' mindfulness, attentiveness, and respectfulness, elements that are as important as the actual interventions delivered.^{293,294} Therapists educated in the family-centered approach are also able to understand the impact of disability on a family as well as the value of support systems such as family and community.²⁶²

Bailey and colleagues²⁶² highlight the particular needs of families who have children diagnosed with genetic disorders to have productive partnerships with health care providers. Therapists should not be reluctant to learn about a rare condition from parents, as many are not "passive recipients of information" but rather "co-producers" of what and how information available may be used in their child's care.^{262,295} Parents can be trusted to be a reliable source in the recognition of their child's condition and needs,²⁹⁶ but in some instances the therapist's role may be to steer families to accurate information or assist with interpreting information which they have discovered. For example, the term "untreatable condition" may be misinterpreted by parents to mean that there are no reasonable interventions that may benefit their child (see Case 13, Part 4).

The *Relational Goal-Oriented Model* (RGM) of service delivery links the "what" with a more in-depth consideration of the "how" (how service providers and organizations can optimize both the process and outcomes of service delivery).²⁹⁷ The role of the family in the child's life and the importance of the insights of parents into their child's abilities and needs²⁹⁸ are crucial. Three important aspects of caregiving—information exchange, respectful and supportive care, and partnership or enabling—are foundational to family-centered care.²⁹⁹ Family-centered service recognizes that each family is unique, that the family is the constant in the child's life, and that the family members are experts in the child's abilities and needs. The family works together with service providers to make informed decisions about the services and supports the child and family receive. The strengths and needs of all family members are considered in family-centered service.³⁰⁰ In the interactional exchange between the child and family and the therapists, understandings occur, commitments and decision are made, the child and family receive affirmation and support, and information is translated into meaningful, usable knowledge through the process of communication.^{301,302} Developing mutual trust and open communication among the child, the family, and the physical and occupational therapists as well as other practitioners is at the core of clinical practice.

Therapists working with children need to recognize and acknowledge the multitude of tasks that all families work to accomplish. In addition to tasks specifically related to caring for a child with a disability, families must perform functions to address the economic, daily care, recreational, social, and educational and vocational needs of both individual members and the family as a whole.

As Turnbull and Turnbull³⁰³ have cautioned, each time professionals intervene with families and children, they can

potentially enhance or hinder the family's ability to meet important family functions. For example, intervention that promotes a child's social skills can be an important support to positive family functioning. On the other hand, intervention that focuses on the child's deficits can have a negative impact on how the family perceives that child and the place of the child in the family. The RGM emphasizes the importance for therapists to join with parents to provide responsive and flexible therapy services in accordance with changing family needs and circumstances.³⁰⁴

The *Life Needs Model*^{292,297} acknowledges the need for therapists to work collaboratively with service providers in other disciplines to improve community participation and quality of life for children and youth with disabilities, based on the expressed needs of the child and his or her family members. Assisting the family in identification of a support group is often helpful for adjustment and continuing encouragement in coping with issues. Support groups can be found at www.geneticalliance.org, a comprehensive website provided by the Alliance of Genetic Support Groups. Family empowerment mediates relationships between family-centered care and improvements in children's behaviors³⁰⁵ and directly affects families' satisfaction with services for their children and their well-being.³⁰⁶

Assessment Strategies

Knowledge of a child's diagnosis can aid in the selection of appropriate assessment tools and can alert the therapist to any potential medical problems or contraindications associated with the specific syndrome that might affect the assessment procedures (tests and measures). Therapists must be careful, however, not to develop preconceived opinions about a child's capabilities on the basis of how other children with similar diagnoses have performed. It is critical to remember that there is wide behavioral and performance variability among children within each genetic disorder. For example, wide variability in the achievement of developmental milestones has been reported among children with Down syndrome.³⁰⁷

The assessment process includes many components that in certain areas are specific to the practice of either physical or occupational therapy. For the physical therapist, use of the *Guide to Physical Therapist Practice*³⁰⁸ is recommended as a framework to identify appropriate tests and measures for impairments or disabilities. For the occupational therapist a useful reference is the assessment section of the textbook *Occupational Therapy for Children*.²³⁷

Typically a therapist's assessment begins with movement observation and analysis followed by testing of the neuromuscular status of the child, such as primitive reflexes, automatic reactions, and muscle tone. For children with orthopedic involvement, assessment of muscle strength, joint range of motion, joint play, and soft tissue mobility is also important. An assessment of the child's developmental level and functional ability should be completed. Such assessments can be used to discriminate between typical and delayed development, to identify the constraints interfering with the achievement of functional skills, and to guide the development of treatment goals and strategies. Most developmental assessment tools fall into one of the following categories: (1) discriminative, (2) predictive, and (3) evaluative measures.³⁰⁹ Each of these three types of developmental assessment tools yields a different type of information. It is

important to understand these differences and the intended purpose for each type of assessment to ensure that evaluation tools are used appropriately. A list of tests and measures commonly used by pediatric physical therapists is summarized in Table 13-4.

Discriminative Assessment

A discriminative assessment is used to compare the ability of an individual with the ability of members of a peer group or with a criterion selected by the test author.³⁰⁹ Such instruments provide information necessary to document children's eligibility for special services but rarely provide information useful for planning or evaluating therapy programs.³¹⁰ Norm-referenced tests such as the Alberta Infant Motor Scale,³¹¹ the Bayley Scales of Infant Development (motor and mental scales),³¹² and the Peabody Developmental Motor Scales³¹³ are examples of tests used with infants and young children to verify developmental delay or to assign age levels. The Test of Infant Motor Performance is used to identify the risk of developmental delay in infants from 32 weeks postconception to 16 weeks after term.³¹⁴ An example of a norm-referenced assessment tool for older children is the Bruininks-Oseretsky Test of Motor Proficiency.³¹⁵

It may be possible to detect improved motor performance by administering a developmental test used to identify children who have motor delays. Such tests, however, usually cannot detect small increments of improvement because there are relatively few test items at each age level and developmental gaps between items are often large. In assessing whether intervention has been effective, the use of most discriminative tools does not examine a child's performance of functional activities in natural environments.³¹⁰

Predictive Assessments

Predictive measures are used to classify individuals according to a set of established categories and to verify whether an individual has been classified correctly.³⁰⁹ Measures designed to predict future performance are often used to detect early signs of motor impairment in infants who are at risk for neuromotor dysfunction.³¹⁰ Knowledge of developmental milestones and the ability to identify typical and atypical movement at various ages is paramount to the therapist's competency in administering a structured assessment such as those used to predict future disability in children. Precht and others³¹⁶ have described how assessment of "general movements" in infants can be used to identify children with cerebral palsy.³¹⁷ The Movement Assessment of Infants³¹⁸ was designed to assess muscle tone, reflex development, automatic reactions, and volitional movement and has value in predicting future neurodevelopmental problems in high-risk infants when administered during the first year of life.^{319,320} The Test of Infant Motor Performance³¹⁴ and the Alberta Infant Motor Scale³¹¹ are other instruments commonly used to predict poor motor outcomes.

Evaluative Assessments

An evaluative measure is used to document change within an individual over time or change occurring as the result of intervention.³⁰⁹ Helping Babies Learn³²¹ is a curriculum-referenced test that provides information about a child's developmental progress relative to a prespecified curriculum sequence.

TABLE 13-4 ■ TESTS AND MEASURES COMMONLY USED IN PEDIATRIC PHYSICAL THERAPY

TESTS AND MEASURES	AGE RANGE	PURPOSE
Alberta Infant Motor Scale (AIMS) ³¹¹	Birth to 18 months	Identifies motor delays and measures changes in motor performance over time
Batelle Developmental Inventory ³⁵⁹	Birth to 8 years	Identifies developmental level and monitors changes over time
Canadian Occupational Performance Measure (COPM) ³⁶⁰	Any age	Identifies changes in parent's perception or child's self-perception of performance over time
Bayley Scales of Infant Development, ed 2 (BSID-II) ^{312,361}	1 to 42 months	Identifies developmental delay in gross motor, fine motor, and cognitive domains; monitors progress over time
Berg Balance Scale ³⁶²	5 years and older	Performance-based measure of balance during specific movement tasks
Bruininks-Oseretsky Test of Motor Proficiency (BOTMP) ³¹⁵	4.5 to 14.5 years	Identifies motor abilities and can be used for program planning; monitors change over long periods of time for child with mild disabilities
Childhood Health Assessment Questionnaire (CHAQ) ³⁶³	Any age	Measures quality of life from patient's or parents' perspective
Child Health Questionnaire ³⁶⁴	2 months to 15 years	Measures quality of life from patient's or parents' perspective
Denver Developmental Screening Test II ³⁶⁵	2 weeks to 6.5 years	Screening tool for developmental delay
Early Intervention Developmental Profile ³⁶⁶	Birth to 3 years	Measures development of gross and fine motor, language, perception, social, and self-care skills
Energy Expenditure Index (EEI) ³⁶⁷	3 years and older	Measures endurance level for activity; monitors changes over time
Functional Independence Measure (FIM) ³²³	7 years and older	Measures changes in mobility and activities of daily living skills; used for program evaluation and rehabilitation outcomes assessment
Functional Independence Measure for Children (WeeFIM II) ³²⁴	6 months to 7 years	Measures changes in mobility and activities of daily living skills; used for program evaluation and rehabilitation outcomes assessment
Functional Reach Test (FRT) ³⁶⁸	4 years and older	Measures anticipatory standing balance during reach
Goal Attainment Scale ³⁶⁹	Any age	Individualized goal-setting format to detect small, patient-relevant changes over time
Gross Motor Function Measure (GMFM) ¹⁵⁷	5 months to 16 years	Measures change in gross motor function over time
Harris Infant Neuromotor Test (HINT) ³⁷⁰	Birth to 12 months	Screening tool to detect early signs of cognitive and neuromotor delay
Health Utilities Index Mark 3 ³⁷¹	Any age	Measures child's functional health status; computes cardinal utility value that represents health-related quality of life
Modified Ashworth Scale (MAS) ³⁷²	4 years and older	Qualitative measurement of spasticity through resistance to passive joint movement
Modified Tardieu Scale ^{373,374}	4 years and older	Qualitative measurement of spasticity through resistance to passive joint movement
Movement Assessment of Infants (MAI) ³¹⁸	Birth to 12 months	Identifies motor abilities or dysfunction
Peabody Developmental Motor Scales (PDMS-2) ³¹³	Birth to 5 years	Identifies gross and fine motor delays; used to monitor progress
Pediatric Clinical Test of Sensory Integration for Balance (P-CTSIB) ³⁷⁵	4 to 10 years	Measures sensory system contributions to standing balance and postural control
Pediatric Evaluation of Disability Inventory (PEDI) ³²⁵	6 months to 7.5 years	Measures self-care and mobility performance in the home and community; monitors progress over time
Pediatric Outcomes Data Collection Instruments (PODCI) ³⁷⁶	0 to 19 years	Assesses overall health, pain, quality-of-life components, and participation in ADLs (and sports in older children)
Pediatric Quality of Life Inventory (PedsQL) ³⁷⁷	2 to 18 years	Parent report and/or child self-report measuring health-related quality of life (HRQOL) in healthy children, adolescents, and those with acute and chronic health conditions
School Function Assessment (SFA) ³²⁶	Kindergarten to 6th grade	Measures function in the school environment
Sensory Integration and Praxis Test ³⁷⁸	4 to 9 years	Measures sensory systems' contribution to balance and motor coordination
Sensory Profile ³⁷⁹	3 to 10 years	Determines which sensory processes contribute to child's performance of activities of daily living
6-Minute Walk Test ³⁸⁰	5 years and older	Measures walking endurance; monitors progress over time
Test of Infant Motor Performance (TIMP) ³¹⁴	32 weeks to 4 months	Provides early identification of motor delay; assesses posture for early skills acquisition
Test of Sensory Function in Infants ³⁸¹	4 to 18 months	Identifies sensory processing dysfunction and those at risk for developmental delay or learning problems
Timed Up and Go (TUG) ³⁸²	4 years and older	Performance-based measure of anticipatory standing balance, gait, and motor function
Toddler and Infant Motor Evaluation (TIME) ³⁸³	4 months to 3.5 years	Identifies children with mild to severe motor problems; measures sensory development; monitors progress over time

ADLs, Activities of daily living.

To determine whether a child's ability to perform meaningful skills in everyday environments has improved, a functional assessment should be used. Functional assessments focus on the accomplishment of specific daily activities rather than on the achievement of developmental milestones. Emphasis is placed on the end result in terms of the achievement of a functional task, although the form or quality of the movement should never be ignored by the therapist. Assistance in the form of people or devices is incorporated into the assessment of progress, with the measurement of progress focusing on the achievement of independence.³²² Qualitative aspects of movement that have important functional implications, such as accuracy, speed, endurance, and adaptability, are also considered.

Functional assessments can be used to screen, diagnose, or describe functional deficits and to determine the resources needed to allow the child to function optimally in specific environments (e.g., school, home). Another use of functional assessments is to evaluate the nature of the problem and the specific task requirements limiting function to develop educational plans and teaching strategies.³²² A final use of functional assessments is to examine and monitor for changes in functional status. Such assessments can be used for program evaluation and for determining the cost-effectiveness of services or programs. (See Chapter 8 for additional information regarding evaluation tools.)

The Functional Independence Measure (FIM) is an example of a functional assessment. The FIM assesses the effectiveness of therapy on functional dependence in the

areas of self-care, sphincter control, mobility, locomotion, communication, and social cognition.³²³ Seven levels of functional dependence ranging from needing total assistance to complete independence are used to determine an individual's status. An adaptation of the FIM places greater emphasis on functional gains as opposed to the level of care. The WeeFIM³²⁴ has been developed for use with children through the age of 6 years.

The Pediatric Evaluation of Disability Inventory (PEDI) is a functional assessment that focuses on the domains of self-care, mobility, and social cognition.³²⁵ The PEDI incorporates three measurement scales: (1) the capability to perform selected functional skills, (2) the level of caregiver assistance that is required, and (3) identification of environmental modifications or equipment needed to perform a particular activity. The PEDI has been standardized and normed and is intended for use with children whose abilities are in the range of a typical 6-month-old to 7-year-old child.

The final example of a functional assessment is the School Function Assessment (SFA).³²⁶ The SFA is designed to measure a student's performance in accomplishing functional tasks in the school environment. It is composed of three sections that focus on (1) the student's participation in major school activities, (2) the task supports needed by the student for participation, and (3) the student's activity performance. The SFA is standardized and was conceptually developed to be reflective of the functional requirements of a student in elementary school. See [Case Study 13-1, Part 2](#).

CASE STUDY 13-1, PART 2 ■ ASSESSMENT STRATEGIES

DYLEN: CONTRASTING FEATURES		DANIKA: CONTRASTING FEATURES	FEATURES OF BOTH GIRLS
9-13 MONTHS OF AGE			
Tests and measures			Both girls have abnormal EEG findings Alberta Infant Motor Scale score: below 5th percentile PEDI: Composite independence in functional skills less than 12% with total caregiver assistance
Development	Regression in motor skills: sitting, rolling, and fine motor Babbling vocalization Emergence of truncal and extremity ataxia	Sits alone at 11 months	Dylen demonstrates skill regression; Danika slowly attains motor skills.
Other objective findings	Cold feet with reddened appearance; normal BP and HR	Emergence of hand-flapping behaviors	Both girls have small head circumference.

BP, Blood pressure; EEG, electroencephalogram; HR, heart rate; PEDI, Pediatric Evaluation of Disability Inventory.

Another role of the therapist is to use assessment instruments that will help establish a baseline of motor and self-help skills and to monitor for progress or regression; the Alberta Infant Motor Scale and the PEDI, respectively, were initially used for these purposes. Lastly, the results of these tests and outcomes of intervention are interpreted and conveyed to the family and the child's pediatricians. In the case of both girls, delays in

motor, language, and self-help skills persisted, and ultimately both girls and their families were referred for genetic evaluation. Both girls received 1 to 2 hours of physical therapy weekly in their natural environment. The Peabody Developmental Motor Scales were added to monitor progress, guide goal development, and justify the need for continued early intervention services.

Family-Driven Goals and Objectives

Therapy Goal Orientation

Goal orientation is a second fundamental feature of effective service. The earlier section on relation-based practice described how relationships among child, family, and therapists are fundamental in providing effective intervention. Goal orientation encompasses both joint goal setting by (1) parents, caregivers, and families and (2) therapists and other service providers³²⁷ and the pursuit of meaningful child-, parent-, and family-selected goals.³²⁸ Goals of parents and families are to create a supportive environment for their child, provide opportunities for growth and belonging, and assist their child to live as adaptive and independent a life as possible.²⁹⁷ Family-centered care incorporates trusting relationships in which the therapist demonstrates respect for the family's values, beliefs, and goals rather than imposing a plan of care on the child and family that aims to correct "deficiencies."

After a child's strengths and needs have been evaluated and the family's objectives identified, therapy goals and objectives can be developed. In the past, establishment of these goals has primarily been the responsibility of professionals and often did not incorporate the needs and desires of the family. More recently, however, professionals have recognized the value of having families guide the process of establishing intervention goals and objectives.^{329,330} This shift toward collaborative goal setting and family-centered care has occurred largely as a result of the belief that families should determine their vision of the future for their children and that professionals should act as consultants and resources to assist families in achieving that vision. The stress that caregivers experience with the everyday care of a child can reduce compliance with a home therapeutic program,³³¹ which further supports the notion that parents should be jointly involved with therapists to determine goals and the means by which to attain identified outcomes.³³² When parents and families contribute to the planning process, they are more likely to believe in goals that are set and to play a role in ensuring that relevant strategies are implemented.²⁹⁷ They gain a sense of control over their child's services, supports, and resources that contributes to their personal and family's well-being.³³³ For children living in the United States, these goals are developed within the context of individualized service plans.

Individualized Service Plans

In the United States, the Individuals with Disabilities Education Act (IDEA) requires public schools to develop an Individualized Education Plan (IEP) for every student with disability. An IEP is designed to meet the unique educational needs of a student with disability as defined by federal regulation 34 CFR 300.320.³³⁴ Under IDEA 2004, a free appropriate public education (FAPE) is provided that is individualized to a specific student with a disability and that emphasizes special education and related services to prepare the student for further education, employment, and independent living [20 U.S.C. 1400 et seq, 20 U.S.C. 1400 © (5)(A)(i)].

Beginning with the enactment of United States Public Law 94-142 in 1975³³⁵ and several important legislative

revisions in 1990 (IDEA),³³⁵⁻³³⁷ 1991 (PL 102-119), 1997 (PL 105-17), and 2004 (PL 108-446, Individuals with Disabilities Education Improvement Act of 2004),³³⁸ physical and occupational therapists working in public school settings are required to establish long-term annual goals and short-term therapy objectives within the framework of each child's educational needs. The document that defines a child's educational needs, including therapy services, from preschool to twelfth grade is the IEP. Similar requirements are in effect for infants to preschool-age children, documented in the individualized family service plan (IFSP). An IFSP must be written after a multidisciplinary assessment of the strengths and needs of the child has been completed. This assessment must include a family-directed assessment of the supports and services necessary to enhance the family's capacity to meet the needs of their child with a disability.^{337,338} A comparative table of the components of an IEP and IFSP is found in Table 13-5.

Functional Objectives

The development of behaviorally written, measurable therapy objectives is crucial for monitoring the effects of intervention in a child with a genetic disorder. Many of the clinical symptoms listed in the descriptions of genetic disorders described earlier in the chapter may be monitored through systematic, periodic, data-keeping procedures. One example is the monitoring of functional hand skills in girls with RS (see [Case Study 13-1, Part 2](#)). Periodic vital capacity measures for a child with OI or a child with Werdnig-Hoffmann disease can reflect progress toward a goal of maintaining respiratory function.

Typically, in the past, therapy objectives focused on a child's deficits. For example, delays in achieving motor milestones are often used to identify gaps in development, and therapy objectives are written and programs established to address these deficits. When the child meets an objective, new deficits are identified and new objectives are developed. A different model for goal development that is consistent with a family-centered intervention philosophy is the "top-down" approach, described by Campbell³³⁹ and later by McEwen³⁴⁰ and Effgren.²⁰⁸ In this model, the child and family identify a desired functional outcome that is the driving factor for the therapeutic intervention plan. An example of this approach is seen in goal attainment scales. Goal attainment scaling (GAS) is an individualized, criterion-referenced measure of small, clinically important changes in a child's functional performance over time.^{341,342} Similar to behavioral objectives, GAS requires (1) identification of observable goals, (2) reproducibility of conditions under which performance is measured, (3) measurable criteria for success, and (4) a time frame for goal achievement. In contrast to behavioral objectives, however, GAS identifies five possible outcomes with accompanying score values. By using five possible levels of attainment, it can be determined whether a child has made progress despite not having achieved the expected outcome or whether progress has exceeded the expected outcome. [Case Study 13-1, Part 3](#) is an example of use of a goal attainment scale to assess a parent and child functional objective of sitting up on the floor to play with toys.

CASE STUDY 13-1, PART 3 ■ FAMILY-DIRECTED GOALS AND OBJECTIVES

Both girls had poor postural control with muscular weakness and hypotonia that limited the activity of sitting. The parents of both girls expressed a desire that their daughters would be able to sit up and play with toys on the family-room floor. The table illustrates the use of GAS for the goal of seated play with toys. In the course of care, Danika made good progress

toward the goal depicted in this goal attainment scale; however, Dylen did not, and in fact demonstrated regression. Dylen's poorer outcome was indicative of the diagnosis of Rett syndrome (RS) that was revealed later. The family's goals for Dylen were revised, and the GAS was still a suitable framework.

SCORE	ATTAINMENT LEVEL IN TIME FRAME (INSERT _____)	CRITERION-REFERENCED GOALS WITHIN EACH RANGE (TIME FRAME: 3 MONTHS)
-2	Much less than expected outcome with therapy	(Child name) ring-sits on the floor supported on one or two hands plus 25% physical assistance for balance support and guided reach and grasp of toys placed near her lap.
-1	Less than expected outcome with therapy	(Child name) ring-sits on the floor with standby assistance and uses both hands to play with toys placed near her lap.
0	Expected outcome with therapy	(Child name) ring-sits on the floor with supervision, reaches and retrieves toys placed in front of her at arm's length away.
+1	Greater than expected outcome with therapy	(Child name) sits on floor independently and plays with toys placed at arm's length in front and to sides of her.
+2	Much greater than expected outcome with therapy	(Child name) sits on floor independently and retrieves toys placed slightly out of reach in front, to sides, and 45 degrees behind her and returns to upright for play.

TABLE 13-5 ■ COMPARISON OF REQUIRED COMPONENTS OF THE INDIVIDUALIZED EDUCATION PLAN (IEP) AND INDIVIDUALIZED FAMILY SERVICE PLAN (IFSP)

CONTENT	IFSP IDEA PART C (34CFR303.344)	IEP IDEA PART B (34CFR300.320 THROUGH 300.324)
Information about child's status	A statement of child's present levels of physical, cognitive, communication, social or emotional, and adaptive development (physical development includes vision, hearing, and health status)	A statement on child's present levels of academic and functional performance
Family information	Statement of family's resources, priorities, and concerns related to enhancing the child's development	Information regarding parent's concerns can be documented in the present information about the child's status
Outcomes	Statement of measurable outcomes expected to be achieved for child and family and the criteria, procedures, and timelines used to determine the degree of progress toward outcomes and whether modification or revisions of outcomes or services were necessary	Statement of measurable annual goals, including academic and functional goals Include a description of how child's progress toward annual goals will be measured and process to report child's progress to parents
Services	Statement of specific Early Intervention (EI) services necessary to meet child's needs; include frequency, intensity, method of service delivery, location of services and natural environments	Statement of specific special education and related services to be provided, modifications, and supplementary aids to be provided to child
Schedule of services	Projected dates for initiation of services, anticipated duration	Projected date for beginning and ending date of service; any modification needed; frequency, location, and duration of services
Service coordinator	Identification of the service coordinator	No comparable requirement
Transition plan	Procedures and steps for transition from EI to preschool services under Part B Establish transition plan: 90 days to 9 months before third birthday	Procedures needed for postsecondary goals related to training, education, employment, and, where appropriate, independent living skills To be in effect when child turns 16 yr of age
Transfer of rights	n/a	Must include statement that child has been informed about reaching the age of majority
Other		Explanation of any time the child will not participate along with nondisabled children

Rather than focusing on a child's deficits, such outcome-focused objectives provide a more positive and supportive context for therapy and at the same time address the family's needs and priorities. This approach to developing therapy goals and objectives in ways that support positive family functioning is also an important aspect of delivering therapy services to children and their families.

General Intervention Principles

Several general treatment principles guide the delivery of therapy services to children with genetic disorders and are detailed in this section. Special considerations for treatment of a child with a specific genetic condition may be found in the preceding section. The reader is also referred to Chapter 9 for information on interventions in neurological rehabilitation.

Focus on Activities and Participation

The goal of any therapeutic program for children should be to improve the quality and quantity of their participation in society. Achievement of basic motor skills such as sitting, standing, and walking is an outcome that can be measured with commonly used clinical tools, but whether or not children actually apply new skills on a regular basis (participation) is more difficult to capture objectively.³⁴³ Therapists need to possess knowledge, skills, and tools if they are to assess and treat children in all domains defined by the World Health Organization (see *Case Study 13-1, Part 1*). With the purpose of improving participation in the end, pediatric therapists employ a variety of intervention strategies to increase opportunities for children to achieve independence and enjoyment of activities at home and school and in the community.

Many of the classic therapeutic approaches for children with neurological disorders incorporate techniques targeting impairments of body structure and function, such as abnormal muscle tone or joint alignment, to improve movement quality.²²⁸ Motor learning science and task-oriented models of neurological rehabilitation are based on the rationale that control of movement arises from appropriate practice of skills within the context of functional activities and enriched environments.³⁴³⁻³⁴⁶ Intervention, therefore, is aimed at teaching motor problem solving (adaptability to varied contexts),³⁴⁷ developing effective compensations that are maximally efficient, and providing practice of new motor skills in functional situations. Rather than teaching individuals to perform movement patterns in a controlled therapy setting, this approach focuses on the learning that must take place for an individual to function independently of a therapist's guidance.^{343,345} Environmental adaptations can take many forms and include assistive technology that aids in the attainment of functional outcomes such as independence in self-help skills, communication, and mobility.³⁴⁸ For example, children with Down syndrome commonly have hypotonia, joint laxity, and delayed walking. Orthotics such as supramalleolar orthoses may be used to improve underlying joint and postural instability,³⁴⁹ and treadmill training has been shown to diminish delays in walking.³⁵⁰

Modern neurophysiologic approaches use hands-on physical guidance with the child during movement practice of functional skills and activities. The inhibition of certain movements and facilitation of others are based on the rationale that less used movements will be eliminated in the

pruning process of the developing brain and frequently used movement patterns will be reinforced^{228,343,351}; therefore approaches of this nature may be beneficial for infants and very young children with movement disorders.

Learning and performance of an activity seldom require just one component of function (e.g., mobility, language, cognition); therefore it should be understood and expected that improvements in one domain may indirectly, but significantly, have a positive impact on another. For example, Damiano³⁵¹ stresses the benefits of a lifetime of regular movement activity, with or without adaptations, on the overall development of children. Regardless of treatment techniques, it is a widely accepted principle that children learn new skills best when they are taught and practiced within the context in which they will be used.³⁵²

Delivery of Services in Natural Environments

The term "natural environment" refers to places and settings in which infants and children typically spend their day.³³⁷ The movement toward integrating therapy into classroom settings is one example of providing services in a natural environment.³⁵³⁻³⁵⁵ In an integrated model of service delivery, therapists work in the classroom with teachers, rather than removing students to an isolated therapy room to provide services. Therapists work closely with the teacher to establish common goals for the student and to devise programs that will allow therapeutic activities to be interwoven into a variety of activities throughout the day in a natural manner.

Another example of providing therapy in a natural environment is providing home-based services for infants and young children. Home-based programs are "normal" options for young children because the natural environment for most infants and toddlers is the home—either their own or that of a day care provider.³⁵³⁻³⁵⁵ For children who are medically fragile, it is the preferred option for therapy.^{356,357} For other families, transportation to a center-based program may be difficult because of the expense or length of travel required.

Incorporating Therapy Activities into Daily Routines

Therapists need to work collaboratively with families to develop activities that incorporate therapeutic activities into the family's daily routine (e.g., during play, dressing, bathing, meals). Rather than practicing narrowly defined tasks in a controlled clinic environment, therapy activities should be interwoven into a variety of activities throughout the day in a natural manner. Practicing skills in the context of daily routines allows the child to learn to adapt to the real-life contingencies that arise during a functional task.³⁴⁵ In addition, activities become more meaningful to both the child and the family (Figure 13-10).

Use of Assistive Technology Devices

The Assistive Technology Act of 2004 defines an assistive technology device as any item, piece of equipment, or product system, whether acquired commercially, modified, or customized, that is used to increase, maintain, or improve functional capabilities of individuals with disabilities (29 U.S.C. Sec 2202[2]).³⁵⁸ Information for clinicians and families can be found in Table 13-1.

As noted previously, an important aspect of providing developmental therapy services is the use of assistive technology devices to maximize a child's functional abilities, level of independence, and inclusion in school and community activities with peers. Examples of assistive technology include mobility devices, augmentative communication devices, and adapted computer keyboards. Assistive technology also includes adaptive devices such as splints, bath chairs, prone standers, and other positioning equipment that can be used to provide optimal body alignment and minimize the risk for contractures or deformities while encouraging a

greater variety of movement patterns. Such devices can be constructed from readily available materials or obtained commercially. The developmental physical or occupational therapist works with the family and other team members to select, construct, or order assistive devices and to assist caregivers in the use of the devices.

Case Example 13-1, Part 4 demonstrates how these general treatment principles are applied to a particular child receiving therapy services. The case example also shows how the family's priorities and needs are considered and supported in the planning and delivery of services.

CASE STUDY 13-1, PART 4 ■ FOCUS ON ACTIVITIES AND PARTICIPATION IN MEANINGFUL ENVIRONMENTS AND ROUTINES

Both families were referred by their respective physicians for genetic counseling and evaluation on the suspicion of AS based on cluster of developmental delay, features of blue eyes and blonde hair, head circumference, and abnormal EEG findings. Danika received an earlier referral to a geneticist at 14 months of age; subsequent test results confirmed the diagnosis of AS by the time she was 16 months old. The course of medical diagnosis for Dylen was confounded by her presenting signs of frequent, intense vomiting coinciding with suspicion of seizure activity. Dylen did not receive genetic testing until she was 30 months of age. In the cases of both girls, their documented response to therapy and course of motor development were weighed by their respective physicians in their course of care and referral for genetics evaluation. AS was ruled out first for Dylen, and subsequent testing confirmed a diagnosis of RS.

During the period immediately after their child's diagnosis, the parents in each family shared many questions and new-found knowledge with the treating therapist. Both families accessed local and national family support groups and were encouraged to learn of activities that their children would likely enjoy. The partnership between the therapists and the families was strengthened by clarifying that "untreatable condition" means that neither condition can be remedied by medical intervention and by focusing on the families' values and priorities.

Both girls had limited postural endurance in sitting and standing that was anticipated to persist for several months. Adaptive equipment for these activities was employed for both girls to allow them to participate in functional upright activities (see Figure 13-7). Danika enjoyed aquatic activities and tricycling more than she tolerated hippotherapy. Dylen was found to enjoy movement activities more when music was employed during treatment.

	DYLEN: CONTRASTING FEATURES	DANIKA: CONTRASTING FEATURES	FEATURES OF BOTH GIRLS
14-36 MONTHS OF AGE			
Diagnosis; body organ or structure and function	Rett syndrome; gastroesophageal reflux	Angelman syndrome; sleep disorder	Global developmental delay, seizures, hypotonia
Activities, limitations, and development	Motor skills plateaued at 9 months' chronological age, followed by period of skills regression to 6 months' developmental level	Ambulatory with assistive devices Persistent absence of expressive language but learns to respond to her name Expresses pleasure with giggles and subtle, jerky motions Uses raking motion to pick up small foods	Attends special education preschool
Physical therapy interventions	Movement-oriented activities with music	Aquatic therapy	Postural strengthening, sensorimotor activities
Assistive and adaptive equipment	Adaptive seating provides best opportunities to interact with others in learning environment	Walks indoors and outdoors with a gait trainer (see Figure 13-7, B) and shorter distances with a conventional posterior four-wheeled walker	Gait trainer Adaptive tricycle Bilateral ankle-foot orthoses
Participation of child and family			Support group events: walk, ride, stroll

Figure 13-10 ■ This child with Angelman syndrome enjoys riding her adaptive tricycle to the park with her family.

SUMMARY

This chapter has addressed several chromosomal abnormalities and specific gene defects that are most likely to be seen in children in a typical developmental therapy setting. The inclusion of family members in all aspects of therapy has been stressed, along with the need to consider family goals, priorities, and resources in the development and implementation of therapy services. The importance of developing functional goals and delivering services in natural environments has also been emphasized. Finally, many diseases or conditions have a genetic component that must be considered in the course of medical management. Physical and occupational therapists should expand their working knowledge of genetics to appropriately refer patients for genetic services. Readers are encouraged to consult [Box 13-1](#) for a list of resources about genetic disorders, education, testing, and interventions not described in this chapter.

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 383 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations..

KEY TERMS

developmental coordination disorder
 learning disabilities
 life span disability
 model of disablement
 motor learning
 neurodevelopmental treatment
 nonverbal learning disabilities
 praxis
 sensory integration
 verbal learning impairments

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Be aware of characteristics that typically identify a child with learning disabilities.
2. Become familiar with accepted definitions and terminology used in the field of learning disabilities.
3. Investigate the proposed causes of learning disabilities.
4. Understand the clinical presentation of subgroups within the learning-disabled population.
5. Become familiar with members of the specialist team and service provision types for children with learning disabilities.
6. Recognize the characteristics of the child with developmental coordination disorder.
7. Identify areas of evaluation to assess motor deficits effectively in the child with a learning disability.
8. Become familiar with theoretical development and intervention techniques applicable to children with learning disabilities and motor deficits.
9. Understand the lifelong ramifications for the individual with learning disabilities.

AN OVERVIEW OF LEARNING DISABILITIES**Clinical Presentation**

Learning disabilities are not a singular disorder but a group of varied and often multidimensional disorders.¹ Difficulties in learning may manifest themselves in various combinations of impairments in language, memory, visual-spatial organization, motor function, and the control of attention and impulses.^{2,3} The characteristics of a child with a learning disability are often diverse and complex. Each child presents a different composite of system problems/impairments, functional deficits, preventing participation in activities and societal limitations.

The most commonly recognized performance difficulties in learning are associated with academic success. Fletcher and colleagues⁴ argued that learning disabilities should be characterized as “unexpected” because the child is not learning up to expectations despite adequate instruction. Typically the areas of deficits are observed in verbal learning, including difficulties with reading, the acquisition of spoken and written language, and arithmetic. Impairments in nonverbal learning are equally important and more recently recognized. The three primary areas affected by nonverbal learning disorders include visual-spatial organization, social-emotional development, and sensorimotor performance.⁵ Accompanying behavioral manifestations may include problems with self-regulatory behaviors, such as lack of attention, hyperactivity, and poor impulse control. Difficulties in social perception and social interactions may also be observed.^{5,6} These learning and behavioral

difficulties may be isolated (e.g., academic, motor, or behavioral), combined (e.g., academic and motor), or global (academic, motor, and behavioral).⁷ In addition to verbal and nonverbal disabilities, specific motor impairments also can be present and affect academic achievement or daily life tasks.^{8,9}

Definition

The heterogeneity of persons with learning disabilities has made consensus on a single definition difficult. Many disciplines describe learning disabilities according to their own frames of reference. Medical professionals tend to relate the deficit to its cause, particularly to cerebral dysfunction. Terms historically used include *brain injured*,¹⁰ *minimal brain dysfunction*,² and *psychoneurological disorder*,¹¹ all implying a neurological cause for the deviation in development. Educational professionals, however, prefer to describe the child’s difficulties in behavioral or functional terms. Educators view children with learning disabilities as “children who fail to learn despite an apparently normal capacity for learning.”¹² Current terminology within the academic environment includes *reading disorder*, *mathematics disorder*, *disorder of written expression*, and *intellectual disabilities* (formerly called *mental retardation*).^{13,14} The lack of consensus for one accepted definition continues to affect consistency in diagnosis, research, and intervention for persons with learning disabilities.

After multiple revisions, the National Joint Committee on Learning Disabilities (NJCLD), which represents

several professional organizations, proposed the following definition:

Learning disability is a general term [for a condition] that:

- Is intrinsic to the individual . . . [the term] refers to a heterogeneous group. (Each individual with learning disabilities presents with a unique profile of strengths and weakness.)
- Results in significant difficulties in the acquisition and use of listening, speaking, reading, writing, reasoning, or mathematical abilities. (These difficulties are evident when appropriate levels of effort by the student do not result in expected performance, even when provided with effective instruction.)
- Is presumed to be due to central nervous system dysfunction and may occur across the life span. (They persist throughout life and may change in their presentation and severity at different stages of life.)
- May occur concomitantly with other impairments or other diagnoses. (For example, difficulties in self regulation and social interaction may exist separately or result from the learning disability. Individuals with attention-deficit disorders, emotional disturbances or intellectual disabilities may experience learning difficulties but these diagnoses do not cause or constitute them.)
- Is not due to extrinsic factors. (Such as insufficient or inappropriate instruction, or cultural differences.)¹⁵

This definition identifies a proposed cause but does not provide a clear exclusion statement regarding what learning disabilities may not result from. A positive component of this definition is the lifelong nature of the condition. Also, by including the behavioral manifestations of regulatory and social difficulties, a more complete picture of functional problems for the individual with learning disabilities is presented. This could assist in the creation of more comprehensive and life-spanning programs of service and ultimately help in the recognition and remediation of functional and societal limitations.

The definition used in educational settings was initially passed in Public Law 94-142 and later incorporated into the Individuals with Disabilities Education Act (IDEA) (Section 602.26).

Children with learning disabilities are defined by IDEA as follows:

- Individuals with a disorder in one or more of the basic psychological processes involved in understanding or using spoken or written language. (This emphasizes the receptive and expressive difficulties a student may demonstrate.)
- Those who are experiencing difficulties in the ability to listen, think, speak, read, write, spell, or do mathematical calculations. (These highlight the academic difficulties the student may experience.)
- Those who may have conditions such as perceptual disabilities, brain injury, minimal brain dysfunction, dyslexia, and developmental aphasia.
- Those who have a learning problem that does not result from other disabilities such as motor deficits, emotional disturbances, or environmental, cultural, or economic differences.

This description does not specifically address cause but does highlight psychological processes versus neurological impairments. The primary disability focus is on language, which may exclude difficulties in learning that involve nonverbal reasoning. This definition does not mention regulatory, reasoning, and social perception difficulties that may contribute to understanding the student's complete profile. On a foundational level this definition formed the basis for creating academic programs and delineating appropriate services for children with learning disabilities.

IDEA mandates that all children will have free and appropriate education and authorizes aid for special education and educationally relevant services for children with disabilities. IDEA influences how children with learning disabilities are identified and classified. The 1997 amendments of IDEA, by promoting the early identification and provision of services, redirected the focus of special education services by adding provisions that would enable children with disabilities to make greater progress and achieve higher levels of functional performance.¹⁶

The IDEA 2004 amendments eliminate a previous requirement that students must exhibit a severe discrepancy between intellectual ability and achievement for eligibility. This "severe discrepancy" policy often mandated that children would have to experience failure for several years to demonstrate the requisite degree of discrepancy.¹⁷ The current goal is to identify ways of serving students more quickly and efficiently once they begin to show signs of difficulty.¹⁷ Congress also indicated specifically that (1) IQ tests could not be required for the identification of students for special education in the learning disabilities category, and (2) states had to allow districts to implement identification models that used Response to Instruction (RTI).¹⁸ The RTI models suggest that the learning difficulty may be intrinsic to the child, inherent in the instruction, or a combination of both. The models propose systematically altering the quality of instruction and repeatedly measuring the child's response to that instruction. Inferences can then be made about the child's deficits contributing to learning difficulties.¹⁹

IDEA 2004 also limits the schools from finding a student eligible for special education services if the learning problems are determined to be caused by a lack of appropriate instruction. The law now encourages schools to use scientific, research-based interventions to maximize a student's opportunity for success in the general education setting (least restrictive environment [LRE]) before being placed in special education. IDEA encourages educators to stress the importance of identifying individual differences and patterns of ability within each child and adjust the educational methods accordingly. Academic achievement relies heavily on the effectiveness of the teacher and the instructional techniques. Studies indicate that learning disabilities do not fall evenly across racial and ethnic groups, with a higher incidence of special education services needed for black, non-Hispanic children.²⁰ The No Child Left Behind Act challenges states and school districts to become more accountable for improving educational standards by intensifying their efforts to close the achievement gap between underachieving students and their peers.

Classifications

The two most widely used classification systems are those of the American Psychiatric Association (*Diagnostic and Statistical Manual of Mental Disorders* [DSM])²¹ and the World Health Organization (WHO) (*International Classification of Diseases* [ICD]).²² Educational professionals prefer the DSM classification for its academic relevance. A variety of specific academically related disorders are outlined in the DSM. The latest edition, DSM-IV-TR, classifies learning disabilities under “disorders usually first diagnosed in infancy, childhood, or adolescence.” It subclassifies disorders into the following categories:

Learning Disorders

- Reading disorder
- Mathematics disorder
- Disorder of written expression

Motor Skills

- Developmental coordination disorder

Communication Disorders

- Expressive language disorder
- Mixed receptive-expressive disorder
- Phonological disorder
- Stuttering

The classification system commonly used by therapists is the ICD. The ICD codes are state mandated diagnostic codes used for billing and information purposes. In the recently revised ICD-10 the category “specific delays in development,” which included “other specific learning difficulties,” was changed to “disorders of psychological development.” The term “learning” is no longer part of this classification. This updated classification is as follows:

Disorders of Psychological Development

- Including specific developmental disorders (SDD) of speech and language (including acquired aphasia with epilepsy)
- SDD of scholastic skills
- SDD of motor function
- Pervasive developmental disorder

Model of Disablement

Beyond classifying learning disabilities as a diagnosis, the National Center for Medical Rehabilitation Research (NCMRR)²³ and WHO have integrated related approaches to classify functional performance. This conceptual approach, the Model of Disablement, describes the multiple dimensions of disability and identifies various internal and external factors that affect the way a disability manifests. The purpose of this model is to shift classification of a disability to include assessment of functional performance and societal participation as opposed to solely identifying component deficit areas.

Five dimensions are outlined in the Model of Disablement. They include pathophysiology, impairments, functional limitations, disabilities, and societal limitations. *Pathophysiology* refers to the underlying disease or injury processes at the tissue or cellular level. Proposed causative factors related to learning disabilities at this level include brain damage, biochemical abnormalities, genetics, and metabolic disorders. The challenge for interventionists is to recognize the signs and symptoms that confirm the diagnosis.²⁴

The second dimension, impairment, includes the organ and system dysfunction that potentially has a negative effect on functional performance. Children with learning disabilities may demonstrate impaired balance, endurance, and coordination of movements. Impairments that occur in one or more systems may lead to functional limitations, the third dimension. The challenge for the clinician is to treat impairments within the context of daily functional performance because impairments do not always result in functional limitation.

Functional limitations involve whole-body functions that are typically assessed but may or may not receive remediation.²⁴ For a child with learning disabilities this may include poor hand function in the performance of manipulation activities involved in dressing and handwriting. When persistent functional limitations are not remediable and cannot be adequately compensated for with assistive technology or other supports, disabilities in daily life occur. The child then fails to be an active participant in life roles, such as activities of daily living and school tasks. Emotional difficulties, such as depression and decreased self-esteem, which may result from learning difficulties, can ultimately impair social interactions.

Community and environmental barriers, called *societal limitations*, also can lead to restriction in social participation. An example of structural or attitudinal barriers that prevent optimal participation in society is a child who cannot use playground equipment because of lack of accessibility. The ultimate goal for the clinician is to facilitate functional abilities and performance as well as provide necessary supports so the child can become an active participant in society.

The Model of Disablement proposes that the environment, purpose, and level of participation should all be considered when evaluating performance. Determination of the presence, severity, or kind of disability should be made on the basis of a combination of these factors. Within this framework, a clinician does not assume that a handicap exists because of an impairment but rather considers levels of functional and societal abilities. This allows the therapist to determine intervention needs based on functional performance in relevant environments rather than being driven purely by diagnosis. A 9-year-old child with learning disabilities, for example, might have impairments in motor components of muscle strength and balance. Although these impairments can be identified on assessment, the Model of Disablement suggests that a disability does not exist unless these deficits affect functional performance (e.g., ascending and descending stairs) and limit societal participation (e.g., child cannot leave house independently to go to school or play). The identified impairments, based on assessment in an academic setting, would have to affect participation within the educational environment (be educationally relevant) to warrant intervention.

Incidence and Prevalence

Current data indicate that 15 million children nationwide have been diagnosed with some kind of learning disability.²⁵ According to a 2007 report to Congress on the implementation of IDEA, nearly 2.6 million students aged 6 to 21 years are receiving special education services for specific learning disabilities. As of 2007, this represents 44%

of students with disabilities nationwide.²⁵ Children with specific learning disabilities represent the highest incidence (number of new cases identified in a given period) among 13 disability categories, representing 44% of the total population of children receiving special education. Overall, the estimated prevalence (total number of cases in a population at a given time) of learning disabilities is approximately 15% of the U.S. population, which translates to one out of seven people.⁹ In children under age 18 years, 8% to 10% of the population have some type of learning disability.²⁶ Boys are more likely than girls to be identified as having a learning disability. According to Child Trends, 10% of boys and 6% of girls aged 3 to 17 years had a learning disability in 2004.²⁷

Perspectives on the Causes of Learning Disabilities

Learning disability is a diverse diagnosis with varied manifestations; therefore searching for a single cause would be inadequate. Historically, researchers have studied causative factors including (1) brain damage or dysfunction caused by birth injury, perinatal anoxia, head injury, fetal malnutrition, encephalitis, and lead poisoning; (2) allergies; (3) biochemical abnormalities or metabolic disorders; (4) genetics; (5) maturational lag; and (6) environmental factors, such as neglect and abuse, a disorganized home, and inadequate stimulation.²⁸⁻³⁰

Current sources agree that possible causes of learning disabilities can include problems with pregnancy and birth (e.g., drug and alcohol use, low birth weight, anoxia, and premature or prolonged labor), and incidents occurring after birth (e.g., head injuries, nutritional deprivation, and exposure to toxic substances such as lead).³¹⁻³⁴ Genetic and hereditary links also have been observed, with learning difficulties often seen across generations within families.³⁴ The emotional and social environment have also been considered as a contributing factor to learning disabilities.¹⁴

Children with learning disabilities frequently display a composite of neuropsychological symptoms that interfere with the ability to store, process, or produce information. These symptoms typically include disorders of speech, spatial orientation, perception, motor coordination, and activity level. Researchers have attempted to identify areas of the brain that may be responsible for these functional limitations. Tools being used include empirical measures of physiological function such as electroencephalography, event-related potentials (ERPs), brain electrical activity mapping (BEAM), regional cerebral blood flow (rCBF), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI). These measures expand the understanding of brain functioning but are best used in conjunction with data on functional and behavioral manifestations.

Research findings on brain structure have documented that certain functions are specialized within each hemisphere and this specialization is optimal for efficient learning.^{35,36} The left hemisphere processes information in a sequential, linear fashion and is more proficient at analyzing details. Academically, this hemisphere is responsible for recognizing words and comprehending material read, performing mathematical calculations, and processing and producing language.

The right hemisphere processes input in a more holistic manner, grasping the overall organization or the “gestalt” of a pattern.^{37,38} This type of organization is advantageous for spatial processing and visual perception. Functionally, the right hemisphere synthesizes nonverbal stimuli, such as environmental sounds and voice intonation, recognizes and interprets facial expressions, and contributes to mathematical reasoning and judgment. Over time these differences in left and right brain processing have become accepted and are commonly labels of cognitive style (i.e., left-brained versus right-brained learner).

A strict left-right dichotomy is oversimplified because it does not take into account many aspects of functional brain organization.^{37,39} Both hemispheres must work together for a variety of specific academic outcomes such as reading and mathematical concepts. In addition to the communication that occurs between the hemispheres via the corpus callosum, essential communication within the hemispheres is also present. Intrahemispheric communication is critical for developing higher level cognitive functions such as memory, language, visual-spatial perception, and praxis.⁴⁰ Research suggests that children with learning disabilities show different patterns of cerebral organization than normal children.^{37,39} However, brain plasticity is the basis for designing and implementing a variety of intervention techniques aimed at improving processing.

Subgroups

In early attempts to classify learning disabilities, Denckla and Rudel⁴¹ determined that approximately 30% of the 190 children they assessed by neurological examination could be classified into three recognizable subgroups. The other 70% exhibited an unclassifiable mixture of signs. Of the 30%, the first subgroup was classified as children having a *specific language disability*. These children, who were failing reading and spelling, showed a pattern of inadequacy in repetition, sequencing, memory, language, motor, and other tasks, all of which require rote functioning. The second group had a specific *visual-spatial disability*. These children had average performance in reading and spelling with delayed arithmetic, writing, and copying skills. The children in this subgroup all had social and/or emotional difficulties. The third group manifested a *dyscontrol syndrome*. These children had decreased motor and impulse control, were behaviorally immature, and were average in language and perceptual functioning.

Grouping children with learning disabilities based on patterns of academic strengths and weakness is as important as grouping them based on neuropsychological or cognitive measures. With an academic classification the heterogeneity of learning disabilities can be more clearly recognized and learning modalities can be adjusted to the individual child. A child with a specific reading difficulty, for example, could be experiencing deficits in word recognition, fluency, or comprehension. Through identification of the specific areas of weakness in reading, intervention can be individualized to improve academic performance.⁴

Based on historical and current trends the following general subgroups will be explored: verbal learning impairments, nonverbal learning disabilities (NVLDs), motor coordination deficits, and social and emotional challenges.

Verbal Learning Impairments

Verbal learning impairments typically include dyslexia, dyscalculia, and dysgraphia. Harris¹³ classifies these deficits in functional terms, with dyslexia including disorders of reading and spelling, dyscalculia denoting a mathematics disorder, and dysgraphia describing a disorder of written expression. These learning disorders may occur individually or concurrently. Each of these verbal learning impairments will significantly influence academic performance.

Dyslexia (Developmental Reading Disorder). Dyslexia is a learning impairment in which the ability to read with accuracy and comprehension is substantially less than expected for age, intelligence, and education and that impairs academic achievement or daily living.²¹ The International Dyslexia Association adopted the following definition in 2002: “Dyslexia is a specific learning disability that is neurological in origin. It is characterized by difficulties with accurate and/or fluent word recognition and by poor spelling and decoding abilities. These difficulties typically result from a deficit in the phonological component of language that is often unexpected in relation to other cognitive abilities and the provision of effective classroom instruction. Secondary consequences may include problems in reading comprehension and reduced reading experience that can impede the growth of vocabulary and background knowledge.”^{7,42}

Characteristics of dyslexia include the following^{43,44}:

- Difficulty learning to recognize written words
- An inability to sound out the pronunciation of an unfamiliar word
- Seeing letters or words in reverse (*b* for *d* or *saw* for *was*)—although seeing words or letters in reverse is common for children younger than 8 who do not have dyslexia, children with dyslexia will continue to see reversals past that age
- Difficulty comprehending rapid instructions or following more than one command at a time
- Problems remembering the sequence of things, such as learning the order of the alphabet or spelling
- Difficulty distinguishing between similar sounds in words; mixing up sounds in multisyllable words (auditory discrimination) (e.g., *aminal* for *animal*, *bisghetti* for *spaghetti*)
- Slow or inaccurate reading, with difficulty reading out loud
- Difficulty rhyming

Dyslexia is the most common learning disorder, affecting as many as 80% of individuals identified as learning disabled.⁴⁵ Prevalence rates range from 10% to 15% of the school-aged population,⁴⁶ with the highest noted estimate of 17.4%.⁴⁷ Historically, dyslexia was considered more common in boys than in girls, but data indicate an equal distribution between the sexes.⁴⁸ Boys are more likely to act out as a result of having a reading difficulty and are therefore more likely to be identified early. Girls, on the other hand, are more likely to try to “hide” their difficulty, becoming quiet and reserved.¹⁸

Causes of dyslexia can be both genetic and neurobiological.^{14,18,42} Genetic causation has been linked to chromosomes 1, 2, 3, 6, 11, 13, 15, and 18.⁴⁹ There is a strong inheritability of the genetic links for dyslexia. Statistics suggest that 30% to 50% of children with dyslexia have a

parent with the disorder.⁵⁰ Neuroanatomical abnormalities, atypical brain symmetry, and disruptions in neural processing have been observed in children with reading disorders.^{14,18,48,51} Anatomically, the measurements that best discriminate between children with and without dyslexia are the right anterior lobe of the cerebellum and the area involving the inferior frontal gyrus of both hemispheres.¹⁸ Dynamic investigations using functional brain imaging techniques (PET, fMRI, and the newer ultrafast echo planar imaging [EPI]) are providing significant information on brain functioning during cognitive tasks such as reading and picture naming.^{14,48}

Reading skills consist of a combination of visually perceiving whole words and phonetically decoding letters, morphemes, and words.⁵² Individuals with reading disorders exhibit brain activation patterns that provide evidence of an imperfectly functioning system for segmenting words into phonological (language) parts and linking the visual representations of letters to the sounds they represent.⁴⁷ These disruptions of the posterior reading system result in increased reliance on ancillary systems during reading tasks, including the frontal lobe and right hemisphere posterior circuitry. This suggests that the child with dyslexia may be compensating for poor phonological skills with other perceptual processes, helping to explain why individuals with dyslexia can develop reading skills, although they often remain slow and nonautomatic.⁴⁸

Dyscalculia (Mathematics Disorder). Dyscalculia is a learning impairment in which mathematical ability is substantially less than expected for age, intelligence, and education and that impairs academic achievement or daily living.²¹ Difficulties occur with comprehending a variety of math concepts, including number quantities, money, time, and measurement. This disorder also involves difficulties with computations and problem solving of specific math functions, which affects the ability to understand, remember, or manipulate numbers or number facts.¹⁸ This heterogeneous disorder may involve both intrinsic and extrinsic factors.⁵³ Intrinsic factors are hypothesized to include deficits in visual-spatial skill, quantitative reasoning, sequencing, memory, or intelligence. Extrinsic factors can be a combination of poor instruction in the mastery of prerequisite skills as well as attitude, interest, and confidence in the subject.

Characteristics of dyscalculia include the following⁵⁴:

- Confusing numbers and math symbols (+, −, ×, ÷)
- Inconsistent ability in addition, subtraction, multiplication, and division
- Problems sequencing numbers, or transposing them when repeated
- Difficulty with abstract concepts of time and direction
- Poor mental math ability
- Difficulty with money, budgeting, balancing checkbooks, and financial thinking (e.g., checking change or estimating the cost of items in a shopping basket)
- Problem reading analog clocks
- Trouble keeping score during games and playing games with flexible rules of scoring such as poker

Prevalence of dyscalculia is 5% to 6% in the school-aged population, with a nearly equal male-to-female

ratio.^{14,55} Geary⁵⁶ concludes that individuals with arithmetic disabilities currently appear to constitute at least two subgroups: those with only mathematic disorders and those with concomitant reading disorders and/or attention-deficit disorder.

Although there is evidence that this disorder is familial and heritable, much less research on its cause is provided than on the causes of most other learning disorders. Dyscalculia shares genetic influences with reading and language measures. The association between dyslexia and dyscalculia seems to be largely genetically mediated.^{14,55} Other risk factors for development of dyscalculia include prematurity and low birth weight. In addition, environmental deprivation, poor teaching, classroom diversity, and untested curricula have been linked to cause.⁵⁵

The neurological cause of dyscalculia was initially hypothesized to be right hemisphere dysfunction because of the strong relation of visual-spatial skills to numerical computation.⁵⁷ Additional research supports the involvement of both hemispheres because mathematics computation involves a complex relation of spatial problem solving, sequential analysis, language processing, and memory.⁵⁵ Specifically involved are portions of the parietal and frontal lobes.¹⁴ In an effort to compensate, individuals with dyscalculia can recruit alternate brain areas, but this substitution often results in inefficient cognitive functioning.⁵⁵

Dysgraphia (Disorder of Written Expression).

Dysgraphia is a learning impairment in which writing ability is substantially less than expected for age, intelligence, and education that impairs academic achievement or daily living.²¹ The DSM, fourth edition (DSM-IV) diagnosis of “disorder of written expression” depends on recognition of “writing skills substantially below those expected given the person’s chronological age, measured intelligence, and age appropriate education” that “significantly interferes with academic achievement or activities of daily living that require composition of written texts.”²¹ Children with dysgraphia have specific difficulties in the ability to write, regardless of the ability to read. This may include problems using words appropriately, putting thoughts into words, or mastering the mechanics of writing. Classifications of dysgraphia can include penmanship-related aspects of writing (e.g., motor control and execution), linguistic aspects of writing (e.g., spelling and composing), or a combination.⁵⁸ This heterogeneous disorder is frequently found in combination with other academic, learning, and attention disorders.^{13,18}

Characteristics of dysgraphia include the following⁵⁹:

- Poor legibility: irregular letter size and shapes, poor spacing
- Mixing uppercase and lowercase letters; unfinished letters
- Spelling difficulties
- Fatigues quickly or complains of pain when writing
- Decreased or increased speed of copying or writing
- Needs to say words out loud while writing
- Struggles with organizing thoughts on paper
- Difficulty writing grammatically correct sentences and organized paragraphs
- Large gap between knowledge base and ability to express ideas in writing
- Awkward pencil grip

Limited data are available on the prevalence of dysgraphia. Although 10% to 30% of school-aged children struggle with handwriting, we cannot assume they have been diagnosed with dysgraphia.⁶⁰ Difficulties in written expression are frequently underidentified and can be masked by reading disorders or considered to be attributable to poor motivation. Studies have suggested that dysgraphia may be as common as reading disorders and may occur in 3% to 4% of the population.^{13,58}

Dysgraphia has been suggested to be a neurological processing disorder that seldom occurs in isolation and can result from a number of other dysfunctions, including attention deficit, auditory or visual processing weakness, and sequencing problems.^{14,61} The complex nature of written expression makes finding the cause difficult. Writing involves integration of spatial and linguistic functions, planning, memory, and motor output. This suggests involvement of both the left and right hemispheres for skill in decoding, spelling, formulating and sequencing ideas, and producing work in correct spatial orientation, all coupled with rules of punctuation and capitalization.

Nonverbal Learning Disability

NVLDs (or NLDs) are considered by some to be a neuropsychological disability. Although this condition has been identified for more than 30 years, it has not yet been included as a diagnostic category in the DSM.⁶² The pioneer in the field, Dr. Byron P. Rourke, first identified in 1985 this separate and distinct learning disability. In 1995 he defined nonverbal disability as “a dysfunction of the brain’s right hemisphere—that part of the brain which processes nonverbal, performance-based information, including visual-spatial, intuitive, organizational and evaluative processing functions.”⁶³ Nonverbal learning disorders affect both academic performance and social interactions in children. Three primary areas affected by NVLDs include visual-spatial organization, sensory-motor integration, and social-emotional development. The social and emotional difficulties for individuals with nonverbal learning disorders are paramount, leading some researchers to label this a *social-emotional learning disability*.^{13,64} NVLDs are generally identified by a distinct pattern of strengths and deficits, with excellent verbal and rote memory skills and poorly developed sensory-motor and graphomotor ability, executive functioning, and social interactions.^{13,65,66}

Characteristics of NVLDs include the following^{14,62,67}:

- Higher verbal IQ compared with performance (nonverbal) on the Wechsler Intelligence Scale for Children (WISC)
- Develops speech, language, and reading skills early
- Strong vocabulary and spelling
- Ability to memorize and repeat a massive amount of information provided it is in spoken form
- Learns better and faster through hearing information rather than seeing it
- Difficulties with constructional and spatial planning tasks
- Fine and gross motor difficulties affecting printing and cursive writing, physical coordination, and balance

- May exhibit limited facial expression, flat affect, unchanging voice intonation, and robotic speech
- Poor interpretation of emotional responses made by others
- Trouble reading and understanding facial expressions, gestures, and voice intonations
- Nuances of spoken language, such as hidden meanings, figures of speech, jokes, and metaphors are interpreted on a concrete level
- Struggles with conversation skills, dealing with new situations, and changing performance in response to interactional cues
- Difficulties in problem solving and understanding cause-effect relationships
- Poor awareness of social space
- Can be intrusive and disruptive

NVLDs make up 5% to 10% of all individuals with learning disabilities.⁶⁸ NVLD is frequently overlooked in the educational arena because children with this disorder are highly verbal and develop an extensive vocabulary at a young age. Well-developed memory for rote verbal information positively influences early academic learning of reading and spelling. Yet these students will have difficulty performing in situations where adaptability and speed are necessary, and their written output will be slow and laborious.⁶⁵ Nonverbal learning disorders are therefore challenging to identify at younger ages but become progressively more apparent and debilitating by adolescence and adulthood. The challenges in early identification, the absence from the DSM-IV, and the different views held by psychological and educational disciplines often result in lack of awareness of, accurate diagnosis of, and appropriate service provision for these students.

Little is known about possible genetic or environmental causes of NVLD. There are no family, twin, adoption, segregation, or linkage studies available.¹⁴ Pennington¹⁴ proposes that both Turner syndrome and fragile X syndrome in females appear to be possible genetic causes of NVLD. Similarities include deficits in executive functions, increased difficulties in math versus reading and spelling, functional structural language but impaired pragmatic language, and social anxiety and shyness.¹⁴ Differential diagnosis is essential because NVLD can occur in conjunction with dyscalculia, attention deficit, adjustment disorder, anxiety and depression, emotional disturbances, and obsessive-compulsive tendencies.

Motor Coordination Deficits

Children with learning disabilities may or may not manifest motor coordination problems. Conversely, some children have motor and coordination problems but do not experience learning difficulties. Children with motor deficits typically have difficulty acquiring age-appropriate motor skills and move in an awkward and clumsy manner. Difficulties in daily functional tasks and performance areas (e.g., school and leisure skills) are common. Motor deficits can result from a wide variety of neurological, physiological, developmental, and environmental factors. These impairments can manifest in diverse ways depending on the severity of the disorder and the areas of motor and social performance affected. This will be discussed at length in the next section.

Social and Emotional Challenges

Behavioral patterns or disorders associated with learning disabilities include frustration, anxiety, depression, attention deficits, conduct problems, and global behavior problems. Ames⁶⁹ stressed that no single behavior pattern is prevalent in children with learning disabilities. Children with learning disabilities not only struggle in the classroom, but experience difficulties in the social arena as well.⁷⁰ Issues in learning and related behaviors affect one another in a complex manner, leaving us to wonder which is the cause and which is the symptom.

Frustration, deflated self-esteem, and other social and emotional difficulties tend to emerge when instruction does not match learning styles.⁷¹ This frustration mounts as the child notices classmates surpassing them, and this often results in exasperation with trying to keep up. The pressure then becomes for the child to “try harder,” when ironically most do not understand just how hard the child is trying. The dissatisfaction in not meeting the teacher’s expectations is often overshadowed by the inability to succeed in personal goals and a lack of self-worth. This can result in the development of internal perfectionism to deal with the lack of competence, with the belief of the child that he or she should not make mistakes.⁷²

Anxiety is another response that may occur with persistent difficulties in understanding and successfully completing schoolwork. This occurs when the child feels out of control and lacks the ability to plan and execute strategies for success.⁷¹ The mismatch between ability, expectations, and outcomes can cause frustration, disappointment, and stress, triggering a range of emotions and behaviors that interfere with everyday functioning in multiple environments.⁷¹

Other emotional difficulties are noted in attention. When a lesson is taught in a manner that is too complex, the child may become inattentive. Attention problems can influence behavior, often relating to difficulties with impulse control, restlessness, and irritability, affecting learning and peer interactions. These issues frequently coincide with frustration, anger, and resentment, which may manifest as a conduct problem (e.g., verbal and nonverbal aggression, destructiveness, and significant difficulties interacting with peers). Children with learning disabilities often become discouraged and fearful, are less motivated, and develop negative and defensive attitudes. These patterns of behavior can worsen with age, contributing to juvenile delinquency.³ Low self-esteem and depression are common during school years and tend to escalate around age 10 years.⁷³

Poor academic progress, additional prompting needed from teachers, and negative attention for disruptive behaviors can cause children with learning disabilities to perceive themselves as being “different.”⁷⁴ Lack of success in school experiences can influence the development of positive self-perception and can have powerfully negative effects on self-esteem.⁷¹ A self-defeating cycle may be established: the child experiences learning problems, school and home environments become increasingly tense, and disruptive behaviors become more pronounced. These responses, in turn, further affect the child’s ability to learn. Lack of success generates more failure until the child anticipates defeat in almost every situation.

Assessment and Intervention

Specialists

Evaluation and intervention for children with learning disabilities should involve an interdisciplinary team owing to the varied nature of presenting problems. Most children with learning disabilities are seen by a group of professionals, the makeup of which depends on the purpose, location, philosophical orientation, or availability of resources of a particular program. **Box 14-1** lists the different professionals and specialists who might participate in assessment or remediation of children with learning disabilities. The types of professionals are grouped into the four categories of education, medicine and nursing, psychology, and special services; they have been listed only once, although some professions could be categorized in multiple ways.

Therapists should be familiar with the roles of the various medical specialists and of primary care physicians. Psychologists have two distinct and often separate roles in the care of children with learning disorders. The first role is in identification of learning strengths and weaknesses. Psychological testing is often essential in the recognition of specific learning problems and may be done by clinical psychologists, school psychologists, or clinical neuropsychologists who specialize in diagnosis of learning disorders. The second role of psychologists is to provide mental health services and support systems to address academic, social-emotional, and behavioral issues. Counseling and behavior management can also be provided by a psychiatrist, behavioral specialist, or social worker. School adjustment or guidance counselors offer support and advice on specific academic difficulties, social conflicts, and affective issues.

Physical educators, adaptive physical educators, physical therapists (PTs), occupational therapists (OTs), and speech therapists also may be involved in the assessment of motor deficits and related areas. Overlap in the areas assessed may occur. The unique training of each professional influences both the selection of tests and the qualitative aspects of assessment on the basis of observations of a child's performance. Although the evaluations may appear similar, differences among professions are apparent in orientation and rationale when interpreting dysfunction.

Planning an assessment protocol can prevent unnecessary duplication of testing and provide comprehensive information related to the referral concerns. The assessment is driven by the referral concerns and the functional difficulties the child is experiencing. Communication of information between professionals and the parents will generate a comprehensive picture of the child's areas of strength and weakness, necessary for effective intervention planning.

Coordinating Multiple Interventions

As the number of disciplines involved in the assessment and therapeutic management of children with learning disabilities has steadily increased, communication for effective programming has become more challenging. Despite the benefits of specific skills brought to the case by each professional, the huge variety of well-meaning recommendations can result in service delivery overkill. **Case Study 14-1** provides an example of the negative impact of overabundant specialized intervention on the child and family. In this case, if all the interventionists had communicated, a more realistic and effective plan could have been developed.

BOX 14-1 ■ TYPES OF SPECIALISTS WORKING WITH CHILDREN WITH LEARNING DISABILITIES

EDUCATION

- Classroom teacher
- Special educator
- Guidance counselor
- Learning disability specialist
- Educational diagnostician
- Reading specialist
- Physical educator
- Adaptive physical educator

MEDICINE AND NURSING

- Family physician
- Pediatrician
- Pediatric neurologist
- Psychiatrist
- School nurse
- Biochemist
- Geneticist
- Endocrinologist
- Nutritionist

- Ophthalmologist or optometrist
- Otologist or ear, nose, and throat (ENT) specialist

PSYCHOLOGY

- Clinical psychologist
- Neuropsychologist
- School psychologist
- Child psychologist

SPECIAL SERVICES

- Occupational therapist
- Physical therapist
- Speech and language pathologist
- Audiologist
- Vision specialist
- Social worker
- Recreational therapist
- Music therapist
- Vocational education specialist

CASE STUDY 14-1 ■ MATT

Matt is an 8-year-old boy who was referred for clinic-based physical therapy intervention for 1 hour per week for remediation of severe motor coordination and planning problems that accompanied his learning disability. In addition to Matt's weekly treatment sessions, suggestions were made to his mother for a home program to be accomplished three times a week for 15 to 30 minutes each time. Meanwhile, Matt also received other services. Although he was mainstreamed into a regular classroom in accordance with the special education law, he was seen by the resource teacher on a daily basis and by the adaptive physical education teacher twice a week to meet his specialized needs. The classroom teacher told Matt's mother that Matt must read at least one book a night because he needed additional reading practice. A reading tutor came to Matt's house on Saturday mornings. Ocular motor problems were identified, so he was evaluated by an optometrist, who recommended weekly visits plus ocular exercises for 30 minutes a day. Matt developed secondary emotional problems, partly

because he was bright yet aware of his learning disability and frustrated by it. Thus Matt also saw a psychotherapist on a weekly basis. The psychotherapist recommended participation in weekly group sessions, in addition to Matt's individual sessions, to help improve peer relationships. Thus Matt's therapists had developed a 12-hour-a-day program for him and his family. It was no wonder that Matt had difficulty in developing peer relationships; he never had time. Matt's schedule also affected interaction in his own family. His mother believed that being a "therapist" to Matt interfered with her role as his mother. She felt unable to carry out the home program and felt guilty for not doing it.

What became apparent with Matt's case was that although each professional involved with him made an important contribution to evaluation and intervention, the massive input, to some extent, had a detrimental effect on Matt and his family. Coordinating interventions and providing additional support at home can create a drain on the family and limit time for family activities and extracurricular participation.

Effective coordination of intervention services presents a dilemma because no single discipline is specifically trained for that role.⁷⁵ Kenny and Burka⁷⁵ stress the need for a person to act as a coordinator for the management and integration of the interventions received by the child. Unfortunately, this role does not exist; therefore the parent must assume this responsibility.

School-Based Service Delivery Models

The model of service delivery for each individual child should be developed to facilitate the student's ability to be successful in the learning environment. A continuum of services exists to enable interventionists to be responsive to all children's needs. The continuum includes consultation, integrated or supervised therapy, and direct service.⁷⁶ Unfortunately, a lack of available resources can influence what type and frequency of services are provided. In creating a plan that truly addresses the issues hindering a child's learning within the academic setting, the team must work together to fabricate relevant and inclusive goals.

IDEA currently requires that all children in special education be educated in the least restrictive environment. The law requires that students with disabilities be educated to the extent appropriate with their peers, within the inclusion classroom. Removing the child from the classroom for special education and intervention is discouraged unless it is absolutely necessary for the student to learn effectively. Although the model of inclusion can be effective for many children, it requires members of the team to work closely together with the regular education teacher. This collaborative effort ensures an understanding of the child's special learning needs and incorporation of therapeutic procedures into the regular classroom to facilitate the best learning environment.

Bricker⁷⁷ contends that adhering strictly to this model can be detrimental to certain students, and each case must be looked at individually. The least restrictive environment

should be determined after assessing the specific needs of the child. If services in a regular classroom, coupled with supplemental aids and services, do not meet the needs of the child, an alternate environment should be considered. The first adaptation might be to have the child participate for the majority of the day in the regular classroom and leave for special instruction for part of the day. In some educational settings, children with learning disabilities are given full-time instruction in a special classroom with a small group of other children with learning disabilities. A special education teacher or a learning disability specialist is in charge of the classroom. The most specialized environment would be a private school only for children with learning disabilities.

LEARNING DISABILITIES AND MOTOR DEFICITS OR DEVELOPMENTAL COORDINATION DISORDER

Approximately half of children with learning disabilities have motor coordination problems.⁷⁸ Motor deficits are often the most overt sign of difficulty for the child with learning disabilities. Lowered academic achievement within any or all areas of learning (reading, spelling, writing) is also seen in children with developmental coordination disorder (DCD).^{8,21} A study by Jongmans and colleagues⁷⁸ indicates that children with concomitant perceptual-motor and learning problems are more severely affected in motor difficulties than those with only DCD or who are only learning disabled. At times, extreme discrepancy in competence over a range of motor skills exists, with strengths in some motor areas and significant weaknesses in others. Presentation of difficulties may change over time depending on developmental maturation, environmental demands, and interventions received.

An International Consensus Meeting on Children and Clumsiness was held in 1994 with expert educators, kinesiologists, OTs, PTs, psychologists, and parents. These experts discussed a common name to identify "clumsy" children

with movement, coordination, and motor planning difficulties. The term *developmental coordination disorder* (DCD), as first described in DSM-III,²¹ was identified to distinguish these children from those with severe motor impairments (such as those with cerebral palsy or paraplegia) and children with normal motor movements. A child with DCD often exhibits difficulty with motoric academic tasks such as handwriting and gym class, self-care skills such as dressing and using utensils, and leisure activities including playground games and social interactions.⁷⁹

Definition

As described in the DSM-IV-TR²¹ as one of the motor skill disorders, DCD has the following criteria:

- A marked impairment in the development of motor coordination (criterion A)
- An impairment that significantly interferes with academic achievement or activities of daily living (criterion B)
- The presence of coordination difficulties that are not the result of a general medical condition (e.g., cerebral palsy, hemiplegia, or muscular dystrophy); the criteria for pervasive developmental disorder are not met (criterion C)
- If mental retardation is present, the motor difficulties are in excess of those usually associated with it (criterion D)

Clinical Presentation

DCD is a childhood disorder characterized by poor coordination and clumsiness. Typically, there is no easily identifiable neurological disorder accompanying this lack of motor skills required for everyday life.⁸⁰ Characteristics can be seen in developmental areas such as gross motor, fine motor, visual motor, self-care, and social-emotional areas. Children tend to develop at a slower rate and require more effort and practice to accomplish age-level tasks. The salient features are coordination difficulties that include decreased anticipation, speed, reaction time, and quality and grading of movement.^{81,82} These children often have difficulties analyzing the task demands of an activity, interpreting cues from the environment, using knowledge of past performance, and transferring and generalizing skills.⁸³

Coordination difficulties are most apparent when complex motor activities are attempted. Physical education class often presents major problems. For example, a 9-year-old boy described his motor problems as follows: “When the gym teacher tells us to do something, I understand exactly what he means. I even know how to do it, I think. But my body never seems to do the job.”⁸⁴ *Case Study 14-2* describes the motor difficulties frequently encountered in children with DCD.

CASE STUDY 14-2 ■ PAUL

The following is a mother’s description of her child, Paul, who had motor coordination problems and learning disabilities: “I think when Paul was first born I tried to ignore the problem. Paul is a child who never climbed or ran or drew pictures the way other kids did. But until he went to nursery school, I didn’t pay much attention to it. Maybe I didn’t want to pay attention to it. Maybe I knew it was there and I didn’t want to know about it. I’m not sure. But Paul was always a verbal child and a creative and imaginative child. He and I had something special because I used to enjoy that kind of creative imaginative play. We used to have our own world of various fantasies, heroes, and places.

“Paul sat up at about 7 months; he crawled and crept on time. He didn’t learn to walk until he was about 15 months old. He walked cautiously, holding on and not letting go. He walked late, but he talked early. He said his first clear word, “cat,” at 6 months. He knew what a cat was and could relate to it. My husband and I were so enthusiastic about his sounds. In those days they said that if you stimulated your child and talked to him and got him ready to talk, he could read early. I was concerned that Paul would be able to talk and have a marvelous vocabulary and read because I had a reading disability and a spelling disability.

“When Paul was 4 years old and in nursery school, at my first conference the teacher said, ‘Look out the window, Mrs. B.—see Paul sitting at the bottom? All the other kids are climbing on top of the jungle gym.’ And then she showed me some art work. Paul couldn’t cut, he couldn’t paste, he couldn’t do any of it. We could definitely, at the age of 3 or 4, see his problems. He was bright, but he couldn’t cut, paste, or draw, he couldn’t climb, and he really didn’t know how to

run. That was where his handicaps were first being noticed, more by other teachers and professionals than by my husband and myself.

“When we had to make the decision as to whether to put Paul into kindergarten or hold him back, we were frustrated because Paul was very bright and very alert. He has always known everything that was going on in the world.

“Now, the kids Paul knows and the kids who know Paul know that he can’t do motor tasks and they’ll come over and play rocket ships with him. But there will come a time, as the kids are getting older, that they won’t want to do this.”

Paul’s mother, who also had learning and motor difficulties, described her own disability as follows:

“The hardest course for me was gym. I was unfortunate enough to have the same gym teacher throughout high school. The teacher always used to think I was a lazy kid, that I just never wanted to try to do the exercises. Although I tried, I couldn’t do the stunts and tumbling for anything. The other girls would do a somersault and I would still do it like a 4-year-old. I’d just about get over.

“I took dance a couple of times. I never could figure out as a kid why I couldn’t point my toes. The teacher would say, ‘Point your toes,’ and it never made any sense to me. I always curled my toes up. Only when somebody sat down with me and actually showed me did I know that that was how you were supposed to point your toes. With other kids, they just did what the teacher did. Nobody had to stop and tell them. I was the klutzy kid. I never could do the nice leaps across the floor. But I would try. After two or three sessions my mother stopped giving me lessons. She was probably embarrassed.

CASE STUDY 14-2 ■ PAUL—cont'd

“As a girl, it wasn’t as traumatic not being athletic. As I got older, the need for a woman to be athletic tended to decrease, whereas for a boy, the need to be athletic and competitive tends to increase. I foresee this as one of the major problems for Paul.

“Most of my life my friendships have always relied on other people. I met most of my friends through other friends because I’ve gone along to things. I think it goes back to being teased as a child about the things I couldn’t do or the way I looked. If you looked at me, I probably looked like a lot of the

learning-disabled kids that you see: my clothes were not put together properly, my shoelaces were untied, and my hair was never quite combed properly.

“It was very difficult for me to learn how to put on makeup and use a hairdryer. It would take many hours of trying to learn. For a long time, my fingernails were cut very short because I didn’t know how to file them. It is still very hard for me to put on eye makeup and look in the mirror and try to figure it out. I still don’t feel as though I am completely put together. And I put a lot of effort and energy into looking good.”

Development of gross and fine motor skills, coupled with the child’s ability to master body movements, enhances feelings of self-esteem and confidence. Through persistence in mastering the varied challenges of motor exploration the child builds self-reliance. The frustrations and accomplishments enhance confidence and the ability to take risks. By engaging in group activities children develop essential social skills, including how to compromise, work as a team, and deal with conflicts and different personality styles.

Poor motor coordination often results in significant social and emotional consequences. When a child is poorly coordinated she or he is often teased and shunned from group play. This may lead to anxiety and avoidance of participation in games, as children frequently judge themselves to be both physically and socially less competent.⁸⁵ Anxiety may be more prevalent in adolescence, most notably in boys.⁸⁶ Because they are often unsuccessful in group participation, difficulties with navigating the changing demands of cooperative play and negotiating with others and reluctance to advocate for themselves often result. Boys with learning and motor coordination problems have been found to demonstrate significantly less effective coping strategies in all domains of functioning compared with a normative sample.⁸⁷ Feelings of incompetence, depression, or frustration are common and can be lifelong problems.^{88,89} The impact of motor coordination difficulties on social behavior is exemplified by this statement from a child with learning disabilities and motor deficits:

“They always pick me last. This morning they were all fighting over which team had to have me. One guy was shouting about it. He said it wasn’t fair because his team had me twice last week. Another kid said they would only take me if his team could be spotted four runs. Later, on the bus, they were all making fun of me, calling me a “fag” and a “spaz.” There are a few good kids, I mean kids who aren’t mean, but they don’t want to play with me. I guess it could hurt their reputation.”⁸⁴

Gross motor characteristics of DCD include the following:

- Diminished core strength and postural control
- Delayed balance reactions
- Often falling, tripping, and bumping into things; acquiring more than the usual number of bruises
- Motor movements that are performed at a slower rate despite practice and repetition⁸²
- Motor milestones that may be achieved in the later range of normal development

- Poor anticipation (do not use knowledge of past performance to prepare)
- Notably different quality of running and ball skills from typical peers
- Difficulty learning bilateral tasks such as riding a bicycle, catching a ball, and jumping rope
- Possible hesitance with and avoidance of new or complex motor tasks (e.g., playground equipment, gym class)
- Possibly poor safety awareness
- Inability to smoothly turn and position body when going up ladder to a slide or to get into a chair
- Possible sedentary activity level; may prefer to engage in solitary play
- Tendency to not play games by the rules
- Often, avoidance of team sports such as T-ball and soccer

Fine motor characteristics of DCD include the following:

- Diminished wrist and hand strength
- Maladaptive or immature grasp patterns
- Possible use of excess or not enough pressure
- Poor refinement of small motor movements with hands (qualitatively, the child looks like he or she is wearing a pair of gloves when trying to manipulate small objects)
- Often dropping or breaking of items
- Delayed dressing skills (buttons, zippers, fasteners, shoelaces)
- Trouble with eating utensils (scooping, piercing)
- Difficulty with tool use (e.g., scissors, pencils, stapler, hole punches)
- Writing that is laborious and often illegible
- Impaired drawing ability characterized by poor motor control, with wobbly lines, inaccurate junctures, and difficulty coloring within the lines.
- Decreased ability with pasting, gluing, manipulating stickers and other art materials
- Difficulty with constructive, manipulative play (e.g., block building, Tinkertoys, Legos)
- Often the presence of associated articulation deficits, possibly because of the fine motor nature demanded for articulation

Visual motor characteristics of DCD include the following:

- Difficulty with visually guided motor actions (i.e., eye-hand and eye-foot coordination)
- Hesitancy or decreased safety on stairs

- Trouble with timing needed for kicking, hitting, and catching ball
- Difficulty with hopscotch and four squares
- Poor judgment of spatial relationships (knowing where the body is in space)
- Delayed development of prepositional and directional concepts
- Difficulty with spatial planning tasks such as puzzles, building models, and constructional toys
- Handwriting that is often labored, with spacing and sizing problems evident; letters may be irregular, illegible, and poorly organized on the page

Self-care characteristics of DCD include the following:

- Slowness to develop independence in activities of daily living
- Overreliance on parents to help with self-care skills
- Clothes that are often on backward or crooked
- Struggles with cutting fingernails, putting on makeup, tying necktie, using a hair dryer
- Difficulty blowing nose with tissue, putting on Band-Aid
- Trouble putting toothpaste on toothbrush
- Messy eater, spills often, does not recognize food on face
- Difficulty pouring from a container, opening lunch box, unwrapping sandwich, opening containers, peeling fruit
- Trouble packing a bag, backpack, or suitcase
- Difficulty sequencing daily routines

Social and emotional characteristics of DCD include the following:

- Often emotionally immature
- May exhibit behavioral difficulties such as acting out or becoming class clown
- May be more introverted and anxious
- Can appear fiercely competitive, hating to lose, complaining that rules are unfair
- Can be self-deprecating, calls self “stupid”
- Often easily frustrated
- May experience depression and feelings of incompetence
- Has difficulty making and maintaining friendships, plays alone
- Has feelings of low self-worth, poor self-esteem⁹⁰
- Perceived by others as lazy, overprotected, or immature⁹¹
- Adolescents may have fewer social pastimes and hobbies than peers

Prevalence

Estimating the prevalence of children with DCD is challenging. Great variety exists in the clinical presentation, with some children exhibiting motor deficits in all areas and others having only isolated concerns. Among professionals there is a lack of clarity on the definition and diagnostic criteria.⁹¹ Overlap of symptoms associated with other conditions such as attention-deficit/hyperactivity disorder (ADHD), autism spectrum disorders, perceptual-motor problems, and speech and language impairments further complicates differential diagnosis.^{14,80,92} In addition, there is no single test or screening measure that can be used to confidently identify the problem.⁹³ Other factors influencing prevalence rates include the criteria used to delineate a child with DCD from a typical peer, differences in terminology, types and methods of testing, reliability of the tests used, and heterogeneity of the test sample.^{79,93,94}

An estimated 5% to 10% of children aged 5 to 11 years had DCD.²¹ Boys diagnosed with DCD outnumber girls by two to one. This difference may reflect higher referral rates for boys as a result of increased behavioral difficulties of boys with motor incoordination.⁹⁵

Perspectives on the Causes of Developmental Coordination Disorder

There is no single explanation for the cause of DCD. Neurological dysfunction, physiological factors, genetic predisposition, and prenatal and perinatal birth factors have been proposed to explain the basis of DCD.^{91,96} It is recognized that DCD is heritable and is genetically distinct from ADHD, although the comorbidity rate is up to 50%.¹⁴ Comorbidity is high with other diagnoses, including autism spectrum disorders,⁸⁰ as well as a variety of developmental learning problems such as math disability, reading disability, specific language disabilities, spelling and writing disabilities, and so on. Correlation has also been noted between preterm infancy and low birth weight with characteristics of DCD. The heterogeneity of DCD makes finding a unitary cause difficult. Children with DCD present wide variability in both locus of specific problems and functional disabilities. Further complicating an understanding of the cause is that the intervention for the child with DCD is driven by competing treatments.⁹⁷

Few studies have been conducted to look at brain images in children with DCD, with no particular patterns of abnormality observed.⁹¹ Hadders-Algra⁹⁸ has suggested that DCD is a result of damage at the cellular level in the neurotransmitter and receptor systems, rather than a specific region of the brain. Resulting coordination difficulties can be from a combination of one or more impairments in proprioception, motor programming, timing, or sequencing of muscle activity.

Possible physiological origins of motor coordination deficits have highlighted multisensory processing. Ayres,⁹⁹ in her theory of sensory integration, suggested that the integration among sensory systems is imperative for refined motor performance in children. She proposed that normal development depends on intrasensory integration, particularly from the somatosensory and vestibular systems. Lane¹⁰⁰ outlines the role of vision, combined with vestibular and proprioceptive inputs, as a foundation to motor performance. In combination, these systems sustain postural tone and equilibrium, provide awareness and coordination of head movements, and stabilize the eyes during movement in space.

More recently, Piek and Dyck¹⁰¹ found support for the correlations between DCD and deficits in kinesthetic perception, visual-spatial processing, and multisensory integration.¹⁰¹ In general, it is thought that reduced rates of processing information and deficits in handling spatial information may underlie the deficits in motor control.⁸⁰ Obviously more work is needed on the cause of DCD.

Subtypes of Developmental Coordination Disorder

Various approaches have been used to investigate subtypes of DCD, including classification by underlying causes, clinical and descriptive approaches, and statistical clustering.⁹⁴ Initial attempts at classifying subtypes within DCD support the heterogeneity of this group of children.¹⁰² Work by

Dewey and Kaplan¹⁰³ suggests that children with DCD may be classified into subgroups based on distinctions in motor planning and motor execution deficits. They identified three subgroups: children who exhibited deficits in motor execution alone, those whose primary deficits were in motor planning, and children who exhibited a generalized impairment in both areas.

Macnab, Miller, and Polatajko¹⁰⁴ identified five different profiles of children with DCD. They used measures of kinesthetic acuity, gross motor skill, static balance, visual perception, and visual motor integration. Two distinct groups emerged, with children exhibiting generalized visual deficits and generalized dysfunction in all areas. Generalized gross motor deficits did not emerge as a distinct subgroup, as the third group demonstrated a discrepancy between static balance and complex gross motor tasks, and the fourth group had poor performance on running but performed well on kinesthetic acuity. Other groups included children with deficits in visual motor and fine motor problems. These results suggest that a subtype based on motor execution or planning problems alone may be too general.

Assessment of Motor Impairments

A variety of professionals may be involved in a comprehensive assessment of motor deficits. Pediatric OTs and PTs are often the core team assessing functional motor concerns. Areas assessed by pediatric OTs and PTs often overlap, so communication is essential to ensure that testing is not replicated. Ideally, performance will be evaluated in multiple environments and include components of skill, functional performance areas, and social and societal participation. Specific recommendations should include activities to enhance performance in the environments in which the child functions on a daily basis.

Clinical judgment of the therapist is important in designing an assessment protocol and synthesizing information to create a complete profile of the child. A variety of standardized and nonstandardized evaluation tools should accompany structured clinical observations and caretaker interviews. Observations of the child can yield more readily usable information than a standardized score,¹⁰⁵ enabling the therapist to view the child in natural routines, self-directed activities, and unstructured play. The interview process is essential to gather information about the child's interactions and participation. This process paints a verbal picture of the child to help us to understand levels of functioning and participation in a variety of environments. Other crucial information obtained is how the child's difficulties are affecting the ability to parent or teach the student.¹⁰⁵

Before choosing an evaluation tool the therapist should be aware of the intended purpose of this measure. Tools used to assess children with DCD are used for distinct purposes: identify impairments, describe severity of impairments, or explore activity or participation limitations.⁸³ The choice of evaluations may also be determined by the setting, frame of reference of the therapist, and functional concerns of the child. A therapist should be familiar with all aspects of test administration and scoring for evaluation tools and should comply with the training requirements described in the test manual. Test construction, reliability, and validity for assessing DCD should be considered. [Appendix 14-A](#)

provides an overview of standardized tests available for the assessment of motor dysfunction in children with learning disabilities. Uses and limitations of the individual tests and test batteries are listed.

Identification of subtle motor difficulties is critical and challenging. These subtle motor difficulties initially can be undetected, leading to unrealistic expectations of age-level motor performance. The child's difficulty with skilled, purposeful manipulative tasks or with finely tuned balance activities may not be readily apparent in the classroom or may be perceived as lack of effort. Children with DCD may be able to perform certain motor tasks with a level of strength, flexibility, and coordination that is qualitatively average but must use increased effort and cognitive control for sustained success.

Levels of performance in gross and fine motor testing may fall in the borderline range. Careful observations are of paramount importance, because the child's deficits are often qualitative rather than quantitative. A child might have age-appropriate balance on testing but lack ability in weight shifting and making quick directional changes, which affects the ability to participate in extracurricular activities such as soccer or baseball. When assessing children with subtle motor deficits, it is important to realize that many evaluation tools have been developed for children with moderate to severe neurological impairments.

Children with DCD do not exhibit obvious evidence of neuropathological disease (i.e., "hard" neurological signs such as a cerebral lesion). Subtle abnormalities of the central nervous system are frequently noted by the presence of "soft" neurological signs. Deficits associated with soft neurological signs include abnormal movements and reflexes, sensory deficits, and coordination difficulties. Evaluation of soft neurological signs is typically part of an examination by a pediatric neurologist, although therapists can assess these areas in conjunction with standardized testing. [Box 14-2](#) lists soft neurological signs frequently used to assess this population.

Researchers suggest that a high percentage of children with learning disabilities exhibit certain soft neurological signs. An early study reported that 75% of 2300 children with positive total "neurological soft sign" ratings had the symptom of poor coordination.¹⁰⁶ More recently, 169 children aged 8 to 13 years were assessed for a relation between soft neurological signs and cognitive functioning, motor skills, and behavior. Those children with a high index for soft neurological signs were found to have significantly worse scores in each domain.¹⁰⁷ The relationship between neurological soft signs and DCD is difficult to validate without more current systematic research; however, they are indicators that intervention may be needed.¹⁰⁸

In general, a composite of soft neurological signs is more predictive of dysfunction than single signs. Children without notable motor difficulties can frequently exhibit one or more soft signs; therefore identification of a single sign must be interpreted cautiously. Neurological signs involving complex processes were found to be the most predictive. The clinician needs to be familiar with typical developmental patterns, as certain soft neurological signs such as motor overflow, right-left confusion, visual tracking difficulties, and articulatory substitution are expected at younger ages and mature in quality over time.

BOX 14-2 ■ COMMON SOFT NEUROLOGICAL SIGNS USED IN ASSESSMENT OF CHILDREN WITH LEARNING DISABILITIES AND MOTOR DEFICITS

MINOR NEUROLOGICAL INDICATORS

Left-right discrimination
Finger agnosia
Visual tracking
Extinction of simultaneous stimuli
Choreiform movement
Tremor
Exaggerated associated movements
Reflex asymmetries

COORDINATION

Finger-to-nose touching
Sequential thumb-finger touching
Diadochokinesia
Heel to shin
Slow controlled motions

Postural-motor measures
Muscle tone
Schilder's arm extension posture
Standing with eyes closed (Romberg test)
Walking a line
Tandem walking (forward and backward)
Hopping, jumping, skipping
Ball throw and catch
Imitation of tongue movements
Pencil and paper tasks
Fine motor tasks (stringing beads, building block towers)

SENSORY INDICATORS

Graphesthesia
Stereognosis
Localization of touch input

Assessment measures of soft neurological signs vary considerably for children with learning disabilities, both in what signs are included in the assessment and how they are grouped. This list represents a compilation of possible soft neurological signs.

Compiling a complete picture of motor deficits in children with learning disabilities involves assessing the following complex skills: (1) postural control and gross motor performance, (2) fine motor and visual motor performance, (3) sensory integration and sensory processing, (4) praxis and motor planning, and (5) physical fitness. Each of these interrelated functions is described in this chapter as an area of clinical assessment.

Postural Control and Gross Motor Performance

Muscle Tone and Strength. Low muscle tone and poor joint stability have been identified as characteristic of some children with learning disabilities. On observation, the child with low tone may look “floppy” and may have an open-mouth posture, lordotic back, sagging belly, and knees positioned closely together. Muscles may be poorly defined and feel “mushy” or soft on palpation, and joints may be hyperextensible. A common method for assessing muscle tone and proximal joint stability involves placing the child in a quadruped position and observing the ability to maintain the position without locking of the elbows, winging of the scapula, or sagging (lordosis) of the trunk. The therapist can determine joint stability by asking the child to “freeze like a statue.” The therapist then provides intermittent pushes to the trunk, assessing the child's ability to remain in a static position.

Children with low tone may develop patterns of compensation called *fixing patterns*. These patterns often include elevated and internally rotated shoulders, internally rotated hips, and pronated feet. The child compensates for low tone by using the stable joint positions and holding himself or herself stiffly for increased stability. These patterns may resemble those of children with slightly increased tone. Careful observation and palpation of muscles will help to differentiate fixing patterns from increased muscle tone. Judgments of muscle tone are primarily made through clinical observations and felt in a hands-on assessment.

Manual muscle testing can provide detailed information about impairment in strength of individual muscles but is not regularly used in assessing children with learning disabilities, unless concerns of a possible degenerative disease exist. More appropriately, strength should be assessed by the child's functional ability to move against gravity during activities. Within developmental assessments, the therapist is observing range of motion against gravity in skills such as reaching, climbing, throwing, and kicking. The therapist also can have the child hold positions against gravity to assess strength and endurance (e.g., prone extension and supine flexion).

Early Postural Reflexes. Early reflexes are essential for the development of normal patterns of motor development. These reflexes facilitate movement patterns that become integrated into purposeful motions. If they are not fully integrated, qualitative differences in muscle tone, postural asymmetries, transitional movement patterns, bilateral coordination, and smooth timing and sequencing of motor tasks may be observed. Residual reactions (e.g., asymmetrical tonic neck reflex [ATNR] and symmetrical tonic neck reflex [STNR]) that might be noted in children with DCD are generally subtle and most often are seen in stressful, nonautomatic tasks. McPhillips and Sheehy looked at incidence of primitive reflex patterns and motor coordination difficulties in children with reading disorders.¹⁰⁹ The group with the lowest reading scores had a significantly higher rate of ATNR and motor impairments when compared with good readers. Assessment for persistence of primitive reflex patterns in children with learning disabilities should emphasize impact on functional aspects of performance.

The effect of lack of integration can be observed during tasks such as writing at a table or gross motor activities such as using ball skills and jumping rope. Persistence of these primitive reflexes may be seen in the child's inability to sit straight forward at the table. The ATNR influence might be observed by a sideways position at the table with the arm on

the face side used in extension. During ball games the child may have diminished ability to throw with directional control because head movements will influence extension of the face-side arm. If the STNR is not fully integrated the child is often unable to flex the legs while sitting at a desk looking down at his or her work (neck flexion). Although residual reflex involvement may affect performance of these tasks, many other components are involved that require consideration.

Righting, Equilibrium, and Balance. Righting and equilibrium are dynamic reactions essential for the development of upright posture and smooth transitional movements. Righting reactions help maintain the head in an upright alignment during movement in all directions. Equilibrium reactions occur in response to a change in body position or surface support to maintain body alignment. In simpler terms, equilibrium reactions get us into a position, and righting reactions keep us in that position. Together these reactions provide continuous automatic adjustments that maintain the center of gravity over the base of support and keep the head in an upright position.

Righting and equilibrium reactions are best assessed on an unsteady surface such as a tilt board or large therapy ball. These reactions occur in all developmental positions, and complete assessment will consider a range of positions during functional performance in gross and fine motor activities. To test equilibrium, the child's center of gravity is quickly tipped off balance. The equilibrium response is one of phasic extension and abduction of the downhill limbs for protection and of flexion of the uphill body side for realignment. In daily actions, most of the righting reactions are subtle and occur continuously to relatively small changes in body position. Subtle shifts of the support surface can be made to assess the child's ability to maintain the head and trunk in a continuous upright position. Righting and equilibrium reactions are the basis for functional balance and postural control.

To balance effectively, we use visual information (about the body and external environment), proprioceptive information (about limb and body position), and vestibular information (about head position and movement), in order to initiate an appropriate corrective response.¹¹⁰ Balance reactions occur as a response to changes in the center of gravity that stimulate the vestibular receptors (utricle and semicircular canals). This stimulation causes muscles to activate, allowing balance to be maintained in static and dynamic activities (e.g., sitting in a chair, walking, standing on a bus). When the vestibular system works in conjunction with vision and information from the muscles (proprioception), balance is easier and more refined. Considering the impact of these sensory systems working together is important during assessment. The therapist should test the child's balance with the child's eyes open and closed and observe differences in ease and quality of performance. Standing with eyes closed relies more on vestibular and proprioceptive input, and difficulty may indicate that the child depends heavily on the visual system for balance. To further assess this sensory interaction, balance should also be observed on steady and unsteady surfaces (e.g., dense foam or a tilt board) with and without visual orientation. Traditional tests of balance include (1) the Romberg position—standing with feet together and eyes closed, (2) Mann position—standing

with feet in tandem with eyes closed, and (3) standing on one leg with eyes open and eyes closed. The Bruininks-Oseretsky Test of Motor Proficiency, second edition (BOT-2)¹¹¹ and the Sensory Integration and Praxis Tests¹¹² have comprehensive balance subtests (see Appendix 14-A).

Postural Control. Postural control is dependent on muscle tone, strength, and endurance of the trunk musculature, as well as automatic postural reactions required to maintain a dynamic upright position. A child has adequate postural control when he or she can maintain upright positions, shift weight in all directions, rotate, and move smoothly between positions. These areas are often deficient in children with DCD, affecting both gross and fine motor performance.

The child may fatigue quickly and fall often during gross motor play. Other body parts may be used for additional support because of weak postural musculature—for example, placing the head on the ground when crawling up an incline or sticking out the tongue when climbing or pumping a swing. In sitting, a child with diminished postural control will fatigue quickly, either leaning on his or her hands for additional support or moving frequently in and out of the chair. These compensations affect the child's ability to perform fine motor tasks or maintain attention for cognitive learning because so much effort is exerted on sitting up. Observing the effects of fatigue is important because both sitting and standing postures may deteriorate over the course of a day. Generally the problem stems from motor programming problems versus muscle power.

Gross Motor Skills. *Gross motor coordination* refers to motor behaviors related to posture and locomotion, from early developmental milestones to finely tuned balance. Children with learning disabilities and DCD may attain reasonably high degrees of motor skill in specific activities. Motor accomplishments frequently remain highly specific to particular motor sequences or tasks and do not necessarily generalize to other activities, regardless of their similarities. When variation in the motor response is required, the response often becomes inaccurate and disorganized.

Although children with DCD can sit, stand, and walk with apparent ease, they may be awkward or slow in rolling, transitioning to standing, running, hopping, and climbing. Skilled tasks such as skipping may be accomplished with increased effort, decreased sequencing and endurance, and associated movements.

Evaluation of gross motor skills should include both novel motor activities and age-appropriate skills. The child, for example, can be asked to imitate a hopping sequence or maneuver around a variety of obstacles. Skills that have been accomplished can be varied slightly (e.g., hopping over a small box). Age-appropriate social participation tasks, such as tag and dodge ball, can be observed for qualitative difficulties in timing and spatial body awareness. Developmentally earlier skills also should be observed to assess the quality of performance. BOT-2¹¹¹ and the Peabody Developmental Motor Scales¹¹³ are examples of tools for standardized assessment of gross motor skills (see Appendix 14-A).

Fine Motor and Visual Motor Performance

Fine Motor Skills. Fine motor coordination involves motor behavior such as discrete finger movements, manipulation, and eye-hand coordination. A child with DCD often

demonstrates multiple fine motor concerns. Areas of difficulty typically include grasp and manipulation of small objects and dexterous hand skills, such as buttoning or putting coins into a vending machine. Assessment should include both standardized assessments and structured observations of functional performance.

A complete fine motor assessment should include observations of proximal trunk control to distal finger movements. Trunk control and shoulder stability affect the accuracy and control of reaching patterns and create a stable base from which both hands can be used to perform bilateral skills. The assessment of distal control considers wrist stability, development of hand arches, and separation of the two sides of the hand, all providing a foundation for the control of distal movement. Qualitative observations of distal fingertip control include finger motions to move objects into and out of the palm of the hand and rotate an object within the hand.

Although standardized assessments such as BOT-2¹¹¹ and the Peabody Developmental Motor Scales¹¹³ have fine motor sections, they do not adequately measure manipulative components described previously. Combining qualitative observations during a variety of fine motor tasks with knowledge of typical development is important. Soft neurological signs, including diadochokinesia (rapid alternation of forearm supination and pronation), sequential thumb-to-finger touching, and stereognosis (identifying objects and shapes without visual input) can provide further qualitative information.

Eye-Hand Coordination, Visual Motor Integration.

Eye-hand coordination is the ability to use the eyes and hands together to guide reaching, grasping, and release of objects. This can include larger motions such as catching and throwing a ball to more refined tasks such as putting pennies in a bank or buttoning a shirt. Coordination of the eyes and the feet (eye-foot coordination) is important for skills such as ascending and descending stairs and kicking a ball. Children with DCD often exhibit difficulties in one or more of these areas. Qualitatively, they demonstrate poor coordination in the timing and sequencing of their actions. Evaluations such as BOT-2,¹¹¹ Movement Assessment Battery for Children, second edition (Movement ABC-2),¹¹⁴ and the Motor Accuracy Test of the Sensory Integration and Praxis Tests¹¹² have subtests that assess eye-hand coordination in a standardized way. Supplemental clinical observations include the assessment of ball skills, fine motor tasks such as stringing beads and building block towers, and written accuracy tasks of drawing or coloring within a boundary.

Visual motor tasks involve the ability to reproduce shapes, figures, or other visual stimuli in written form. This skill is multidimensional, involving perceiving a visual image, remembering it, and integrating it to a written response. Visual motor integration is the foundational skill needed for handwriting. In addition, handwriting involves combination of fine motor control, motor planning, and sensory feedback to be accurate and legible. Children who have difficulties with handwriting commonly produce sloppy work with incorrect letter formations or reversals, inconsistent size and height of letters, variable slant, and irregular spacing between words and letters.

Assessment of visual motor skills can be completed through standardized measures such as the Developmental Test of Visual Motor Integration (BEERY VMI, Fifth Revision),¹¹⁵

the Test of Visual Motor Skills,¹¹⁶ and the Spatial Awareness Skills Program (SASP).¹¹⁷ The production of handwritten work can be assessed by using the Evaluation Tool of Children's Handwriting (ETCH),¹¹⁸ the Test of Handwriting Skills (THS),¹¹⁹ and Handwriting Without Tears: The Print Tool.¹²⁰ Handwriting and drawing samples provide important information regarding functional abilities in written production.

Sensory Integration and Sensory Processing

Ayres⁹⁹ originally defined sensory integration as “the ability to organize sensory information for use.” Information is received through the senses and organized throughout the nervous system to help us participate effectively in social, motor, and academic learning. Integration of sensory input underlies basic functions such as arousal state, attention, regulation, and postural and ocular control. Skills such as eye-hand coordination, bilateral coordination, projecting body movements in space (projected action sequences), motor planning, and skilled motor execution are end products of efficient sensory processing. More recently, it has been proposed that the term *sensory processing* be used for the assessment and diagnosis of sensory challenges impairing daily routines.¹²¹

The process begins with *registration* or recognition of incoming sensory input (“*What is it?*”). The incoming information is quickly scanned for relevance in a process called *sensory modulation* (“*Is it important?*”). Sensory modulation determines the appropriate action for a situation and regulates arousal. Our system needs to respond strongly and quickly if our hand moves near a hot stove, but should not respond as strongly if we are unexpectedly bumped. *Discrimination* of sensory input involves discerning subtle differences in sensation to learn about the qualities of objects and refine body movements within space. When we are receiving clear information from our sensory receptors we can understand and label what is happening (e.g., sour-sweet, hot-cold, soft-firm, heavy-light, up-down, fast-slow). Efficient sensory registration, modulation, and discrimination result in organized social and motor behavior.

Children with DCD often experience sensory processing difficulties. Diminished registration of sensation can result in poor body and environmental awareness, low arousal levels, and delayed postural reactions and motor coordination. These children may be sedentary or seek out strong sensation. *Sensory modulation* difficulties manifest primarily in emotional and behavioral responses. Behaviors often include oversensitivity, with aversive or exaggerated responses to sensation. These children struggle to remain regulated during typical daily events, and may avoid uncomfortable sensations, demonstrate behavioral disorganization, seek strong, potentially unsafe input, become aggressive, or have tantrums. They often have difficulty performing in situations involving integration of multiple inputs (e.g., cafeteria, gym class, playground, team sports). Sensitivity to movement input can also cause the child to avoid playground equipment or become nauseated during car rides. Delayed *sensory discrimination* typically results in poor body awareness that may underlie qualitative motor difficulties observed in children with DCD. They often exhibit poor motor coordination and planning, deficient safety awareness, and poor grading of force, as well as timing and sequencing difficulties. These children may avoid complex

motor challenges, team sports, and playground activities. Discrimination difficulties can also affect the acquisition of prepositional concepts (up, down, left, right, in front of, behind, next to). The child who has difficulty discriminating information from the body typically exhibits deficits in skilled actions involving balance, timing movements in space, bilateral and eye-hand coordination, fine motor control, and handwriting.

Clinical observation of a child's responses to a variety of sensory inputs and the ability to organize multiple inputs provides essential information regarding the integration of sensory input. Sensory modulation dysfunction is not easily identified with standardized, skill-based measures because of its physiological basis. Caregiver questionnaires, such as the Sensory Processing Measure^{122,123} and the Sensory Profile^{124,125} can provide valuable information on modulation and regulation.

Gross and fine motor tasks that involve postural and ocular responses, bilateral motor coordination, planning, and sequencing reflect efficient sensory processing. Soft neurological signs, coupled with observations of play (e.g., playground, gym class, recess) can provide qualitative information on sensory discrimination and planning. The Clinical Observations of Motor and Postural Skills (COMPS) assessment tool¹²⁶ is a set of six standardized clinical observations and soft signs that can be useful in identifying motor deficit with a postural component. The Sensory Integration and Praxis Tests,¹¹² the Miller Assessment for Preschoolers,¹²⁷ and the Toddler and Infant Motor Evaluation (TIME)¹²⁸ are used most commonly to assess various aspects of sensory integration function. Other tests, such as BOT-2¹¹¹ and the Movement ABC-2,¹¹⁴ can provide qualitative observations in addition to quantitative measures of motor skill.

Praxis and Motor Planning

Praxis involves the ability to plan and carry out a new or unusual action when adequate cognitive and motor skills are present. The components of praxis include *ideation* or generating an idea of how one might act in the environment, *planning* or organizing a program of action, and *execution* of the action sequence. Motor planning involves the same components relative to a novel motor task.

Children with praxis difficulties, or dyspraxia, may exhibit a paucity of ideas. The child may enter a room filled with toys or equipment and have limited capacity to experiment and play. Other children with dyspraxia may move from one activity to the next without generating effective plans for participating in or completing tasks. Lack of variation and adaptation in play can be another indication of planning problems. Observations of typically developing children show continuous modifications in play, with spontaneous adaptations to motor sequences, making explorations varied and increasingly successful. Children with dyspraxia often have difficulties in situations characterized by changing demands, such as unstructured group play. Transitions also may be difficult because they involve the creation or adaptation of a plan. Frustration and difficulties with peer interactions frequently are part of the composite.

Observations of motor planning deficits may include trouble figuring out new motor activities, disorganized approaches, resistance or inability to vary performance when a

task is not successful, and awkward motor execution. Poor planning abilities can lead to the child being adult dependent, hesitant, or resistant to trying new activities. At times, children with dyspraxia also may exhibit poor anticipation of their actions. They can quickly engage in play with the equipment but demonstrate little regard for safety (e.g., kicking a large ball across the room where other children are playing). Movements are often performed with an excessive expenditure of energy and with inaccurate judgment of the required force, tempo, and amplitude.¹²⁹ Such children typically require more practice and repetition to master more complex, sequential movements. Frequently, children with planning problems recognize the differences between their performance and that of other children the same age, which significantly affects their self-esteem.

Manifestations of poor motor planning ability are apparent in many daily tasks. Dressing is often difficult. Children are not able to plan where or how to move their limbs to put on clothes. Problems are often demonstrated in constructive manipulatory play, such as building with toys, cutting, and pasting. Similarly, learning how to use utensils, such as a knife, fork, pencil, or scissors, is difficult. The child with dyspraxia often also has problems with handwriting.

Standardized assessments of praxis include the tests of Postural Praxis, Sequencing Praxis, Praxis on Verbal Command, Oral Praxis, Constructional Praxis, and Design Copy of the Sensory Integration and Praxis Tests.¹¹² The First-STEP¹³⁰ is a preschool screening tool with a section assessing motor planning abilities. Clinical observations can add valuable information regarding the child's ability to see the potential for action, organize and sequence motor actions for success, and anticipate the outcome of an action.

Physical Fitness

Physical fitness involves a person's ability to perform physical activities that require aerobic fitness, endurance, strength, or flexibility. Factors influencing fitness include motor competency, frequency of exercise, physical health, and genetically inherited ability. Physical fitness can encompass health-related and skill-related fitness.¹³¹ Cardiorespiratory endurance, muscular strength and endurance, flexibility, and body composition are components of health-related fitness and important to monitor. Agility, speed, and power are the skill-related fitness components and are needed for the acquisition of motor skills and sports and recreational activities.¹³²

Children with DCD often have performance difficulties in games and athletic activities. They are often less active than typical peers and withdraw from physical activity. As a result, the level of physical fitness, strength, muscular endurance, flexibility, and cardiorespiratory endurance may be poorly developed. Hands and Larkin¹³¹ found that body mass index (BMI) in children with motor difficulties was higher than in a control group of typical peers.¹³¹ The percentage of overweight and obese 10- to 12-year-olds was found to be significantly higher in a DCD group than in typically developing peers.¹³³ This increased weight may further increase their movement difficulties.

In a study of 52 children aged 5 to 8 years with DCD, Hands and Larkin¹³¹ revealed significantly lower scores on tests for cardiorespiratory endurance, flexibility, abdominal strength, speed, and power than the age- and gender-matched

controls. Another study of 261 children aged 4 to 12 years found similar disparities for children with DCD, with poor performance in fitness tests, with the exception of flexibility.¹³³ These disparities in fitness were found to increase with age between the two groups.¹³³

One task of the PT is to differentiate between poor physical fitness, resulting from low motor activity as opposed to problems of low muscle tone, joint limitations, decreased strength, and reduced endurance. The low motor activity is a neurologic sign and leads to a developmental lag or deviation in motor function. Collaboration among the physical educator, the adaptive physical educator, and the PT is critical. The President's Challenge is a physical fitness test administered twice a year in schools across the country. Children complete five events that assess their level of physical fitness in strength, speed, endurance, and flexibility. The test was founded in 1956 by Dwight Eisenhower to encourage American children to be healthy and active, after a study indicating that American youths are less physically fit than European children.¹³⁴ Standardized assessments of gross motor functioning, such as BOT-2,¹¹¹ that assess strength, speed, and endurance can provide information related to a child's fitness level.

INTERVENTION FOR THE CHILD WITH LEARNING DISABILITIES AND MOTOR DEFICITS OR DEVELOPMENTAL COORDINATION DISORDER

Creating an Intervention Plan

Using the information gathered throughout the assessment process, the therapist synthesizes areas of strength and weakness to develop an intervention plan. If impairments, activity limitations, and participation restrictions exist that affect the child's successful performance, intervention may be warranted. Children with DCD, for example, might demonstrate impairments in coordination or balance that underlie activity limitations in catching or throwing a ball, which create participation restrictions in playing baseball with peers.¹³⁵ Determining the child's functional difficulties and identifying the severity of the impairment will be important to justify service and guide the service delivery model and type of intervention. For children with DCD who have greater impairment and activity limitations, individualized treatment may be more beneficial, whereas those with less involvement may thrive with group intervention.¹³⁶

Interpreting test data, integrating findings, identifying functional limitations, and creating goals is a complex process. Initial impressions of the child's areas of difficulty may result in the recommendation for further examination before outlining refined goals relevant to functional performance. Collecting additional assessment information may involve observations in other environments or during functional daily tasks, and/or formal testing. The end product is the creation of statements that delineate the type and quality of behavior desired as a result of remediation. In other words, the therapist must set treatment goals to be achieved through intervention.

Setting goals for the child with learning disabilities with motor deficits must be done by considering a variety of factors:

1. Referral information and age of the child
2. Medical, developmental, and sensory processing history
3. Parents' and teachers' perception of the child's strengths and concerns about functional impairments
4. Educational information
 - a. Major difficulties experienced in school
 - b. How motor problems are interfering with the child's daily participation
 - c. Current services being received
5. Child's peer relationships, play and leisure activities, and self-esteem
6. Therapists' observations and assessment of the child through informal and formal evaluation, both standardized and nonstandardized
7. Functional expectations and abilities at home and school

Goals for the child should be stated in terms of long-term and short-term objectives. Goal setting ideally involves establishing specific, measurable, attainable, realistic, and time-targeted objectives. Short-term objectives are generally composed of three parts: (1) the *behavioral statement* is what will be accomplished by the child; (2) the *condition statement* provides details regarding how the skill or behavior will be accomplished; and (3) the *performance statement* denotes how the skill or behavior will be measured for success. The most important consideration is ensuring that the goals and objectives chosen are relevant to the child's functional daily performance and are meaningful to the team, including the family, working with the child. **Case Study 14-3** provides an example of functional objectives.

CASE STUDY 14-3 ■ JONATHAN

Jonathan was a 6-year-old referred for an occupational therapy evaluation by his parents and teacher because of concerns regarding motor skill development. Assessment results revealed several areas of impairment, including poor discrimination of his body position and movement in space, diminished postural control and balance reactions, motor planning deficits, delayed eye-hand coordination, qualitative fine motor deficits, and delayed visual-motor integration affecting his handwriting. Jonathan's mother reported that he was clumsy and seemed to bump into things constantly. Of greater concern was that Jonathan seemed fearful of activities that his peers found pleasurable, such as

climbing the jungle gym and coming down the slide at the neighborhood playground. Jonathan tended to play on the outskirts of groups. When he did attempt to interact he became angry because the children would not play the game by his rules. At home, Jonathan often was frustrated by tasks of daily living such as putting on his coat, snapping his pants, and tying his shoes. His mother reported that Jonathan frequently called himself "stupid" when he could not independently complete self-care skills.

When determining appropriate behavioral objectives for Jonathan, looking at the areas of functional relevance such as pleasure and safety in gross motor play, peer interactions, and

CASE STUDY 14-3 ■ JONATHAN—cont'd

independence in age-appropriate activities of daily living is critical. These areas of concern for Jonathan were consistent with those of his parents. His parents wanted him to feel more competent and less frustrated in play, at home, and at school. Jonathan's goal was to "not be so stupid that kids won't play with me." The OT believed that through remediation of sensory discrimination and motor deficits Jonathan could develop improved motor competence and planning abilities. This would lead to greater success in peer interactions and improved feelings of self-confidence. Based on these common desires the following goals and objectives were made.

One of the long-term goals was *Improve Jonathan's planning and coordination abilities to increase his confidence and success in gross motor activities*. Jonathan was interested in learning to ride a bicycle without training wheels, and his parents were hopeful that he could become more confident at the neighborhood playground. These behavioral objectives would measure the development of improved proficiency in discrimination of his body in space, postural control balance reactions, and motor planning. The following objectives were written:

1. Jonathan will independently climb the ladder and come down the slide without exhibiting fear, bumping into other children, or falling.
2. Jonathan will develop the ability to ride his bicycle without training wheels in straight lines and will learn to turn corners. (*Note: Successfully riding the bicycle becomes the performance measure of behavior in this objective.*)

To address improvement in independence for self-care:

1. Jonathan will put on his coat independently in correct orientation and successfully zip it four out of five times.
2. Jonathan will successfully tie his shoes without assistance in a timely manner.

To address greater success in peer interactions:

1. Jonathan will participate in a structured game, following the rules, for 10 minutes.
2. Jonathan will play outside with the children in the neighborhood without conflict for at least 1 hour.

Although impairment level objectives could have been written to address the same areas, they would have been of limited relevance to Jonathan and the team working with him. Balance and postural control also could be addressed by an objective stating that Jonathan would stand on one foot for 10 seconds. The functional implications of this objective would not have been clear, and Jonathan and his parents would be without an outcome measure that was measurable and meaningful to them. Thus it would have negated the effects of working as a cohesive team toward a common goal.

If the OT or PT is working as a member of a team within the school, behavioral objectives will have implications for the child's performance in the school environment. Within the school system, statements of goals and specific objectives are included in the Individualized Educational Plan (IEP). In Jonathan's case, specific objectives that were meaningful to the classroom situation included the ability to sit in the chair to complete written assignments for 15 minutes and increase accuracy of letter formation, size, and spacing on written assignments. Other areas related to gross and fine motor skills and peer interactions also were influential to Jonathan's success at school. Specific objectives written pertaining to school would have functional outcome measures chosen from tasks within the school environment such as gym class, playground interactions, and classroom expectations.

Models of Intervention

Improvements in motor deficits can be achieved through a variety of models of intervention, both indirect and direct. Indirect intervention involves working with key people in the child's life to help them facilitate the child's delineated goals. An indirect model can occur through consultation, specialized instruction, and coaching. Direct intervention involves the therapist working directly with the child on specific goal areas or skills.

Mild deficits, subtly affecting participation in activities, may be addressed through a consultative (indirect) approach. This model of service provision incorporates the use of another team member's expertise to be responsible for the outcome of the child.^{76,137} The therapist may suggest environmental or task adaptations to facilitate more successful participation. Consultation with parents would be appropriate for the goal of riding a bicycle without training wheels. Parents may not understand the complexity of the task and may be focused only on the end product, which can cause frustration for all involved. To facilitate confidence and success, the therapist might recommend environmental modifications such as beginning on an open stretch of grass or dirt, with no other people around to decrease the child's anxiety. Breaking the task down into incremental steps for the parent

and child (i.e., practicing getting on and off bike, balancing on still bike, gliding, braking, steering, pedaling) can allow success at each step.

Within a school setting, environmental adaptations might include changing the height or position of the desk or decreasing extraneous visual and auditory distracters. Task accommodations could include using a special grip to facilitate more refined pencil grasp or allowing more time for written work. In these instances the teacher would be responsible for carrying out the program and determining its effectiveness. Communication between the therapist and teacher encourages problem solving and changing action plans over time. Kemmis and Dunn¹³⁸ demonstrated positive outcomes on a variety of functional classroom goals when an OT and teacher met weekly throughout the school year in what they called a "collaborative consultation approach." Using this model they achieved 63% (134 of 213) of their outlined goals. This collaborative effort supports the shared responsibility for identifying the problem or weakness of the child, creating possible solutions, implementing the intervention as the solution, and altering the plan as necessary for increased effectiveness.⁷⁶

Another model of indirect therapy involves teaching members of the team to implement treatment strategies.

Specialized instruction or coaching allows the therapist to support a child within the natural environment by working with care providers who are with the child every day. The aim is to educate key people in the child's life to coach the child within the context of teachable moments.¹³⁹ These moments, when a child is interested and working on acquiring a new skill, occur throughout the day and in many different environments.¹⁴⁰ This allows for therapeutic consistency and repeated practice, thereby increasing the chances for skill acquisition within the context of daily routines.

With this model, the therapist observes children and adults doing familiar routines and collaborates with the adults to enhance those routines in varied environments.¹⁴¹ When implementing an intervention strategy, the therapist might teach another adult to guide specific, developmentally appropriate skill sets with the child, or problem solve to create strategies for greater success. Over time parents and other caregivers are empowered to look at a toy, an activity, or an experience and find ways to adapt it to increase successful involvement and skill development. Successful coaching can enhance parent-child relationships indirectly by helping parents to feel more comfortable and competent in their abilities to meet their child's needs.¹⁴²

Direct intervention involves designing individualized treatment plans and carrying them out with the child individually or in a small group. This approach can focus on developing the foundations that underlie motor performance such as sensory processing, postural control, and motor planning. Specific skills, such as shoe tying or bike riding, can be practiced with the therapist as well, breaking these tasks down into component skills. Through combining approaches, adapting methods over the course of therapy, and responding to the changing needs of the child over time, progress is achieved more effectively.⁹⁷ Best practice dictates that direct therapy should always be provided in conjunction with one of the other service models to ensure generalization of skills to natural settings.⁷⁶ Without the use of other models, therapists cannot be confident that changes observed in the isolated setting are affecting the child's overall performance.

Intervention Approaches

According to the International Classification of Functioning, Disability and Health (ICF),¹⁴³ interventions should be directed toward several distinct goals:

- To remediate impairment
- To reduce activity limitations
- To improve participation

Interventions focused on remediating impairments generally target the improvement of processing abilities (e.g., visual, proprioceptive, and vestibular) or performance components (e.g., balance and strength). The tenet is that by strengthening these foundational skills the child will develop greater success in appropriate activities and participation. This type of intervention is referred to as a "bottom-up" approach and is based on neuromaturational or hierarchical theories. Ayres's sensory integration therapy is an example of bottom-up intervention. Missiuna, Rivard, and Bartlett⁸³ suggest that addressing secondary, preventable impairments, such as loss of strength and endurance,

may be an appropriate focus of intervention for children with DCD.

Typically, skill-based interventions are used to address activity limitations. These interventions emphasize the development of specific skills, rather than underlying components alone. This is referred to as a "top-down" approach, using cognitive strategies and problem solving. The therapist, family, and child identify specific functional activities to work on. Breaking the activity into smaller, incremental steps can facilitate the ease of learning by encouraging success. Shoe tying is a good example of a skill best taught in steps.

At times, skill-based intervention and practice occur outside the context where the child will typically perform that task. Certain skills may not be easily generalized and would be best taught in the context where the child would do the skill, such as tooth brushing. Progress is seen more rapidly when a task-related behavior that is meaningful to the child is used. Eye-hand coordination tasks, for example, become more meaningful within the context of a game of hot potato or baseball. Barnhart⁹⁵ suggests an integrated approach to facilitating development in the child with DCD, including both bottom-up, physiological interventions, and top-down, cognitive strategies.

Recently, emphasis has shifted to models of treatment that highlight participation. Intervention focuses on increasing the child's ability to take part in the typical activities of childhood.⁸³ These treatment methods assume that skill acquisition emerges from interaction among the child, the task, and the environment.⁹⁷ Intervention is contextually based, occurring in everyday situations and focusing on the activities and tasks inherent to that situation. Problem solving, preparatory activities, and skill training may be used together to increase successful participation. This type of approach may minimize the challenges of learning new skills for a child who cannot easily generalize learning to new situations.

The intervention methods presented in this chapter for remediation of motor deficits in the child with learning disabilities include Ayres sensory integration; neurodevelopmental treatment (NDT); motor learning approaches (e.g., Cognitive Orientation to Daily Occupational Performance [CO-OP])¹⁴⁴; sensorimotor treatment techniques; motor skill training approaches (e.g., Ecological Intervention¹⁴⁵); and physical fitness. None are mutually exclusive, and each requires a level of training and practice for competence as well as experience in normal development. Most therapists synthesize information from different intervention techniques and use an eclectic approach, pulling relevant pieces from a variety of intervention modalities to best meet the needs of each child.

Ayres Sensory Integration

The sensory integration theory and treatment were developed by A. Jean Ayres,^{99,112} with concepts drawn from neurophysiology, neuropsychology, and development. Her purpose in theoretical development was to explain the observed relationship between difficulties organizing sensory input and deficits in academic and neuromotor "learning" observed in some children with learning disabilities and motor deficits.¹⁴⁶ The theory proposes that "learning is dependent on the ability of normal individuals to take in

sensory information derived from the environment and from movement of their bodies, to process and integrate these sensory inputs within the central nervous system, and to use this sensory information to plan and organize behavior.”¹⁴⁶ Ayres¹¹² used “learning” in a broad sense to include the development of concepts, adaptive motor responses, and behavioral change.

The goal of sensory integration intervention is to elicit responses that result in better organization of sensory input for enhanced participation and generalization of functional skills. Sensory integration treatment is based on the belief that active involvement in individually designed, meaningful activities that are rich in sensory input will enhance the nervous system’s organization and integration of sensation.¹⁴⁷ Active exploration and variation in the context of play results in adaptive responses,¹⁴⁸ which positively affect the child’s ability to participate in daily life activities. During intervention, sensory input is provided in a planned and organized manner while eliciting progressively harder adaptive behavioral and motor responses. The therapist strives to find activities that are motivating and tap the child’s inner drive to encourage adaptation. “Evinces an adaptive behavior promotes sensory integration, and, in turn, the ability to produce an adaptive behavior reflects sensory integration.”⁹⁹ Effective intervention requires melding the science of a neurophysiological theory with the art of “playing” with the child.

A sensory integration treatment session for a child with postural difficulties might involve having the child riding a swing pretending to be a fisherman while keeping a lookout for whales that might bump his boat. This “pretend play” scenario taps the child’s motivation and inner drive to be productive (fishing), while challenging him with a potential “out of my control” situation (whales). The therapist will adapt this activity in a variety of ways to maintain an appropriate level of challenge and adaptation (adaptive response). The type and amount of sensory input, postural demands, bilateral control, timing, and planning requirements are all considered and can be adapted to an easier or harder level to maintain adaptation and learning. Sensory input can be controlled through the speed and direction the boat moves and the amount of work the child must do with his arms to propel the boat and catch fish. Additional sensory input can be provided through “rocky seas” and “whales crashing the side of the boat.” The boat can facilitate more or less postural adaptation by the amount of support it provides and the speed of its movement. The child can pull a rope to propel the swing, or the therapist can provide the movement to decrease the bilateral coordination and postural demands. A more demanding bilateral response could include pulling a rope and catching a fish simultaneously. Unexpected movements of the boat, fish, and whales will require greater timing and planning for success.

For this intervention technique to be appropriate, the motor and planning difficulties observed in a child with learning disabilities need to be a result of deficits in processing sensory information. Each child’s intervention plan should be individualized based on the results of a comprehensive evaluation and responses to sensory input within therapy. Contributions of sensory registration, modulation, and discrimination should be considered for their impact on functional

performance including social, emotional, and motor development. Children with sensory processing difficulties will exhibit problems that limit their occupational performance in a variety of environments.¹⁴⁹

Vestibular, proprioceptive, and tactile sensory inputs used in therapy are powerful and must be applied with caution. The autonomic and behavioral responses of the child must be monitored carefully. The therapist should be knowledgeable about sensory integration theory and intervention before using these procedures. Monitoring behavioral responses after the therapy session also is suggested through parent or teacher consultation. Intervention precautions are elaborated by Ayres,⁹⁹ Koomar and Bundy,¹⁵⁰ and Bundy.¹⁵¹

Research on the Effects of Sensory Integration Procedures. Sensory integration is an evolving theory, based on developments in the fields of neuroscience, research, and clinical practice.¹⁵² The current neuroscience literature supports the basic tenets of sensory integration including neuroplasticity, and positive changes in behavior and learning as a result of enriched environmental conditions, dynamic participation in meaningful activities, and developmentally appropriate sensory motor experiences.¹⁴⁷ Within the field of occupational therapy, sensory integration is the most extensively researched intervention procedure, with over 80 research studies that measure some aspect of treatment effectiveness.¹⁵³ Clinically, sensory integration principles are estimated to be used by approximately 90% of American OTs working in the school system for children with learning disabilities and motor deficits.¹⁵⁴ Despite over 35 years of theoretical development, research, and intervention practice, the value and effectiveness of this therapeutic modality continues to be questioned and critiqued.¹⁵⁵⁻¹⁵⁸ The complexity of sensory integration theory, the individualized approaches that treatment warrants, and the difficulty finding sensitive outcome measures create many challenges in designing appropriate and valid research studies.

Clinicians using sensory integration procedures attest to the effectiveness of this treatment approach in making important functional changes. Testimonials from parents of children who have received occupational therapy with sensory integration procedures are frequently heard. In Cohn’s research, parents identified two important outcome measures for intervention.¹⁵⁹ The first included change in the child, such as improved self-regulation, perceived competence, and social participation. The second was related to parents developing the ability to understand their child’s behavior in a new way and having their experiences validated to better support and advocate for the child.

Accurate analysis of the efficacy of sensory integration is complicated by a wide variety of methodological design flaws in the available research. The majority of the studies include heterogeneous samples, small sample sizes, and inconsistencies in the frequency, length, and duration of treatment. Schaaf and Miller¹⁵³ note that a major challenge in interpreting the existing research is related to the outcome measures used. Researchers have not consistently used a theoretical base to explain how treatment techniques influence the outcomes chosen.¹⁵³ In addition, the dependent variables measured were often not related to the expected outcomes of treatment, were too many in number, or were poor measures of change over time.^{153,156} Many studies

include outcome measures that are not sensitive to small increments of change or meaningful to parents as treatment priorities.¹⁵⁹

Perhaps the most challenging aspect of developing strong research studies is the variability of sensory integration intervention. Treatment is individualized and adapted frequently in response to the child's changing needs and successes.¹⁶⁰ Many of the studies that claim to be using sensory integration therapy do not adhere to the core theoretical principles, or they violate them.¹⁶¹ Developing standardized and replicable treatment is a major challenge for future research studies. Researchers and clinicians have focused extensively on improving the quality of efficacy research, resulting in the development of improved functional outcome measures (goal attainment scaling)¹⁶² and treatment fidelity (fidelity measure).¹⁶¹ Significant progress has also been made in defining homogeneous subgroups for analysis, describing replicable treatments, and choosing valid outcome measures.¹⁵³

Schaaf and Miller¹⁵³ note that diverse findings are not surprising given the current level of research. The knowledge base in sensory integration research is still in its infancy, with the need for substantial work to generate more rigorous empirical data to support the efficacy of this intervention approach.¹⁵³ Increased emphasis on high-quality, randomized controlled studies is essential.¹⁶³

Approximately half of the research studies conducted to date show some positive effects, with sensory integration treatment being more effective than or equally as effective as other approaches used.¹⁵³ In a recent systematic review of 27 research studies, May-Benson and Koomar¹⁶⁴ concluded that the synthesis of evidence indicates that sensory integration may result in a variety of positive outcomes. Specific areas identified included sensory-motor skills, motor planning, social skills, attention, behavioral regulation, and reading and reading-related activities, as well as functional outcomes as measured by individually designed goal attainment scales (e.g., improved sleep patterns, increased food repertoire, pumping a swing, and manipulating fasteners). Positive gains in motor performance were found in 10 of 14 studies reviewed, with the implication that the gains were maintained after the cessation of treatment. Arbesman and Lieberman¹⁴⁹ identified that the positive development of motor skills as a result of sensory integration intervention was most consistently noted in their review of 198 articles. Other recent, well designed studies have demonstrated positive effects on behavioral outcomes including significant gains in attention, cognitive and social skills,¹⁶³ and socialization¹⁶⁵ and increased engagement, with decreased aggression.¹⁶⁶ May-Benson and Koomar¹⁶⁴ suggest that given the current level of positive results, OTs can begin to use this information to support the use of sensory integration treatment, particularly for sensory motor outcomes and client-centered functional goals.

Neurodevelopmental Treatment

NDT is a treatment technique formulated by Karel and Berta Bobath^{167,168} to enhance the development of gross motor skills, balance, quality of movement, hand skills, and daily tasks such as mobility and self-care for individuals with movement disorders.^{169,170} These techniques were

originally designed for use with children with cerebral palsy in whom the underlying problem was a lesion in the central nervous system that produced abnormal muscle tone and deficits in coordination of posture and movement, affecting functional performance.¹⁶⁸ The original framework was based on hierarchical levels of reflex integration in the nervous system and the normal developmental sequence. Abnormal postural responses were lower-level hierarchical reactions that did not integrate in a typical time frame (e.g., ATNR, STNR), thereby inhibiting the development of mature postural mechanisms and voluntary movements. The NDT approach emphasized specific ways to inhibit abnormal reactions and facilitate more normal muscle tone and movement.^{171,172} The assumption was that encouraging more normalized automatic movement patterns would lead to functional carryover.¹⁷²

The original hierarchical "impairment-based" model of reflex integration has been replaced with a more dynamic "interactive systems" model that emphasizes both internal and external factors of motor control. Currently, NDT therapists view the execution of movement as a complex interaction of the neural and body systems, organized by the specific task requirements and constrained by physical laws of the environment.¹⁷⁰ The nervous system is viewed as dynamic and adaptable, capable of initiating, anticipating, and controlling movements with ongoing sensory feed-forward information and feedback.^{170,173} Many body factors are recognized as contributing to dysfunctional movement patterns, including abnormal muscle tone, primitive reflex patterns, delayed development of righting and equilibrium reactions, specific muscle weakness, body biomechanics, cardiovascular or respiratory weakness, lack of fitness, and sensory, cognitive, or perceptual impairments.^{170,173,174} As NDT's theoretical and clinical development progressed, there was acknowledgement that intervention had not automatically carried over into functional performance as had been anticipated. As a result, treatment strategies began to shift, with preparation for specific functional tasks done in settings where children typically participate.¹⁷⁵ The focus on normalizing muscle tone and altering movement patterns as a foundation for performance was replaced with emphasis on activity-related impairments and client-directed functional outcomes.^{170,172,173} Ecological, family-centered intervention was identified as essential to target key environments, activities, and functional outcomes.¹⁷⁰ This dynamic treatment approach now emphasizes active involvement in meaningful tasks to enhance independent participation in various environments. The goal of NDT intervention is for the child to use more efficient movement strategies to complete life skills with greater success. Over the life span these strategies will minimize secondary impairments that can create additional functional limitations or disability.^{170,174}

NDT uses physical handling techniques directed toward developing the components of movement necessary for functional motor performance. Movement components of postural alignment and stability, mobility skills, weight bearing, weight shifting, and balance are all foundations for smoothly executed movements in space.¹⁶⁹ Assessment and analysis of posture and movement components are ongoing, using a problem-solving approach that identifies and builds on the child's strengths and limitations.¹⁷⁰

Therapists employ a combination of handling techniques and encouragement of active movements targeted toward the specific functional skills on which the child is working.⁹⁸ Feedback involves both tactile-proprioceptive (“hands-on”) and verbal cues, which are graded back or changed according to the needs and emerging skills of the individual child.¹⁷² The therapist’s hands guide the reactions, with the child actively participating in problem solving and adapting performance. Practice of more effective postural reactions and reduction of abnormal movement patterns are embedded into meaningful activities. A skilled therapist balances the quality of movement patterns with the importance of active involvement in learning new motor tasks.¹⁷³ At times, participation and independent task completion are more important than qualitatively normal movement patterns.

Although NDT was developed for children with central nervous system insults resulting in deficient postural and movement control for daily skills, it lends its use to children with more minimal motor involvement. Of particular relevance to the child with learning disabilities and DCD is facilitation of improved righting and equilibrium responses, automatic postural adjustments, and balance reactions. Handling techniques can help develop improved qualitative control, as well as encouraging active problem solving and task adaptation by the child.

Research on the Effects of Neurodevelopmental Treatment. NDT is an evolving theoretical and treatment approach, based on principles derived from research in neural plasticity, motor development, motor control, and motor learning.¹⁷⁰ It is the most commonly used treatment framework for children with cerebral palsy.¹⁷⁶ Despite this, relatively few studies are available on the efficacy of NDT to date.¹⁷² Those that are available have not definitively shown NDT to be effective as a treatment modality or more valuable than other therapies.^{175,177} One of the major problems confounding interpretation of the current state of research has been the significant change in theoretical development and clinical application over time. The revised practice model of NDT is better reflected in the current research, which shows more promise.^{170,178} It has been suggested by Bain¹⁷² that studies conducted before 2000, when NDT was defined with outdated operational definitions, should not be considered as evidence that current practice is ineffective.

Methodological concerns in many of the available studies make interpretation of efficacy more challenging. In a review of older treatment studies, Royeen and DeGangi¹⁶⁹ noted significant methodological problems that were attributable to the lack of conclusive evidence regarding NDT. These included poorly defined objective outcome measures, overreliance on subjective clinical observations, and small sample sizes. In addition, sample populations varied greatly, including adults and children with cerebral palsy and Down syndrome as well as high-risk infants. More recently Sharkey and colleagues¹⁷⁸ highlighted difficulties in developing well designed treatment studies, including the heterogeneity of children with cerebral palsy, both in functional limitations and goals, small sample sizes, and ineffectiveness of standardized outcome measures to assess qualitative and functional changes. Butler and Darrah¹⁷⁵ cautioned interpretation of efficacy from

the 21 studies they reviewed owing to unclear population definitions, unclear treatment protocols and goals, and lack of clarity regarding therapist skill levels.

Several current research studies have demonstrated positive changes in gross motor performance as a result of intensive NDT intervention.^{176,179,180} Arndt and colleagues¹⁷⁹ used an operational definition of NDT based on trunk coactivation for treating infants with posture and movement difficulties. After 10 hours of treatment over 15 days, the infants who received the NDT protocol significantly improved in gross motor function compared with infants in the control play group. These skills were maintained at a 3-week follow-up evaluation. Bar-Haim and colleagues¹⁷⁶ used a randomized controlled trial for 24 children with cerebral palsy, with 40 hours of treatment over a period of 4 weeks. They compared intensive NDT treatment with the use of the Adeli suit (AST), which stabilizes the trunk and extremities of the wearer to help normalize motor actions. Although there was no superiority noted between these two intensive treatment modalities, both groups made significant gains in gross motor function that were sustained after nine months. Tsorlakis and colleagues¹⁸⁰ further assessed the variable of intensity of services in their 16-week treatment study. The efficacy of NDT for children with spastic cerebral palsy was supported by this study, as both groups of children who received NDT intervention demonstrated statistically significant gains in gross motor function. Increased intensity of services was also supported, as motor gains were statistically greater for the group that received intervention five times a week compared with two times a week.

Brown and Burns¹⁷⁷ completed the only systematic review that was identified as high quality by colleagues.¹⁸¹ They selected 17 studies to include on the basis of use of NDT as the treatment modality, reported clinical outcomes, and random group assignment. Their analysis did not provide definitive evidence that NDT is beneficial for children with neurological dysfunction. The authors suggest that available research did not reveal either efficacy or inefficacy of NDT as a treatment approach. Butler and Darrah¹⁷⁵ suggest that absence of evidence on the effectiveness of NDT should not be construed as proof that the treatment is not effective, but certainly reflects areas in which more meaningful research is needed. Sharkey and colleagues¹⁷⁸ suggest that recognition of these limitations will encourage practitioners to implement “second-generation” research that is characterized by well designed studies that systematically evaluate operationally defined intervention techniques and determine what works for specific ages and diagnoses of children.

Motor Learning Theories

Motor learning refers to the process of acquiring, expanding, and improving skilled motor actions. The basic treatment premise of motor learning theories is that improvement in movement skills is elicited through appropriate practice and timely feedback. Motor learning has taken place when a permanent change in the child’s ability to respond to a movement problem or achieve a movement goal has occurred, regardless of the environment.¹⁸² Therefore therapists measure learning through tests that measure retention and transfer of skills.¹⁸³

The closed-loop theory of Adams¹⁸⁴ is recognized as the first comprehensive explanation for motor learning. Adams believed that the central nervous system, based on sensory feedback, controls the execution of movement. He proposed that once a movement has occurred, errors are detected and compared with existing “memory traces.” With practice, these memory traces become stronger and the accuracy of the movement increases, thus emphasizing learning through feedback.

In 1975 Schmidt contributed the idea of “open loop” motor learning, which emphasized the ability to produce rapid action sequences in the absence of sensory feedback (e.g., hitting a baseball). He proposed that new movements were created from previously stored motor programs (schemas) of similar movements, as opposed to feedback from individual motor actions.¹⁸⁵ Schemas comprise general rules for a specific group of actions that can be applied to a variety of situations.¹⁸⁶ When a motor action occurs, the initial movement conditions, parameters used, outcomes, and sensory consequences of the action are stored in memory. With each goal-directed movement, specific parameters are used (e.g., force needed to pour juice into a glass), and consequences occur (e.g., spillage or not). Repeated actions using different parameters and creating different outcomes create data sets that help refine the motor program, reducing errors and improving anticipation or feed-forward information.¹⁸⁶ Schmidt’s¹⁸⁵ schema theory contributed to current theories of motor learning principles regarding practice schedules and feedback about outcome of movements, known as *knowledge of results*.

Based on the knowledge of motor skill development in children with DCD, four key variables are important to consider in targeted intervention. They include stage of the learner, type of task, scheduling of practice, and type of feedback.

Three stages of the learner have been proposed^{187,188}: the *cognitive stage*, the *associative stage*, and the *autonomous stage*. As a child learns and develops new motor actions, he or she progresses through the various stages at different rates, depending on the complexity of the skill. The *cognitive stage* is the initial phase of learning in which there is large variability as the child gets the general idea of the movement.¹³⁵ Awkward body postures are observed, errors are often made, and awareness of what needs to be improved or changed does not exist. (Consider when a young child attempts to throw a ball; the throw is a gross movement, the projection of the ball varies, and the movement appears uncoordinated.) As practice continues, the degree of accuracy increases, which is characteristic of the *associative stage*. Fewer errors are made and error information is used to correct the movement patterns. (As the child continues to throw the ball, the ball may get closer to the target with improved coordination observed.) During the *autonomous stage*, the skill is performed fluently and automatically, without as much effort or thought. Improvements in accuracy continue and errors are detected, with corrections made automatically. (The child can now throw a ball at a target and hit the target with coordinated, accurate movements, such as pitching; however, if a child were introduced to throwing a curve ball, the stages would start over.)

The type of task is a mechanism to classify motor skills in a dimensional fashion. Task components contribute

to intervention decisions. The types of tasks are *gross motor* or *fine motor*; *simple* or *complex*; *discrete*, *serial*, or *continuous*; and *environment changing* or *stationary*. Gross and fine motor tasks are classified according to the type of muscle groups required.¹⁸⁹ *Gross motor skills* use large muscles and tend to be fundamental skills (e.g., walking and running). *Fine motor skills* tend to require greater control of small muscles and usually have to be taught (e.g., handwriting, cutting). Task complexity refers to the level of difficulty and amount of feedback required. *Simple* tasks, such as reaching, require a decision followed by a response. A *complex* task, such as cutting out a picture, requires continual monitoring and feedback until completion. Tasks can require simple single actions or the coordination of sequential motions for completion. A single *discrete* movement has a clear beginning and ending, such as activating a button. *Serial* movements require a series of distinct movements combined to achieve the outcome, such as writing a sentence. *Continuous* movements, such as running, contain movements that are repetitive. Tasks that are discrete or serial can be practiced in parts, but continuous tasks usually need to be practiced as a continuous segment.

Environmental variations can greatly increase the complexity of the task, requiring higher levels of feed-forward information and feedback. In an unstable or *changing* environment, the child has to learn the movement and monitor the environment to adapt to changes—for example, running on an uneven surface. The more predictable and stable the task and environments are, the easier it is to learn and replicate motor skills. Tooth brushing is an example of a task that generally occurs in a *stationary* environment. Home and classrooms can be stable, in that many elements within these settings are fixed and do not change. The size and shape of chairs, location of toys on the floor, and movements of other children are considered “variable features” within these stable environments. These variable features require a greater amount of motor control because the child must adjust movements and actions to the changing demands. Therapists generally practice in stable environments and therefore must ensure that the children are able to function under varied circumstances encountered in daily life situations.

Practice is believed to increase learning of a skill or movement. Variations in practice can occur in the order tasks are performed, in the environment where the tasks are practiced, and by changing aspects of the task. Practice schedules can be developed based on the practice techniques (*blocked* or *random*), or how task learning is approached (*component* or *whole task*). *Blocked* practice means the task is repeatedly rehearsed, sometimes focusing on one aspect of a technique or a specific motor sequence (e.g., hitting a golf ball off a tee with the same club). Repetitive, blocked practice often leads to improved immediate performance, particularly in situations that are stable. *Random* practice involves performing a number of different tasks in varied order or employing several different aspects of technique (e.g., hitting golf balls from a tee, sand trap, and rough with the appropriate club). Random practice encourages learners to compare and contrast strategies used in performing the task, which positively influences performance in changeable environments.

If a task is discrete or contains multiple parts, breaking it down into *components* for blocked practice may be beneficial. For success in changeable situations in which the task component is integrated into skilled action, *whole-task* practice is essential—for example, practicing shooting basketballs, then practicing while moving or running toward the basket. When generalization is the goal, practice sessions can progress from stable (shooting from specific positions on the court) to a changeable environment (such as shooting basketballs with a person trying to block the shot). Opportunity and variety in practice appear to improve motor learning, particularly when skills are practiced in a random manner. Practice should therefore be varied and occur in multiple environments (e.g., home and school) to maximize motor learning.

Different types of feedback also affect the process of learning. *Intrinsic* feedback is received from any of the child's internal sensory systems and is usually not perceived consciously unless external direction draws attention to it (e.g., when a child performs a task with his or her tongue sticking out). *Extrinsic* feedback is received from an outside source observing the results of an action and can be provided in the form of knowledge of performance (KP) or knowledge of results (KR). KP focuses on movements used to achieve the goal, whereas KR focuses on the outcome.

Therapists tend to provide excessive feedback, especially when task performance is below what is expected. Low frequency and fading feedback, progressively decreasing the rate at which feedback is provided, appear to be most effective in facilitating learning.¹²⁹ One proposed reason is that with less feedback the individual can more readily engage in the processes that enable learning versus focusing on external cues. During intervention, feedback should not be provided for every movement or task execution. It is more beneficial to offer children the opportunity to self-evaluate and correct their own performance. The therapist can provide feedback as necessary to encourage successful task completion and reduce frustration. Verbal feedback can be general—"Did that work?"—or specific—"Do you need to throw it harder or softer to reach the target?"

Children with DCD often lack the skills required to analyze task demands, interpret environmental cues, use knowledge of performance to alter movements, or adapt to situational demands.¹⁹⁰ They therefore do not interpret and use sensory or performance feedback as well as children who are developing typically.¹⁸³ Motor observations of the child with DCD often reveal clumsiness, difficulty judging force, timing, and amplitude of motions, and deficits in anticipating the results of a motor action. Reactions, movements, and response times are typically slower.¹⁹¹ With this in mind, the type of task and the method of teaching should be considered when recommending participation in sports and leisure activities.¹³⁵ Children with DCD can become successful in repetitive sports, such as swimming, skating, skiing, and bicycling. Ball-related sports, however, such as hockey, baseball, tennis, football, and basketball, tend to be more difficult and frustrating owing to the high level of unpredictability and frequent changes in the direction, force, speed, and distance of the movement.¹³⁵

When using the motor learning model of practice, the therapist should incorporate a variety of teaching techniques including verbal instructions, positioning, and handling, as well as observational learning (demonstrations).¹⁸³ The task and environment should be structured with extrinsic and intrinsic feedback provided, using a practice schedule that is optimal for the type of task.¹⁹² Children with DCD benefit from experiential and guided learning when practice is performed so that each repetition of the action becomes a new problem-solving experience. To test whether motor learning has occurred, the therapist must create opportunities for demonstration of retention (repeating what was learned in a previous session), transfer (perform a different but closely related task), and generalization (perform a learned task in a new environment).

One method of intervention based on the principles of motor learning is the CO-OP, a frame of reference developed as a treatment approach specifically for children with DCD.¹⁴⁴ In this cognitive-based approach, the therapist focuses on the movement goal and facilitates the child's identification of the important aspects of the task, examines the child's performance during the task, identifies where the child is having the most difficulty, and problem solves alternative solutions.¹⁹² Rather than using verbal instructions, this approach uses guided questions to help the child discover the problems, generate solutions, and evaluate his or her attempts in a supportive environment. Furthermore, the therapist solicits verbal strategies from the child that can help guide the motor behavior, such as typical verbal cues that the therapist tends to provide during intervention.

To benefit from the CO-OP approach, the child must have sufficient cognitive and language ability to rate the level of his or her performance and satisfaction of self-identified goals using the Canadian Occupational Performance Measure (COPM).¹⁹³ The basic objectives of this approach include skill acquisition, cognitive strategy development, and generalization or transfer of skills into daily performance. CO-OP is delivered over 12 one-on-one sessions, each lasting approximately 1 hour. The therapy process is divided into five phases: preparation, assessment, introduction, acquisition, and consolidation. Children are taught to talk themselves through performance issues using an approach of Goal-Plan-Do-Check. Domain-specific strategies are used to enhance performance, with the purpose of helping the child to see how he or she can set goals, plan actions, talk through doing, and check outcomes. Using this frame of reference, therapists help the child acquire occupational performance skills using a metacognitive problem-solving process.¹⁴⁴

Research on the CO-OP Model of Motor Learning.

Current beliefs regarding the nature of motor learning for children with DCD suggest that assessment of participation, versus impairments, should be used to determine change over time.¹⁸³ By increasing the child's ability to participate in childhood activities, secondary deficits such as loss of strength and endurance might be prevented. Relatively new intervention strategies that employ contemporary motor learning principles emphasize the role of cognitive processes (top down) in development of specific skills. The CO-OP model uses this approach to help children achieve their functional goals.¹⁴⁴

Research on the effectiveness of this approach to improve motor skills and functional performance is limited but shows promise. Polatajko and Cantin¹⁹⁴ reviewed three articles describing four studies and concluded that there was convergent evidence for the effectiveness of the CO-OP approach for children with DCD.

An exploratory study completed in 1994 by Wilcox as part of his graduate work was discussed by Polatajko and colleagues.¹⁹⁵ This initial single case study included 10 children aged 7 to 12 years who were referred to occupational therapy for motor problems. Using a global problem-solving approach to intervention, this study sought to identify whether children with DCD could use these strategies to acquire skills of their choice, and, once learned, whether the skills were maintained and performance in other areas enhanced. Children selected skills that were challenging and meaningful for them, such as shuffling playing cards, applying nail polish, making a bed, and writing legibly. Each of the 10 children made gains in the chosen activity, with 29 of the 30 targeted skills showing improvement.

A pilot study compared the CO-OP model to a traditional treatment approach with a group of 20 children aged 7 to 12 years. Findings indicated that the CO-OP model of intervention produced larger gains on client-selected goals. Improvements in self-ratings of performance and satisfaction were greater than in the comparative group. Although informal, the follow-up data suggested that children maintained their acquired skills and applied strategies to other motor goals.

Limitations in making conclusions regarding the effectiveness of this treatment are mandated by the small number of research studies, primarily carried out by the same research group. Mandich and colleagues⁹⁷ suggest that larger studies with control groups are needed. Suggestions for future research include identification of the salient features of this treatment approach, as well as determining the generalization and skill transfer to other settings.

Sensorimotor Intervention

Sensorimotor activities provide the foundation for the development of play in children.¹⁹⁶ The first level of play (i.e., sensorimotor) is pleasurable, intrinsically motivated activity that involves the exploration of sensation and movement.¹⁹⁶ As children react with adaptive motor responses to the array of sensations from their bodies and the environment, central nervous system organization occurs. The assumption that the organization of sensory and motor experiences is essential to effective motor performance is the premise of sensorimotor intervention.¹⁹⁷ Treatment encourages the child to actively engage in a variety of sensory-rich, motor-based activities, to enhance functional motor performance.¹⁹⁵ Evolution of sensorimotor intervention has not revolved around a single, unified theory but has incorporated a variety of theoretical foundations.¹⁹⁸

The goals of sensorimotor intervention are outcome based, with emphasis on the development of age-appropriate perceptual-motor and gross motor skills. The therapist chooses activities that meet the child's developmental levels, promote sensory and motor foundations, and encourage practice of appropriate motor skills. For the child having

difficulty keeping up with the skilled activities in gym class such as rope jumping, components of these activities will be encouraged, with emphasis on sequencing and timing. The therapist may use a heavier jump rope or wrist and ankle weights to provide more sensory information for improved task performance.

In sensorimotor intervention, tasks are chosen for their innate sensory and motor components. The child is directed to activities that encourage the use of the body in space to complete a structured motor sequence. Activities incorporate sensory components such as movement (vestibular), touch (tactile), and heavy work for the muscles and joints (proprioception). Play interactions are considered important to encourage sensorimotor integration within the context of meaningful interactions with persons and objects.¹⁹⁶ Children may propel themselves prone on a scooter board through an "obstacle maze" while looking for matching shapes, for example. This activity provides tactile, proprioceptive, and vestibular sensory input and encourages the development of postural strength and endurance while addressing perceptual skill development.

Research on Sensorimotor Intervention. Sensorimotor intervention is a widely accepted modality, used by 92% of school-based therapists as a foundation for improving handwriting.¹⁹⁹ The activities used and goals addressed in treatment are extremely varied, as all functional motor skills involve some level of sensory and motor organization. Activities can range from horseback riding to using a vibrating pen when learning how to write letters. Owing to the enormous variation in intervention strategies and outcome measures, operationalizing treatment to make comparisons between research studies can be difficult. In a recent systematic review Polatajko and Cantin¹⁹⁴ found five studies that met their criteria for using sensorimotor intervention. In those five studies both the techniques used (e.g., therapeutic riding, movement therapy, educational kinesiology) and the populations addressed (autism, sensory modulation disorder, DCD) varied greatly. This review suggested that evidence for the effectiveness of sensorimotor intervention was "inconclusive," with the heterogeneity of diagnoses and functional problems limiting the ability to interpret efficacy.¹⁹⁴

Overall, relatively few studies have investigated the efficacy of sensorimotor integration. In an early comparison study, DeGangi and colleagues²⁰⁰ found that children provided with structured sensorimotor therapy made greater gains in sensory integrative foundations, gross motor skills, and performance areas such as self-care than children who engaged in child-centered activity. More recently, Chia and Chua²⁰¹ used sensorimotor intervention in a random controlled study of 14 children with learning disabilities and DCD. Intervention consisted of providing sensory stimuli and facilitating a normal motor response while remediating impairments in posture and muscle weakness. Positive results in neuromotor functioning were noted. In a second study, Inder and Sullivan²⁰² used educational kinesiology techniques in four single-subject design experiments. Positive gains were documented in some aspects of sensory organization and in an overall decrease in the number of falls children had.

Four studies have explored the effects of sensorimotor remediation on handwriting. Those programs that used sensorimotor interventions over only a short period of time did not yield positive results. Sudsawad and colleagues²⁰³ compared the effects of kinesthetic-based intervention with handwriting practice with 45 first graders over a 4-week period. They found neither group to make significant improvements in handwriting, and suggest that there is no support that kinesthetic training improves handwriting legibility for this age. In 2006, Denton and colleagues²⁰⁴ compared sensorimotor intervention with therapeutic practice in 38 school-age children with handwriting difficulties over 5 weeks. These authors noted moderate improvements in handwriting with therapeutic practice and a decline in ability in the sensorimotor group. They suggest that although sensorimotor foundations did improve with sensorimotor intervention, there is no indication that these foundations affect the development of handwriting. Their findings suggest that structured therapeutic practice using motor learning principles has a much stronger impact on the development of handwriting.

Two studies that investigated the combined effects of sensorimotor intervention and higher-level teaching strategies did demonstrate a positive impact on handwriting.^{205,206} Peterson and Nelson²⁰⁵ found that low socioeconomic first graders who received 20 sessions of occupational therapy combining sensorimotor, biomechanical, and teaching-learning strategies made significant gains over those receiving academic instruction alone. Weintraub and colleagues²⁰⁶ compared a control group with two treatment conditions (task-oriented approach versus combination of sensorimotor and task orientation). Immediately after treatment, and at a 4-month follow-up, significant gains in handwriting were observed in both treatment groups compared with the control group. The authors support the use of “higher-level” teaching strategies to improve the skill of handwriting.

Motor Skill Training

Motor skill training involves learning skills and subskills functionally relevant to the child’s daily performance. Tasks are taught in a sequential manner by developmental ages or by steps from simple to complex. Skill training can occur for a wide variety of gross, fine, and visual motor tasks, as well as activities of daily living. An assortment of theoretical models and techniques may be used based on the child’s impairment and activity and participation deficits.

Motor skill training can involve both indirect and direct facilitation of specific motor tasks. Activities that include balance, locomotion, body awareness, and hand-eye coordination can improve functional skills such as being able to sit at a desk within the classroom and complete written work, as well as success in recess games such as basketball. Specific skills such as dribbling and foul shooting can also be specifically taught and practiced. The goal is to provide a great variety of motor activities at the child’s developmental motor level to promote motor generalizations for more successful participation.

An example of this approach is Sugden and Henderson’s¹⁴⁵ “ecological intervention,” which is a method of skill training for children with DCD. In this model the therapist, called a *movement coach*, provides instruction to many individuals

who interact with the child on how to develop specific targeted skills. All caregivers are actively involved in goal development and achievement. By having a variety of individuals work together across daily life environments, children more quickly become skilled.¹⁴⁵ This approach also develops the caregivers’ ability to understand the demands of specific tasks and to help facilitate the child’s performance in all settings.

Physical Fitness Training

As previously reviewed, children with DCD are at great risk of low levels of physical fitness. The benefits of fitness and physical activity in minimizing disease and maximizing overall wellness are well documented. Deleterious effects resulting from DCD or factors associated with it include but are not limited to fatigue, hypoactivity, poor muscle strength and endurance, decreased flexibility, poor speed and agility, and diminished power.

Specific muscular training may be needed to undo the effects of reduced activity.²⁰⁷ Poor muscle strength, especially in the abdominal area, can lead to musculoskeletal issues such as back pain because posture and pelvic alignment require adequate muscle strength. Children with DCD often require specific instruction to perform muscle strengthening activities (e.g., sit-ups, push-ups) with appropriate form. Decreased flexibility and muscle tightness in the lower extremities can contribute to difficulties in running, jumping, and hopping. Flexibility can be encouraged with a regimen of stretches specific to the areas of tightness. Gentle and regular stretching can be incorporated into warmups during sessions or physical activities.

Fitness can improve and be maintained when children participate in regular, preferably daily, physical activity. These activities often require more structure and direction for children with movement difficulties. As therapists, our overall goal should be to educate children about the value and enjoyment of regular activity.²⁰⁷ Hands and Larkin²⁰⁷ suggest the following plan to ensure children with DCD learn or rediscover the joy of movement:

- Educate children to understand and monitor their bodies’ responses to exercising (e.g., heart rate increases when they run).
- Assist them in finding developmentally appropriate activities they will enjoy with some success.
- Encourage them to maintain a healthy, active lifestyle by encouraging participation in lifelong activities such as swimming, cycling, golf, sailing, yoga, or weight training.

In sports and leisure activities, the emphasis should be on participation and fitness rather than competition. Encourage activities that do not require constant adaptation, as children with DCD tend to be more successful in sports that have a repetitive nature to the movements (e.g., swimming, running, skating, skiing).^{135,207} Sports that have a high degree of spatial challenge or unpredictability, such as baseball, hockey, football, and basketball, are less likely to be successful for children with DCD.²⁰⁸ Activities that are taught through sequential verbal guidance, such as karate, may be easier to learn.¹³⁵

PTs and OTs can have a positive impact on participation in fitness activities for children with DCD. A summary of key suggestions,⁸³ including the following, can assist with

encouraging involvement in community sports and leisure activities:

- Provide frequent encouragement and reward effort.
- Encourage participation, rather than competition; emphasize fun, fitness, and skill building.
- Use a variety of teaching methods to demonstrate new skills (one-on-one instruction, verbal cues, demonstration).
- Provide hand-over-hand instruction during the early acquisition phase.
- Break down skills into smaller, meaningful parts.
- Keep the environment as predictable as possible.
- Modify or adapt equipment for safety (e.g., use foam balls instead of hard balls).
- Focus on the enjoyment, not the product.
- Encourage multiple roles in some activities (e.g., referee, scorekeeper, time keeper).
- Recognize the child's strengths, and reinforce social interaction.

Encouraging and facilitating participation in a healthy lifestyle can aid in ending the vicious cycle of withdrawal, diminished opportunities for physical development, and decreased fitness and strength over time, a pattern very commonly seen in children with DCD.⁸³

LEARNING DISABILITIES AND DEVELOPMENTAL COORDINATION DISORDER ACROSS THE LIFE SPAN

Learning disabilities persist into adulthood and present lifelong challenges. Continuing issues with attention, cognition, emotional adjustment, and interpersonal skills can affect education, employment, family life, and daily routines. Adolescents and adults with learning disabilities frequently struggle with the concentration and organization needed to effectively manage daily routines and finances, vocational education or training, job procurement and retention, and finances.^{209,210}

A recent longitudinal study²¹¹ demonstrated that IQ scores remain stable from childhood to adulthood, as do deficit areas. Therefore, poor readers remain poor readers, poor spellers remain poor spellers, and delayed math skills persist. In addition, adults who had affective illness or mood disorders as children have a significant risk of recurrent episodes (e.g., depression, bipolar disorder). An early 20-year longitudinal study of individuals with learning disabilities cited a rate of 42% for adult psychological disturbance (e.g., depression, alcohol abuse, anxiety disorders), compared with 10% in the general population.²¹²

More recently, Seo and colleagues²¹³ found more optimistic results in their comparison of outcomes for individuals age 21 and 24, with and without documented learning disabilities. No significant differences were found in post-secondary school achievement or employment rates and earned income, although the 21-year-olds with learning disabilities did receive significantly more public aid, such as food stamps, social security, and unemployment. The learning-disabled group did not have increased incidence of committing crimes or feeling victimized as young adults. Emotional health²¹¹ and strong social relationships²¹⁴ are crucial for success; therefore children should be supported to develop healthy social connections and personal talents.

Several attributes have been identified as predictors of success for adults with learning disabilities.^{212,215} A combination of internal and external factors supports the individual in the belief that he or she can take control, evaluate needs, and develop appropriate coping strategies, while knowing when to seek additional help.²¹⁵ The ability to be proactive, set goals, and persevere is a key internal element to attaining success. Having an understanding of one's learning disability, with recognition of strengths and limitations, affords more thoughtful choices in life roles. Self-esteem and confidence are promoted with external emotional support and positive feedback from family, friends, teachers, work colleagues, and employers.

The persistent motor coordination difficulties attributed to DCD further affect perceptions of competence^{89,216} and successful accomplishment of daily life skills.²¹⁷ Raskind and colleagues²¹² found that physical status, including motor impairment, was an important variable in determining success in adulthood. Slowness and variability in movement continue to be a pervasive feature, causing difficulties in tasks that require sequencing and dual-task performance, such as driving a car.²¹⁷ Adults with DCD report higher levels of difficulty with motor-related tasks such as self-care and handwriting.²¹⁸ Compared with adults with dyslexia, a greater number of adults with DCD continue to live at home with their parents, have fewer spare-time activities, and are more socially isolated.^{218,219}

Learning disabilities with motor impairments appear to have a persistent effect on a sense of competence and self-concept.^{8,219} Many individuals develop negative perceptions of themselves as they experience frustration and ineffectiveness. They set lower aspirations, further reinforcing the cycle of failure. A combination of ADHD and DCD was found to be the most important predictor of poor psychosocial functioning in early adulthood.²²⁰ Higher incidence of drug and alcohol abuse, affective disorders, crime conviction, and unemployment have been documented. Without adequate support, adults with DCD have difficulties reaching their potential. They may benefit from counseling about their condition, vocational assessment and guidance to assist with finding a suitable work environment, time management and organizational strategies, workplace and academic accommodations, and behavioral management.

These cycles of ineptitude, frustration, and poor self-concept are highlighted in **Case Study 14-2**. Paul's mother, Mrs. B., was not diagnosed with learning disabilities until age 20 years. Nevertheless, she completed both bachelor's and master's degrees in counseling. Although the academic frustrations are no longer an issue, the learning disability continues to interfere with her work and home performance. Mrs. B. describes her organizational difficulties and identifies a continuous need to make lists to function in her job. She concentrates on not looking "clumsy" and is fearful she will trip over things and look foolish. Learning and accomplishing tasks continue to require increased effort compared with her peers. Thus even in adulthood the learning disability continues to present difficulty in functional performance.

A letter from a woman with learning disabilities, motor coordination impairments, and sensory integration problems is included in **Box 14-3**. She describes how her learning disability affects her current functioning and how it affected her when she was a child.

BOX 14-3 ■ A LETTER FROM AN ADULT WITH A LEARNING DISABILITY

I am 26 years old, a professional bassoonist with a master's degree in music performance. My name is Wendy. Through Jane, an occupational therapist, I discovered when I was 24 years old that I had learning problems and sensory integration problems.

I invert letters and especially numbers. When people speak English to me, I feel it's a foreign language. There's translation lag time. When learning new things, I either understand intuitively or never. I can't seem to go through step-by-step learning processes.

Physically, I'm extremely sensitive to motion. When I was little, we moved every year. I spent the first 5 years of my life feeling sick. It seems that I feel everything more strongly than most people. I have an extremely low threshold of pain, and even pleasure tends to overload me. If I am touched unexpectedly it hurts, it's so jarring. This causes a lot of problems with interpersonal relationships. I can't stand to have people close to me; it produces an adrenalin reaction.

Motor activities are also a problem; my muscles don't seem to remember past motions. Despite the many times I've walked down steps and through doors, I still have to think about how high to lift my foot and about planning my movements. When eating, I have to think about chewing or I bite my tongue or mouth. I don't think other people think about these things. I'm physically inept; I can bump into the same table 10 times running. I'm always bruised, and as a child people constantly labeled me as clumsy. Physical education courses were hell as a child, especially gymnastics, where you are forced to leave the ground and swing or walk on balance beams or uneven bars. I cannot begin to explain the terror or disorientation.

Academically, I was labeled stupid or, more frequently, lazy. I was told that I was not trying. Actually, my IQ is high and my coping mechanisms are complex. If they only knew how hard I was trying. I was lucky because I taught myself to read at an early age. I would never have learned to read otherwise. Even so, my first grade teacher wouldn't believe that I could read so far past my age. She called me a liar when I said that I had finished each "Dick and Jane" book. I was forced to read each one 50 times before she would give me a new one.

Not all teachers were so insensitive. My fourth grade teacher made every effort to let me go at my own pace, letting me read on a college level and do 2 years of math on my own. Left to my own devices, I can learn and love to do so. My fifth grade teacher forced me to do math the long way with steps. I just know the answer by looking at multiplication or division problems, even algebra problems, but to this day I cannot understand how one does it in steps. If a teacher didn't accept this, I was in for a year of hell. I cried a lot in school, from frustration mostly, and I pretended to be sick a lot.

I never had friends until college. I guess I was too different to be acceptable. I grew up in a rigid, repressive, religious community, which made it especially difficult to be accepted. My differences were labeled evil, or, at best, I was ignored. I left high school at age 16 for college, where at least I could structure what I wanted to learn. It's never been easy for me to make friends, although it's better now. Music circles tend to be a bit crazy so I fit in more easily.

My learning disabilities still are problems. My motor and learning problems get in the way of my music, but my coping mechanisms are strong. I deal better with my clumsiness now. Just being diagnosed by Jane has made a big difference. To have things labeled, to be told and realize that it's not my fault, has given me a sense of peace. It's also allowed me to turn from inward depression to outward anger at those who labeled me stupid and clumsy. Just being able to admit anger allows one to let it go.

Other than my testing and subsequent conversations with Jane, I have not received treatment for my problems. I believe that adults with my problems can be helped. I wish programs were available in all areas of the country. At age 26, I feel much better about myself than I did even at age 24. It's a matter of growth and coping with major differences.

The greatest advice I would give to educators and therapists working with problem children is to accept. Accept what they can do well; don't make an issue of what they can't do. We all have our strengths and weaknesses. If a child can't do math, so what! Buy the child a calculator and the child will do a lot better with it than with a label of stupidity following her through life.

SUMMARY

Learning disabilities are heterogeneous and multidimensional in their presentation. Research continues to work on identifying the causes and the associated functional deficits of learning disabilities, as well as developing effective intervention techniques. The variability of the group suggests a spectrum of neurological processing difficulties. As physiological measures of brain function improve, our theoretical understanding increases.

Assessment and teaching methods continue to be refined to identify underlying deficits and effective remediation strategies. The current trend is to recognize issues inherent

in the child (i.e., a true learning disability) versus issues from inadequate or ineffective instruction. Early identification of difficulties and systematic alteration of instruction methods are advocated to serve students more quickly and efficiently. The challenge for the clinician is to recognize the multitude of components that interact to impede functional abilities and social participation for the child with learning disabilities.

Children with learning disabilities frequently manifest motor coordination problems. These motor deficits may be subtle and difficult to identify in a neurological evaluation or standardized testing. With better awareness and assessment

measures, more children are being identified and diagnosed with DCD. Many theoretical models have been developed in an attempt to explain the qualitative motor deficits observed in children with learning disabilities as well as provide constructs to develop intervention programs. Continued formal research and careful documentation of clinical outcomes are needed to synthesize therapeutic approaches that best meet the individual needs of the child.

Identification, advocacy, teaching, and remediation are important aspects of the OT's and PT's roles. The goal is to formulate an intervention program that best addresses the underlying deficits in foundation skills and the functional weaknesses in daily life tasks. The experienced interventionist will combine knowledge from many areas of theoretical development and remediation to facilitate the best performance in each child.

It is clear that learning disabilities and DCD both persist across the life span and can have a multitude of detrimental effects. All areas of daily life performance can be affected,

including social and emotional functioning, self-care, education, vocation, and interpersonal relationships. Both intrinsic factors (perseverance, insight, sense of control) and extrinsic factors (emotional support, mentoring, positive feedback) play a role in the ultimate success of the individual with learning and motor challenges. Our role as a pediatric therapist is to provide the necessary extrinsic support and effective intervention to alleviate the deleterious effects of living with a disability.

Source

American Guidance Service, Inc., Circle Pines, MN 55014

Ages

4 to 21 years

Administration

Individual. Complete form: 45 minutes to 1 hour. Short form: 15 to 20 minutes.

Equipment

Test kit needed

Description

The Bruininks-Oseretsky Test of Motor Proficiency–2 is the most recent revision of the Oseretsky Tests of Motor Proficiency, first published in Russia in 1923. The Bruininks-Oseretsky Test is designed to provide information on a wide range of motor skills and is sensitive enough to identify mild to moderate motor control problems. In this revision the authors worked to improve the test item presentation, quality of the test kit, and functional relevance of test content. They also expanded the norms through age 21 and improved the test items for 4- to 5-year-olds. The BOT-2 yields standard scores, scaled scores, and percentile ranks, separately for males and females, and combined. Age equivalency scores are also available. The test assesses motor functioning in eight areas:

1. **Fine Motor Precision:** Functionally relevant drawing, paper folding, and cutting item that focuses on assessment of precise finger control. These items are untimed and they focus on qualitative refinement.
2. **Fine Motor Integration:** Copying geometric shapes of increasing complexity as accurately as possible. These items are untimed, as they focus on precision.
3. **Manual Dexterity:** Goal-directed activities that involve reaching, grasping, and bimanual coordination with small objects (pennies, pegboard, card sorting, and stringing beads). Emphasis is placed on speed and accuracy (dexterity), and all items are timed.
4. **Bilateral Coordination:** Items that measure skill in sequential and simultaneous coordination of the upper and lower extremities. Includes both familiar tasks (e.g., jumping jacks and finger pivots [“itsy-bitsy spider”]), as well as novel tasks (e.g., tapping feet and fingers with opposite sides of the body).
5. **Balance:** Static and dynamic balance items measure motor control for maintaining posture when standing, walking, and making transitional movements in space (e.g., reaching for a plate on a shelf). Assesses three areas that affect balance: trunk stability, static and dynamic postural control, and use of visual cues.
6. **Running Speed and Agility:** Four activities to assess speed and agility (shuttle run, hopping on one and both feet, stepping over balance beam).
7. **Upper-Limb Coordination:** Items that involve visual tracking and coordinated hand and arm movements (eye-hand coordination). Tasks include catching, throwing, and dribbling, with one or both hands together.
8. **Strength:** Assesses trunk and upper and lower extremity strength necessary for effective gross motor performance in daily activities.

Construction and Reliability

The Bruininks-Oseretsky Test has been carefully standardized on 1520 subjects from 38 states, stratified across sex, ethnicity, socioeconomic, and disability status. Sample sizes were larger in the younger age ranges, as children develop more rapidly than adolescents. Three measures of reliability were determined for subtests, composites, short form, and complete form: internal consistency, test-retest, and interrater. In general all were high, with best reliability shown when the complete form was used.

Comment

The Bruininks-Oseretsky Test of Motor Proficiency–2 appears to be one of the better standardized tests of motor performance. The 1978 version has been one of the most widely used tests to assess motor proficiency and has been used in research to identify motor deficits in individuals with DCD.^{221,222} It offers various levels of testing and screening with a comprehensive “complete form” that provides the most reliable measure of overall motor proficiency. The short form can be used for screening, to determine if further evaluation is necessary. In addition, only those single subtests or composites that are relevant to the child’s areas of difficulty can be administered. When qualifying a student for special education, it is suggested that this thorough assessment be used. In this revision the authors focused on including a variety of tasks that are engaging and goal directed, assessing both quantitative and qualitative aspects of motor performance. When testing children with motor dysfunction, careful attention must be paid to qualitative performance on individual items. A child may demonstrate the ability to complete a test item, but qualitatively it is accomplished with increased effort, decreased refinement, and speed.

Movement Assessment Battery for Children (Movement ABC-2) (2007)¹¹⁴

Authors

Sheila E. Henderson, David A. Sugden, and Anna L. Barnett

Source

Harcourt Assessment, Proctor House, 1 Proctor Street, London, WC1V6EU

Ages

3 to 16 years

Administration

Individual; 20 to 30 minutes

Equipment

Test kit required

Description

The Movement ABC-2 is a recent revision of the M-ABC, which was originally developed from the Test of Motor Impairment (TOMI)–Henderson Revision. The Movement ABC-2 is a norm-based assessment of gross and fine motor performance whose main intent is to identify and describe children with movement difficulties. The test was also designed for intervention planning, program evaluation, and research. There are three components of the Movement ABC-2: the standardized evaluation, a checklist of competency in specific daily motor behaviors, and a companion manual for program planning (Ecological Approach to Intervention).¹⁴⁵ The evaluation tool yields standard and percentile scores, with two determined cut-off points delineating definite movement difficulties and children at risk. The age ranges have been expanded, and the test is divided into three age brackets: children aged 3 to 6 years, 7 to 10 years, and 11 to 16 years. The test items vary in each age range, with increased complexity and skill required in the older age

Continued

APPENDIX 14-A ■ A Summary of Standardized Motor Tests—cont'd

bands. There are eight tasks assessing three areas of coordination: manual dexterity, ball skills, and static and dynamic balance.

1. **Manual Dexterity:** Speed and dexterity with the preferred hand. Includes two manipulative tasks such as coins in a bank, stringing beads, pegs in a pegboard, threading lace, and turning pegs and nuts and bolts, as well as a written maze.
2. **Ball Skills:** Eye-hand coordination is assessed with two beanbag and ball tasks emphasizing aiming at a target and catching.
3. **Static and Dynamic Balance:** One task of static balance with eyes open, and two tasks of dynamic balance that emphasize spatial precision and control of momentum.

Construction and Reliability

The standardization sample included 1172 children in the United Kingdom. A stratified sampling was done to ensure that representative proportions of age, gender, race and ethnicity, and parent educational level were included. Before the main study, testing was done around the world and revealed no culture-specific problems. The researchers consider this revision to be similar enough to the M-ABC that the studies employed with that test remain relevant. Test-retest reliability for consistency of individual item scores fell within a range deemed acceptable, from 0.64 to 0.86. The mean of 0.77 was achieved for the test as a whole. Interrater reliability was excellent, exceeding 0.95.

Comment

This revision is the culmination of a lengthy program of research and development begun in 1966 by two groups of researchers. The Movement ABC-2 offers some additional advantages: (1) the checklist helps teachers identify children with movement problems; (2) information is provided for a cognitive-motor approach to intervention across environments. The test items are easy to administer and score. Although the manual provides a clear picture of what the task looks like, there are no standardized verbal instructions given in this revision. Scoring is based on a traffic light system, with the red zone (at or below 5th percentile) indicating significant movement difficulty, amber zone (6th to 15th percentile) delineating children at risk, and the green zone (above 15th percentile) indicating the absence of movement difficulties. Percentile scores are useful for parents and teachers because they are easily understood, but therapists should recognize that they do not form an equal interval scale, tending to cluster near the median of the normal curve. Therefore for subtest raw scores near the median, a change of 1 point to the raw score could result in an increase of 8 percentile points, whereas at either end of the normal curve this might only translate to 2 percentile points.

Peabody Developmental Motor Scales, Second Edition (PDMS-2) (2000)¹¹³

Authors

M. Rhonda Folio and Rebecca R. Fewell

Source

Pro-Ed, 8700 Shoal Creek Boulevard, Austin, TX 78757

Ages

Birth to 5 years

Administration

40 to 60 minutes (test items may be scored by direct observation or by parent or teacher report)

Description

An early childhood motor development program that provides, in one package, both in-depth assessment and training or remediation of gross and fine motor skills. The assessment is composed of six

subtests that measure interrelated motor abilities that develop early in life. The PDMS-2 can be used by OTs, PTs, diagnosticians, early intervention specialists, adapted physical education teachers, psychologists, and others who are interested in examining the motor abilities of young children. The PDMS was designed for use with children who show delay or disability in fine and gross motor skills. Test items are similar to those on other developmental scales, but only motor items are included. Items are scored on a 3-point scale: 0 for unsuccessful, 1 for partial, and 2 for successful performance. Age-equivalent scores, motor quotients, percentile rankings, and standard scores are provided. Scoring software for the PDMS-2 is available to convert the PDMS-2 scores into standard scores, percentile ranks, and age equivalents and generate composite quotients. The software also can be used to compare PDMS-2 subtest performances and composite performances to identify intraindividual differences and provide a printed report of the student information, including treatment goals and objectives.

Subtests

1. **Reflexes:** This eight-item subtest measures a child's ability to automatically react to environmental events. Because reflexes typically become integrated by the time a child is 12 months old, this subtest is given only to children from birth through 11 months.
2. **Stationary:** This 30-item subtest measures a child's ability to sustain control of his or her body within its center of gravity and retain equilibrium.
3. **Locomotion:** This 89-item subtest measures a child's ability to move from one place to another. The actions measured include crawling, walking, running, hopping, and jumping forward.
4. **Object manipulation:** This 24-item subtest measures a child's ability to manipulate balls. Examples of the actions measured include catching, throwing, and kicking. Because these skills are not apparent until a child has reached the age of 11 months, this subtest is given only to children aged 12 months and older.
5. **Grasping:** This 26-item subtest measures a child's ability to use his or her hands. It begins with the ability to hold an object with one hand and progresses up to actions involving the controlled use of the fingers of both hands.
6. **Visual-motor integration:** This 72-item subtest measures a child's ability to use his or her visual perceptual skills to perform complex eye-hand coordination tasks such as reaching and grasping for an object, building with blocks, and copying designs.

Composites

1. **Gross Motor Quotient:** This composite is a combination of results on the subtests that measure the use of the large muscle systems:
 - Reflexes (birth to 11 months only)
 - Stationary (all ages)
 - Locomotion (all ages)
 - Object manipulation (12 months and older)
2. **Fine Motor Quotient:** This composite is a combination of results on the subtests that measure the use of the small muscle systems:
 - Grasping (all ages)
 - Visual-motor integration (all ages)
3. **Total Motor Quotient:** This composite is formed by a combination of results on the gross and fine motor subtests. Because of this, it is the best estimate of overall motor abilities.

APPENDIX 14-A ■ A Summary of Standardized Motor Tests—cont'd

Construction and Reliability

Reliability coefficients were computed for subgroups of the normative sample (e.g., individuals with motor disabilities, African Americans, Hispanic Americans, girls, and boys) as well as for the entire normative sample. The normative sample consisted of 2003 persons residing in 46 states and was collected in the winter of 1997 and spring of 1998. Normative samples relative to geography, sex, race, and other critical variables are therefore representative of the current U.S. population.

A test-retest reliability of 0.84 for the Gross Motor Scale and of 0.73 for the Fine Motor Scale (0.89 Total Motor) was reported based on a sample of 30 children from Austin, Texas, in the age range of 2 to 11 months. A second group of 30 children from Nacogdoches, Texas, ages 12 to 17 months, were tested with a test-retest reliability of 0.93 for the Gross Motor Scale and 0.94 for the Fine Motor Scale (0.96 Total Motor). These values are of sufficient magnitude for a tester's confidence in the test scores' stability over a period of time. The correlation coefficients between the PDMS and the PDMS-2 for criterion-prediction validity in the Gross and Fine Motor Quotients exceed 0.80, which supports the equivalency of the tests.

The PDMS-2 scores were correlated with those of the Mullen Scales of Early Learning: AGS Edition (MSEL:A) when both tests were administered on the same day to 29 children, aged 2 months to 66 months, in Evansville, Indiana. The relations of the PDMS-2 and MSEL:A demonstrated that Gross and Fine Motor Quotients exceed 0.80, high enough to support the equivalency of the tests. When the concurrent validity of the age equivalent and standard scores of the Bayley Scales of Infant Development II (BSID-II) Motor Scale and PDMS-2 were calculated, the standard scores show poor agreement and had low concurrent validity, particularly the BSID-II Motor Scale and the PDMS-2 Locomotion Subscale.²²³ The differences in the scores of these two tests warrant concern when using one test to make clinical decisions for service eligibility.

Comment

The PDMS-2 is primarily useful for children with mild to moderate motor deficits, such as a child with learning disabilities or a child with developmental delay. The test does not discriminate among children with moderate to severe motor disability because they fall far below the standard scores given. The skill categories are unevenly distributed and have too few items at some age levels to be meaningful. Despite the drawbacks, the PDMS-2 is probably the most valuable motor scale test currently available for preschool children.

Clinical Observations of Motor and Postural Skills, Second Edition (COMPS) (2000)¹²⁶

Authors

Brenda N. Wilson, MS, OT(C), Nancy Pollock, MSc, OT(C), Brenda Kaplan, PhD, and Mary Law, PhD, OT(C)

Source

Therapro Inc., 225 Arlington Street, Framingham, MA 01702

Ages

5 to 11 years

Administration

Individual; 15 to 20 minutes

Equipment

Test kit required for ATNR measurement tools. Stopwatch and mat needed for certain items.

Description

The COMPS is a standardized screening tool using six clinical observations suggested by Ayres^{99,224} of "soft neurological signs" to identify motor problems with a postural component. Historically,

the clinical observations used by therapists have not had standardized administration or objective scoring and they have not taken into account the child's age and changes in abilities as the child matures. The authors felt it was important to objectify these observations and relate performance to age, as neuromotor maturation is very rapid in this age group. The test is designed to measure cerebellar function, postural control (stability), and motor coordination (mobility). Motor planning and sequencing are not intended to be measured directly, and repetition of directions, therapist prompting, and item practice are meant to separate motor performance from the cognitive aspects of planning. The test has six test items:

1. **Slow Movements:** Assesses the ability to move arms in a slow and symmetrical manner. Scoring is based on quality of performance, speed, and symmetry.
2. **Rapid Forearm Rotation:** A test of diadochokinesis; score is based on the number of forearm rotations accurately completed in 10 seconds.
3. **Finger-Nose Touching:** Measures proprioceptive mechanisms of motor control by switching midtask from eyes open to eyes closed. Scoring is based on accuracy, fluidity of motion, and force of touch.
4. **Prone Extension Posture:** The child holds a position of extension against gravity. Scoring is based on the duration of ability to hold position, quality of extension, and effort.
5. **Asymmetrical Tonic Neck Reflex:** The degree of inhibition of this reflex is looked at by measuring elbow flexion with manual head turn in a quadruped position. This test is also useful for identifying poor postural stability through observations including needing a wide base of support to sustain the position and locking elbows for stability.
6. **Supine Flexion Posture:** The child holds a position of flexion against gravity. Scoring is based on the duration of ability to hold position, quality of extension, and effort.

Construction and Reliability

Standardization of the test was done in two cities (Calgary and Hamilton) on a sample of 123 children, 67 who demonstrated DCD and 56 with no known motor problem. Test-retest reliability, interrater reliability, internal consistency, and construct validity were completed with a sample of 132 children with and without DCD. Test-retest reliability over 2 weeks was 0.98, and interrater reliability for pediatric OTs was 0.87. The internal consistency was high, indicating that the test discriminates well between children with and without motor problems, although the sample size was small.

Comment

The COMPS is a useful standardized tool for identifying subtle motor problems in children and was designed for and tested on children with DCD. The COMPS was not designed for children with known neurological or neuromotor problems such as intellectual delay, cerebral palsy, or epilepsy. It can be used as a screening tool for motor dysfunction, to assist in determining intervention approaches that would be beneficial for the child, and possibly to measure change over time. Children with motor performance problems can score within normal limits on the COMPS, and children who demonstrate low scores may not be exhibiting functional difficulties. The association between these clinical observations and functional performance is not always clear; therefore it is essential to gather information regarding the child's current functioning from observation and interview.

Miller Assessment for Preschoolers (MAP) (1988)¹²⁷

Author

Lucy Jane Miller, PhD

Source

Psychological Corporation, 555 Academic Court, San Antonio, TX 78204-0952

Ages

2 years, 9 months to 5 years, 8 months

Administration

Individual; 20 to 30 minutes, including scoring

Equipment

The MAP Test Kit

Description

The MAP was designed to identify preschool children who exhibit mild to moderate developmental delays. The MAP is a developmental assessment intended for use by educational and clinical personnel to identify children in need of further evaluation and remediation. It can also be used to provide a comprehensive, clinical framework that would be helpful in defining a child's strengths and weaknesses and that would indicate possible avenues of remediation. The test is composed of 27 items and a series of structured observations. The test items are divided into five performance indexes:

1. Foundations: Items generally found on standard neurological examinations and sensory integrative and neurodevelopmental tests
2. Coordination: Gross, fine, and oral motor abilities and articulation
3. Verbal: Cognitive language abilities, including memory, sequencing, comprehension, association, following directions, and expression
4. Nonverbal: Cognitive abilities such as visual figure-ground, puzzles, memory, and sequencing
5. Complex Tasks: Tasks requiring an interaction of sensory, motor, and cognitive abilities

Construction and Reliability

The MAP has been well standardized on a random sample of 1200 preschool children. The sample was stratified by age, race, sex, size of residence, community, and socioeconomic factors. Data were collected nationwide in each of nine U.S. Census Bureau regions. Reported reliabilities are good. In a test-retest on 90 children, 81% of the children's scores remained stable. The coefficient of internal consistency on the total sample was 0.798. Interrater reliability on 40 children was reported as 0.98.

Comment

The MAP was developed by an OT and provides information that is of particular relevance to therapists. It is carefully standardized and fills a need for early identification of learning and motor deficits in children. Several articles have been published supporting the validity of this test as a screening instrument.²²⁵⁻²²⁸ Reviews of the MAP in the *Ninth Mental Measurements Yearbook* have described it as "the best available screening test for identifying preschool children with moderate preacademic problems"²²⁹ and "an extremely promising instrument which should find wide use among clinical psychologists, school psychologists, and OTs in assessing mild to moderate learning disabilities in preschool children."²³⁰ A more complete review of this test is provided by King-Thomas and Hacker.²³¹

FirstSTEP (Screening Test for Evaluating Preschoolers) (1993)¹³⁰

Author

Lucy J. Miller, PhD

Psychological Corporation, 555 Academic Court, San Antonio, TX 78204-0952

Ages

2 years, 9 months to 6 years, 2 months

Administration

Individual; 15 minutes

Equipment

Test kit

Description

The FirstSTEP is a quick screening test for identifying developmental delays in all five areas defined by IDEA and mandated by PL 99-457: cognition, communication, physical, social-emotional, and adaptive functioning. Twelve subtests assess cognitive, communication, and motor domains. An optional Social-Emotional Scale includes 25 items from five areas (task confidence, cooperative mood, temperament and emotionality, uncooperative antisocial behavior, and attention communication difficulties) that are scored on the basis of behaviors observed by the examiner during the test session. The Adaptive Behavior Checklist is an optional measure completed by parent interview to assess the child's self-help and adaptive living skills. The Parent/Teacher Scale provides additional information about the child's typical behavior.

Cognitive Domain

1. Money Game (quantitative reasoning): The child is asked a series of questions about coins, regarding quantity, amount, comparisons, size, and numeration. This subtest requires cognitive understanding of simple arithmetic concepts.
2. What's Missing? Game (picture completion): The child is asked to identify what is missing from the pictures of common objects or events by naming or pointing. This subtest measures visual figure-ground as well as gestalt closure abilities.
3. Which Way? Game (visual position in space): The child is asked to look at a stimulus figure that is turned in a specific direction. The child then selects the response figure that matches. This subtest measures visual discrimination and the ability to perceive directionality visually.
4. Put Together Game (problem solving): The child is asked to select the pieces that best fit a certain space. The subtest requires abstract thinking.

Language Domain

1. Listen Game (auditory discrimination): This two-part activity requires the child to listen as the examiner names and points to three similar-sounding pictures. Then the child chooses the pictures that represent the words. The second part requires the child to discriminate between words that are the same and words that are different. This task taps phoneme discrimination and requires good auditory processing skills.
2. How Many Can You Say? Game (word retrieval): The child's linguistic fluency and word-finding skills are measured by asking the child to count, recall animals, and recite rhyming words.
3. Finish Up Game (association): The child is asked to complete a phrase that is initiated by the examiner. The subtest requires the child to demonstrate an understanding of the association between concepts (e.g., big and little).
4. Copy Me Game (sentence and digit repetition): The child is asked to repeat a series of meaningful verbal stimuli and then a series of numbers. This subtest measures verbal memory, grammatical abilities, and verbal expression skills.

APPENDIX 14-A ■ A Summary of Standardized Motor Tests—cont'd

Motor Domain

1. Drawing Game (visual-motor integration): The child is presented with paper and pencil tasks. This subtest requires the integration of fine motor and visual-perceptual abilities.
2. Things with Strings Game (fine motor planning): The child is asked to perform a series of motor movements with the upper extremities with a wooden cube and a string. These items tap the ability to plan and execute a series of motor actions and measure fine motor planning or praxis.
3. Statue Game (balance): The child is asked to assume a series of increasingly more difficult positions that require the child to balance with eyes open and vision occluded. The subtest taps the abilities needed to maintain equilibrium and screens for proprioception, vestibular perception, and visual processing difficulties.
4. Jumping Game (gross motor planning): The child is asked to imitate the examiner through a series of increasingly more difficult tasks that involve jumping in specific patterns. Gross motor and motor planning abilities are measured.

Construction and Reliability

The FirstSTEP is norm referenced and was standardized on 1433 children. Norms are provided in 6-month intervals for each of seven age groups. The standardization sample closely matches demographic characteristics provided by the U.S. Census Bureau. Scores are reported in standard scores as well as a three-category, color-coded risk status to indicate whether the child is functioning in the normal or delayed range. The FirstSTEP is a highly reliable instrument. Overall test reliability (split half) is 0.90, with individual domains ranging from 0.71 to 0.87. Test-retest reliability indicated a high degree of consistency in the classification of a child's performance across two test sessions (90% agreement for composite score; 85% to 93% for individual domain scores). Results also indicated a high level of interrater agreement ($r = 0.94$ on composite scores).

Validity studies of the FirstSTEP indicate that the FirstSTEP has good construct, content, and discriminant validity. Therefore it can effectively identify children with developmental delays. A study of 900 children demonstrated that children with delays perform 1.5 to 2 standard deviations below the mean in all domains. The results of a concurrent validity study suggest that the motor domain of the FirstSTEP measures constructs similar to those measured by the Bruininks-Oseretsky Test of Motor Proficiency and support the use of the motor domain of the FirstSTEP as an indicator of the child's motor functioning.

Comment

The FirstSTEP is an easy-to-administer test that is highly effective as a screening instrument. The FirstSTEP was developed by the OT who also developed the MAP (the Miller Assessment for Preschoolers), and like the MAP the test provides information that is of particular relevance to therapists. Although individual items on the FirstSTEP differ from the MAP, many are derived from the MAP, and the test is based on the same theoretical framework as the MAP. Area domains, social-emotional scales, and the adaptive behavior checklist from this tool can also be used in conjunction with other tests to provide additional information on the child's areas of strengths and weakness. A Spanish version, Primer Paso, is also available for use.

School Function Assessment (SFA) 1998²³²

Authors

Wendy Coster, PhD, OTR/L, Theresa Deeney, EdD, Jane Haltiwanger, PhD, and Stephen Haley, PhD, PT

Source

Pro-Ed, 8700 Shoal Creek Boulevard, Austin, TX 78757-6897

Website: www.proedinc.com

Ages

5 to 12 years

Administration

Individual; untimed. Individual scales may be completed in 5 to 10 minutes.

Equipment

Record form; rating scale guides

Description

The SFA is a judgment-based, criterion-referenced assessment to evaluate and monitor a student's performance on functional tasks that support school participation. This measure was designed to facilitate collaborative program planning for students with a variety of physical and cognitive disabilities. The SFA measures a student's ability to perform activities within the school setting that support participation in the academic and social aspects of an elementary program (grades K-6). Functional skills such as moving around the school, using classroom materials, interacting with peers, and caring for personal needs are included. The instrument is best completed by school professionals who are familiar with the student's typical performance. Task items are written in measurable, behavioral terms that can be used directly in the student's IEP. Criterion cut-off scores are provided for use in determining eligibility for special services. The SFA contains three parts:

1. Participation: Rates the student's involvement in six major school activity settings: regular or special education classroom, playground or recess, transportation, bathroom and toileting activities, transitions to and from class, and meal-time or snack time.
2. Task Supports: Identifies and rates the assistance and adaptations currently provided to the student for both physical and cognitive and behavioral tasks. Two types of task supports are examined separately: assistance (adult help) and adaptations (modifications to the environment or program, such as specialized equipment or adapted materials).
3. Activity Performance: Examines the student's performance of specific school-related functional activities. Physical Tasks include travel, maintaining and changing positions, recreational movement, manipulation with movement, using materials, setup and cleanup, eating and drinking, hygiene, clothing management, going up and down stairs, written work, and computer and equipment use. Cognitive/Behavioral Tasks include functional communication, memory and understanding, following social conventions, compliance with adult directives and school rules, task behavior and completion, positive interaction, behavior regulation, personal care awareness, and safety.

Construction and Reliability

A sample of 678 students in two groups participated in the standardization of SFA. One group included children with special needs (363 students). These students had a variety of disabilities, including motor impairment, communication impairment, emotional or behavioral difficulties, and cognitive limitations. The second group included 315 students in regular education programs. Internal consistency was excellent at 0.92 to 0.98, indicating that items in a scale relate to one another and measure the same construct. Test-retest reliability was 0.82 to 0.98.

Continued

APPENDIX 14-A ■ A Summary of Standardized Motor Tests—cont'd

Comment

This assessment is unique in its focus on activity and participation levels, versus identifying impairments. It helps school personnel recognize and ameliorate functional limitations that are affecting successful school participation. The comprehensiveness of assessment and functional IEP-ready goals makes it a useful tool to qualify and develop programs for children in need of special education services. Complete instructions are contained in the assessment booklet. Therefore the respondent does not need to refer to a manual to complete items, easing data collection. The manual is then used to compute transformed scores and interpret results.

The Sensory Integration and Praxis Tests (SIPT) (1989)¹¹²

Author

A. Jean Ayres

Source

Western Psychological Services, 12031 Wilshire Boulevard, Los Angeles, CA 90025

Ages

4 years to 8 years, 11 months

Administration

Individual; 2 hours; examiner certification required

Equipment

SIPT Test Kit

Description

The SIPT is a major revision and restandardization of the Southern California Sensory Integration Tests.²³⁹ Four new tests of praxis were added, five tests underwent major revisions, eight tests underwent minor revisions, and four tests were deleted. The tests are designed to identify sensory integration and praxis deficits in children with learning disabilities. The 17 tests are described as follows:

1. Space Visualization: Select from two blocks the one that will fit into a form board. Mentally manipulating the forms is required to arrive at the correct choice on the more difficult test items.
2. Figure-Ground Perception: The child selects from six pictures the three that are superimposed or embedded with other forms on the test plates.
3. Manual Form Perception: Part I—A geometric form is held in the hand and the counterpart is selected from a visual display. Part II—A geometric form is felt with one hand while its match is selected from several choices with the other hand.
4. Kinesthesia: With vision occluded, the child attempts to place his or her finger on a point at which this finger had been placed previously by the examiner; a separate recording sheet is provided for each child.
5. Finger Identification: With hands screened from view, the examiner touches the child's finger, the shield is removed, and the child then points to the finger touched.
6. Graphesthesia: The examiner uses his or her finger to draw a design on the back of the child's hand without the child looking; the child then reproduces the design.
7. Localization of Tactile Stimuli: With vision occluded, the child touches the spot on his or her hand or arm that was touched by the examiner with a specially designed pen.
8. Praxis on Verbal Command: The examiner verbally describes a series of body movements, and the child executes them.

9. Design Copying: Part I—The child copies a design by connecting dots on a dot grid. Part II—The child copies a design without the use of a dot grid; both process and product are scored.
10. Constructional Praxis: Working with blocks, the child attempts to duplicate two different block structures. In the first structure, the child observes the examiner building the model; the second structure is preassembled.
11. Postural Praxis: The child imitates unusual body positions demonstrated by the examiner.
12. Oral Praxis: The child imitates movements of the tongue, lips, and jaw demonstrated by the examiner.
13. Sequencing Praxis: The child imitates a series of simple arm and hand movements demonstrated by the examiner.
14. Bilateral Motor Coordination: The child imitates a series of bilateral arm and foot movements demonstrated by the examiner.
15. Standing and Walking Balance: This subtest consists of 15 items in which the child assumes various standing and walking postures.
16. Motor Accuracy: The child traces a printed, curved black line with a red, nylon-tipped pen, first with the preferred hand and then with the nonpreferred hand.
17. Postrotatory Nystagmus: The child is rotated first counterclockwise and then clockwise on a rotation board; the duration of postrotatory nystagmus, a vestibulo-ocular reflex, is observed.

In addition to these 17 tests, a series of clinical observations aids in interpreting the SIPT. These clinical observations include the following:

- Eye dominance
- Eye movements
- Muscle tone
- Co-contraction
- Postural background movements
- Postural security
- Equilibrium reactions and protective extension
- Schilder's arm extension posture
- Supine flexion
- Prone extension
- Asymmetrical tonic neck reflex
- Hyperactivity, distractibility
- Tactile defensiveness
- Ability to perform slow motions
- Thumb-finger touching
- Diadochokinesis
- Tongue-to-lip movements
- Hopping, jumping, skipping

Construction and Reliability

The construction of the SIPT was based on a theoretical model developed from observation of children with learning disabilities and supported by factor analytical and cluster analysis studies. Interpretation follows a clinical model based on patterns of scores rather than a poor score on any one test.

The SIPT was nationally standardized on 1997 children from across the United States and Canada. Sex, geographical location, ethnicity, and type of community are represented in proportion to the 1980 U.S. Census. Test-retest reliability was evaluated in a sample of 41 dysfunctional children and 10 normally functioning children with ranges from moderate to high. As a group, the praxis

APPENDIX 14-A ■ A Summary of Standardized Motor Tests—cont'd

tests had the highest reliabilities. Interrater reliability is excellent, with most correlations between raters at 0.90 or higher.

Comment

The SIPT is computer scored and interpreted, and a full eight-color profile (WPS Chronograph) is provided that summarizes major SIPT testing and statistical results in a clear manner. Initial validity studies of the SIPT indicate a good ability to discriminate between normal and dysfunctional groups and across ages. The SIPT is the most comprehensive assessment of sensory integration and praxis; however, it requires specialized training for administration and interpretation, and the test kit and scoring of protocols are expensive.

Beery-Buktenica Developmental Test of Visual-Motor Integration (BEERY VMI), Fifth Revision (2010)¹¹⁵

Authors

Keith E. Beery, PhD, Norman A. Buktenica, and Natasha A. Beery

Source

Multi-Health Systems, Inc., 3770 Victoria Park Ave, Toronto, Ontario, Canada M2H 3M6 Email: customerservice@mhs.com; website: www.mhs.com

Ages

2 to 18 years

Administration

Individual or group; 5 to 15 minutes

Equipment

Protocol booklets (test forms), No. 2 pencil

Description

The BEERY VMI was developed for early screening and intervention of visual-motor deficits. It tests the ability to integrate visual and motor abilities by presenting 30 geometric forms of increasing difficulty to copy. A booklet is provided; below the design is a blank space in which the child replicates the form. A shorter format including the first 21 items is best suited for children aged 2 to 7 years. Items are judged pass or fail on criteria given in the manual, and scores are reported in standard scores and percentiles. Age equivalents are also available. If the child has significant difficulty completing the test or scores below the average range, this may be indicative of a visual-motor integration delay. To further assess where the difficulties lie, two additional tests are available to assess visual perception and motor coordination separately.

1. Visual Perception: Visual perception is assessed by limiting the motor response to pointing. The child matches geometric forms to a stimulus. Administration takes approximately 3 minutes.
2. Motor Coordination: Motor accuracy is assessed on a task of drawing within a double-lined path. Administration takes approximately 5 minutes.

Construction and Reliability

The Beery VMI is based on a significant amount of research on visual-motor integration, coordination, and development. The test has been normed five times between 1964 and 2003, with a total of more than 11,000 children. For this revision the Visual Perception and Motor tests were standardized on the same sample of 2512 children. This test has an extensive range of age-specific norms, with 600 children for the age range of 2 to 6 years. Test-retest reliability is high for the three test components, ranging from 0.90 to 0.92. Various studies of interrater reliability, internal consistency, and concurrent and construct validity are reported in the manual. Comparisons to other tests assessing visual-motor integration supported the validity the Beery VMI.

Comment

The VMI provides a quick and easy method to assess the development of a child's ability to copy geometric forms. The uses are varied, including identification of significant difficulties with visual-motor integration and determination of an effective intervention program, as well as use as a research tool. For complete assessment of the child with learning disabilities and DCD, it is best used in conjunction with other tests of gross motor, fine motor, visual perception, and eye-hand coordination. This culture-free, nonverbal assessment is suitable for children with diverse educational, environmental, and language backgrounds. New to this addition are teaching materials to promote visual-motor integration for children from birth through elementary school. These include *My Book of Letters and Numbers*; *My Book of Shapes*; a laminated wall chart of basic gross motor, fine motor, and visual developmental milestones; and a checklist for parents of over 200 developmental "stepping stones" to help parents observe skill development and track progress.

Test of Visual-Motor Skills Revised (TVMS-R) (1995)¹¹⁶

Author

Morrison F. Gardner

Source

Children's Hospital of San Francisco, Publication Department OPR-110, PO Box 3805, San Francisco, CA 94119

Ages

3 to 13 years

Administration

Individual or group; three to six children

Equipment

Protocol booklet, No. 2 pencil

Description

The TVMS-R consists of a series of 23 forms to be copied by the child. Each form is on a separate page of the booklet. The booklet contains some forms commonly used in visual-motor tests (e.g., lines and circles), but many forms are unique to this test. Care was taken to avoid forms that resemble language symbols. The revision of the TVMS has updated norms, standardization, and scoring criteria.

Two different scoring methods are now available. Modifications in scoring the TVMS-R include a classification system to characterize errors in one of eight categories. The eight classifications are closure, angles, intersecting and overlapping lines, size of design, rotation or reversals, line length, overpenetration or underpenetration, and modification of design. Scoring of each design is completed by following a definitive criterion, with errors and strengths identified. The examiner can identify specific areas of strength and weakness in visual-motor integration on the basis of the number of errors and accuracies recorded. Standard scores, scaled scores, percentile ranks, and stanines are available for both weaknesses and strengths. An alternative scoring method (ASM) was also designed to allow a straight point system designation for each form. The forms are scored on a 0- to 3-point scale. A score of 0 indicates that the child is unable to copy the form with any degree of motor accuracy. Scores of 1 and 2 indicate various visual-motor errors for which criteria are both written and illustrated. A score of 3 demonstrates precision in execution. Age equivalents, standard scores, scaled scores, percentile ranks, and stanines are provided.

Continued

APPENDIX 14-A ■ A Summary of Standardized Motor Tests—cont'd

Construction and Reliability

The TVMS-R was administered to 1484 children in the San Francisco Bay area aged 3 years to 13 years, 11 months. The overall sample was 51.9% male and 48.1% female. Cronbach's coefficient alpha was used to determine the internal consistency of the test. These reliability coefficients ranged from 0.72 to 0.84 over the age ranges, with a value of 0.90 for the sample as a whole. Test-retest reliability was not reported in the manual, but the author noted the need for research in that area.

Comment

The TVMS-R is a companion test to the Test of Visual-Perceptual Skills (TVPS), which is a motor-free test of form perception. Using the tests together can determine whether the child's form reproduction reflects incorrect visual perception or whether the problem is in motor execution. The TVMS-R places greater expectations on motor precision than do other visual-motor tests. For example, a line must touch an intersecting line without crossing over it. Therefore this test should be used only when motor control and constructive abilities are important.

Spatial Awareness Skills Program (SASP) (1999)¹¹⁷

Author

Jerome Rosner

Source

Pro-Ed, 8700 Shoal Creek Boulevard, Austin, TX 78757

Ages

4 to 10 years

Administration

Individual; 5 minutes to administer

Equipment

Protocol booklet, test booklet, No. 2 pencil, and transparent scoring guide

Description

The SASP test and curriculum was developed and revised from two earlier programs by the same author called *Perceptual Skills Curriculum* (PSC) and *Preparation for Learning* (PREP). These programs focused on teaching analytical abilities to improve visual and auditory perceptual skills that are important for academic learning. The SASP test is designed to assess spatial analysis and organizational skills through copying progressively harder spatial figures. Items are judged pass or fail on criteria given in the manual and through use of a scoring transparency. Raw scores are converted to age equivalents and used to determine the child's placement level within the SASP curriculum. The assessment and curriculum are designed to address the visual motor deficits exhibited by children with often hard-to-explain learning problems.

Spatial awareness refers to the ability to recognize what one can see, as well as understand space and time concepts that cannot be seen. It is a critical precursor to elementary school achievement as a foundation to spatial concepts such as decoding words and performing mathematical calculations. The SASP curriculum teaches spatial analysis skills with activities that show children how to break patterns into their structural elements, paying attention to features such as absolute and relative qualities, position, and magnitude. This type of organization enhances the ability to chunk information into larger units for more efficient processing of information. Spatial reasoning forms the logic of coding systems used for spelling, reading, writing, and math.

Construction and Reliability

The SASP was field tested on a sample of 322 children aged 4 to 11 years attending two schools in Houston, Texas. These schools were selected for their demographic diversity. The small sample size was deemed appropriate given the nature of the test. The internal consistency reliability was examined using Cronbach's coefficient analysis, yielding an average score of 0.76, indicating overall reliability of the SASP across ages. Interrater reliability was 0.96. Content description and content identification were found to be valid for the limited purpose of this assessment, indicating that examiners can use the SASP test with confidence to determine entry points for the SASP curriculum.

Comment

Spatial awareness skills are considered to develop both hierarchically and cyclically, with the child developing a more complex understanding of global and part relationships over time. By the age of 10 the foundational spatial skills assessed by the SASP are thought to be fully developed. Therefore a maximum score is expected for children aged 10 or older. Although the SASP was normed for children aged 4 through 10, it is possible to use it with individuals above this age. If an older child does not perform appropriately on testing, and academic achievement is consistent with this standard score, then the remedial program can be used to encourage spatial awareness skills. The author cautions that the remedial program will not eliminate academic deficits but will provide strategies to assist in learning.

Evaluation Tool of Children's Handwriting (ETCH) (1995)¹¹⁸

Author

Susan J. Amundson

Source

O.T. Kids, PO Box 1118, Homer, AK 99603

Ages

First through sixth grades (6 to 11 years)

Administration

Individual

Equipment

Protocol booklet, task sheets and wall charts, stopwatch, No. 2 pencil

Description

The ETCH is designed to evaluate manuscript and cursive writing for components of legibility and speed. Specific components of the child's handwriting, including letter formation, spacing, size, and alignment, are included for assessment. The following tasks are presented in order:

1. Lowercase alphabet letters (from memory)
2. Uppercase alphabet letters (from memory)
3. Numeral writing (from memory)
4. Near point copying (visual model)
5. Far point copying (visual model)
6. Dictation (verbal)
7. Sentence composition (independent)

A quick reference card is included with standardized directions and timing criteria. Written and illustrated scoring criteria have been designed to assist the evaluator in determining the legibility of letters and numbers. The primary focus of scoring is whether the written material is readable.

Construction and Reliability

Based on the efforts of numerous occupational therapy practitioners, students, and professors, the ETCH itself has evolved through scientific investigation. Pilots of the ETCH were designed by using

APPENDIX 14-A ■ A Summary of Standardized Motor Tests—cont'd

adaptations of written tasks from existing tools. Three editions of the ETCH have been sampled by practitioners working in school systems, with feedback given on the examiner's manual, ease of administration and scoring, item selection, scoring procedures, and face validity of the instrument. When the ETCH was published, it lacked normative and psychometric information. Since that time, test reliability, validity, and normative data of the ETCH are being compiled through various research studies. Eight studies of handwriting speed are included for reference in the manual. The most recent examination of test-retest reliability studies²³⁴ identified adequate stability of total word (0.95), letter (0.88), and number (0.84) scores. Individual letter, word, and number subtests were not as stable and should be used cautiously in interpretation of problems. Interrater reliability ranged from 0.63 to 0.94 for individual manuscript items and 0.64 to 0.97 for cursive. Overall, the total word reliability is more stable than task scores, ranging from 0.90 to 0.98.

Comment

The ETCH assesses functional writing skills that are relevant to academic performance. The varied tasks allow the examiner to identify areas of strength and weakness in written performance, including legibility components, speed, and composition models (visual, verbal, and memory). Information received from the ETCH is qualitative at this point because of the lack of normative samples. The author suggests that the ETCH be used in conjunction with observations of the child's writing activity in natural environments, such as classroom and home, as a determination of difficulties in functional written performance.

Test of Handwriting Skills (THS)¹¹⁹

Author

Morrison F. Gardner

Source

Psychological and Educational Publications, Inc., PO Box 520, Hydesville, CA, 95547

Ages

5 through 11 years; manuscript norms 5 to 8 years, cursive norms 9 to 11 years

Administration

Individual or group administration; 15 to 20 minutes

Equipment

THS manual, manuscript or cursive test booklet, No. 2 pencil, and stopwatch

Description

The purpose of the THS is to assess a child's neurosensory integration ability in handwriting, with focus on uppercase and lowercase letter formation as well as numbers. It is designed to assess strengths and weaknesses in the motoric aspects of handwriting, including legibility and speed. Varied aspects of written performance are assessed, including the following:

1. Spontaneously writing, from memory, uppercase and lowercase letters of the alphabet in sequence
2. Writing, from dictation, uppercase and lowercase letters of the alphabet out of alphabetical sequence
3. Writing, from dictation, numbers out of numerical order
4. Copying selected letters of the alphabet
5. Copying selected words
6. Copying selected sentences
7. Writing selected words from dictation

Scoring criteria are well delineated in the manual. Sample visual representations are given to illustrate the quality needed to

achieve each score and provide information on typical developmental performance and error types. Possible errors include overextended or underextended lines, broken lines, overlapping or reworked lines, parts missing, distortion of shape, or omitted dots or line crossings. Additional scoring looks at the speed of performance as well as reversed letters, case substitutions, and touching letters.

Construction and Reliability

The THS was standardized with children from various parts of the United States. Approximately equal numbers of boys and girls were tested, with representation for both right and left handedness. The manuscript version was administered to 494 children with a median age of 6 years, 11 months; 406 were right handed and 61 were left handed. The cursive version was administered to 345 children with a median age of 9 years, 8 months; 309 were right handed and 36 were left handed. Norms were derived for each of the 10 subtests as well as the additional scores. Cronbach's alpha was used to calculate the internal consistency of the test at each age level. These reliability coefficients ranged from 0.51 to 0.78 for the manuscript version and 0.29 to 0.87 for the cursive version. Two items on each version had low reliabilities (writing eight numbers and copying 10 letters), probably a result of the small number of items in the subtest. Scores on the manuscript version correlated positively with scores on the TVMS-R, indicating that the handwriting skills being tested involve a visual-motor component.

Comment

This test was developed primarily as a means for various professionals to measure children's handwriting skills. The THS can be administered by OTs, teachers, psychologists, resource specialists, educational diagnosticians, learning specialists, and optometrists. While gathering pertinent information for test development, the author arranged two conferences with teachers from kindergarten to fifth grade and obtained information from various professionals throughout the United States. In designing this test he recognized that three main methods of handwriting were being taught (D'Nealian, Palmer, and Zaner-Bloser) and that children, in general, have better accuracy for copied letters and words versus dictation that involves holding symbols in memory.

This test is functional and relevant to academic performance. The varied tasks and additional scoring allow the clinician to identify areas of strength and weakness in written performance. This can provide the foundation for recommendations within the classroom and/or guide intervention.

The Print Tool¹²⁰

APPENDIX 14-A ■ A Summary of Standardized Motor Tests—cont'd

remediation plan forms to develop goals; and strategies for remediation

Description

The Print Tool is a formal printing assessment to use in evidence-based remediation programs. The Print Tool is used to evaluate handwriting skills, plan intervention, and measure progress in students experiencing handwriting difficulty. A student's ability to print dictated letters and numbers is assessed. Evaluation scores for each specific skill area assessed help identify the student's strengths and needs. The Print Tool provides general remediation suggestions and specific strategies to be carried out with the author's remedial Handwriting Without Tears curriculum. This tool can be used in all school and therapy settings and with all curricula. Eight handwriting components for capitals, lowercase letters, and numbers are considered:

1. Memory: remembering and writing dictated letters and numbers
2. Orientation: Facing letters and numbers in the correct direction
3. Placement: Putting letters and numbers on the baseline
4. Size: How big or small a child chooses to write
5. Start: Where each letter or number begins
6. Sequence: Order and stroke direction of the letter or number parts
7. Control: Neatness and proportion of letters and numbers
8. Spacing: Amount of space between letters in words and between words in sentences

Construction and Reliability

The Print Tool has been recently released. Standardization has not been completed; however, suggested age-related expectations are provided in the manual. Data collection is in process for standardization in the future.

Continuing education is recommended to understand the complete process of observing, scoring, and compiling a remediation plan with The Print Tool. A Level 1 Certification is offered by the Handwriting Without Tears organization. Both the assessment and the award-winning Handwriting Without Tears curriculum were developed based on the authors' many years of successful practice in evaluating and remediating handwriting problems. The Handwriting Without Tears program is a structured remedial program geared toward different age and skill levels. It is multisensory, developmentally based, and easy to implement. Support is provided via the Handwriting Without Tears website.

CHAPTER 15 Spina Bifida: A Congenital Spinal Cord Injury

KRISTIN J. KROSSCHELL, PT, MA, PCS, and MARI JO PESAVENTO, PT, PCS

KEY TERMS

Chiari malformation
crouch-control ankle-foot orthosis
diastematomyelia
hydrocephalus
lipomeningocele
myelodysplasia
myelomeningocele
reciprocating gait orthosis
sacral agenesis
spina bifida cystica
spina bifida occulta
standing A-frame
tethered spinal cord

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Identify the various types of spina bifida.
2. Recognize the incidence and etiology of spina bifida.
3. Identify the clinical manifestations of myelomeningocele, including neurological, orthopedic, and urological sequelae.
4. Comprehend medical management in the newborn period and beyond.
5. Determine physical and occupational therapy evaluations, including manual muscle testing, range of motion, sensory testing, reflex testing, developmental and functional and mobility assessments, and perceptual and cognitive evaluations.
6. List the major physical and occupational therapy goals and appropriate therapeutic management for each of the following stages: (a) before surgical closure of sac, (b) after surgery during hospitalization, (c) preambulatory, (d) toddler through preschool age, (e) primary school age through adolescence, and (f) transition to adulthood.
7. Identify psychological adjustment to congenital spinal cord injury.

A spinal cord injury is a complex disability. When a spinal cord lesion exists from birth, additional complexity is added. This congenital condition predisposes many areas of the central nervous system (CNS) to not develop or function adequately. In addition, all areas of development (physical, cognitive, and psychosocial) that depend heavily on central functioning will likely be impaired. The clinician therefore must be aware of the significant impact this neurological defect has on motor function as well as a variety of related human capacities.

A developmental framework, the *Guide to Physical Therapist Practice*,¹ and the International Classification of Functioning, Disability and Health (ICF) have been used to aid in understanding the sequential problems of the child with spina bifida. The developmental model, however, must always stay in line with the functional model for adult trauma because the problems of the congenitally involved child grow quickly into limitations in functional activities and participation in life of the injured adult. With concentration on the present but with an eye to the future, appropriate management goals can be achieved.

OVERVIEW OF CONGENITAL SPINAL CORD INJURY

A congenital spinal cord lesion occurs in utero and is present at the time of birth. Understanding how this malformation develops requires an appreciation of normal nervous system maturation. The nervous system develops from a portion of embryonic ectoderm called the *neural plate*. During gestation, the neural plate develops folds that begin to close, forming the neural tube (Figure 15-1). The neural tube differentiates into the CNS, which is composed of

brain and spinal cord tissue. In the normal embryo, neural tube closure begins in the cervical region and proceeds cranially and caudally. Closure is generally complete by the twenty-sixth day.

Types of Spina Bifida

Spina bifida involves a defect in the neural tube closure and the overlying posterior vertebral arches. The extent of the defect may result in one of two types of spina bifida: occulta or cystica. Spina bifida occulta is characterized by a failure of one or more of the vertebral arches to meet and fuse in the third month of development. The spinal cord and meninges are unharmed and remain within the vertebral canal (Figure 15-2, A). The bony defect is covered with skin that may be marked by a dimple, pigmentation, or patch of hair.² The common site for this defect is the lumbosacral area, and it is usually associated with no disturbance of neurological or musculoskeletal functioning. Spina bifida cystica results when the neural and overlying vertebral arches fail to close appropriately. Cystic protrusion of the meninges or the spinal cord and meninges is present through the defective vertebral arches.

The milder form of spina bifida cystica, called *meningocele*, involves protrusion of the meninges and cerebrospinal fluid (CSF) only into the cystic sac (see Figure 15-2, B). The spinal cord remains within the vertebral canal, but it may exhibit abnormalities.³ Clinical signs vary (according to spinal cord anomalies) or may not be apparent. This is a relatively uncommon form of spina bifida cystica.

A more severe form of spina bifida cystica, called *myelocele* or *myelocystocele*, is present when the central canal of the spinal cord is dilated, producing a large, skin-covered

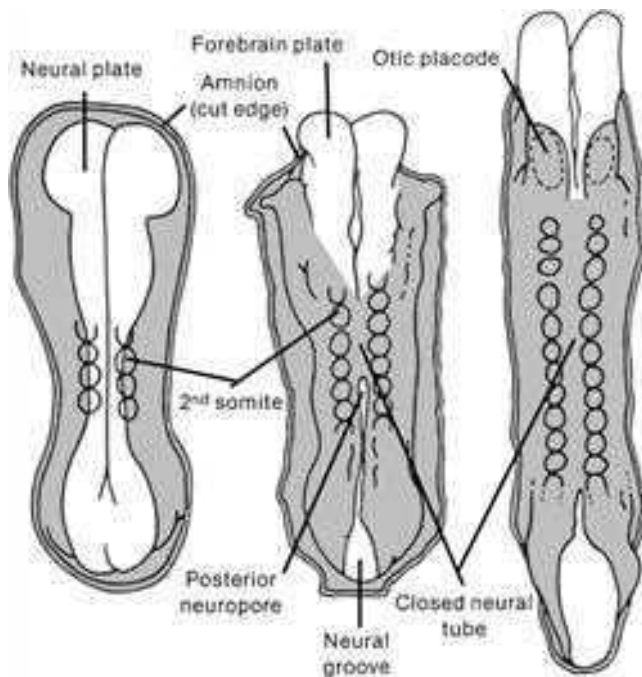

Figure 15-1 ■ Neural tube forming. (From Stark GD: *Spina bifida: problems and management*, London, 1977, Blackwell Scientific.)

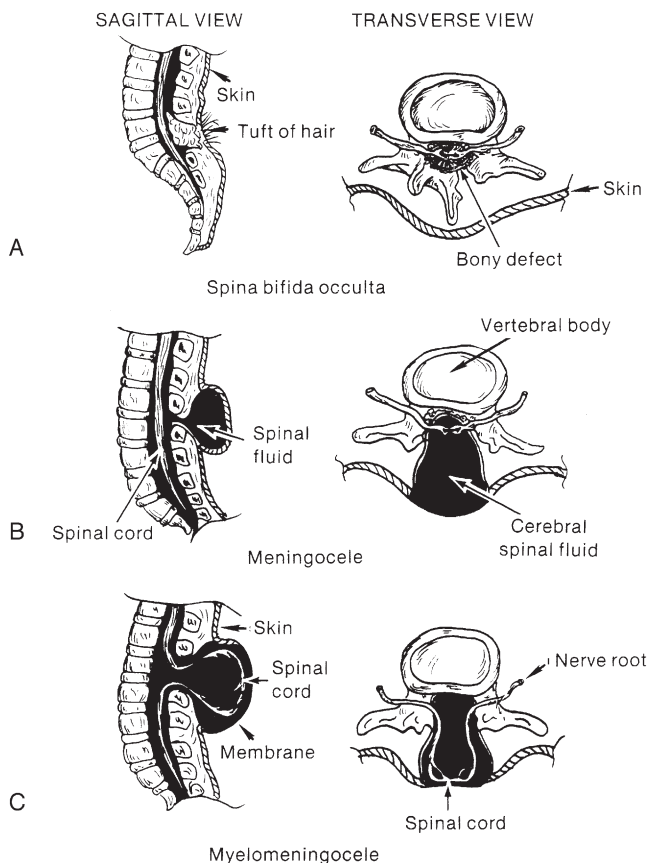

Figure 15-2 ■ Types of spina bifida. A, Spina bifida occulta. B, Meningocele. C, Myelomeningocele. (From McLone DG: *An introduction to spina bifida*, Chicago, 1980, Northwestern University.)

cyst. The neural tube appears to close normally but is distended from the cystic swelling. The CSF may ceaselessly expand the neural canal. Prompt medical attention is mandatory. This form of spina bifida is also rare.⁴

The more common and severe form of the defect is known as *myelomeningocele*, in which both spinal cord and meninges are contained in the cystic sac (see Figure 15-2, C). Within the sac the spinal cord and associated neural tissue show extensive abnormalities. In incomplete closure of the neural tube (dysraphism), abnormal growth of the cord and a tortuous pathway of neural elements make normal transmission of nervous impulses abnormal. The result is a variable sensory and motor impairment at the level of the lesion and below.² In an open myelomeningocele, nerve roots and spinal cord may be exposed, with dura and skin evident at the margin of the lesion. Exposure of the open neural tube to the amniotic fluid environment leads to neuroepithelial degeneration, with massive loss of neural tissue by the end of pregnancy.⁵

Although spina bifida cystica can occur at any level of the spinal cord, myelomeningoceles are most common in the thoracic and lumbosacral regions. Myelomeningocele occurs in 94% of the cases of spina bifida cystica, and two thirds of open lesions involve the thoracolumbar junction.² The terms *spina bifida*, *myelodysplasia*, and *myelomeningocele* are frequently used interchangeably.

Other forms of spinal dysraphism include diastematomyelia, lipomeningocele, and sacral agenesis. Diastematomyelia is present in 30% to 40% of patients with myelomeningocele and is secondary to partial or complete clefting of the spinal cord.⁶ Lipomeningocele, another form of spina bifida cystica, is usually caused by a vertebral defect associated with a superficial fatty mass (lipoma or fatty tumor) that merges with the lower level of the spinal cord. No associated hydrocephalus is present, and neurological deficit is generally minimal; however, problems with urinary control and motor control of the lower extremities may be noted.⁷ Neurological tissue invasion may be caused by a tethered spinal cord; therefore early lipoma resection is indicated for cosmesis and to minimize neurological sequelae. Lumbosacral or sacral agenesis may occur and is caused by an absence of the caudal part of the spine and sacrum. Children with this form of dysraphism may have narrow, flattened buttocks, weak gluteal muscles, and a shortened intergluteal cleft. The normal lumbar lordosis is absent, although the lower lumbar spine may be prominent. Calf muscles may be atrophic or absent. The pelvic ring is completed with either direct opposition of the iliac bones or with interposition of the lumbar spine replacing the absent sacrum. These children may have scoliosis, motor and sensory loss, and visceral abnormalities including anal atresia, fused kidneys, and congenital heart malformations. Management is started early and is symptomatic for each system.⁸

Failure of fusion of the cranial end of the neural tube results in a condition known as *anencephaly*. In this condition some brain tissue may be evident, but forebrain development is usually absent.⁹ Sustained life is not possible with this neural tube defect; therefore this condition is not discussed further.

Incidence, Etiology, and Economic Impact

Statistics about the incidence of spina bifida vary considerably in different parts of the world. Spina bifida and anencephaly, the most common forms of neural tube defects,

affect about 300,000 newborns each year worldwide.¹⁰ In the United States the incidence is currently 2.48 per 10,000, down from approximately 7.23 per 10,000 births from 1974 through 1979 (before the folic acid mandate).^{11,12} Current worldwide folic acid fortification programs have resulted in decreased incidence of spina bifida,^{13,14} with annual decreases of 6600 folic acid–preventable spina bifida and anencephaly births reported since 2006.¹⁵ There was a 31% decline in spina bifida prevalence rates in the immediate postfortification period (October 1998 through December 1999).¹³ There was a continued decline in spina bifida prevalence rates from 1999 to 2004 of 10%.¹⁶ Studies have also demonstrated that decline varied by ethnicity and race from prefortification to optional fortification to mandatory fortification in the United States.^{16,17} Initially after fortification, the largest decline in prevalence was noted in Hispanic and non-Hispanic white races or ethnicities. Despite this initial decline, postfortification prevalence rates remain highest in infants born to Hispanic mothers, and less in infants born to non-Hispanic white and non-Hispanic black mothers.¹⁶ In addition to periconceptual folate supplementation, it is thought that incidence has decreased subsequent to food fortification in several countries, decreased exposure to environmental teratogens, and increased and more accurate prenatal screening for fetal anomalies.¹⁰

Spina bifida is thought to be more common in females than in males, although some studies suggest no real sex difference.³ A study of the association of race and sex with different neurological levels of myelomeningocele found the proportions of whites and females to be significantly higher in patients with thoracic-level spina bifida.⁴ A significant relation also has been noted between social class and spina bifida: the lower the social class, the higher the incidence.^{18,19}

A multifactorial genetic inheritance has been proposed as the cause of spina bifida, coupled with environmental factors, of which nutrition, including folic acid intake, are key. Cytoplasmic factors, polygenic or oligogenic inheritance, chromosomal aberrations, and environmental influences (e.g., teratogens) have all been considered as possible causes.^{5,15} Genetic factors seem to influence the occurrence of spina bifida. The chances of having a second affected child are between 1% and 2%, whereas in the general population the percentage drops to one fifth of 1%.^{20,21} Although these factors are related to the incidence of spina bifida, the cause of this defect remains in question. Environmental conditions, such as hyperthermia in the first weeks of pregnancy, or dietary factors, such as eating canned meats or potatoes or drinking tea, have been implicated but not substantiated.^{22,23} In addition, historically, nutritional deficiencies, such as of folic acid and vitamin A, have been implicated as a cause of primary neural tube defects.²⁴⁻²⁷ Approximately 50% to 70% of neural tube defects can be prevented if a woman of childbearing age consumes sufficient folic acid daily before conception and throughout the first trimester of pregnancy. As a result of research findings in support of folic acid implementation, the U.S. Public Health Service has mandated folic acid fortification since 1998 as a public health strategy. Prenatal vitamins, especially folic acid, are recommended to discourage the condition's development. Current fortification programs are preventing about 22,000 cases, or 9% of the estimated folic

acid–preventable spina bifida and anencephaly cases.¹⁵ Genetic considerations, such as an Rh blood type, a specific gene type (HLA-B27), an X-linked gene, and variations in the many folate pathway genes have been implicated, but not conclusively.^{28,29} Malformations are attributed to abnormal interaction of several regulating and modifying genes in early fetal development.³⁰ Disturbance of any of the sequential events of embryonic neurulation produces neural tube defects (NTDs), with the phenotype (i.e., spina bifida, anencephaly) varying depending on the region of the neural tube that remains exposed.⁵ Environmental factors combined with genetic predisposition appear to trigger the development of spina bifida, although definitive evidence is not available to support this claim.³¹

The incidence of spina bifida has declined since the advent of amniocentesis and the use of ultrasonography for prenatal screening. The presence of significant levels of alpha fetoprotein in the amniotic fluid has led to the detection of large numbers of affected fetuses.³² Currently, maternal serum alpha-fetoprotein levels have been effective in detecting approximately 80% of neural tube defects.³³ Prenatal screening can be most effective when a combination of serum levels, amniocentesis or amniography, and ultrasonography is used.³⁴⁻³⁶ Although this screening is not yet performed routinely, it is suggested for those at risk for the defect. Knowledge of the defect allows for preparation for cesarean birth and immediate postnatal care. This includes mobilization of the interdisciplinary team that will continue to care for the child. For parents who decide to carry an involved fetus to term, adjustment to their child's disability can begin before birth, which includes mobilizing their own support system. Education from an integrated team regarding what will follow after delivery and neurosurgical closure is imperative to aid families in decision making and to allow families to assess and understand the child's disability and future care options.

Other advances in the field of prenatal medicine that affect spina bifida management and outcome include in utero treatment of hydrocephalus and in utero surgical repair to close the myelomeningocele. This challenging surgical procedure is practiced in only a few specialty centers and so far has been shown to offer palliation of the defect at best.³⁷ Treatment such as this, in conjunction with prenatal diagnosis, has been shown to have a positive impact on the incidence and severity of complications associated with spina bifida.³⁸⁻⁴⁵ Limitations of current postnatal treatment strategies and considerations of prenatal treatment options continue to be explored. Ethics, timing of repair, and surgical procedures are all being investigated. In addition, continued assessment of outcomes from those who have undergone presurgical management requires continued exploration. The Management of Myelomeningocele Study (MOMS) was initiated in 2003 as a large randomized, clinical trial designed to compare the two approaches to the treatment of infants with spina bifida (prenatal or fetal surgery versus postnatal surgery) to determine if one approach was better than the other. The primary end point of this trial was the need for a shunt at one year, and secondary end points included neurologic function, cognitive outcome, and maternal morbidity after prenatal repair. This study had 112 patients enrolled in 2007 with a projected enrollment of 200.⁴⁶⁻⁴⁹ The trial was stopped for efficacy of prenatal

surgery after enrollment of just 183 infants. Results demonstrated that prenatal surgery significantly reduced the need for shunting and improved mental and motor function at 30 months. Reduced incidence of hindbrain herniation at 12 months and successful ambulation by 30 months were also reported. While prenatal surgery was associated with improved function and reduced need for shunting, maternal and fetal risks, including preterm delivery and uterine dehiscence at delivery were reported.^{49a}

In 1996 the lifetime cost to society per affected person with spina bifida was estimated to be \$635,000.^{50,51} More recent estimates have not been reported; however, with an economy in flux it is likely that this value underestimates costs to society today. In addition to medical management costs per child, there are additional costs that affect both the family and society across the life span that are variable and often related to differential market forces and social welfare policies.⁵⁰

In 2007, Ouyang⁵² reported that average medical expenditures during the first year of life for those with spina bifida during 2002 and 2003 averaged \$50,000 (using MarketScan 2003 database). The majority of expenditures during infancy were from inpatient admissions secondary to surgeries being concentrated during this time period for those with spina bifida. After infancy, average medical care expenditures during 2003 ranged from \$15,000 to \$16,000 per year among different age groups of persons with spina bifida. Incremental expenditures associated with medical care were not stable, but decreased with increasing age, from \$14,000 per year for children to \$10,000 per year for adults 45 to 64 years of age.⁵²

Clinical Manifestations

The most obvious clinical manifestation of myelomeningocele is the loss of sensory and motor functions in the lower limbs. The extent of loss, while primarily dependent on the degree of the spinal cord abnormality, is secondarily dependent on a number of factors. These include the amount of traction or stretch resulting from the abnormally tethered spinal cord, the trauma to exposed neural tissue during delivery, and postnatal damage resulting from drying or infection of the neural plate.² Specific clinical impairments that commonly lead to functional limitations for the child with spina bifida are addressed in this section.

Sensory Impairment

Children with spina bifida have impaired sensation below the level of the lesion. The loss often does not match exactly the level of the lesion and needs to be carefully assessed. Sensory loss includes kinesthetic, proprioceptive, and somatosensory information. Because of this, children will often have to rely heavily on vision and other sensory systems to substitute for this loss.

Musculoskeletal Impairment

Weakness and Paralysis. Determining neurological involvement is not as straightforward as assumed. At birth, two main types of motor dysfunction in the lower extremities have been identified. The first type involves a complete loss of function below the level of the lesion, resulting in a flaccid paralysis, loss of sensation, and absent reflexes. The extent of involvement can be determined by comparing the

level of the lesion with a chart delineating the segmental innervation of the lower limb muscles. Orthopedic deformities may result from the unopposed action of muscles above the level of the lesion. This unopposed pull commonly leads to hip flexion, knee extension, and ankle dorsiflexion contractures.

When the spinal cord remains intact below the level of the lesion, the effect is an area of flaccid paralysis immediately below the lesion and possible hyperactive spinal reflexes distal to that area. This condition is quite similar to the neurological state of the severed cord seen in traumatic injury. This second type of neurological involvement again results in orthopedic deformities, depending on the level of the lesion, the spasticity present, and the muscle groups involved.

Orthopedic Deformities. The orthopedic problems that occur with myelomeningocele may be the result of (1) the imbalance between muscle groups; (2) the effects of stress, posture, and gravity; and (3) associated congenital malformations. Decreased sensation and neurological complications also may lead to orthopedic abnormalities.⁵³

Besides the obvious malformation of vertebrae at the site of the lesion, hemivertebrae and deformities of other vertebral bodies and their corresponding ribs also may be present.^{53,54} Lumbar kyphosis may be present as a result of the original deformity. In addition, as a result of the bifid vertebral bodies, the misaligned pull of the extensor muscles surrounding the deformity, as well as the unopposed flexor muscles, contributes further to the lumbar kyphosis. As the child grows, the weight of the trunk in the upright position also may be a contributing factor.⁵⁴ Scoliosis may be present at birth because of vertebral abnormalities or may become evident as the child grows older. The incidence of scoliosis is lower in low lumbar or sacral level deformities.^{54,55} Scoliosis may also be neurogenic, secondary to weakness or asymmetrical spasticity of paraspinal muscles, tethered cord syndrome (TCS), or hydromyelia.⁵⁵ Lordosis or lordoscoliosis is often found in the adolescent and is usually associated with hip flexion deformities and a large spinal defect.^{3,54} Many of these trunk and postural deformities exist at birth but are exacerbated by the effects of gravity as the child grows. They can compromise vital functions (cardiac and respiratory) and therefore should be closely monitored by the therapist and the family.

As has been alluded to previously, the type and extent of deformity in the lower extremities depend on the muscles that are active or inactive. In total flaccid paralysis, in utero deformities may be present at birth, resulting from passive positioning within the womb. Equinovarus (clubfoot) and “rocker-bottom” deformity are two of the most common foot abnormalities. Knee flexion and extension contractures also may be present at birth. Other common deformities are hip flexion, adduction, and internal rotation, usually leading to a subluxed or dislocated hip. Although many of these problems may be present at birth, preventing positional deformity (such as the frog-leg position), which may result from improper positioning of flaccid extremities, is of the utmost importance. Orthopedic care varies throughout the course of the child’s life. Changes in clinical orthopedic management have evolved to establish evidence-based interventions.⁵⁶

Osteoporosis. Because the paralyzed limbs of the child with spina bifida have increased amounts of unmineralized osteoid tissue, they are prone to fractures, particularly after

periods of immobilization.^{57,58} Early mobilization and weight bearing can aid in decreasing osteoporosis.^{54,59} Fortunately, these fractures heal quickly with appropriate medical management.

Neurological Impairment

Hydrocephalus. Hydrocephalus develops in 80% to 90% of children with myelomeningocele.^{21,60} Hydrocephalus results from a blockage of the normal flow of CSF between the ventricles and spinal canal. The most obvious effect of the buildup of CSF is abnormal increase in head size, which may be present at birth because of the great compliance of the cranial sutures in the fetus, or it may develop postnatally.⁶¹ Other signs of hydrocephalus include bulging fontanels and irritability. Internally, a concomitant dilation of the lateral ventricles and thinning of the cerebral white matter are usually present. Without reduction of the buildup of CSF, increased brain damage and death may result.

Chiari Malformation. Patients with myelomeningocele have a 99% chance of having an associated Chiari II malformation.⁶ Cardinal features of the Chiari II malformation include myelomeningocele in the thoracolumbar spine, venting of the intracranial CSF through the central canal, hypoplasia of the posterior fossa, herniation of the hindbrain into the cervical spinal canal, and compressive damage to cranial nerves. This malformation is a congenital anomaly of the hindbrain that involves herniation of the medulla and at times the pons, fourth ventricle, and inferior aspect of the cerebellum into the upper cervical canal. The herniation usually occurs between C1 and C4 but may extend down to T1.^{6,62,63} In those with Chiari II malformations and spina bifida there is a significant reduction in cerebellar volume, and within the cerebellum the anterior lobe is enlarged and the posterior lobe is reduced.⁶⁴ Not all Chiari II malformations are symptomatic. As a result of a symptomatic Chiari malformation, problems with respiratory and bulbar function may be evident in the child with spina bifida.² Paralysis of the vocal cords occurs in a small percentage of patients and is associated with respiratory stridor. Apneic episodes also may be evident, although their direct cause remains in question. Children with spina bifida also may exhibit difficulty in swallowing and have an abnormal gag reflex.² Problems with aspiration, weakness and cry, and upper-extremity weakness also may be present in children with a symptomatic Chiari II malformation.^{65,66} Thus, depending on the orthopedic deformities present and the neurological involvement, severe respiratory involvement is possible in the affected child. These symptoms may be caused by significant compression of the hindbrain structures or dysplasia of posterior fossa contents, which can also occur in patients with Chiari II malformation.^{6,67} This complex hindbrain malformation is a common cause of death in children with myelomeningocele despite surgical intervention and aggressive medical management.⁶⁸

Association Pathways. Diffusion tensor tractography studies of association pathways in children with spina bifida have revealed characteristics of abnormal development, impairment in myelination, and abnormalities in intrinsic axonal characteristics and extraaxonal or extracellular space. These changes in diffusion metrics observed in children with spina bifida are suggestive of abnormal white matter development and persistent degeneration with increased age.⁶⁹

Hydromyelia. Twenty percent to 80% of patients with myelomeningocele have hydromyelia.^{6,70,71} Hydromyelia signifies dilation of the center canal of the spinal cord as hydrocephalus signifies dilation of the ventricles of the brain. The area of hydromyelia may be focal, multiple, or diffuse, extending throughout the spinal cord. The hydromyelia may be a consequence of untreated or inadequately treated hydrocephalus with resultant transmission of CSF through the obex into the central canal, with distention a result of increased hydrostatic pressure from above.⁶ The increased collection of fluid may cause pressure necrosis of the spinal cord, leading to muscle weakness and scoliosis. Common symptoms of hydromyelia include rapidly progressive scoliosis, upper-extremity weakness, spasticity, and ascending motor loss in the lower extremities.^{6,72} Aggressive treatment of hydromyelia at the onset of clinical signs of increasing scoliosis is mandatory and may lead to improvement in or stabilization of the curve in 80% of cases. Surgical interventions may include revision of a CSF shunt, posterior cervical decompression, or a central canal to pleural cavity shunt with a flushing device.^{6,67}

Tethered Cord. *Tethered spinal cord* is defined as a pathological fixation of the spinal cord in an abnormal caudal location (Figure 15-3). This fixation produces mechanical stretch, distortion, and ischemia with daily activities, growth, and development.⁷³ Ischemic injury from traction of the conus directly correlates with degree of oxidative metabolism and degree of neurologic compromise. In addition to ischemic injury, traction of the conus by the filum may also mechanically alter the neuronal membranes, resulting in altered electrical activity.⁷⁴⁻⁷⁸ The presence of tethered cord syndrome (TCS) should be suspected in any patient with abnormal neurulation (including patients with myelomeningocele, lipomeningocele, dermal sinus, diastematomyelia, myelocystocele, tight filum terminale, and lumbosacral agenesis). Presenting symptoms may include decreased strength (often asymmetrical), development of lower-extremity spasticity, back pain at the site of sac closure, early development of or increasing degree of scoliosis (especially in the low lumbar or sacral level),^{79,80} or change in urological function.^{68,81-83} Approximately 10% to 30% of children will develop TCS after repair of a myelomeningocele. Because essentially all children with repaired myelomeningocele will have a tethered spinal cord, as demonstrated on magnetic resonance imaging (MRI), the

Figure 15-3 ■ Tethered cord in myelodysplasia. (From Staheli LT: *Practice of pediatric orthopedics*, Philadelphia, 2001, Lippincott Williams & Wilkins.)

diagnosis of TCS is made based on clinical criteria. The six common clinical presentations of TCS are increased weakness (55%), worsening gait (54%), scoliosis (51%), pain (32%), orthopedic deformity (11%), and urological dysfunction (6%).⁸⁴ This clinical spectrum may be primarily associated with these dysraphic lesions or may be caused by spinal surgical procedures.⁷³ The cord may be tethered by scar tissue or by an inclusion epidermoid or lipoma at the repair site.⁶ The primary goal of surgery is to detach the spinal cord where it is adherent to the thecal sac, relieving the stretch on the terminal portion of the cord. Surgery to untether the spinal cord (tethered cord release [TCR]) is performed to prevent further loss of muscle function, decrease the spasticity, help control the scoliosis,^{80,85} or relieve back pain.^{86,87}

The effectiveness of a TCR may be demonstrated by an increase in muscle function, relief of back pain, and stabilization or reversal of scoliosis.^{80,85,87} It has been reported that scoliosis response to untethering and progression of scoliosis after untethering vary with location of tethering^{80,87} as well as Risser grade⁸⁸ and Cobb angle.⁸⁹ Those with Risser grade 3 to 5 and Cobb angle less than 40 degrees are less likely to experience curve progression after untethering. Those with Risser grades 0 to 2 and Cobb angle greater than 40 degrees are at higher risk of recurrence.^{74,89} Spasticity, however, is not always alleviated in all patients.⁹⁰ Selective posterior rhizotomy has been advocated for patients whose persistent or progressive spastic status after tethered cord repair continues to interfere with their mobility and functional independence.^{68,70}

Bowel and Bladder Dysfunction. Because of the usual involvement of the sacral plexus, the child with spina bifida commonly deals with some form of bowel and bladder dysfunction. Besides various forms of incontinence, incomplete emptying of the bladder remains a constant concern because infection of the urinary tract and possible kidney damage may result.⁹¹ Regulation of bowel evacuation must be established so that neither constipation nor diarrhea occurs. Negative social aspects of incontinence can be minimized by instituting intervention that emphasizes patient and family education and a regular, consistently timed, reflex-triggered bowel evacuation.⁹²

Cognitive Impairment and Learning Issues. The last major clinical manifestation resulting from the neurological involvement of myelomeningocele is impaired intellectual function. Although children with spina bifida without hydrocephalus may have normal intellectual potential, children with hydrocephalus, particularly those who have shunt infections, are likely to have below-average intelligence.⁹³⁻⁹⁵ These children often demonstrate learning disabilities and poor academic achievement.⁹⁶ Even those with a normal IQ show moderate to severe visual-motor perceptual deficits.⁹⁷ The inability to coordinate eye and hand movements affects learning and may interfere with activities of daily living (ADLs), such as buttoning a shirt or opening a lunchbox.⁹⁸ Difficulties with spatial relations, body image, and development of hand dominance may also be evident.^{2,98} Children with myelomeningocele demonstrate poorer hand function than age-matched peers. This decreased hand function appears to be caused by cerebellar and cervical cord abnormalities rather than hydrocephalus or a cortical pathological condition (see Chapter 21).⁹⁹

Prenatal studies have shown that the CNS as a whole is abnormally developed in fetuses with myelomeningocele.¹⁰⁰⁻¹⁰³

The impairment of intellectual and perceptual abilities has been linked to damage to the white matter caused by ventricular enlargement.² This damage to association tracts, particularly in the frontal, occipital, and parietal areas, could account for the often severe perceptual-cognitive deficits noted in the child with spina bifida.^{69,104} Lesser involvement of the temporal areas may account for the preservation of speech, whereas the semantics of speech, which depends on association areas, is impaired. The “cocktail party speech” of children with spina bifida can be deceptive because they generally use well-constructed sentences and precocious vocabulary. A closer look, however, reveals a repetitive, inappropriate, and often meaningless use of language not associated with higher intellectual functioning. Research on learning difficulties in children with spina bifida and hydrocephalus suggests that many of these children experience difficulties. Tasks and skills affected include memory, reasoning, math, handwriting, organization, problem solving, attention, sensory integration, auditory processing, visual perception, and sequencing.¹⁰¹⁻¹⁰³

Integumentary Impairment

Latex allergy and sensitivity have been noted with increasing frequency in children with myelomeningocele, with frequent reports of intraoperative anaphylaxis.¹⁰⁵⁻¹⁰⁹ These children have also been reported to have a higher than expected prevalence of atopic disease.¹¹⁰ A 1991 Food and Drug Administration Medical Bulletin estimated that 18% to 40% of patients with spina bifida demonstrate latex sensitivity,^{105,111} with others reporting an incidence of 20% to 67%.^{112,113} Within latex is 2% to 3% of a residual-free protein material that is thought to be the antigenic agent.¹⁰⁷ Frequent exposure to this material results in the development of the immunoglobulin E antibody. Children with spina bifida are more likely to develop the immunoglobulin E sensitivity because of repeated parental or mucosal exposure to the latex antigen.¹¹⁴ Because of the risk of an anaphylactic reaction, exposure to any latex-containing products such as rubber gloves, therapy balls, pacifiers, spandex, dental dams, elastic or rubber bands, balloons, adhesive bandages, or exercise bands should be avoided. Latex-free gloves, therapy balls, treatment mats, and exercise bands are now widely available and should be considered for standard use in all clinics treating children with spina bifida. Spina bifida, even in the absence of multiple surgical interventions, may be an independent risk factor for latex sensitivity. Foods reported to be highly associated with latex allergy include avocado, banana, chestnut, and kiwi.¹¹⁵ Latex-free precautions from birth are more effective in preventing latex sensitization than are similar precautions instituted later in life.¹¹⁵⁻¹¹⁷ Latex sensitization decreased from 26.7% to 4.5% in children treated in a latex-free environment from birth.¹¹⁷

The presence of paralysis and lack of sensation on the skin places the child with spina bifida at major risk for pressure sores and decreased skin integrity. Various types of skin breakdown have occurred in 85% to 95% of all children with spina bifida by the time they reach young adulthood.¹¹⁸ Common areas at risk for pressure sores include the lower back, kyphotic or scoliotic prominences, heels, feet, toes, and perineum. A pressure sore may result from excessive skin pressure that can cause reduced capillary flow, tissue anoxia, and eventual skin necrosis. Excessive pressure may

manifest itself early as reactive hyperemia, a blister, and later as an open sore or overt necrosis. Chronic, untreated sores may lead to osteomyelitis and eventual sepsis.¹¹⁰ Pressure sores often result in loss of time from school and work and can lead to financial hardship from medical treatment and hospitalizations. These negative consequences can largely be prevented with attention to education and instruction of the child and family. The goal of such education is to foster an understanding of the causes of skin breakdown and the necessary meticulous attention to skin care that must be carried out on a regular basis.

Growth and Nutrition

Nutritional intake and weight gain and loss have been found to be problematic in children with myelomeningocele. Early on, infants with spina bifida may have feeding issues as a result of an impaired gag reflex, swallowing difficulties, and a high incidence of aspiration.^{2,66} Altered oral-motor function has been attributed to the Chiari II malformation.¹¹⁹ These impairments may lead to nutritional issues and delayed growth and weight gain. Speech, physical, and occupational therapists as a team are often needed to address these issues.

Conversely, obesity can be a significant issue for children with spina bifida. This problem is complex and multifactorial.¹²⁰ Mobility limitations and decreased energy expenditure result in lower physical activity levels. In addition, decreased lower limb mass diminishes the ability to burn calories, which leads to weight gain. Decreased caloric intake as well as a lifelong engagement in rewarding and physically challenging physical activities are both necessary to enhance weight control and control obesity.

Children with myelomeningocele are short in stature. Growth in these children may be influenced by growth-retarding factors as a result of a neurological deficit such as tethered cord.¹²¹ Endocrine disorders and growth hormone deficiency have also been found to contribute to short stature in this population.¹²² As a result of complex CNS anomalies (midline defects, hydrocephalus, Arnold-Chiari malformation), these children are at risk for hypothalamopituitary dysfunction leading to growth hormone deficiency.^{123,124} Treatment with recombinant human growth hormone has proven successful in fostering growth acceleration in these children.^{123,125,126}

Psychosocial Issues

Considering all the clinical manifestations resulting from this congenital neurological defect, social and emotional difficulties will arise for these children and their families. These will be considered as appropriate when discussing the stages of recovery and rehabilitation from birth through adolescence.

The preceding discussion concerning the clinical problems of the child with spina bifida is intended to inform, not overwhelm, the clinician. With a firm understanding of the difficulties to be faced, evaluation and intervention can be more efficient and effective.

Medical Management

At or before birth, the myelomeningocele sac presents a dynamic rather than a static disability. The residual neurological damage will be contingent on the early medical management that the fetus or newborn receives.

Neurosurgical Management

Since the early 1960s the presence of a myelomeningocele has been treated as a life-threatening situation, and sac closure most often takes place within the first 24 to 48 hours of life.^{2,127} Recent advances in treatment have led to investigational treatment in utero to repair the defect before birth.³⁸ The aim of either surgery is to replace the nervous tissue into the vertebral canal, cover the spinal defect, and achieve a watertight sac closure.¹²⁸ This early management has decreased the possibility of infection and further injury to the exposed neural cord.^{24,128,129}

Progressive hydrocephalus may be evident at birth in a small percentage of children born with myelomeningocele. A greater majority, however, have hydrocephalus 5 to 10 days after the back lesion has been closed.^{128,130-132} With the advent of computed tomography (CT), early diagnosis of hydrocephalus can be made in the newborn without the need for clinical examination.

Although clinical signs are not always definitive, hydrocephalus may be suspected if (1) the fontanels become full, bulging, or tense; (2) the head circumference increases rapidly; (3) a separation of the coronal and sagittal sutures is palpable; (4) the infant's eyes appear to look downward only, with the cornea prominent over the iris ("sunsetting sign"); and (5) the infant becomes irritable or lethargic and has a high-pitched cry, persistent vomiting, difficult feeding, or seizures (Table 15-1).^{21,61,133}

If the results of CT confirm hydrocephalus, a ventricular shunt is indicated. This procedure involves diverting the excess CSF from the ventricles to some site for absorption. In general, two types of procedures—the ventriculoatrial (VA) and ventriculoperitoneal (VP) shunt—are currently used, the latter being the most common (Figure 15-4). The shunt apparatus is constructed from Silastic tubing and consists of three parts: a proximal catheter, a distal catheter, and

TABLE 15-1 ■ SIGNS AND SYMPTOMS OF SHUNT MALFUNCTION

Infants	Bulging fontanel Swelling along the shunt tract Prominent veins on scalp Downward eye deviation ("sunsetting") Vomiting or change in appetite Irritability or drowsiness Seizures
Toddler	High-pitched cry Headache Vomiting or change in appetite Lethargy or irritability Swelling along the shunt tract Seizures
Older child	Onset of or increased strabismus All the above, plus: Deterioration in school performance Neck pain or pain over myelomeningocele site Personality change Decrease in sensory or motor functions Incontinence that begins or worsens Onset of or increased spasticity

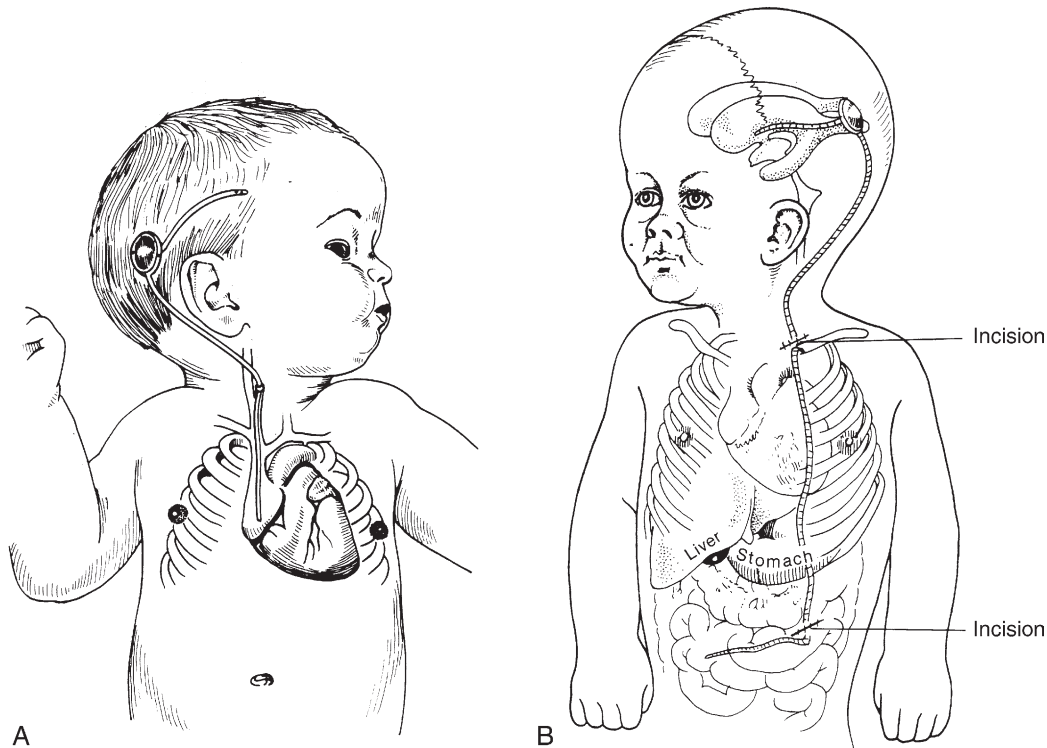

Figure 15-4 ■ A, Ventriculoatrial shunt. B, Ventriculoperitoneal shunt. (From Stark GD: *Spina bifida: problems and management*, London, 1977, Blackwell Scientific.)

a one-way valve. As CSF is pumped from the ventricles toward its final destination, backflow is prevented by the valve system. In this manner intracranial pressure is controlled, CSF is regulated, and hydrocephalus is prevented from causing damage to brain structures. An alternate means of controlling hydrocephalus may be the use of endoscopic third ventriculostomy (EVT). EVT is a procedure that, in selected patients with obstructive hydrocephalus, allows egress of CSF from the ventricles to the subarachnoid space. This can decompress the ventricles and allow normal intracranial pressures and brain growth. This procedure is typically reserved for last resort.¹³⁴

Unfortunately for children with spina bifida, their problems do not end after the back is surgically closed and a shunt is in place. Management strategies in the care of shunted hydrocephalus vary.¹³⁵ Shunt complications occur frequently and require an average of two revisions before age 10 years.⁶⁰ The most common causes of complications are shunt obstruction and infection.^{2,136} Revising the blocked end of the shunt can clear obstructions. Infections may be handled by external ventricular drainage and courses of antibiotic therapy followed by insertion of a new shunting system.² The problem of separation of shunt components has been largely overcome by the use of a one-piece shunting system. The single-piece shunt decreases the complications of shunting procedures.

Prophylactic antibiotic therapy 6 to 12 hours before surgery and 1 to 2 days postoperatively is effective in controlling infection for both sac repair and shunt insertion.⁷¹ This brief course of antibiotics has not led to resistant organisms. The main cause of death in children with myelomeningocele remains increased intracranial pressure

and infections of the CNS. With the use of antibiotics, shunting, and early sac closure, the survival rate has increased from 20% to 85%.^{61,94,137}

Urological Management

Initial newborn workup should include a urological assessment. The urology team aims to preserve renal function and promote efficient bladder management. An early start to therapy helps to preserve renal function for children with spina bifida.¹³⁸ Initially, a renal and bladder ultrasound is performed to assess those structures.¹⁰⁰ Urodynamic testing can be performed to determine any blockage in the lower urinary tract. Functioning of the bladder outlet and sphincters, as well as ureteric reflux, also can be evaluated. These tests, plus clinical observations of voiding patterns, help the urologist classify the infant's bladder function. If the bladder has neither sensory nor motor supply, a constant flow of urine is present. In this case infection is rare because the bladder does not store urine and the sphincters are always open.¹³⁹

If no sensation but some involuntary muscle control of the sphincter exists, the bladder will fill, but emptying will not occur properly. Overflow or stress incontinence results in dribbling urine until the pressure is relieved. Because of constant residual urine, infection is a potential problem and kidney damage may result.¹³⁹ When some voluntary muscle control but no sensation is present, the bladder will fill and empty automatically. The child can eventually be taught to empty the bladder at regular intervals to avoid unnecessary accidents.

Regardless of the type of bladder functioning, urine specimens are taken to check for infection, and blood

samples are taken to determine the kidney's ability to filter the body's fluids. On the basis of clinical findings, the urologist will suggest the appropriate intervention.

A program of clean intermittent catheterization (CIC) done every 3 to 4 hours prevents infection and maintains the urological system.¹⁴⁰⁻¹⁴³ Parents are taught this method and can then begin to take on this aspect of their child's care. At the age of 4 or 5 years, children with spina bifida can be taught CIC; thus they become independent in bladder care at a young age. Achieving this form of independence adds to the normal psychological development of these children. Some children may require urinary diversion through the abdominal wall (ileal conduit) or through the appendix (Mitrofanoff principle appendicovesicotomy)¹⁴⁴⁻¹⁴⁶ or other, less common methods, such as intravesical transurethral bladder stimulation, to handle their urinary condition.^{140,147} Although CIC is not possible for all children with spina bifida, it remains the method of choice for bladder management.

Bowel management and training programs should be started early. Medications, enemas, and attention to fiber content in the diet are all of value in establishing a bowel management program. The Malone antegrade continence enema (ACE) procedure is an important adjunct in the case of adults and children with problems of fecal elimination in whom standard medical therapies have failed.^{148,149}

Orthopedic Management

Orthopedic management of the newborn with a myelomeningocele will generally concentrate on the feet and hips. Soft tissue releases of the feet may take place during surgery for sac closure. Casting the feet (Figure 15-5) and performing early aggressive taping are also effective in the management of clubfoot deformities.^{150,151} Short-leg posterior splints (ankle-foot orthoses [AFOs]) may be used to maintain range and prevent foot deformities.

The orthopedist also will evaluate the stability of the hips. In children with lower-level lesions, attempts to prevent dislocation are made by using a hip abductor brace (Figure 15-6, A) or a total-body splint (Figure 15-6, B) for a few months after birth. With higher-level lesions, dislocated hips are no longer treated because they do not appear to have an effect on later rehabilitation efforts.^{133,152-154}

Orthopedic management needs to be ongoing throughout the child's lifetime, with continued assessment of orthopedic

Figure 15-5 ■ Plaster cast of the foot and ankle to reduce clubfoot deformities.

deformities and need for surgical intervention. Important management issues relevant to function that the physical therapist (PT) should be aware of may include hip dislocation, knee valgus stress, scoliosis, foot deformities, fractures, osteoporosis, and postoperative management.

Hip Dislocation. Hip dislocations may occur at any level of neurologic deficit.¹⁵⁵ The goal of treatment for those with hip dislocation should be maximum function, not radiographic realignment. The most important factor in determining ability to walk is the level of neural involvement and not the status of the hip.^{153,156-159} A level pelvis and good hip range of motion (ROM) are more important than hip relocation. In those with lower lumbar lesions and asymmetry caused by contracture, treatment will be directed at releasing the contracture and no attempts will be made to reduce the hip. Hip dislocations in those with sacral level lesions should be considered as lever-arm dysfunction, and surgical hip relocation is indicated.^{56,155,157,158} Immobilization after hip dislocation may lead to a frozen immobile joint from an open reduction procedure, redislocation from a lack of significant dynamic forces available for joint stability around the hip joint, and an increased fracture risk. Recently a questionnaire, the Spina Bifida Hips Questionnaire (SBHQ), to evaluate the ADLs that are important to children with spina bifida and dislocated hips and their families has been developed and has demonstrated construct validity as well as reliability.¹⁶⁰

Knee Valgus Stress. Many children with spina bifida who walk have excessive trunk and pelvic movement, knee flexion contractures, and rotational malalignment that may lead to excessive knee valgus stress. The most common deformities leading to this problem are rotational malalignment of the femur and femoral anteversion in association with excessive anterior tibial torsion. These deformities should be addressed via surgical correction as excessive knee valgus stress can lead to knee pain and arthritis in adult life.^{56,159,161,162} In addition, the PT may need to reassess the child's gait pattern and use of assistive aids and bracing to minimize stress and maintain long-term joint viability for those with spina bifida over the life span.

Scoliosis. The prevalence of scoliosis in spina bifida is estimated to be as high as 50%. Increasing scoliosis can lead to loss of trunk stability when curves are greater than 40 degrees and when associated pelvic obliquity becomes 25 degrees or more. Surgical intervention, often recommended to prevent further progression, may improve or further impair sitting balance, ambulation, and performance of ADLs.¹⁶³ Various authors have reported that although surgery can improve curves by up to 50%, surgical morbidity must be considered and complications may be as high as 40% to 50%. Functional benefits are largely unsubstantiated owing to poorly constructed studies.¹⁶⁴⁻¹⁶⁶ Wai¹⁶⁶ suggests that spinal deformity may not affect overall physical function or self-perception. After surgical correction it may take up to 18 months to appreciate functional improvement, and walking may be difficult for those who were just exercise ambulators before correction. Although surgical repair of scoliosis does improve quality of life in patients with cerebral palsy and muscular dystrophy, this has not been demonstrated in those with spina bifida.¹⁶⁷ Interventions such as chair modifications to shift the trunk to improve balance in the coronal plane and reduce pelvic obliquity and truncal

Figure 15-6 ■ A, Hip abductor brace. B, Total body splint.

asymmetry should be considered as a first option, before surgical correction.^{163,167}

Back Pain. Back pain needs to be efficaciously evaluated in those with spina bifida who report back pain. Knowing when the patient experiences pain, what increases pain, what positions exacerbate pain, and what region of the body is affected can help lead to appropriate referral, testing, and management. Knowing if your patient has a shunt, spinal rods, and/or a Chiari malformation will also be important to your assessment and management. Pain in the neck, shoulders, and upper back with associated weakness and/or abnormal sensory findings should be evaluated by the treating neurosurgeon to rule out shunt malfunction. Spinal rods that have broken or that are breaking through the skin may also be a source of pain in this area. Pain not caused by rods, a shunt, Chiari issues, or a syrinx may have a mechanical cause and could be a result of poor posture, tension, or weight gain. A patient who reports low back pain may have a symptomatic tethered cord if the patient is also reporting changes in gait, increased tripping or falling, bladder changes, and/or pain shooting down the legs. Manual muscle testing (MMT) and urodynamic testing (refer to Chapter 29) are appropriate at this point and should be compared with baseline testing findings. Mechanical low back pain may be a result of abnormal gait mechanics, asymmetrical strength, and use of older orthotics that no longer fit. Assessment of seating and support systems, including cushions, and gait mechanics and use of orthotics and ambulatory aids are mandatory to increase stability and redistribute balance

over stressed joints and to maximize reduction of the patient's pain and discomfort. Strengthening, particularly of the gluteal muscles, for those who are ambulatory may also be indicated. In addition, programs aimed at weight reduction may be necessary to alleviate stress and pain to preserve long-term viability of tissues. In addition, for women the chest may cause tension on the upper back, and breast reduction has been advocated for some to relieve this tension.¹⁶⁸⁻¹⁷⁰

Foot Deformity. The goal of treatment of the foot in spina bifida should be a flexible and supple foot. An insensate flail foot often becomes rigid over time, and foot management can become complicated by pressure sores. Up to 95% of patients will use an orthosis, and a supple flail foot will be easier to manage over time. Surgeries that are extraarticular with avoidance of arthrodesis, as well as simple tenotomies versus tendon releases and lengthenings, may best manage outcomes for bracing and ambulation.⁵⁶ Equinovarus deformities may be managed with early and intensive taping in the newborn period, known as the *French method*,^{171,172} stretching and casting, and surgical intervention. The Ponsetti method, advocated by some, also has been reported to have positive outcomes; however, the significant investment in time and commitment by the family for frequent cast changes may affect the ability to carry out other ADLs without disruption.¹⁵⁵ In those with lipomas, foot deformity that may be acquired over time is best managed in a similar manner. Maintaining a supple and plantigrade foot with adequate muscle balance with use of soft tissue

correction through tendon lengthening, tendon transfer, and plantar fascial release is recommended until 8 years of age. After that time, deformities may become more rigid and may necessitate more bony procedures.¹⁷³

Osteoporosis, Osteopenia, and Fracture. Osteoporosis (thinning of the bone) and osteopenia (low bone mineral density [BMD]) in the legs and spine have been described in children and teens with spina bifida. These conditions increase the risk of fracture, increase the time for healing after fracture, and may lead to back pain. A study by Valtonen and colleagues in 2006 documented the occurrence of osteoporosis in adults with spina bifida. This condition often is not recognized.¹⁷⁴ Medical factors such as physical inactivity, decreased vitamin D, diminished exposure to sunlight, urinary diversion, renal insufficiency, hypercalciuria, medication for epilepsy, and oral cortisone treatment for more than 3 months increase the risk of osteoporosis.^{59,175,176} It can be assumed that patients with meningocele are at potential risk to develop osteoporosis at a younger age because of impaired walking ability and subsequent low physical loading of the lower limbs. Older age and higher levels have been associated with increased numbers of fractures in spina bifida.¹⁷⁴ The optimal strategies for prevention and treatment of osteoporosis in this population have not been established. Further research is required to see if the methods used to prevent and treat osteoporosis in individuals without spina bifida also work for teens and adults who have spina bifida. Considering the effects of prolonged immobilization on independence in daily activities and quality of life, there should be no disagreement that all efforts are necessary to prevent these fractures. Furthermore, osteoporotic fracture may lead to a vicious cycle of immobilization, decreased bone density, and repeated fractures.¹⁷⁴ Annual incidence of fracture is 0.029% in adolescents and 0.018% in adults.¹⁷⁷ Studies have shown promising results of regular functional electric stimulation–assisted training, but this is often nearly impossible to carry out in daily life.¹⁷⁸ The effects of standing programs on bone density are unclear.^{179,180} The prevention of fractures should be among the major goals in the rehabilitation of people with meningocele. The assessment of BMD is worthwhile in patients with risk factors for osteoporosis, because low BMD is a known risk factor for fractures.¹⁷⁵

Postoperative Management. Care should be taken to avoid postoperative complications such as skin breakdown and postimmobilization fractures in the postoperative period. To decrease the risk of nonunion and allow for early mobilization and weight bearing, one should consider rigid internal fixation versus Kirschner wire fixation. After surgery, immobilization in a custom-molded body splint rather than a hip spica cast is preferred. Postoperative physical therapy should begin as soon as wounds are stable and healing is occurring. Therapy should focus on ROM (active and passive) and early weight bearing. Crawling should be strictly forbidden for a minimum of 3 to 4 weeks postimmobilization to reduce the risk of fracture.¹⁵⁹

EVALUATIONS

In attempting to evaluate the child with spina bifida, a number of evaluations can be chosen, each designed to test specific yet perhaps unrelated components of function. The following section discusses those test procedures or specific standardized tests that would best define the complexity of the problem.

Manual Muscle Testing

The first and most obvious request for evaluation may be to determine the extent of motor paralysis. In the newborn, testing may be done in the first 24 to 48 hours before the back is surgically closed. In this case, care must be taken not to injure the exposed neural tissue during testing. Prone and side lying to either side are the most convenient and safe positions for evaluation during this time. Subsequent testing is done soon after the back has been closed and as indicated throughout childhood. The traditional form of MMT is not appropriate or possible for the infant or young child. Following is a discussion of how muscle testing can and must be adapted for this age group.

In evaluating the newborn, the importance of alertness is paramount. A sleeping or drowsy infant will not respond appropriately during the evaluation. The infant must be in the alert or crying state to elicit the appropriate movement responses. Testing hungry or crying infants provides an advantage because they are likely to demonstrate more spontaneous movements in these behavioral states.

The cumulative effect of a variety of sensory stimuli may be more effective in bringing the infant to alertness than using one stimulus in isolation. For example, the infant may be picked up and rocked vertically to allow maximum stimulation to the vestibular system and to help bring the child to an alert state. In addition, the therapist may talk to the child to help him or her fixate visually on the therapist's face. Tactile stimuli above the level of the lesion further add to the child's level of arousal, thus contributing to more conclusive test results. In this way the CNS receives an accumulation of information from a variety of sensory systems rather than relying on transmission from one system that may be weak or inefficient.

As the child is aroused, spontaneous movements can be observed and muscle groups palpated. Additional methods to stimulate movement may be necessary. For example, tickling the infant generally produces a variety of spontaneous movements in the upper and lower extremities. Passive positioning of children in adverse positions may stimulate them to move. For example, if the legs are held in marked hip and knee flexion, the infant may attempt to use extensor musculature to move out of that position. If the legs are held in adduction, the child may abduct to get free. Holding a limb in an antigravity position may elicit an automatic "holding" response from a muscle group when spontaneous movements cannot be obtained in any other way.

In grading muscle strength, differentiation between spontaneous, voluntary movement and reflexive movement is important. After severing of a spinal cord, distal segments of the cord may respond to stimuli in a reflexive manner. This results from the preservation of the spinal reflex arc and is known as *distal sparing*. If distal sparing of the spinal cord is present, the muscles may respond to stimulation or muscular stretch with reflexive, stereotypical movement patterns. The quality of this reflexive movement will be different from that of spontaneous movement and must be distinguished when testing for level of voluntary muscle functioning.

Muscle strength is generally graded for groups of muscles and can be graded by using either a numerical (1 to 5) or an alphabetical designation (Figure 15-7) or simply by noting presence or absence of muscular contraction by a

plus or a minus on the muscle test form. The last method may be sufficient initially, but as the child matures a more definitive muscle grade should be determined.

By use of a MMT form that lists the spinal segmental level for each muscle group, an approximate level of lesion can be determined from the test results (see Figure 15-7). Because the spinal cord is often damaged asymmetrically, MMT does not always accurately reflect the level of the lesion. If reflex activity is also noted on the form, the presence of distal sparing of the spinal cord can be determined. Muscle testing of the newborn gives the clinician an appreciation of muscle function and possible potential for later ambulation as well as an awareness of possible deforming forces. For example, if hip extensors or abductors are not functioning, then the action of hip flexors and adductors must be countered to prevent future deformities.

Muscle testing of the toddler or young child may require some of the techniques previously described. In addition, developmental positions can be used to assess muscle strength in an uncooperative youngster. For example, strength of hip extensors and abductors can be assessed as a child attempts to creep up steps or onto a low mat table. With addition of resistance to movements, fairly accurate muscle grades can be determined. To elicit hip flexor action in sitting, if an interesting toy or object is placed on the child's ankle or between the toes, the child will often lift the leg spontaneously to reach for it. Ingenuity and creativity are prerequisites for muscle testing in the young child. Reliability of MMT in children with spina bifida younger than 5 years is difficult but has been demonstrated in a clinic setting where all therapists were trained in specific MMT technique to ascertain consistency in testing.¹⁸¹ By the age of 4 or 5 years, muscle grades can generally be determined by traditional testing techniques, although the reliability of the test results will increase with the age of the child.¹⁸² In most clinics MMT is used to assess strength and changes in strength over time. Reliability of MMT may be called into question when trying to assess meaningful detectable changes in power against gravity. If that is the case, one can use hand-held dynamometry (HHD) to test muscles with a grade of 3 or greater. Excellent intertester reliability of HHD for children with spina bifida has been demonstrated.¹⁸³

Muscle testing is indicated before and after any surgical procedure and at periodic intervals of 6 months to 1 year to detect any change in muscle function. Timely detection of any loss in strength is critical, as the child may encounter increased weakness resulting from tethering of the spinal cord or shunt malfunction as he or she grows. The level of innervation should not decrease throughout the life of the child with spina bifida. In the growing child or adolescent, an increasing weakness resulting from shunt malfunction, tethering of the spinal cord, or hydromyelia frequently can be substantiated by a muscle test of the lower extremities. The MMT is also valuable in determining the motor level so that potential future functional level can be determined (Figure 15-8).

Sensory Testing

Sensory testing of the infant and young child is simplified to determine the level of sensation as accurately as possible with a minimal amount of testing. Full sensory tests are not possible until the child has acquired sufficient

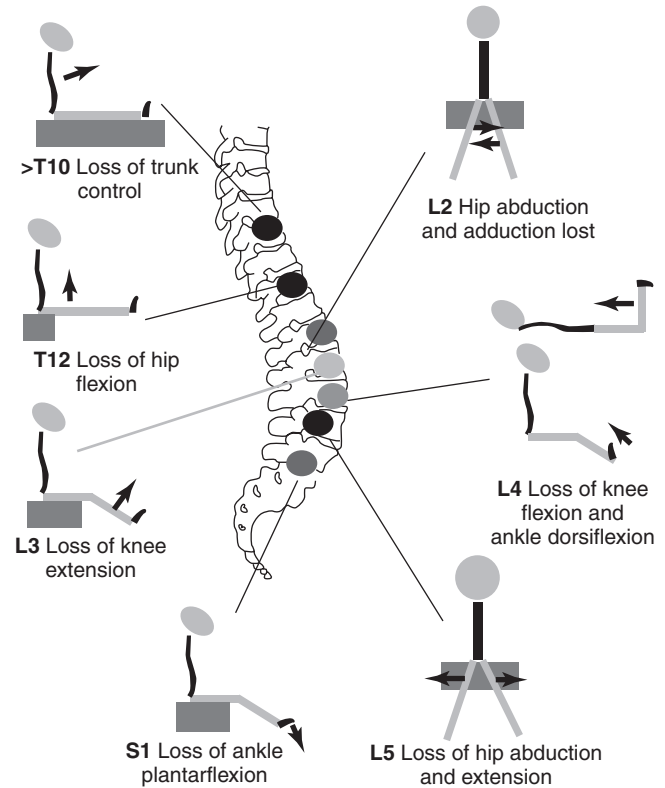

Figure 15-8 ■ Weakness related to level of spinal defect. (From Staheli LT: *Practice of pediatric orthopedics*, Philadelphia, 2001, Lippincott Williams & Wilkins.)

cognitive and language abilities to respond appropriately to testing.

In the newborn, sensory testing can best be done if the child is in a quiet state. Beginning at the lowest level of sacral innervation, the skin is stroked with a pin or other sharp object until a reaction to pain is noted. Although none of these methods is fail-safe, they may be helpful in adapting a muscle test to a newborn or young infant. Repeated evaluation may be necessary to get an accurate picture of muscle function.

Because of dermatome innervation the pin is usually drawn from the anal area across the buttocks, down the posterior thigh and leg, then to the anterior surface of the leg and thigh, and finally across the abdominal muscles. Reactions to be noted are a facial grimace or cry, which indicates that the painful sensation has reached a cortical level. Care must be taken to see that each sensory dermatome has been evaluated. Results can be recorded by shading in the dermatomes where sensation is present (Figure 15-9).

The therapist may be called on to evaluate the newborn before surgical closure of the spinal meningocele. Although sensory and motor levels can be determined as previously described, the infant's general condition should be considered in interpreting test findings. Any medication taken by the mother during labor and delivery may influence the neonate's performance and thus should be noted. In addition, the physiological disorganization normally seen in all infants during the first few days after birth may also affect testing.¹⁸⁴ At best, this presurgical evaluation establishes a tentative baseline, but significant changes in the infant's neurological status in the first few weeks of life should not be surprising to the clinician.

Figure 15-9 ■ Lower-limb dermatomes. (From Brocklehurst G: Spina bifida for the clinician. *Clin Dev Med* 57:53, 1976.)

In the young child from 2 to 7 years of age, light touch sensation and position sense can be tested in addition to pain sensation. Again, to elicit an appropriate response and reliable test results, the ingenuity of the therapist will be required. Using games such as “Tell me when the puppet touches you” may be more effective for the young child than traditional testing methods. Sensory dermatome mapping using the chart in **Figure 15-9**, or a similar form such as the WeeSTeP once the child with spina bifida gets older, can aid in establishing sensory level as well as insensate areas that may be at high risk of injury.¹⁸⁵

From age 7 years through adolescence, additional sensory tests of temperature and two-point discrimination may be added. Traditional methods are usually sufficient to ensure reliable testing, but a more behavioral approach may be indicated depending on the individual’s cognitive functioning.

After testing, a survey of the sensory dermatome chart should indicate whether sensation is normal, absent, or impaired. MMT and sensory testing (dermatomes) can assist in determining spinal level of function (**Figure 15-10**).

Range-of-Motion Evaluation

A complete ROM evaluation of the lower extremities is indicated for the newborn with spina bifida. The therapist must be aware of normal physiological flexion that is greatest at the hip and knees. In the normal newborn these apparent “contractures” of up to 35 degrees are eliminated as the child gains more control of extensor musculature and kicks more frequently into extension.

In the child with spina bifida, contractures may be evident at multiple joints at birth because of unopposed musculature (**Figure 15-11**). Hip adduction should not be tested beyond the neutral position to avoid dislocation of hips, which are often unstable. Range should be done slowly and without excessive force to avoid fractures so often experienced in paralytic lower extremities. ROM should be checked with the same frequency as MMT. Active ROM of the upper extremities can be assessed by observation and handling the infant. A formal ROM evaluation for the upper extremities is not usually indicated. A baseline ROM and tone assessment of the upper extremities should be completed.

Reflex Testing

The purpose of reflex testing is twofold: to check for the presence of normal reflex activity and to check for the integration of primitive reflexes and the establishment of more mature reactions. In the newborn, for example, strong rooting and sucking reflexes are expected. In the child with spina bifida, because of possible involvement of the CNS as previously described, these reflexes may be depressed or absent. Because these reflexes play an integral part in obtaining nutrients for the infant, their value is obvious. On the other hand, primitive reflexes that persist past their expected span also may indicate abnormality. For example, if the asymmetrical tonic neck reflex persists past 4 months, it will limit the infant’s ability to bring the hands to midline for visual and tactile exploration.

As the primitive reflexes (initially needed for survival and to experience movement) become integrated, they are

replaced by more mature and functional reactions. The righting and equilibrium reactions help the child attain the erect position and counteract changes in the center of gravity. Because these reactions depend on an intact CNS as well as a certain level of postural control, they may be delayed, incomplete, or absent in the child with spina bifida. For example, a child with a low thoracic spinal cord lesion may show an incomplete equilibrium reaction in sitting. This may be caused by the lack of a stable postural base or by lack of initiation of the reaction centrally. Both the neurological and muscular components of these reactions must be considered. Reflex testing for the child with spina bifida may not be as intensive as that for a child with cerebral palsy. It may, however, provide a check on the progress of normal development and as such reflect the integrity of the CNS (see Chapters 3 and 16).

Developmental and Functional Evaluations

Besides being aware of a child's sensory and motor levels, assessing the functional level is also important. Two important questions need to be asked: "Does the child show normal components of posture and movement synergies?" and "What is the child's level of function and mobility?" Several developmental and functional evaluations can be used with the child with spina bifida. The following are some suggestions for evaluation approaches or specifically designed tests to assist in assessment of this area.

Initially, a developmental sequence may be used to assess how a child is functioning. In each position used, both posture and movement are evaluated. The goals in using this type of assessment are to determine what a child can and cannot do, the quality of the action, and what is limiting the child. The progression begins in the supine position, rolling to prone, prone on elbows, prone on hands, up to sitting, on hands and knees, kneeling, half-kneeling, standing, and walking. Both the ability to attain and the ability to maintain the positions should be assessed.

The way in which a task is accomplished is as important to evaluate as the accomplishment itself. For example, in rolling, is head righting sufficient to keep the head off the

supporting surface? From the hands-knees position, can reciprocal crawling be initiated without the lower extremities being held in wide abduction? Can the child pull to stand easily by using trunk rotation? Assessing the quality of the child's abilities will assist the clinician in determining where therapeutic measures should begin and what the goals of such intervention will be. Standardized assessments may provide the families with guidelines and a record of motor skills over time (see Chapter 3).

There are no standardized functional or motor assessments specific to those with spina bifida. Some assessments look at development relative to standardized norms and may guide the family and therapist in determining treatment goals and challenges. This information may be invaluable in determining bracing needs and other equipment needs as well as timing of various interventions. If a standardized assessment were desired to use with the infant with spina bifida, the Alberta Infant Motor Scale (AIMS) might be appropriate. The AIMS¹⁸⁶ is designed to measure motor development from birth to 18 months of age. It is a 58-item observational test of infants in supine, prone, sitting, and standing positions. Each item includes detailed descriptions of the weight-bearing surface, the infant's posture, and anti-gravity movements expected of the infant in that position. The AIMS requires minimal handling of the infant and can be completed in 20 to 30 minutes. The test was normed on a cross-sectional sample of 2200 infants in Alberta, Canada. Interrater and test-retest reliability are high (0.95 to 0.99), as is concurrent validity with the Peabody Developmental Motor Scales (PDMS) (0.99) and the Bayley Scales of Infant Development (0.97). Predictive validity of the AIMS appears to be fair.¹⁸⁷ For the child with spina bifida the AIMS could be used to assess current motor development and track progress in motor development over time.

The Milani-Comparetti Motor Development Screening Test for Infants and Young Children may also be useful in assessing the functional level of the child with spina bifida. This screening examination is designed to evaluate motor development from birth to 2 years of age (Figure 15-12).¹⁸⁸ It requires no special equipment and can be administered in 4 to 8 minutes. The test evaluates both spontaneous behavior and evoked responses. Spontaneous behavior includes postural control of the head and body in various positions as well as a sequence of active movement patterns. Primitive reflexes, righting, and equilibrium reactions constitute the evoked responses. The Milani-Comparetti test was normed on a sample of 312 children from Omaha, Nebraska. Interrater reliability percent of agreement was 89% to 95%. Test-retest reliability percent agreement was 82% to 100%. Predictive validity of the test has not been well established.¹⁸⁸ The Milani-Comparetti test should assist the clinician in evaluating each child's underlying postural mechanisms and his or her ability to attain the erect position. The test manual provides information on special examination procedures and scoring.

The Ages and Stages Questionnaire (ASQ) is a screening assessment that assesses developmental and social-emotional delays during crucial early ages of life. This test is available in English and Spanish and can be completed in 10 to 15 minutes.¹⁸⁹ It was developed and validated on 15,138 children in all 50 states and several U.S. territories. The test-retest reliability (0.92), interrater reliability (0.93), validity (0.82 to 0.88),

sensitivity (0.86), and specificity (0.85) have been well documented.¹⁸⁹ This test provides parents and providers with a checklist to easily assess change over time.

The PDMS-2 is another standardized assessment that may prove helpful in evaluating a child with congenital spinal cord injury.¹⁹⁰ The PDMS-2 was developed using item response theory (IRT) and consists of six gross and fine motor subtests from birth through 6 years of age. The test

takes 45 to 60 minutes to complete or 20 to 30 minutes per subtest. The two scales allow a comparison of the child's motor performance with a normative sample of children at various age levels. A stratified sample of 2003 children from 46 states in the United States was used to develop PDMS-2 test norms. Test-retest and interrater reliability are high. Content, construct, and concurrent validity have been well established. Although the child with activity limitations would not

be expected to succeed on many of the gross motor items at the later age levels, the scale still serves as a reminder of expected gross motor performance at each age. The fine motor scale offers a chance to assess fine motor performance of children with congenital spinal cord injury. This area has been frequently overlooked in children with myelomeningocele. Fine motor development, however, may be affected because of congenital abnormalities in brain development associated with myelomeningocele or related to tethering of the spinal cord that can result in fine motor paresis. In addition, the PDMS-2 offers guidelines for administering the test to children with various activity limitations.¹⁹⁰

The Bruininks-Oseretsky Test of Motor Proficiency, second edition (BOT-2) can be used to evaluate the higher functioning ambulatory child with lower lumbar or sacral level spina bifida.¹⁹¹ Fine manual control, manual coordination, body coordination, and strength and agility subtests can be used to assist in evaluating areas of fine motor control, balance, and coordination difficulties. This test has been standardized on a sample of 1520 subjects from age 4 through 21 years.¹⁹¹

The Movement Assessment Battery for Children, second edition (Movement ABC-2), can be used to identify children who are significantly behind their peers in motor development, assist in planning an intervention program in either a school or a clinical setting, and measure change as a result of intervention or can serve as a measurement instrument in research involving motor development. This tool may be useful to assess children with lower lumbar and sacral level myelomeningocele, as well as children with lipomeningocele. The Movement ABC identifies and evaluates the movement problems that can determine a child's participation and social adjustment at home or school. The Movement ABC Checklist provides classroom assessment of movement difficulties, screening for "at risk" children (ages 5 to 12 years), and systematic monitoring of treatment programs. It provides a comprehensive assessment for those identified as "at risk" (3 to 16 years, 11 months), yielding both normative and qualitative measures of movement competence, manual dexterity, ball skills, and static and dynamic balance.¹⁹²

Finally, the Pediatric Evaluation of Disability Inventory (PEDI) is a comprehensive assessment of function in children aged 6 months to 7 years.¹⁹³ The PEDI measures both capability and performance of functional activities in three areas: self-care, mobility, and social function. Capability is a measure of the functional skills for which the child has demonstrated mastery. Functional performance is measured by the level of caregiver assistance needed to accomplish a task. A modifications scale provides a measure of environmental modifications and equipment needed in daily functioning. The PEDI has been standardized on a normative sample of 412 children from New England. Some data from clinical samples ($N = 102$) are also available. Interrater reliability of the PEDI is high as demonstrated by high intraclass correlation coefficients ($ICCs = 0.96$ to 0.99). Concurrent validity of the PEDI with the WeeFIM (child's version of the Functional Independence Measure) was also high ($r = .80$ to 0.97).¹⁹³ The PEDI can be administered in approximately 45 minutes by clinicians or educators familiar with the child or by structured interview of the parent. The PEDI should provide a descriptive measure of the functional level of the child with myelomeningocele as well as a

method for tracking change over time. The PEDI has had a rich tradition in helping to document functional development, and new methods proposed for the next generation of the PEDI include using item banks and computer adaptive testing. The computer adaptive testing feature and the revised and expanded content of the new PEDI will enable therapists to more efficiently assess children's functioning to a broader age group of children.^{194,195}

Another assessment of motor performance that may be commonly used with the school-age child with spina bifida is the School Function Assessment (SFA). The SFA is standardized and was conceptually developed to reflect the functional abilities and needs of a student in elementary school. The three areas assessed include the student's participation in school activities, task supports required by the student for participation, and the student's activity performance.^{196,197} It was designed to facilitate collaborative program planning for students with a variety of disabling conditions. The instrument is a judgment-based (questionnaire) assessment that is completed by one or more school professionals who know the student well and have observed his or her typical performance on the school-related tasks and activities being assessed. Items have been written in measurable, behavioral terms that can be used directly in the student's Individualized Educational Plan (IEP).¹⁹⁶

Gait Analysis

Formal computerized gait analysis was initially used to evaluate children with cerebral palsy. Increasingly it is being used to evaluate children with meningomyelocele once they have established a gait pattern to determine factors leading to changes in gait, including changes in alignment, muscle length, muscle torque, and symmetry. The gait analysis may aid in decision making regarding orthotic and orthopedic interventions. Whether it is useful to do formal gait analyses in all children with spina bifida remains to be determined.¹⁹⁸ Gait analyses have also been useful in establishing a database of trends in kinetics and kinematics for various levels of spina bifida.

Perceptual and Cognitive Evaluations

When evaluating a child with spina bifida, some assessment of perceptual and cognitive status is important to include. The appropriate assessment depends largely on the age of the child. The assessment may be performed by the physical, occupational, or speech therapist, depending on the setting.

For the newborn from 3 to 30 days old, the Brazelton Neonatal Behavioral Assessment scale may be adapted to assess the infant's organization in terms of physiological response to stress, state control, motoric control, and social interaction.¹⁸⁴ Ideally the infant should be medically stable and free from CNS-depressant drugs before evaluation. Generally this evaluation will occur after the back lesion has been closed and a shunt has been positioned to relieve the hydrocephalic condition.

Although test results may not have prognostic value because of the plasticity of the nervous system at this young age, they supply the clinician with information concerning the current status of the child. This information can be conveyed to the infant's caregivers—both medical personnel and parents—so that strengths can be appreciated and weaknesses anticipated and handled appropriately. Helping

parents identify that their infant has his or her own unique characteristics and assisting them in dealing with these characteristics does a great deal to strengthen already precarious parent-infant bonding.

Repeated administration of the Brazelton Neonatal Behavioral Assessment scale in the first month of life may help monitor the infant's progress in organization and reflect the curve of recovery. Although the manual for this behavioral assessment is complete, proper administration, scoring, and interpretation require direct training with someone already proficient in using the scale.¹⁹⁹ Excellent training videos for the Brazelton Neonatal Behavioral Assessment scale are available through the Brazelton Institute for purchase or through the local university's learning resource centers.²⁰⁰

A full developmental evaluation appropriate for the infant and toddler with spina bifida is the Bayley Scales of Infant and Toddler Development, Third Edition (BSID-III).²⁰¹ The Bayley Scales, consisting of a mental and motor scale and a behavioral rating scale, can be used to test children from age 1 month to 42 months. The test provides information on gross motor, fine motor, language, social-emotional, adaptive, and cognitive development.

The BSID-III is well standardized and reliable and takes approximately 45 minutes to administer. It is not an easy test to learn and initially requires supervision of an experienced tester. This edition provides new normative data, extended age range, expanded content coverage, and improved psychometric qualities.

The BSID-III provides the clinician with a broader view of the child's total development. The gross motor information from this developmental assessment will not be specific enough for a therapist evaluating a child with spina bifida. The additional information on fine motor, language, personal-social, and cognitive development, however, is sufficient and will be important in planning a comprehensive intervention program.²⁰¹

Various tests are available as screening tools to test visual-motor integration and perception. The Beery-Buktenica Developmental Test of Visual-Motor Integration, 6th Edition (Beery VMI) is an early screening tool to aid in diagnosis of learning problems in children. It assesses integration of visual perception and motor control of children from age 2 years through 18 years. The test takes 10 to 15 minutes to complete and requires the child to be able to copy designs. The Beery VMI is norm referenced and was standardized on a large sample of children chosen from throughout the United States. There is also an adult version that can be used with individuals 19 to 100 years of age that facilitates identification of neurological and related problems in the adult.²⁰²

Children with spina bifida often exhibit upper-extremity weakness in addition to probable sensory dysfunction. As a result, fine motor skills in children with spina bifida are often impeded by slowness and inadequate adjustment of manipulative forces, and a non-motor-perceptual test is often desired.²⁰³⁻²⁰⁵ The Motor-Free Visual Perception Test, Third Edition (MVPT-3)²⁰⁶ and the Test of Visual Perceptual Skills, Non-Motor, Third Edition (TVPS-3)²⁰⁷ can be used to determine the child's visual perceptual processing skills on the basis of a non-motor assessment of these skills. Both tests evaluate visual discrimination, visual memory, spatial relations, figure-ground, and visual closure. The TVPS-3 also evaluates form constancy and sequential memory. The

MVPT-3 can be used with individuals from 4 to 70 years of age, and the TVPS-3 can be used with children from 4 to 18 years of age. The TVPS-3 has two levels; the lower level tests children from ages 4 to 12 years, and the upper level tests children from ages 12 years to 17 years, 11 months. Both tests are easy and quick to administer (less than 15 minutes) and, based on the examiner's experience and training, interpretations can be made with prescription for remediation. The MVPT-3 was standardized on a nationally representative sample. The test-retest reliability of the MVPT-3 was 0.81.²⁰⁶ Performance on the motor-free test has been shown to be independent of the degree of motor involvement when compared with other tests of visual perception.²⁰⁶ The TVPS-3 was standardized on a nationally stratified sample of 2000 children across the United States.

With a firm database provided by a thorough physical and occupational therapy evaluation with referrals to other professionals as appropriate, a reasonable treatment plan can be developed and updated as necessary.

TREATMENT PLANNING AND REHABILITATION RELATED TO SIGNIFICANT STAGES OF DEVELOPMENT

Newborn to Toddler (Preambulatory Phase)

Stage 1: Before Closure of Myelomeningocele—Early Newborn Period

Physical therapy management of the infant in stage 1 is limited by his or her medical condition (Table 15-2). Therapists are called on a regular basis in large tertiary care centers to carry out preoperative MMT to help to ascertain functional motor level. Physicians (neurosurgeons and orthopedic surgeons) on the spina bifida care team rely on this assessment to guide their discussion with the families regarding care and prognosis. When carrying out the preoperative MMT, great care must be taken to avoid contaminating an open sac, which is usually covered with a Telfa non-adherent dressing or a wet sterile dressing that must be kept moist with a saline solution.

Stage 2: After Surgery, during Hospitalization, and Transition to Home—Newborn through Early Infancy

Therapeutic intervention after surgical back closure during stage 2 is often limited by the infant's neurological and orthopedic status. A major goal during this stage is to prevent contractures and maintain ROM while giving stimulation to provide as normal an environment as possible. Traditional ROM exercises can be taught to nursing staff and family. They also can be carried out while the child is being held at the adult's shoulder or prone over the adult's lap. These positions allow closeness between the caregiver and infant, thus encouraging maximal relaxation and interaction between them. ROM movements and positioning in prone or side lying may be initiated to prevent or decrease contractures in the lower extremities. If clubfeet are present, soft tissue stretching may be indicated. Stretching begins distally on the soft tissue of the forefoot and proceeds proximally toward the calcaneus. This is done to take advantage of the pliability of soft tissue structures and to minimize fixed deformity later. In addition, taping may be used to maintain optimal ROM and alignment between periods of

TABLE 15-2 ■ SUMMARY OF TREATMENT PLANNING AND REHABILITATION RELATED TO SIGNIFICANT STAGES OF DEVELOPMENT

STAGE OF RECOVERY	MAJOR PHYSICAL THERAPY GOALS	PHYSICAL THERAPY MANAGEMENT
NEWBORN TO TODDLER (PREAMBULATORY PHASE)		
Stage 1: before surgical closure of myelomeningocele—newborn	Determine functional motor level	Preoperative manual muscle testing
Stage 2: after surgery, during hospitalization—newborn to infant	Confirm functional motor level Prevent contracture and deformity Encourage normal sensorimotor development	Postoperative manual muscle testing ROM exercises taught to hospital personnel and family Positioning in prone and side lying Provide toys of various colors, textures, and shapes Graded auditory and visual stimuli: music boxes, squeaky toys, brightly colored objects Therapeutic handling to encourage good head and trunk control
Stage 3: condition stabilized—infant to toddler	Confirm functional motor level Encourage normal development sequence	Manual muscle testing once or twice per year Work in sitting on head righting and equilibrium reactions Eye-hand coordination activities Early weight bearing on lower extremities Encourage prone progression Weight shifting in standing frame Comprehensive home program
TODDLER THROUGH ADOLESCENT (AMBULATORY PHASE)		
Stage 4: toddler through preschool	Confirm functional motor level Begin ambulation Continue development in cognitive and psychosocial areas Collaborate on goals with other team members	Manual muscle testing once or twice per year Choose appropriate orthotic device Gait training Development and strengthening of righting and equilibrium reactions Consider referral to EI program Public preschool program Continue home program Open communication with other team members
Stage 5: primary school through adolescence	Confirm functional motor level Reevaluate ambulation potential Maintain present level of functioning Prevent skin breakdown as child becomes more sedentary Promote independence in self-care skills Remediate any perceptual-motor problems Provide appropriate adaptive devices Promote self-esteem and social-sexual adjustment	Postoperative manual muscle testing Replace orthotic device as necessary Wheelchair prescriptions as necessary Teach locomotion activities Maintain strength in trunk and extremities Teach skin care Work with team members to teach dressing, feeding, hygiene, and bowel and bladder care Provide program and activities for sensorimotor integration Check for fit and proper use of adaptive devices Collaborate with other team members in counseling efforts

EI, Early intervention; *ROM*, range of motion.

stretching.¹⁵⁰ In treating the newborn after surgery, great care must be taken to avoid contaminating the surgical dressing, which is usually covered with Xeroform Petroleum Gauze (3% bismuth tribromophenate in a special petrolatum blend on fine mesh gauze). This dressing is nonadherent and clings and conforms to all body contours. The Xeroform dressing is covered with Telfa. This postoperative dressing remains on for 2 weeks.

Because of their medical conditions, hospitalized infants often experience early separation from their parents. Teaching the family to handle the child as described may enhance parent-infant bonding. Adequate bonding is essential for normal psychosocial development to occur.

When the child is not being handled, resting positions can be used to maintain ROM and enhance development. The prone position is the most advantageous because it prevents hip flexion contractures and encourages development of extensor musculature as the child lifts his or her head. Side lying, which allows the hands to come to midline and generally encourages symmetrical posture, can be used for alternate positioning. As much as possible, the supine position should be avoided because the child is most dominated by primitive reflexes and the effects of gravity in this position. For example, for the child with spina bifida with CNS involvement, the effects of the tonic labyrinthine reflex combined with paralytic lower extremities may make movement

from the supine position extremely difficult. Before initiating activities in the supine position, the therapist should obtain medical clearance.

A normal sensory experience should be presented to the child in spite of the hospital setting. Toys of various colors, textures, and shapes should be available. Musical mobiles held low enough for the child to reach provide a variety of sensory experiences. Stimuli such as squeaky toys or the human face and voice can be used to encourage visual and auditory tracking. Controlled stimulation relevant to the infant's neurological state, rather than overstimulation, should be the rule. Depending on the age of the child, appropriate learning situations must be presented to provide the child with as normal an environment as possible for perceptual and cognitive growth.

A major therapeutic goal is to guide the child through the developmental sequence, ultimately preparing him or her to assume the upright posture. In this immediate postsurgical stage, the primary emphasis should be on attaining good head and trunk control and eliciting appropriate righting reactions. For example, the child can be seated on the therapist's lap, facing the therapist, and alternately lowered slowly backward and side to side. This action helps stimulate head righting and strengthen neck and abdominal muscles. Weight shifting in various positions and through therapeutic handling is important to enhance development of early head and trunk control. Developmental handling may be limited by surgical interventions that limit mobility.

This second stage ends as the child is discharged from the hospital. After discharge the child should be monitored closely by the spina bifida team, which may include a neurosurgeon, an orthopedist, a urologist, a nurse clinician, a PT, an occupational therapist (OT), an orthotist, and a social worker. Before discharge, a definitive home program as well as referral to the local Early Intervention (EI) program should be given to the family because the child will most likely require ongoing therapy, including both PT and OT. Other professionals who may be involved in the child's EI program may include speech and language pathologists (SLPs), developmental therapists (DTs), social workers, and psychologists.

Stage 3: Condition Stabilized—Infant to Toddler (Preambulatory)

In the third stage of rehabilitation, the major emphasis is on preparing the child mentally and physically for upright standing and mobility. In addition, routine MMT should be performed every 6 to 12 months to reassess functional motor level and to ascertain that no change in status has occurred. Goals of preventing contractures and maintaining ROM will remain throughout the child's life. Unless this is done, standing and ambulation become more difficult and often impossible. If possible, prone positioning during play and sleeping assists greatly in stretching tight musculature. Resting splints for the lower extremities or a total-body splint can be used as necessary to position and maintain ROM and alignment.

Developmental strategies should be aimed at facilitating movement and motor control. Assuming that the child has previously gained good head and trunk control, the next step is development of sitting equilibrium reactions. As sitting balance improves, fine motor and eye-hand coordination

activities should be introduced. Upper-extremity functioning is often overlooked in the child with spina bifida, whose problems appear to be concentrated in the lower extremities. However, most children with spina bifida show decreased fine motor coordination, and this problem should be addressed as developmentally appropriate. The normal infant begins to reach and grasp by 6 months of age; therefore the child with spina bifida must be given ample opportunities to practice and perfect these same skills at an early age. Because many children with spina bifida may be receiving PT as their primary service through EI in these early months, referral to and consultation with an OT at this age are highly recommended.

Following a normal developmental sequence, the child with spina bifida will usually begin some form of prone progression as trunk and upper-extremity stability improve. This is a significant phase of development because it allows for the development of a sensorimotor base as the child expands environmental horizons. During this phase of high mobility, insensate skin must be checked for injury frequently and often must be protected by heavier clothing. This may help prevent any major skin breakdown, which could significantly delay the rehabilitation process. For some children with high-level lesions in whom prone mobility is not safe or practical for long distances, a Star Car (Tash) (Figure 15-13), the Ready Racer (Tumble Forms), or the PlasmaCar may be used. These provide the child with a means of exploring the environment safely but independently.

Emphasis on head and trunk control and strengthening exercises in a variety of sitting postures is quite important in this early preambulatory phase. Development of adequate strength and motor control for trunk righting, equilibrium reactions, and protective reactions will ultimately lead to improved sitting balance. Hands-free sitting with good balance is the optimal goal in this stage to allow for

Figure 15-13 ■ Caster cart used for independent mobility.

independence and freedom in play skills. In addition, hands-free sitting is a necessary precursor to ambulation with lower-extremity bracing and often is the determinant in deciding if a child will use a standing frame or will become a functional ambulator.

Early weight bearing is also of utmost importance, both physiologically and psychologically. The upright position has beneficial effects on circulation and renal and bladder functioning as well as on the promotion of bone growth and density.^{59,176,208,209} Psychologically, weight bearing in an upright posture allows a normal view of the world and contributes to more normal perceptual, cognitive, and emotional growth. One way to achieve this weight bearing is in the kneeling position. This is developmentally appropriate because children 8 to 10 months old frequently use kneeling as a transition from all fours to standing.

Because young infants are frequently held in the standing position and bounced on their parents' laps, this form of weight bearing on the lower extremities is appropriate from birth onward. Failure to promote weight bearing in this manner may deprive the child with spina bifida of the normal experience of standing at a very early age. When standing these children, however, care must be taken to see that the lower extremities are in good alignment and that undue pressure is not exerted on them (Figure 15-14). In this way the risk of fractures is minimized and a normal weight-bearing experience is provided.

Also in this phase of preambulation, transitions from one position to another should be assessed and facilitated. Teaching the child strategies for transitions will enhance his or her optimal functional independence. Compensations may be taught to substitute for weakened musculature. In addition, adaptive equipment and mobility devices may be recommended to enhance acquisition of age-appropriate

Figure 15-14 ■ Assisted standing with normal postural alignment.

milestones. Providing appropriate facilitation of mobility at a level similar to that of a child's peers is important for psychosocial growth and development (Figure 15-15).

When the child attempts to pull to a standing position or would be expected to do so normally (at 10 to 12 months of age), the use of a standing device is indicated. Generally a standing frame is the first orthosis chosen. This is a relatively inexpensive tubular frame to which adjustable parts are attached (Figure 15-16). Because it is not custom made, it can be fitted fairly quickly, although adjustments may be necessary to accommodate spinal deformities. This standing device offers support of the trunk, hips, and knees and leaves the hands free for other activities. Time spent in the standing frame should be increased gradually. This allows the child to adjust to the upright position in terms of muscle strength, endurance, blood pressure, and pressure on skin surfaces.

After children have built up a tolerance for standing, they may be taught to move in the device by shifting their weight from side to side. Initial shifting of weight onto one side of the body is necessary to allow the other side to move forward. This preliminary weight shift is also a prerequisite for developing equilibrium reactions in the standing position and thus will prepare the child for later ambulation. As the child shifts weight, the trunk musculature on the weight-bearing side should elongate and on the non-weight-bearing side should shorten as muscle strength allows. This normal reaction to weight shifting also includes righting of the head and should be closely monitored by the therapist for completeness.

A therapy program must be designed to meet the individual's needs in each area. Age alone does not determine the appropriate therapeutic goals. Goals that are not suited for the child's cognitive and emotional needs, in addition to physical needs, will not facilitate best outcomes. For example, an 18-month-old may have the physical capabilities to ambulate independently with crutches and braces. The child may not, however, have the cognitive skills necessary to learn a four-point gait or be ready emotionally to separate from his or her mother for intensive therapy sessions. A more realistic goal may be to let the child walk holding onto furniture (cruising) while a wheeled walker for more independent ambulation is slowly introduced. Another alternative to using a conventional walker is to encourage the child to play with push toys such as grocery carts and baby buggies.

During this preambulatory stage, therapy goals may be accomplished through a comprehensive home program, with frequent checks to note progress or problems and to change the program accordingly. For the more involved child, increased frequency of direct intervention may be indicated to achieve optimal developmental progress.

The program often must be reevaluated and goals changed if conditions such as shunt malfunctions or fractures occur. The warning signs for shunt dysfunctions are generally those previously described for suspected hydrocephalus. In addition, swelling along the shunt site may indicate a malfunction. Swelling and local heat or redness of a limb are the usual signs of a fracture. The limb may also look misaligned. Fever may accompany a fracture. As previously mentioned, these fractures generally heal quickly with proper medical intervention and minimally interrupt rehabilitation efforts.

Figure 15-15 ■ Adaptive devices can help the young child with spina bifida reach major milestones at the same time as peers. (From Ratcliffe KT: *Clinical pediatric physical therapy*, St Louis, 1998, Mosby.)

Figure 15-16 ■ Standing frame. **A**, Anterior view. **B**, Lateral view.

Toddler through Adolescent (Ambulatory Phase)

Stage 4: Toddler through Preschool

The fourth period in development marks the end of infancy and the beginning of childhood. For the typically developing child who has developed a strong sensorimotor foundation, physical development is marked by increased coordination and refinement of movement patterns. In addition, a great variety of motor skills will be achieved as the typically developing child learns to throw, catch, run, hop, and jump. This is also a period of great cognitive growth, as children's

use of mental imagery and physical knowledge of their environments expand. Concepts of size, number, color, form, and space are all developing. Emotionally, most children are becoming more independent and begin to break away from the sheltered environment of the home. They are now more interested in interacting with others and become social beings to a greater extent.

All these changes in physical, cognitive, and emotional development will be evident in the child with spina bifida, although the degree depends on the extent of the functional limitations and their effect on the child's ability to participate in life. The characteristics of normal development must be understood so that cognitive, emotional, and motor behaviors can be nurtured and enhanced in the child with spina bifida.

Goals for this as for any other stage must address physical, cognitive, and emotional development. The most obvious goal at this stage is to help the child who is already standing to progress to an ambulatory status. Even the child with a low thoracic lesion can usually manage some form of ambulation.

Thus far, the child has learned to shift weight in the standing frame. By rotating the trunk toward the weighted side, the non-weight-bearing side can be shifted forward (Figure 15-17). By reversing the weight shift, the opposite side can be moved forward and a type of "pivoting forward" progression can be accomplished. To maintain balance while shifting, the child may initially use a two-wheeled walker. The therapist may help initiate weight shift and trunk rotation by alternately pulling the arms forward.²¹⁰ Once the child has gained this form of mobility, the type of permanent bracing chosen will depend on the level of the lesion and a variety of other factors.

The overall goal for ambulatory training is to promote efficient, independent mobility with the least amount of bracing while maintaining optimal joint integrity. Ambulatory potential as well as choice of bracing depends on many factors, including neurosegmental level of the lesion, motor power at the neurosegmental level, extent and degree of orthopedic deformity, balance, age, height, weight, sex, motivation, spasticity, design and effectiveness of the orthosis,

Figure 15-17 ■ Weight shift and forward rotation in standing frame.

effectiveness of PT intervention, environmental factors, upper-extremity strength and control, and cognitive level.^{163,211} The best prognosis for ambulation is most often seen in the child who is not shunted and has good cognition, good quadriceps power, no deformity, a stable neurological condition, and hands-free sitting balance. Factors that may limit potential for ambulation include hydrocephalus, high-level lesions, kyphosis or kyphoscoliosis, and unstable neurology.

Developmental progression preceding ambulation in spina bifida shows a high degree of variability.²¹² A study by Bartonek in 2010²¹² confirmed that those with greater muscle power of the lower limb muscles ambulated earlier and more frequently. Those engaged in physical therapy programs aimed at achieving the specific goal of walking are also likely to make earlier strides toward ambulation, although this has not been formally studied. Those who have been enrolled in early treadmill body-weight support training (BWST) programs as infants have demonstrated early stepping responsiveness, and it has been suggested that BWST training intervention could promote muscle strengthening and take advantage of neural plasticity to promote development of the neuromuscular patterns necessary to support the onset of gait. There is also potential to improve bone density, cardiovascular function, and the integrity of lower spinal sensorimotor function. Infants with spina bifida demonstrate developmental delay as early as 3 months of age, and BWST intervention during the first postnatal year has the potential to reduce this delay and promote earlier onset of gait in the population with spina bifida.²¹³ Efficacy of enhanced sensory inputs during treadmill stepping in children with spina bifida has also been examined. Increasing friction by using Dycem matting and enhancing visual flow by using a checkerboard pattern on the treadmill belt both appear to be more effective than the standard black treadmill belt in eliciting stepping.²¹⁴ Teulier and colleagues²¹⁵ studied stepping responses in infants with spina bifida. They reported a decrease in number of steps per

minute compared with typically developing peers (14.4 versus 40.8 steps per minute) and a decrease in frequency of alternating steps. In contrast to these interlimb coordination differences, they reported that within-limb step parameters in infants with spina bifida were quite similar to those in children who were typically developing.

For thoracic and high-level lumbar lesions, a parapodium is often chosen. The parapodium was developed by the Ontario Crippled Children's Centre in 1970 and is similar to the standing frame except that hinges at the hips and knees allow for sitting and standing.²¹⁰ It also can be adjusted for growth and can accommodate orthopedic deformities. As with the standing frame, proper alignment of the parapodium is critical. The therapist, in conjunction with the orthotist, should check for correct standing alignment. The prevention of additional orthopedic deformities, development of good muscular control, and normal body image depend on a well fitting orthosis.

After a pivoting gait has been learned with the parapodium, a swing-to or swing-through gait can be attempted. By 4 to 5 years of age, a swing-through gait, with the child using Lofstrand crutches, can usually be accomplished. Variations of the parapodium allow for easier locking and unlocking of hip and knee joints. A swivel or pivot walker also may be attached to the footplate to allow for crutchless walking.

Another type of orthosis for the child with a thoracic or high lumbar lesion is the Orthotic Research and Locomotion Assessment Unit (ORLAU) swivel walker. It consists of modular design similar to that of the standing frame, with a chest strap and knee blocks attached to swiveling footplates.²¹⁶ Rather than the whole base moving forward, as when weight is shifted in the parapodium, in the swivel walker each footplate is spring-loaded and is able to swivel forward independently. This allows for independent balance on one foot and therefore crutchless ambulation. The ORLAU swivel walker is manufactured in the United Kingdom, and assembly kits may be ordered; however, availability is limited ([Appendix 15-A](#)).²¹⁷ Another parapodium in use is the Rochester parapodium. Separate hip and knee joints allow a variety of free movement for sitting and bending down. The lower portion remains rigid and supportive when hips are flexed. Therefore a child can bend and pick up objects from the floor, and the unlockable hip and knee joints will relock automatically on extension.²¹⁸

There is a perception that although children with myelomeningocele use orthoses effectively, very few continue ambulation into adulthood. Two studies of patients with thoracic-level myelomeningocele²¹⁹ demonstrated that the ORLAU can be used effectively into the adult years. Both studies noted a 58% to 59.4% compliance rate. Patients in the studies who started using the ORLAU after 11 years of age continued use for 3 to 24 years. Mazur and colleagues²¹⁹ noted that those with myelomeningocele who did not ambulate had a fivefold increase in pressure sores and twice the number of fractures compared with those who did ambulate. Vigorous walking programs should be considered to assist long-term health.

Both the parapodium and swivel walker have had some problems with instability, ease of application, and cosmesis. New designs attempt to correct these problems.²²⁰ Nevertheless, existing limitations in the parapodium and swivel walker, particularly energy cost of walking, slow rate of locomotion, and cosmesis, have limited their use, primarily to the younger

child. These devices, however, remain an effective means of preventing musculoskeletal deformities caused by long-term sitting, wheelchair positioning, and general immobility. They also enhance social-emotional development gained from the upright position.^{216,221} Another option for the child with a higher-level lesion and good sitting balance is the reciprocating gait orthosis (RGO). This brace consists of bilateral long-leg braces with a pelvic band and thoracic extension, if necessary. The hip joints are connected by a cable system that can work in two ways: If the child has active hip flexors, he or she can activate the cable system by shifting weight and flexing the non-weight-bearing extremity. This brings the weight-bearing extremity into relative extension in preparation for the next step. Without hip flexors, the child extends his or her trunk over one extremity, thus positioning it in relative extension. By virtue of the cable system, the non-weight-bearing extremity moves into flexion, thus initiating a step. Several types of the RGO are in use, including the dual-cable LSU²²² and the horizontal-cable type.²²³

Most recently the Isocentric Reciprocating Gait Orthosis (I-RGO) (Center for Orthotics Design, Campbell, California) has been used for children with high-level spina bifida. It has a more cosmetic and efficient design compared with the dual-cable LSU or horizontal-cable-type RGO. This cable-less brace has two to three times less friction and therefore is more energy efficient. The brace stabilizes the hip, knee, and ankle joints and balances the person, enabling him or her to stand hands free without the use of crutches or a walker (Figure 15-18).²²³ Leg advancement for walking occurs

Figure 15-18 ■ Reciprocating gait orthosis.

through use of hip flexor or lower abdominal muscle contraction or through use of active or passive trunk extension. In a study of 15 patients with lesions from T10-L3, use of the RGO produced favorable results. It was used effectively by 13 of the 15 patients. Initial use of the RGO was initiated at 5 years, and eight of the 15 discontinued use at 10 years of age. During the period of use, four became community ambulators, nine were household ambulators, and two remained nonfunctional (standing only). Average daily use ranged from 6 hours for those ambulating in the community to 30 minutes for those who were nonfunctional ambulators. Six of the 15 had no quadriceps power yet were able to functionally use the RGO for ambulation. Strong motivation and realistic goals are important to successful use.²²⁴

A more common means of maintaining the upright position has been through the use of long- or short-leg braces. Polypropylene braces and carbon-reinforced braces are considerably lighter than metal bracing and therefore reduce the energy cost of walking for the child with spina bifida. They allow close contact and can be slipped into the shoe rather than worn externally, thus affording the patient a better-fitting, more cosmetic orthosis.

The type of orthosis chosen (long-leg, with or without pelvic band, or short-leg) depends on the level of the myelomeningocele and the muscle power within that level (Table 15-3). Because lesions are frequently incomplete, muscle strength must be accurately assessed before bracing is prescribed. Independent sitting balance with hands free also is a prerequisite for use of long- or short-leg braces. Even children with L3 to L4 lesions who demonstrate incomplete knee extension may be able to use a short-leg brace with an anterior shell rather than requiring long-leg bracing.²²⁵ This crouch-control AFO (CCAFO) will prevent a crouching gait pattern by improving knee extension during gait (Figure 15-19).²²⁶ Another alternative to a standard solid ankle AFO may be the carbon fiber spring AFO. This brace provides dynamic assist, supports the patient through the entire stance phase, and increases the energy return during the third rocker phase of push-off, simulating the natural push-off action.²²⁷ For children demonstrating excessive knee valgus caused by hip adduction, use of a Ferrari KAFO (FKAFO) may be considered.²²⁸ The PT must work in conjunction with the orthopedist and orthotist to have each child fitted with the minimal amount of bracing that allows for joint stability and a good gait pattern (see Chapter 34).

Children with lower-level lesions (L5-S1) who use below-knee bracing often develop the ability to or choose to ambulate without assistive devices. However, recent studies have shown that crutch use may decrease excessive pelvic motion, which results in reducing abnormal joint forces.^{162,229} Use of crutches may prevent abnormal joint forces, maintain joint integrity, and decrease the risk of additional orthopedic complications.

Literature has suggested that crutch-assisted ambulation may result in long-term pathology. In patients with higher lumbar lesions (L3-L4) who use Lofstrand crutches, the dynamics and kinematics of upper-extremity function were explored during swing-through and four-point reciprocal modes of gait. Although there were better joint kinematics in the shoulder and other upper-extremity joints during swing-through gait, kinetics were more problematic with increased force and torque in shoulder and wrist joints in

TABLE 15-3 ■ COMMON GAIT PATTERNS AND LEVELS OF ASSISTANCE REQUIRED IN MYELOMENINGOCELE

LEVEL OF LESION	MUSCLE PERFORMANCE	RECOMMENDED LEVEL OF ASSISTANCE AND BRACING	AMBULATORY PROGRESSION
T8-L1 and above	Flaccid LEs with fair to poor trunk	Parapodium: ORLAU, Toronto, Rochester Assistive devices often unnecessary with ORLAU but may improve function with Toronto or Rochester braces.	
L1-L2	Flaccid LEs with hip flexors present	Parapodium with progression to RGO	Begin ambulating with a walker, progress to forearm crutches.
L3-L4	Fair quadriceps with weak or absent hamstrings	RGO, ambulating with hips locked. HKAFOs may be used with severe lordosis because of weak or absent gluteal musculature and decreased trunk control or to control rotation and abduction and adduction. If quadriceps are less than fair strength, KAFOs may be needed. As the patient progresses he or she may be cut down from KAFOs to AFOs; AFOs may be used with or without twister cables.	Four-point or swing-through gait. Begin ambulating with a walker, progress to forearm crutches. Four-point gait. Begin ambulating with a walker and progress to forearm crutches. In some rare cases the patient may progress to no assistive device at all depending on the gait pattern. With increased use of trunk reversal the patient should be returned to forearm crutches to allow for a pattern that is more cosmetic and energy efficient. Four-point gait pattern.
L5	Good hip flexors and quadriceps; fair anterior tibialis; weak gluteus medius and maximus, toe extensors and gastrosoleus	AFOs with or without twisters depending on gluteal strength. AFO is used to prevent a crouch gait pattern from weak gastrosoleus.	Forearm crutches or no assistive devices. Four-point gait.
S1	Good hip flexors, quadriceps, gluteus medius, and toe extensors; weak gluteus maximus and gastrosoleus	AFO	Generally no assistive device is used unless decreased balance reactions or excessive lateral trunk flexion is present.
S2-S3	Good hip flexors, quadriceps, gluteus medius and maximus, and gastrosoleus	Often no bracing needed.	Often no assistive devices needed.

AFO, Ankle-foot-orthosis; HKAFO, hip-knee-ankle-foot orthosis; KAFO, knee-ankle-foot orthosis; LE, lower extremity; RGO, reciprocating gait orthosis.

those using a swing-through gait. Whereas the swing-through gait allows a potentially faster mode of ambulation, long-term use of this pattern may lead to increased upper-extremity pathology. Careful monitoring of all joints, including upper-extremity joints, during gait reassessment should be considered in order to deter and manage these potential issues that may compromise overall joint integrity and function.²³⁰

The excessive femoral torsion present in all newborns at birth does not decrease with growth and development in the child with spina bifida because of abnormal gait and activity.¹⁵⁹ Children ambulating with AFOs often show excessive rotation at the knee because of the lack of functioning lateral hamstrings. Rather than going to a higher level of bracing, a twister cable can be added, which often decreases the rotary component during gait.¹⁵⁹ Twister cables can be heavy-duty torsion or more flexible elastic webbing, depending on function. Typically, the young child who is just beginning to pull to stand and remains reliant on floor mobility as the primary

means of mobility should have elastic twistors prescribed to allow for ease of creeping and transitions. The older and more active child will require heavy-duty torsion cables. Rotational stresses may eventually lead to onset of late degenerative changes around the knee. A tibial derotation osteotomy may be indicated to prevent these changes from occurring.^{159,231,232}

For children with low lumbar or sacral lesions who have at least fair strength in their dorsiflexors and plantar flexors, often a University of California Biomechanics Laboratory (UCBL) or polypropylene shoe insert to control foot position is the only bracing needed. These inserts fit snugly inside the shoe and help control calcaneal and forefoot instabilities. A supramalleolar orthosis (SMO) will also fit easily inside the shoe but will provide additional medial and lateral support and stability that an insert would not provide. Even though a child may be able to ambulate without an assistive device or bracing, consideration must be given to the stresses that occur at the joints that over time may lead to

Figure 15-19 ■ Crouch control ankle-foot orthosis.

orthopedic deformity. The greatest risk of joint instability often occurs at the knee. Barefoot walking versus use of an AFO has shown increased instability, joint stress, and pain at the hip and knee as well as increased energy expenditure.²³³⁻²³⁵ Even though children may be able to ambulate without the use of crutches, comparison of gait kinetics and kinematics of walking with crutches has shown a significant decrease of valgus forces at the knee and better overall alignment of the lower extremities.²²⁹ Treatment aimed at strengthening the gluteus medius and maximus to aid in increasing pelvic stability and reducing kinematic compensations can also be important in the management of patients with lesions at this level to enhance their efficiency during ambulation.^{236,237}

Gait training, begun as the child first starts to stand, can now continue in a more formalized manner. By using the appropriate orthosis and assistive devices (walker, crutches, or cane), each child must be helped to achieve the most efficient and effective gait pattern possible (see [Table 15-3](#)). As a part of gait training, the child should be taken out of the bracing and “challenged” so that righting and equilibrium reactions can be developed to their maximum. For example, having a child maintain balance while sitting on a ball or other movable surface (tilt board, trampoline) requires the participation of all available musculature, especially abdominal and trunk extensor muscles ([Figure 15-20](#)). Strengthening available musculature is a primary objective in this phase of treatment. Slow gains in muscle strength are often the result of continued emphasis on strengthening during physical therapy. In addition to trunk muscles, the gluteus medius, gluteus maximus, and quadriceps are often targeted. Prone activities such as picking up toys while over a Swiss ball or moving around while prone on a scooter

Figure 15-20 ■ Balance and strengthening exercises done on a movable surface.

board require use of these muscles while providing an enjoyable exercise for the child. Participation in hippotherapy and aquatherapy programs at this age can also be beneficial. These treatment approaches can be used to improve muscle strength in general and the gait pattern when bracing is reapplied. Regardless of the strengthening activities chosen, the pediatric therapist has the special task of using creativity to involve the child in therapeutic play activities. The ideas for creative activities are limitless but essential for combining therapy with age-appropriate cognitive abilities.

Studies examining the effects of strength and endurance training in those with spina bifida²³⁸⁻²⁴⁰ have demonstrated enhanced functional outcomes. These studies included individuals in wheelchairs as well as ambulators. Interventions aimed at strengthening those with spina bifida, including electrical stimulation,^{241,242} behavioral treatment,^{243,244} and motor skills training²⁴³ have been reported. The evidence supporting strengthening, using exercise, electrical stimulation, and motor skills training was recently examined by Dagenais and colleagues in a systemic review.²⁴⁵ This review synthesized six studies supporting interventions in strengthening.²⁴⁰⁻²⁴⁶ The level of evidence for the studies was determined using the American Academy of Cerebral Palsy and Developmental Medicine Levels of evidence.²⁴⁷ Levels of evaluated studies were graded and noted to be II (smaller randomized controlled trials with wider confidence intervals, $n < 100$), IV (case series or cohort study without concurrent control, case-control study) or V (case study).

The total number of subjects in all of the studies was 26, with 50% of those subjects in the Andrade and colleagues²⁴⁶ study. All six studies reported improvements in strength; however, only three noted statistically significant results. Although the evidence suggests the possibility of being able to increase muscle strength using these modalities, in this population one must interpret the results with caution owing to lack of rigor, small subject populations, and variability across studies.

Spina bifida is a congenital-onset condition that requires intervention by the PT from infancy through adolescence. Most of the impairments and functional deficits described throughout this chapter last throughout a lifetime. Health providers familiar with the complexity of the secondary impairments should follow individuals with spina bifida on a regular basis. The PT plays an important role in screening for potential problems and providing recommendations for maintenance of mobility and health-related fitness as well as promoting activity and participation for children with spina bifida. OTs within the school systems often provide interventions within the area of integration of perceptual function. However, additional research needs to be done to guide “best practice,” as there is little support for those interventions that expert clinicians deem beneficial in the habilitation of these patients.

Obesity affects ability for interaction and participation at multiple levels across the life span of those with spina bifida. Obesity may affect independence in transfers and ambulation, self-care and mobility, as well as personal social interactions at all ages. Often the child with spina bifida may be the last to be asked to participate and/or the child’s inability may affect his or her ability or willingness to participate in physical games and activities with peers. Equipment and orthotic needs can also be complicated by increases in weight gain and obesity as the child ages.

Studies using dual-emission x-ray absorptiometry (DEXA) have shown that those with spina bifida have significantly decreased lean body mass as compared with controls.²⁴⁸ Children with spina bifida likely have lower metabolic rates secondary to decreased muscle mass and decreased ability to burn calories. Those with higher-level lesions often have greater issues with obesity owing to decreased lower-extremity muscle activity, decreased physical activity, and decreased overall muscle mass. Adult wheelchair users have been shown to require 1500 fewer calories per day, and overall nutritional intake should be lower for those with spina bifida than their typically developing peers.²⁴⁹⁻²⁵¹ Interventions to address physical inactivity and obesity may include increased physical activity, regular exercise, behavioral modifications, nutrition education programs, and attention to weight control. Exercise programs targeting upper-extremity resistance combined with aerobic activities such as swimming and arm-cycling using arm-ergometry can be helpful in addressing obesity in those with spina bifida. Adolescents with spina bifida who used an upper-extremity cycling program that was integrated with video gaming three times per week for 16 weeks improved oxygen uptake and maximum work capability.^{248,252,253}

Sensory limitations may impede progress during early ambulation training. Because of limited kinesthesia and proprioception, available sensory systems must be augmented and the child taught to substitute with nonimpaired sensory systems. Impaired kinesthesia in children with myelomeningocele

impedes their ability to anticipate changes in terrain and poses a safety problem. Vision may be the most relevant system to allow them to scan and preplan for changes in their walking environment.

Gait training and muscle strengthening are not the only consideration of the therapist. How cognitive and psychosocial development can be enhanced during this stage of the child’s development is also important. One appropriate solution is to place the child in a center-based EI program. Although these programs may vary in the services they provide, most usually include age-appropriate play activities and some type of parental counseling. In addition, many offer therapeutic intervention from physical, occupational, and speech therapists. This intervention may occur in groups or individually and typically occurs in the child’s natural environment.

In addition to the socialization that center-based EI programs provide for the child with myelomeningocele, they also teach the child age-appropriate ADLs, such as dressing and undressing. At this age ADL skills are more appropriately taught in a group setting than individually. For many children the EI program, along with individualized therapy, is sufficient to enhance development in the physical, cognitive, and psychosocial realms.

Presently, when children reach age 3 years, public school education becomes available to them. The pre-school or early childhood (EC) program continues to offer the same fundamental benefits as the EI program. It is the role of the EI therapist to communicate the specific needs of each child entering the public school system. In this way continuity in the child’s rehabilitation program is preserved.

The spina bifida team, usually headed by a pediatrician or clinical nurse specialist, continues to follow the child closely during this stage. The neurosurgeon checks shunt functioning and performs revisions as necessary. The orthopedist supervises bracing efforts to prevent and correct deformities in the spine and lower extremities. Well-child care and general medical treatment are the responsibility of the pediatrician on the team. The urologist continues to monitor renal functioning while keeping the child dry and free of infection. At this stage the clinical nurse specialist will usually teach bowel and bladder training to the child and family. This clinician generally initiates this training according to age-appropriate developmental guidelines.

Bladder training usually consists of transferring the job of CIC from the parents to the child. Children as young as 3 years, but certainly by the age of 5 years, can learn CIC in a short period.²⁵⁴ Children may first practice on dolls with male and female genitalia. Next, using mirrors to understand their own genital anatomy, they are able to accomplish the technique on themselves. CIC in conjunction with pharmacotherapy is useful in achieving continence in children with spina bifida.¹⁴⁰ Another method of bladder training recently being used in the United States is intravesical transurethral bladder stimulation. This technique has allowed children with neurogenic bladder to rehabilitate their bladder function so that they can detect bladder fullness and generate effective detrusor contractions, leading to improved continence.^{100,255}

Bowel training can be achieved through proper diet, regular evacuation times, and appropriate use of stool

softeners and suppositories.¹⁰⁰ Constipation (and resulting bypass diarrhea) can be prevented by proper habit training and use of fiber supplements. Stool softeners (not laxatives and enemas) and suppositories should be used to keep the stools soft and help stimulate evacuation. Finally, toilet training, which amounts to scheduled toileting in time with the stool stimulants, usually achieves bowel continence. Surgical procedures, such as the Malone ACE procedure,⁹¹ may be necessary when other interventions have failed. The Malone ACE procedure, performed in conjunction with a Mitrofanoff procedure to gain urinary continence, can help these patients attain a better quality of life. Consistency at each step along the way is the key to successful bowel training. A therapist may be called on to assist the parents and child in achieving independence in this ADL.

Other members of the team, such as the psychologist, social worker, and dietician, continue to function in their appropriate roles, interacting with the child and family as necessary. PTs and OTs, as members of the team, must collaborate with the efforts of other team members in the creation of their treatment plans.

Mobility and bladder and bowel dysfunction in toddlers and school-age children represent ongoing stressors for parents of children with spina bifida. It has been noted by many that spina bifida represents a considerable challenge to all family members, particularly mothers. Family climate, parents' partner relationships, and social support networks play a considerable role in balancing stress and psychological adjustment for parents. Awareness of available systems of support for the patient and family as well as resources to which parents and their children can be referred for psychological and social support as needed is important for all health care practitioners.^{256,257}

Stage 5: Primary School through Adolescence

The fifth stage of development is marked by less rapid growth than earlier childhood but ends with a period of rapid physiological growth. Children in the 6- to 10-year age group are interested in a wider variety of physical activities as they challenge their bodies to perform. The adolescent, however, is going through a period of great sexual differentiation as primary and secondary sexual characteristics develop more fully.

Cognitively, children are able to solve problems in a more sophisticated manner, although they revert to illogical thinking with complex problems. As they reach adolescence, they become capable of hypothetical reasoning and their thought processes approach those of adults.

Emotionally, the 6- to 10-year-old is in a period of relative calm. Children are interested in schoolwork and are eager to produce. This is a period during which they are developing relationships outside of the family and beginning to assume an identity and autonomy. Problem-solving and decision-making skills are at the crux of this time period. However, it is also challenging to promote independence and minimize self-reliant behaviors. Social passivity may ensue as "learned helplessness" behaviors emerge. Therefore professionals, including both PTs and OTs, should begin targeting independent function early, and before adolescence.²⁵⁸ Relevant family education regarding this issue should be inherent in all care plans, and independent

behaviors should be promoted from very early on. Engagement in family decision making and opportunities for active problem solving have been linked to increased positive self-esteem and ego development.²⁵⁹ During this time period, children with spina bifida are at risk for developmental delays in social functioning.²⁵⁸

During this period, they are building the skills of the future, preparing them for adult work. This is a prime time to introduce and teach new skills while fostering increased autonomy and independence. Autonomy is difficult for the youngster with spina bifida. Motor skills impeding progress toward autonomy vary for each child and are dependent on the level of spina bifida as well as any cognitive impairment. However, it has been observed that the motor skills hardest to attain are those that involve motor planning and that the process skills hardest to attain are related to adaptation of performance and initiation of new steps. Thus guidance to learn not only how to do things but how to get things done is important.²⁶⁰ Interventions targeting independence have been embedded into several camp programs throughout the country geared specifically toward those with spina bifida. O'Mahar and colleagues²⁶¹ report on one such camp program focused on campers 7 to 14 years of age in northern Illinois. Camp Ability emphasized individualized collaborative (i.e., parent and camper) goal setting, group sessions with psychoeducation and cognitive tools, and goal monitoring by the camp counselor. Campers reported significant gains in individual goals, management of spina bifida responsibilities, and independence. Medium effect sizes in goal attainment and progress from the start to the end of the camp session were noted.²⁶¹ It appears that these camps may have significant benefit in addressing management of one's disability as well as independence in self-care skills. An added benefit is the social interaction and physical activity that the camp participants engaged in while working toward their goals.

As the energy cost of walking becomes too high, use of a wheelchair for locomotion often becomes appropriate. To a teenager whose emotional needs include a strong peer identity, transitioning to a wheelchair may foster increased independence owing to improved ability to participate and engage with peers. Appropriate alternatives may be to delay the decision to use a wheelchair full time or limit ambulation to short distances or to those places most important to the child. Again, goals must be tailored to the child's needs and encompass his or her whole being.

In accordance with the child's growth spurts, frequent adjustment or reordering of bracing will be necessary. Continual reevaluation of orthotic needs may reveal that the level of bracing may decrease as the child grows and becomes stronger; the opposite development is also a possibility.

Usually during this stage, if it has not occurred previously, the evaluation of future ambulation potential occurs. The child whose larger size and limited abilities make ambulation more difficult each day frequently requests this evaluation. Strength does not increase in the same proportion as body weight.¹²⁷ Ambulation, although possible for the young child, may be impossible for that same person as a young adult.

Although no guidelines include every patient, generally children with thoracic-level lesions are rarely ambulators by the late teens.^{152,262,263} Those with upper lumbar lesions may

be household ambulators with long-leg bracing but will require wheelchairs for quick and efficient mobility as adults. With low lumbar lesions, most adults can become community ambulators. Patients with sacral-level lesions are usually able to ambulate freely within the community. Many require minimal bracing and ambulate without assistive devices.^{152,159} It must be remembered that ambulatory status is not determined by level of the lesion alone. The muscle power available; degree of orthopedic deformity; age, height, and weight of the patient; and, of course, motivation are also determining factors.^{82,154,159,264}

Because a large number of older children with spina bifida will become wheelchair dependent, potential problems connected with a sedentary existence must be explored. Skin care, always a concern for the child with spina bifida, becomes a priority for the constant sitter. Mirrors may be used for self-inspection of the skin twice daily. Well-constructed foam, gel, or air-cell seat cushions are essential for distributing pressure evenly. Children should be taught frequent weight shifting within the chair to relieve pressure areas. Clothing should not be constricting but should be heavy enough to protect sensitive skin from wheelchair parts. Children must also be taught to avoid extremes of temperature and environmental hazards, such as radiators, sharp objects, and abrasive surfaces. The therapist must reinforce the importance of skin care to prevent setbacks in the rehabilitation process that may result when skin breakdown develops.

Children with higher-level lesions may need spinal support to prevent deformities. A polyethylene body jacket or thoracolumbar-sacral orthosis (TLSO) can be used to provide this support and, it is hoped, prevent the progression of any paralytic deformities. Whatever type of device or wheelchair padding is used, the therapist must check to see that weight is distributed equally through both buttocks and that the spine is supported as needed. Part of the therapeutic intervention is to provide strengthening exercises or activities to be done out of the supporting orthosis. This is necessary to maintain existing trunk strength and to preserve the child's present level of function.

Generally, in late childhood or early adolescence, orthopedic deformities that have been gradually developing require surgical intervention. Progressive scoliosis or kyphosis may require internal fixation when conservative methods fail.²⁶⁵ Sectioning of tight or contracted muscles at the hip and knee is often required.¹⁵² The iliopsoas, adductors, and hamstrings are frequently the offending muscles. These surgeries, followed by strengthening exercises and gait training, often add to the ambulatory life of the child with spina bifida. For example, in a child who displays an extreme lordotic posture, hip flexion contractures may be present and surgical lengthening of the tight muscles may be required to allow improved biomechanical alignment for standing and balance. Strengthening of the hip extensors and abdominals also helps prevent future muscle imbalances that may lead to contractures and tightness. A postoperative therapeutic program might include periods of prone lying to prevent future contractures and strengthening of hip extensors and abdominals that were previously overstretched by the lordotic position.

Of primary importance during this stage is preparing the child for independence in ADLs, which may be broken down into self-care, locomotion-related, and social

interaction activities. In conjunction with the nurse, PT, and OT, self-care skills of dressing, eating, and food preparation; general hygiene; and bowel and bladder care can be addressed. Because the adolescent is so concerned with achieving independence, he or she is more likely to comply with a regimen of strengthening exercises if shown how they relate to functional independence. A creative therapist may, for example, incorporate trunk stability and upper-extremity strengthening work in activities such as making popcorn or getting ready for a dance. In addition, fostering social and recreational independence through adaptive sports and fitness programs and leisure activities should not be overlooked. Participation in adaptive sports can aid immensely in improving strength, endurance, and self-esteem. Community adaptive recreational programs may include T-ball, martial arts, swimming, tennis, basketball, skiing, bowling, and many other common sports and leisure activities (Figures 15-21 through 15-23).

Locomotion activities should include all gait-related skills, such as falling down, getting up, and ambulation on various terrains and stairs. Transfers of all types should also be included in locomotion activities. Again, a creative therapeutic program helps make achievement of skills more palatable. For example, school-aged children may enjoy a competitive relay race situation in which each child falls, gets up, walks across the room, and sits down in a chair safely. This type of activity combines gait-training activities with group socialization and may meet a variety of goals (motor and psychosocial) at the same time.

Achievement of independence in ADLs for the child and adult with spina bifida does not depend solely on the level of paralysis. Also important are psychosocial and environmental factors. Mean ages for the achievement of various ADL activities have been developed and may assist the therapist in establishing realistic therapeutic goals in this area.²⁶⁶

Figure 15-23 ■ Participation in adaptive tennis. (Courtesy Su Metznel.)

Often during this stage of rehabilitation the therapist is asked to assist in assessing cognitive function. The perceptual and cognitive evaluations previously discussed may be administered and the results interpreted for parents and school personnel.

Also as previously discussed, children with spina bifida have a general perceptual deficit that can manifest itself in a variety of ways. First, the child may have difficulty recognizing objects and the relations that they have to one another. He or she may therefore perceive the world in a distorted manner and have reactions that are unstable and unpredictable. These perceptual difficulties will most likely affect academic learning, and the child may associate failure with the learning process. Difficulties in attaining independence in ADLs are also linked to perceptual problems. Finally, emotional disturbances may be attributed in part to the perceptual difficulties of the child with spina bifida.⁹⁸

Remedial programs, such as the Frostig Program for the Development of Visual Perception, have been effective in improving the visual perception of children with spina bifida.⁹⁸ Programs of this type are most effective when remediation begins early—preferably at or before the time the child enters school. Developmental optometry examination and remediation programs focusing on vision training may also be of benefit.

Children with spina bifida may also have difficulties with tasks requiring sensorimotor integration. Children requiring programs for sensorimotor integration should be referred to a therapist certified in this area. If one is not available, many appropriate activities for sensorimotor integration may be adapted from Ayres²⁶⁷ or Montgomery and Richter.²⁶⁸

Regardless of the school setting chosen for the child, the therapist should be able to serve the classroom teacher as a consultant. Advice on adaptive seating and therapeutic goals appropriate for the classroom help ensure that the rehabilitation process will continue in the classroom as well as promote optimal conditions for learning.

When a child is moving from the preschool to the elementary school setting, the support of the therapeutic team is essential and invaluable. The teacher's expectations, as created by the therapist, regarding the child's special needs and abilities often spell the difference between success and failure of complete academic and psychosocial integration within the school setting. Even though the child may no longer require direct therapeutic intervention, periodic consultation, including site classroom visits, is recommended to prevent minor problems from developing into major ones. For example, bowel and bladder accidents can be avoided by scheduling regular times for toileting. The teacher may be able to make minor adjustments in the teaching schedule to accommodate this scheduling. Also, full-control braces (from hip to ankles) may seem overwhelming to the layperson. If the teacher is shown how the braces lock and unlock to allow the child to sit or stand to walk, he or she may feel more at ease if ever called on to assist the child.

The psychological perspective of the child colors therapeutic goals in this stage. As the child nears adolescence, these psychosocial aspects become of paramount importance. Although the therapist should not take on the role of the psychologist, collaborative efforts in the area of counseling will be necessary. Questions will arise many times during physical and occupational therapy sessions, requiring factual answers that the therapist can and should provide.

TRANSITIONS: ADOLESCENCE

The consequences of the physical, medical, and cognitive effects of spina bifida extend into young adulthood and have an impact on quality of life.²⁶⁹ Adolescence is a

stormy emotional period. Adolescents remain in turmoil as they seek their identities through sexual, social, and vocational activities. As their value systems develop, they feel less ambivalence between remaining as children and striving for independence. For the child with myelomeningocele, adolescence is not an optimal time to introduce new skills leading toward self-care and independence.

TRANSITION TO ADULTHOOD

Eighty-five percent of infants born with spina bifida will reach their adult years.¹⁶⁹ For the adolescent with spina bifida the transition to adulthood includes a new set of expectations. Independent mobility expands to driving or arranging public transportation and getting to the correct destination in unfamiliar surroundings, including accessibility to the community for leisure and recreation, continued education, or job opportunities. Self-care includes performing ADLs but expands to household management and financial responsibilities. Social relationships expand to a larger arena including long-term partnerships with friends and business contacts and encounters with equipment vendors, insurance professionals, and medical providers and may include hiring, firing, and directing personal health care assistants. Recent information from the *American Journal of Public Health* indicates that 50% to 70% of adults with spina bifida live with family or in an assisted-living arrangement.²⁷⁰ For some adults with spina bifida, living independently in our society is a difficult goal to reach.

The individual with spina bifida continues to require assistance with management of and resources related to medical, rehabilitative, and social-emotional needs through adulthood.^{169,270-272} Secondary impairments span a wide range of domains, but management of secondary health conditions is a priority in reducing mortality, deterioration of general health, and further impairments through the adult years. Renal, respiratory, and cardiac complications have been identified as frequent causes of death.¹⁶⁹ Living with the long-term consequences of spina bifida places increased demands on the musculoskeletal system, and the effects of aging can appear earlier than usual. Osteoporosis, increased risk of fractures, risk of osteoarthritis, and muscular pain from overuse of the upper extremities with use of crutches, longer-distance wheelchair propulsion over all terrains, increased transitions for self-care management and routines, and abnormal stresses placed on the knee from weak hip abductors and calf muscles can lead to degenerative changes and joint pain. Obesity and weight gain resulting from a more sedentary lifestyle and hypertension, heart disease, and diabetes are common problems with aging.²⁷³ Thinner and less elastic skin that is susceptible to breakdown, insufficient pressure relief and poor tissue perfusion, incontinence and perspiration, wound infections after surgical procedures, burns and bumps that occur to insensate limbs, and long-term immobilization during hospitalizations have been major sources of decreased skin integrity.^{169,273,274}

Muscular strength, flexibility, balance, and endurance decrease during the aging process. Changes in the CNS affect memory, reaction time, and attention span. An increased risk of depression and anxiety has been documented in several studies that measure quality of life in the adult with spina bifida.^{169,272,275} Secondary conditions in adults with spina bifida have been linked to admission rates

to hospitals that are nine times higher than in the nondisabled population. Adults with spina bifida have medical expenditures that are three to six times greater than those of adults without spina bifida.¹⁶⁹

Although there are few standard protocols to follow in the medical management of adults with spina bifida, the coordinated interdisciplinary approach shown to be effective in the care of children and adolescents is not available to most adults with spina bifida. A recent study from the Netherlands that reviewed life span issues of people with childhood-onset disabilities reported that more than 50% requested more information on their specific medical condition and the consequences of this condition on adulthood recreation.²⁷⁵ In a 2009 study from the University of Pittsburgh that surveyed 179 adults from 19 to 64 years of age, 75% could not name their primary care physician and had not seen a medical professional in over a year.¹⁶⁹

Dicianno and colleagues¹⁶⁹ identified five key elements necessary for the successful transition from pediatric to adult medical care. These included early preparation and education of the individual and family, flexible timing of the transition, introduction to the transition clinic, interested adult center providers, and a coordinated transfer of care approach among the individual, family, pediatric primary care providers, and adult specialists. The barriers included child health care providers refusing to “let go,” reluctance to leave a family-centered care program, and adult care providers having limited knowledge about or interest in caring for these individuals. Finding a primary care physician or physiatrist who can assist with identifying a team of health care specialists for referrals as needed is a major concern for this adult population. The Spina Bifida Association of America publishes a health guide for adults living with spina bifida, based on feedback from adults across the United States. The *Health Guide* was sponsored by a grant from the National Center for Birth Defects and Developmental Disabilities and the Centers for Disease Control and Prevention.

Additional unmet needs reported by adults surveyed were related to functional mobility, household management, and active recreation. Being independent with regard to mobility was the most important determinant in quality-of-life surveys.^{16,275} A review of the literature of the past few years has indicated high unemployment rates for people with disabilities. For those with spina bifida, 47% of adults were in competitive employment, 15% were in sheltered or supported employment, and 38% were unemployed or had never been employed.²⁷⁶ Limited mobility accounts for only part of the high unemployment rate. Accessibility into public buildings is another factor that limits employment opportunities. Tight doorways, steep ramped entrances and exits, inefficient workstations, and unreliable public transportation all play a role in a lower employment rate. Universal design (broad-spectrum solutions that produce products and environments that are usable and effective for everyone), construction of newer buildings with attention to adjustable work tables for computers and equipment access for people with different body proportions, wider doorways, lower counters, doors that open electrically, and bathroom modifications (for both manual and power wheelchair users) with Americans with Disabilities Act (ADA) specifications for building modifications will improve universal access for all people with and without disabilities. Modifications of

bathrooms that accommodate wheelchair and crutch users including different height grab bars and roll-in shower arrangements, sloping landscape for entrances and exits, and room modification with lower counters and closet access, to name a few considerations, may enhance travel and leisure time and recreational opportunities.

According to the *American Journal of Public Health*, most adults with spina bifida use some form of assistive technology (AT) that plays a significant role in increasing independence at home and in the community.²⁷² Thirty-five percent use bracing, 23% use walking devices, and 57% to 65% use lightweight wheelchairs (both manual and power assisted). PTs and OTs have extensive knowledge in the field of rehabilitation. Mobility equipment needs change as people age. Therapists have expertise in adaption and modification and can recommend solutions for decreased mobility. Physical changes in the workplace and home to decrease excessive stress on joints while maintaining flexibility and musculoskeletal alignment for efficiency without pain may also be required. Evaluating the individual needs of the client and locating and selecting the types of technology that may enhance the adult's personal care management and improve efficiency in household tasks may make the difference in helping the client have a more satisfying quality of life. Cell phones, computer access, and watch timers for pressure relief and personal care routines can all assist memory and organizational skills.²⁷²

AFOs with carbon springs that store energy, crutch tips that can be changed to accommodate different surfaces (e.g., with spikes attached for snow and ice), forearm crutches with hand grips and forearm cuffs that distribute weight and reduce joint stress to shoulders and wrists, powered add-on devices for manual wheelchairs to reduce stress on painful shoulders, adjustable furniture, and wrist rests, footrests, and arm supports to ensure correct posture and reduce cervical and lumbar strain are examples of current and experimental AT that may promote greater independence. Specific devices are supported by the individual needs assessment of the patient by the therapist and education in the device's maintenance for appropriate use and durability. It is beyond the scope of this chapter to discuss specific equipment items.

Spina bifida is a congenital-onset condition that requires intervention by the therapists from infancy through adolescence. Most of the impairments and functional deficits described throughout this chapter last throughout a lifetime. Health providers familiar with the complexity of the secondary impairments should follow individuals with spina bifida on a regular basis. Both PTs and OTs play an important role in screening for potential problems and providing recommendations for maintenance of mobility and health-related fitness.

Adolescents with spina bifida show great concern about self-esteem and social-sexual adjustment.²⁷⁷ These concerns appear directly related to efficient bowel and bladder management.²⁷⁸ Strategies to cope with bowel and bladder difficulties, as previously outlined, combined with appropriate emotional support from family and medical personnel help alleviate this concern.

Although great advances in medical management of children with myelomeningocele have occurred, a contrasting lack of improvement related to sexual function and reproductive issues exists. Five factors have contributed to

delayed social and sexual growth in these adolescents: (1) severity of the mental handicap, (2) poor manual dexterity, (3) lack of education, (4) overprotective parents, and (5) limitations in health care personnel's ability to address sexuality with physically disabled patients and their families.²⁷⁹ Either the parents or the child may bring up questions about sexuality. Parents of children with spina bifida realize the need to teach their children about sexuality, but they often feel inadequate about doing so and are reluctant to bring up questions to health care professionals.²⁸⁰ The therapist must be open, informed, and able to provide resources to both parents and children.

Generally, the sexual capacity of the female with spina bifida is near normal—that is, she has potential for a normal orgasmic response, is fertile, and can bear children.²⁸¹ The pregnancy, however, may be considered high risk, depending on existing orthopedic abnormalities. Affected males are frequently sterile and have small testicles and penises. Their potential for erection and ejaculation depends on the level of the lesion. In many cases psychological problems may be a primary cause of sexual failure. Sexuality is not merely a process involving the genitalia; it also depends on a positive body image and a feeling of self-esteem that is nurtured from birth.²⁸²

PSYCHOSOCIAL ADJUSTMENT TO CONGENITAL CORD LESIONS

The previous sections on goal setting and rehabilitation of the child with spina bifida covered birth through adolescence. After adolescence, rehabilitation can be handled in much the same manner as an adult spinal cord injury. Keeping in mind the global effects of spina bifida on the growing child as he or she approaches adulthood is important, however.

Because of the congenital nature of spina bifida, psychological adjustment is somewhat different from adjustment to a traumatic spinal cord injury. The psychological adjustment to this congenital disability must be considered from the perspective of the parents, the family, and, of course, the child.²⁸³

A longitudinal study concerning the psychological aspects of spina bifida showed that the parents go through a series of steps in the adjustment process. From birth to approximately 6 months of age, the parents experience shock and bewilderment. Information given during this time may be rejected or misinterpreted. Health care professionals therefore must be ready to repeat the same information to parents on several occasions during the first few years of the rehabilitation process. The period of 6 to 18 months of the child's life may be the most stressful on parents. Frequent hospitalizations during this time place increased pressure on the whole family. Parents are now able to comprehend fully the implications of their child's functional limitations and inability to participate in life. They begin to worry about the future and the impact of the disability on the rest of the family structure. The period from age 2 years through the preschool years is relatively peaceful. The parents are more concerned with toilet training, social acceptability, and general information on child rearing. They seem less aware of their child's cognitive limitations as he or she continues to develop into a relatively happy, well-adjusted child.

By the age of 6 years, children are becoming more aware of their limitations and parents are concerned about problems that may arise as their children enter elementary

school. The child's psychological adjustment depends on the severity of the motor problems but primarily on the attitude of the parents and family and on the environmental conditions to which he or she is exposed.^{284,285}

Because of their disabilities, children with spina bifida are often denied small tasks or chores that promote a sense of responsibility in the growing child. To promote emotional growth and psychological well-being, caregivers must be

persuaded to let go. Children with spina bifida must develop responsibility and independence by being given the chance to interact and even compete with their peers. During adolescence, concerns regarding independent living situations and vocational placement must be addressed. With a foundation of strong support systems fostering emotional maturity, the future can be bright for the child with a congenital spinal cord injury (Case Study 15-1).

CASE STUDY 15-1 ■ MICHAEL

This case study focuses on the physical therapy management of Michael, a teenage boy with myelomeningocele, a congenital spinal cord injury. Michael is now 16 years old and a sophomore in high school.

A spinal cord injury is a complex disability. When a spinal cord lesion exists from birth, an additional level of complexity is added. This congenital condition predisposes the CNS to have many areas that may not develop or function adequately. In addition, all areas of development—physical, cognitive, and psychosocial—that depend heavily on central functioning will likely be impaired. The clinician therefore must be aware of the significant impact this neurological defect has on motor function as well as a variety of related human capacities. Management can best be organized by using the *Guide to Physical Therapist Practice*. The following case study uses the concepts in the *Guide* to discuss several episodes of care throughout Michael's life.

The *Guide to Physical Therapist Practice* is designed to provide a framework for the PT to assist in client management.¹ During the infant to adolescent period of life, Michael's specific PT needs will change. Michael's presentation of congenital spinal cord dysfunction may be best represented through the life span by preferred practice patterns, which may include the following¹:

- 4F: Impaired joint mobility, motor function, muscle performance, range of motion, and reflex integrity associated with spinal disorders
- 5C: Impaired motor function and sensory integrity associated with nonprogressive disorders of the central nervous system—congenital origin or acquired in infancy or childhood
- 6E: Impaired ventilation and respiration or gas exchange associated with ventilatory pump dysfunction or failure
- 7A: Primary prevention and risk reduction for integumentary disorders

Examination (evaluation) is a comprehensive screening and specific testing process that leads to a diagnostic classification required before intervention and is performed for all clients. It consists of three components: client history, systems review, and tests and measures. The PT may identify impairments, functional limitations and disability, and changes in physical function or overall health status. The PT synthesizes the findings to establish a working diagnosis (ICD-9 code 741.0). Results from the evaluation are established, and interventions with anticipated outcomes are made.¹ Refer to Tables 15-4 to 15-10 for a detailed synopsis of Michael's episodes of physical therapy during his 16 years. The OT should go through a similar process of screening and testing to develop a conceptual

model for case management within the scope of occupational therapy. Many of the examination tools and intervention strategies may be the same, although the objective outcome may focus on different expectations.

NEWBORN EPISODE OF CARE

Michael was a term baby delivered by planned cesarean section with a prenatal diagnosis of myelomeningocele. The diagnosis was made during the second trimester after fetal ultrasound evaluation and amniocentesis. The family met with the neurosurgeon before delivery. Michael was delivered at 38 weeks of gestation and was transferred at 1 day of age to the local children's hospital for a planned surgical closure of his spina bifida. An orthopedic, urological, neurosurgical, and physical therapy assessment occurred at 1 day of age before back closure. Michael was the second child for this family. His mother was diagnosed with breast cancer at his birth. His sister is 2 years older and lives at home. Both parents are professional working parents; they have a nanny to assist with child care.

Presurgical MMT showed the presence of hip and knee musculature (L2-L4). Three days after the back closure, Michael required VP shunt insertion to control hydrocephalus. Postoperative MMT findings at 7 days of age were identical to preoperative results. Before discharge at 8 days of age, the parents were instructed in ROM exercises, positioning, and developmental handling. Michael would be monitored in a myelomeningocele clinic twice a year for an MMT and functional assessment with a team of health care providers (see Table 15-4).

EPISODE OF CARE: 6-MONTH FOLLOW-UP

At the age of 6 months Michael was readmitted to the hospital because of a shunt malfunction that necessitated VP shunt revision. After 2 weeks at home Michael returned to the clinic for postoperative follow-up. No medical concerns were present, but clinicians discovered that Michael had not yet begun to roll over. An evaluation with a standardized test was conducted. The AIMS was administered as well as additional tests of ROM, strength (by observation), reflexes, muscle tone, and endurance to establish a developmental baseline. At this visit a total-body night splint was fabricated to maintain hip alignment and prevent contractures of the lower extremities. Family education in latex precautions was provided. The need for assistive and adaptive devices was also assessed.

At this point, Michael had not received physical therapy because of the mother's health issues. Because of this situation, physical therapy that could be provided at home was recommended. The family was given a referral to their local EI system and a list of local pediatric physical therapy providers to obtain services (see Table 15-5).

Continued

CASE STUDY 15-1 ■ MICHAEL—cont'd**EPISODE OF CARE: EARLY INTERVENTION**

The family contacted their local EI program after the previous clinic visit. An evaluation and assessment determined Michael was eligible for services. A variety of appropriate developmental assessments were used to determine eligibility (see Table 15-6). At the individual family service plan meeting, physical therapy intervention was determined to be the primary service at this time. Occupational, developmental, and speech therapies were not recommended. Michael received weekly physical therapy from age 6 months through 3 years. Therapy focused on developmental exercises to promote mobility, sitting and standing balance activities, strengthening available lower-extremity musculature, and orthotic assessment and gait training. The EI PT instructed the family in activities to complement the weekly physical therapy program. Michael began crawling at 1 year. At 10 months he used a vertical stander to initiate an upright stand position and began gait training at 15 months. Michael began walking with AFOs and a forward walker at 30 months (see Table 15-6).

EPISODE OF CARE: EARLY CHILDHOOD

At age 3 years, Michael transitioned into an EC program at his local school. Physical therapy was a related service that was included as part of his IEP. The transition meeting from EI to EC programming provided continuity of care unique to his needs. A global assessment tool to assess his mobility and self-care skills was administered. This test, the PEDI, was administered by the PT. Physical therapy management included ROM, strengthening, and gait training as it affected his ability to function in the preschool classroom and surrounding play areas. The school he attended was environmentally appropriate for his needs. It was one level, with wide doorways that allowed the use of his walker and then progressive use of forearm crutches with AFOs to advance his mobility skills. At the suggestion of his PT in the outpatient myelomeningocele clinic, Michael became involved in a toddler swimming program at the park district. A tricycle was adapted at the recommendation of the same therapist to assist with strengthening his lower extremities and to allow him to efficiently keep pace with his peers (see Table 15-7).

Another framework that can organize the management of Michael's interventions is the ICF. The ICF identifies components of health and contextual factors that are important for achievement of desired outcomes.²⁸⁶ Relationships between components of health and contextual factors change over time. An example is given for one episode of care in EC (Figure 15-24).

At age 5.5 years, an IEP meeting was conducted before Michael entered kindergarten. The family and school team decided that no resources or special adaptations were necessary to enhance his education. The school he was to attend was determined to be environmentally appropriate to meet his needs.

EPISODE OF CARE: TETHERED CORD EPISODE (AGE 6 YEARS)

At his semiannual visit to the myelomeningocele clinic, the parents mentioned that Michael was falling frequently while using his forearm crutches and AFOs. Reddened areas at the left lateral calcaneus were noted. Routine MMT showed decreased strength in his left leg with an increase in muscle tone through his left leg. An MRI revealed a tethered spinal cord. A neurosurgical TCR was performed and his AFOs were revised. Two months after TCR Michael was again independent in ambulation and had progressed to stair climbing with one rail. His next routine 6-month MMT showed a return of strength to the level that preceded his tethered cord episode (see Table 15-8).

EPISODE OF CARE: PREADOLESCENCE (7 TO 10 YEARS OF AGE)

Michael's physical conditioning continued to progress, and from ages 7 to 10 years he participated in adaptive sports and activities in his community. Swimming had become a favorite activity. He had been swimming to increase strength and endurance since he was a toddler at the suggestion of his PT. Because of his activity level and independence in most functional activities, routine physical therapy had been discontinued, with only biannual clinic visits remaining. Michael and his family continued intensive stretching and a prone positioning program that they had been performing since Michael was a toddler. At his 10-year clinic visit, the therapist administered formal MMT and ROM assessment and also carried out the PEDI. Scaled scores on the PEDI were used because he was above the age of normed standards for the test. An area of skin breakdown was noted on the left malleolus and decreased weight bearing was noted during gait. MMT and orthopedic examinations showed no changes. A brace check noted the AFO was too small and needed to be replaced. The brace was replaced and the PT reviewed skin care and brace fit with Michael and his family (see Table 15-9).

EPISODE OF CARE: ADOLESCENCE (AGE 13 YEARS)

At age 13 years Michael had gained a significant amount of weight that was limiting endurance for long-distance ambulation. Michael was referred to a nutritionist for counseling. The PT in conjunction with the physician discussed with Michael and his parents the possibility of using a wheelchair for long-distance travel. After much discussion and initial resistance from Michael, Michael and his family decided to try a wheelchair. At age 16 years, Michael continues to be an independent ambulator and uses a wheelchair for long distances only. He continues to be monitored on an annual basis or as needed as problems arise. Michael's physical therapy has encouraged and continued to motivate him to maintain his participation in sports activities during his teenage years (see Table 15-10).

EPISODE OF CARE: ADULTHOOD

Michael has graduated from high school and has been attending college on a large campus the past few years as a graduate student majoring in history. He works part time as a tour guide at the Museum of Natural History. As he drives to work, he is required to transfer to and from his car on a regular basis. He needs to disassemble his chair to get it in and out of his car efficiently. Increased frequency of transfers to and from the car, as well as the need to disassemble and reassemble his chair on a regular basis, has led to an increase in shoulder pain and discomfort. He continues to use his crutches for short distances (150 feet) at work using a swing-through gait. He uses an ultra-light manual wheelchair for all other mobility throughout the day. His wheelchair is equipped with carrying loops for his crutches at the back of his chair. Michael returned to his primary care physician because of his new episode of pain. He was referred to PT to address his issues with pain. The PT has evaluated his gait and recommended that to minimize stress on his shoulders he should switch from a swing-through to a four-point gait pattern (Table 15-11). He has also been referred to OT for further assessment of efficient transfer techniques to and from the car. In addition, a referral to an AT team has been recommended to evaluate the need for assisted power wheels as well as an additional means of transportation to reduce stress on his shoulders.

TABLE 15-4 ■ NEWBORN EPISODE OF CARE FOR CHILD WITH SPINA BIFIDA

PRACTICE PATTERNS	SYSTEMS TO REVIEW	TESTS AND RESULTS	INTERVENTIONS	ANTICIPATED GOALS AND EXPECTED OUTCOMES
4F 7A 6E 5C	Musculoskeletal Integumentary Cardiopulmonary Neuromuscular Cognition and communication	MMT: No innervation below L4 Muscle length: WFL ROM: WFL Skin integrity: WFL HR/RR/CE: WFL Reflexes: Absent DTRs below knee (+) Suck/swallow (+) Galant Muscle tone: Flaccid below L4; low in trunk; UEs WFL Motor skills: On informal testing turns head, kicks, clears head in prone Observation: Decreased pain in LEs	Collaborate and coordinate systems review evaluation results with health care team. Document impairments, functional limitations, and strengths. Prepare a plan of treatment. Therapeutic exercises to improve balance, muscle strength, and mobility. Family training: instruction in ROM; developmental positioning for function and enhancement of performance; instruction regarding sensory impairment and skin integrity and areas of pressure; and instruction in signs of VP shunt malfunction.	Joint integrity and mobility improves. Postural control and muscle performance improves. Sensory awareness develops appropriately. Risk prevention: parents understand signs and symptoms of VP shunt malfunction. Caregivers understand importance of checking skin for irritation and breakdown. Cognition and language develops appropriately. Improved infant and family sense of well-being. Stressors decrease.

CE, Cardiorespiratory endurance; *DTR*, deep tendon reflex; *HR*, heart rate; *LE*, lower extremity; *MMT*, manual muscle testing; *ROM*, range of motion; *RR*, respiratory rate; *UE*, upper extremity; *VP*, ventriculoperitoneal; *WFL*, within functional limits.

CHAPTER 16 Traumatic Spinal Cord Injury

MYRTICE B. ATRICE, PT, BS, SARAH A. MORRISON, PT, BS,
SHARI L. McDOWELL, PT, BS, PAULA M. ACKERMAN, MS, OTR/L,
TERESA A. FOY, OT, BS, and CANDY TEFERTILLER, DPT, ATP, NCS

KEY TERMS

American Spinal Injury Association (ASIA)
autonomic dysfunction
autonomic dysreflexia
body-weight-supported treadmill (BWST)
bulbocavernosus reflex
complete lesion
deep vein thrombosis (DVT)
discomplete
Functional Independence Measure (FIM)
incomplete lesion
intermittent catheterization
locomotor training
lower motor neuron
mobile arm support (MAS)
neuroprosthetics
offset feeder
orthostatic hypotension
paraplegia
pressure ulcer
pulmonary embolism (PE)
spinal cord injury (SCI)
spinal shock
tenodesis
tetraplegia
upper motor neuron

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe the demographics, etiology, and mechanism of injury of spinal cord injury.
2. Discuss the acute medical management of person with spinal cord injury.
3. Describe the secondary complications of spinal cord injury, the appropriate interventions, and the impact of complications on the rehabilitation process.
4. Identify the basic components of the examination process.
5. Identify patient problems based on the examination, establish appropriate goals, and plan individualized treatment programs for patients with a spinal cord injury.
6. Describe adaptive equipment available to increase function.
7. Discuss progression of each individual and the process of discharge planning throughout the rehabilitation process.
8. Describe functional expectations for individuals with complete spinal cord injuries.
9. Identify equipment needs for a given spinal cord injury lesion.
10. Describe various aspects of activity-based therapies to promote recovery after spinal cord injury.

Spinal cord injury (SCI) is a catastrophic condition that, depending on its severity, may cause dramatic changes in a person's life. SCI usually happens to active, independent people who at one moment are in control of their lives and in the next moment are paralyzed, with loss of sensation and loss of bodily functions, which can lead to dependence on others for even the most basic needs. To reduce negative impact, individuals with SCI need a well-coordinated, specialized rehabilitation program to assist them in maximizing the development of skills necessary to live a satisfying and productive postinjury life.^{1,2}

A successful rehabilitation program requires a team of health care professionals who work in unison to address alterations in body function, increase the individual's independence in all daily activities, and return the individual to the highest level of community participation specific to that individual's life situations. Minimally, the team should include a physician, case manager, occupational therapist, physical therapist, therapeutic recreation specialist, prosthetist or orthotist, nurse, speech-language

pathologist, dietician, assistive technologist, respiratory care practitioner, psychologist, social worker, vocational counselor, rehabilitation engineer, and chaplain.³⁻⁵ The most important element determining success in any rehabilitation program is the patient's and family's active participation throughout the rehabilitation process.

This chapter provides a general overview for the management of individuals with SCI throughout inpatient and postacute phases of the rehabilitation continuum. The information is intended to aid health care professionals in the treatment of individuals with SCI by providing guidelines to maximize each individual's return to their preinjury lifestyle.

SPINAL CORD LESIONS

SCI occurs when the spinal cord is damaged as a result of trauma, disease processes, vascular compromise, or congenital neural tube defect. The clinical manifestations of the injury vary depending on the extent and location of the damage to the spinal cord.

Tetraplegia

Tetraplegia (preferred to *quadriplegia*) refers to impairment or loss of motor and/or sensory function as a result of damage to the cervical segments of the spinal cord. Function in the upper extremities, lower extremities, and trunk is affected. It does not include brachial plexus lesions or injury to peripheral nerves outside the neural canal.⁶

Paraplegia

Paraplegia refers to impairment or loss of motor or sensory function as a result of damage to the thoracic, lumbar, or sacral segments of the spinal cord. Depending on the level of the damage, function may be impaired in the trunk and/or lower extremities. This term is used to refer to cauda equina and conus medullaris injuries but not to lumbosacral plexus lesions or injury to peripheral nerves, which are considered outside of the central nervous system.⁶

Complete, Discomplete, and Incomplete Lesions

In a complete lesion, sensory and motor function in the lowest sacral segments (S4-S5) is absent postinjury.⁶ The American Spinal Injury Association (ASIA) classification for this type of injury is ASIA Impairment Scale (AIS) A. Complete injuries to the spinal cord are usually the result of extensive trauma or disease and are often segmentally associated with damage to the nerve roots in the intervertebral foramina.⁷ Function of the roots originating from the more cranial portion of the intact cord can be expected to return within 6 months.⁷

Discomplete injury is a relatively new term in SCI research and practice. It is defined as a lesion that is “clinically complete but which is accompanied by neurophysiological evidence of residual brain influence on spinal cord function below the level of the lesion.”⁸ Studies of persons whose spinal cord injuries were considered complete under ASIA standards have shown that in a large percentage (84%) there was residual brain influence on the spinal cord below the level of the lesion.^{8,9} The current gold standard for testing, the AIS, is unable to detect this residual function, which suggests that AIS testing may be providing an inaccurate picture of the patients’ neurological plasticity and recovery potential. The Brain Motor Control Assessment (BMCA) is emerging as a desirable adjunct to the standard ASIA testing.⁹ In the BMCA, surface electromyography (EMG) is used to quantify the motor unit activity of the lower extremities in response to a standard testing protocol including active and passive movement of the lower extremities, reinforcement maneuvers (e.g., Jendrassik or Valsalva) performed above the level of injury, tendon taps and vibration, and elicitation and suppression of reflex activity. The motor unit responses are quantified and compared with normative data to establish a voluntary response index and a similarity index. In other words, the results of the BMCA help to determine how different the subjects’ motor responses are from those of persons with intact neurological systems.⁸⁻¹¹ This testing requires specialty equipment but can easily be administered by physical therapists once they have received the appropriate training.

With incomplete lesions there is detectable residual sensory or motor function below the neurological level and specifically in the lowest sacral segment. According to ASIA

standards, any sensation in the anal mucocutaneous junction, or deep anal sensation, indicates that the lesion is incomplete. If only sensation is preserved, the injury is classified as AIS B. If motor function in key muscles is maintained to some degree, patients may achieve level C, D, or E classification. This testing will be reviewed further in this chapter.^{6,12}

DEMOGRAPHICS

The incidence of traumatic SCI in the United States is approximately 12,000 new cases per year.¹³ Approximately 3000 new cases of spinal cord impairment resulting from disease and congenital anomalies occur each year. The number of people living in the United States today with SCI is between 231,000 and 311,000.¹³ Fifty-three percent of traumatic SCIs occur in persons aged 16 to 30 years. However, the median age of the general population of the United States has increased by 8 years since the mid 1970s, and the average age of the SCI population has steadily increased. Since 2005, the mean age at the time of injury is 40.2 years.^{13,14} Persons older than 60 years of age at injury have increased from 4.7% before 1980 to 11.5% for injuries occurring since 2000. This trend explains the increase in the median age during this same time period from 27.9 years to 35.3 years. Table 16-1 lists additional demographics.

In 2005 the average length of inpatient stay was 50 days (12 days in an acute-care facility and 38 days in rehabilitation). The average yearly health care and living expenses

TABLE 16-1 ■ SPINAL CORD INJURY DEMOGRAPHICS

Mean age at injury	40.2 years
Most common age at injury	19.0 years
SEX	
Male	80.9%
Female	19.1%
CAUSES OF INJURY	
Motor vehicle accident	41.3%
Falls	27.3%
Violent acts	15.0%
Sports injuries	7.9%
Other	8.5%
NEUROLOGICAL CATEGORIES AT DISCHARGE	
Incomplete tetraplegia	38.3%
Complete paraplegia	22.9%
Incomplete paraplegia	21.5%
Complete tetraplegia	16.9%
No deficits	0.7%
COMMON INJURY SITES⁶⁴	
C5	14.9%
C4	13.6%
C6	10.8%
T12	6.7%
C7	5.3%

Data from National Spinal Cord Injury Statistical Center: *Spinal cord injury: facts and figures at a glance*, February 2010, Birmingham, AL, 2010, University of Alabama, National Spinal Cord Injury Statistical Center. Available at www.uab.edu/NSCISC.

vary according to severity of injury. In the first year, individuals with high tetraplegia spend \$829,843, whereas individuals with paraplegia spend an average of \$303,220.¹³ Today 87.7% of persons with SCI are discharged to a non-institutional residence. Life expectancies for patients with SCI continue to increase but are still below the national average of persons without SCI. Mortality rates are significantly higher during the first year after injury, especially for severely injured persons. According to the National SCI Database, the leading causes of death after an SCI are pneumonia, pulmonary emboli, and septicemia.¹³

Statistics suggest a high incidence of multiple trauma associated with a traumatic SCI (55.2%).¹⁵ The most common injuries are fractures (29.3%) and loss of consciousness (28.2%).¹⁵ Traumatic pneumothorax or hemothorax are reported in 17.8% of persons with SCI. Traumatic head injuries of sufficient severity to affect cognitive or emotional functioning are reported in 11.5% of all cases.¹⁵ Skull and facial fractures, along with traumatic head injuries and vertebral artery and esophageal disruptions, are common in cervical injuries.¹⁶ Limb fractures and intrathoracic injuries (rib fractures and hemothorax) are frequent in thoracic injuries, whereas intraabdominal injuries to the liver, spleen, and kidneys are associated with lumbar and cauda equina injuries.¹⁶

SEQUELAE OF TRAUMATIC SPINAL CORD INJURY

As stated previously, most spinal cord injuries occur as a result of trauma, be it motor vehicle accidents, falls, violence, or sports-related injury. The degree and type of forces that are exerted on the spine at the time of the trauma determine the location and severity of damage to the spinal cord.¹⁷ Injuries to the vertebral column can be classified biomechanically as flexion or flexion-rotation injuries, hyperextension injuries, and compression injuries.¹⁸ Penetrating injuries to the cord are usually the result of gunshot or knife wounds.¹⁸

Spinal cord damage can also be caused by nontraumatic mechanisms. Circulatory compromise to the spinal cord resulting in ischemia causes neurological damage at and below the involved cord level. This can be caused by a thrombus, swelling, compression, or vascular malformations and dysfunction. Degenerative bone diseases can cause compression of the spinal cord by creating a stenosis of the spinal canal and intervertebral foramina. Stenosis can also result from the prolapse of the intervertebral disc into the neural canal. The encroachment of tumors or abscesses within the spinal cord, the spinal canal, or the surrounding tissues can also lead to SCI. Congenital malformation of the spinal structures, as in spina bifida, can also compromise the spinal cord and its protective layers of connective tissue. Some of the more common diseases and conditions that result in compromise of the spinal cord include Guillain-Barré syndrome, transverse myelitis, amyotrophic lateral sclerosis, and multiple sclerosis.¹²

After the spinal cord has sustained damage, cellular events occur in response to the injury and are classified in three phases of progression: acute, secondary, and chronic responses. The acute process begins on occurrence of an injury and continues for 3 to 5 days.¹⁹ Abrupt necrosis or cell death can result from both mechanical and ischemic events. The impact of an SCI often causes direct mechanical

damage to neural and other soft tissues as well as severe hemorrhaging in the surrounding gray and white matter, resulting in immediate cell death.^{20,21} In the next few minutes after the insult, injured nerve cells respond with trauma-induced action potentials, which lead to increased levels of intracellular sodium. The result of this influx is an increase in osmotic pressure movement of water into the area. Edema generally develops in up to three levels above and below the original insult and leads to further tissue deconstruction.^{19,21,22} Increased levels of extracellular potassium and intracellular concentrations of calcium also result in an electrolyte imbalance that contributes to a toxic environment.²³⁻²⁵ Abnormal concentrations of calcium within the damaged cells disrupt their functioning and cause breakdown of protein and phospholipids, leading to demyelination and destruction of the cell membrane.²⁵ The cascade of these events consequentially contributes to a dysfunctional nervous system.

During this acute phase, evidence of spinal shock may be present. Spinal shock occurs 30 to 60 minutes after spinal trauma and is characterized by flaccid paralysis and absence of all spinal cord reflex activity below the level of the spinal cord lesion.^{26,27} This condition lasts for about 24 hours after injury, represents a generalized failure of circuitry in the spinal neural network, and is thought to be directly related to a conduction block resulting from leakage of potassium into the extracellular matrix.²⁸ The completeness of the lesion cannot be determined until spinal shock is resolved. The signs of spinal shock resolution are controversial; however, the return of reflexes may be a good indication.

The secondary phase of the injury occurs within the course of minutes to weeks after the acute process and is characterized by the continuation of ischemic cellular death, electrolytic shifts, and edema. Extracellular concentrations of glutamate and other excitatory amino acids reach concentrations that are six to eight times greater than normal within the first 15 minutes after an injury.²⁴ In addition, lipid peroxidation and free radical production also occur.²⁹ Apoptosis (a secondary programmable cell death) occurs and involves reactive gliosis. There is also an important immune response that adds to the secondary damage that may be a result of a damaged blood-brain barrier, microglial activation, and increased local concentrations of cytokines and chemokines.³⁰ The lesion enlarges from the initial core of cell death, expanding from the perilesional region to a larger region of cell loss.

In the chronic phase, which occurs over a period of days to years, apoptosis continues both rostrally and caudally. Receptors and ion channels are altered, and with penetrating injuries scarring and tethering of the cord occurs. Conduction deficits persist owing to demyelination, and permanent hyperexcitability develops with consequential chronic pain syndromes and spasticity in many SCI patients.²⁶ Changes in neural circuits result from alterations in excitatory and inhibitory inputs, and axons may exhibit regenerative and sprouting responses but go no farther than 1 mm.²⁴

Medical interventions are evolving to limit the impact of the acute SCI and the subsequent progression that follows. Growing interest in protection and repair of the injured nervous system has led to an improved understanding of the pathophysiology associated with SCI and has resulted in the implementation of several therapeutic strategies that are

currently being investigated in phase 1 and 2 clinical trials. The effects of methylprednisolone sodium succinate, tirilizad mesylate, monosialotetrahexosylganglioside, thyrotropin-releasing hormone, gacyclidine, naloxone, and nimodipine have all been examined in randomized controlled trials over the last few years. Although the primary outcomes in these studies did not demonstrate statistically significant effects, a secondary analysis demonstrated that methylprednisolone sodium succinate given within 8 hours of injury was associated with modest clinical benefits.¹⁷ Phase 2 trials with monosialotetrahexosylganglioside and thyrotropin-releasing hormone also yielded some therapeutic benefits, but further studies need to be completed to determine efficacy. Several current or planned studies exist to evaluate the potential benefits of early surgical decompression and electrical field stimulation, neuroprotective strategies such as riluzole and minocycline, the inactivation of myelin inhibition by blocking Nogo and Rho, and the transplantation of various substrates into the injured spinal cord.¹⁷ Promising clinical trials are also underway to minimize the secondary phase of injury and to promote healing and neuronal regeneration (Table 16-2). If medical interventions can bridge the central lesion or limit the secondary progression, the functional loss that follows SCI will be minimized and chances of recovery improved.

TABLE 16-2 ■ PHASES OF INJURY TABLE

PHASE	DESCRIPTION	
Acute	Systemic hypotension and spinal shock	
	Hemorrhage	
	Cell death from direct insult or ischemia	
	Edema	
	Vasospasm	
	Shifts in electrolytes	
	Accumulation of neurotransmitters	
	Induced hypothermic treatment	
	Secondary	Continued cell death
		Continued edema
Continued shifts in electrolytes		
Free-radical production		
Lipid peroxidation		
Neutrophil and lymphocyte invasion and release of cytokines		
Chronic	Apoptosis	
	Calcium entry into cells	
	Continued apoptosis radiating from site of injury	
	Alteration of ion channels and receptors	
	Formation of fluid-filled cavity	
	Scarring of spinal cord by glial cells	
	Demyelination	
Regenerative processes, including sprouting by neurons		
Altered neurocircuits		
Syringomyelia

CLINICAL SYNDROMES

Some incomplete lesions have a distinct clinical picture with specific signs and symptoms. An understanding of the various syndromes can be helpful to the patient’s team in planning the rehabilitation program. Figure 16-1 depicts the anatomy of the spinal cord.^{30,31} This basic anatomy of the spinal cord can be referred to as the various syndromes are described.

Central Cord Syndrome

Hyperextension injuries usually result in a central cord syndrome.³¹ This injury causes bleeding into the central gray matter of the spinal cord, resulting in more impairment of function in the upper extremities than in the lower extremities.³¹ Most incomplete lesions result in this syndrome, especially in elderly individuals when cervical stenosis is present.³⁰ Although the prognosis for functional recovery is good for individuals with central cord syndrome, the pattern of recovery is such that intrinsic hand function is the last thing to return. Approximately 77% of clients with central cord syndrome will attain some level of ambulatory function, 53% bowel and bladder control, and 42% hand function.^{12,32,33}

Anterior Spinal Artery Syndrome

Anterior spinal artery syndrome is usually caused by flexion injuries in which bone or cartilage spicules compromise the anterior spinal artery.³¹ Motor function and pain and temperature sensation are lost bilaterally below the injured segment.³¹ The prognosis is extremely poor for return of bowel and bladder function, hand function, and ambulation.^{12,33}

Brown-Séquard Syndrome

Occasionally, as a result of penetrating injuries (gunshot or stab wounds), only one half of the spinal cord is damaged. The Brown-Séquard syndrome is characterized by ipsilateral loss of motor function and position sense and contralateral loss of pain sensation several levels below the lesion.³¹ The prognosis for recovery is good. Nearly all clients attain some level of ambulatory function, 80% regain hand function, 100% have bladder control, and 80% have bowel control.^{12,33}

Posterior Cord Syndrome

Posterior cord syndrome is rare, resulting from compression by tumor or infarction of the posterior spinal artery. Clinically, proprioception, stereognosis, two-point discrimination, and vibration sense are lost below the level of the lesion.³¹

Figure 16-1 ■ Cross-sectional anatomy of the spinal cord.

Cauda Equina Syndrome

Damage to the cauda equina occurs with injuries at or below the L1 vertebral level. This syndrome results in a lower motor neuron lesion that is usually incomplete. This lesion results in flaccid paralysis with no spinal reflex activity present.^{12,26}

Conus Medullaris Syndrome

Injury of the sacral cord and lumbar nerve roots within the neural canal results in a clinical picture of lower-extremity motor and sensory loss and areflexic bladder and bowel.^{12,31}

MEDICAL MANAGEMENT

Short-term medical treatment includes anatomical realignment and stabilization interventions and pharmacological management to prevent further neurological trauma and enhance neural recovery.

Surgical Stabilization

One of the first interventions after acute traumatic SCI is to stabilize the spine to prevent further cord or nerve root damage. In the emergency department, diagnostic studies reveal the severity of the spinal injury and the type and degree of the instability. On the basis of these findings, the physician, client, and family decide on treatment. Many options must be considered regarding the optimal operative strategy. Indications for surgical intervention include, but are not limited to, signs of progressive neurological involvement, type and extent of bony lesions, and degree of spinal cord damage.³⁴ The following discussion describes nonsurgical and surgical interventions.

Cervical Spine

At the scene of the accident, emergency medical professionals exercise extreme caution to immobilize the injured patient and prevent excessive movement. If there is compression of neurological tissue, vertebral fracture, or dislocation, reduction must occur to minimize ischemia and edema formation.³⁵ In the emergency department, reduction is accomplished by cervical traction with the goal of immediate and proper alignment of bone fragments and decompression of the spinal cord until further stabilization.^{34,36,37} The most widely used traction method is the Gardner-Wells tongs (Figure 16-2), which are inserted into the skull. Weights are added at approximately 5 pounds of traction per level of injury to achieve reduction of the dislocation and to maintain alignment.³⁶

Precautions must be taken during therapy to prevent unnecessary movement at the injury site. The traction rope must be kept in alignment with the long axis of the cervical spine, and the weights must be allowed to hang freely. Cervical rotation must be prevented. In addition, continued traction should be maintained at all times.

When surgical stabilization is indicated, common surgical protocols include posterior and anterior approaches. Figure 16-3 shows radiographs of a person who had an anterior and lateral cervical fusion at C3-C4. Unstable compression injuries are usually managed by a posterior procedure except when there is a deficient anterior column. Anterior approaches are indicated for patients with evidence of residual anterior spinal cord or nerve root compression and persistent neurological deficits.³⁴

Figure 16-2 ■ Gardner-Wells tongs. Reduction is accomplished through weights attached to the traction rope. (Courtesy Dr. H. Herndon Murray, Assistant Medical Director, Shepherd Spinal Center, Atlanta, Georgia.)

After cervical surgical stabilization, a hard collar such as a Philadelphia collar (Figure 16-4) or sternal-occipital-mandibular immobilizer (SOMI) brace is used until solid bony fusion has developed. The Aspen collar also provides this stability (Figure 16-5). The solid bony fusion usually takes 6 to 8 weeks. Postoperatively, care must be taken to protect the bony fusion.

When surgery is not indicated, or when more postoperative stabilization is required, halo traction may be indicated. The halo device restricts more movement in the upper cervical spine compared with the lower cervical spine.³⁸ The halo traction device consists of three parts: the ring, the uprights, and the jacket (Figure 16-6). The ring fits around the skull, just above the ears. It is held in place by four pins that are inserted into the skull. The uprights are attached to the ring and jacket by bolts. The jacket is usually made of polypropylene and lined with sheepskin. This equipment is left in place for 6 to 12 weeks until bony healing is satisfactory.⁵ The advantage of using the halo device is the ability to mobilize the client as soon as the device has been applied without compromising spinal alignment. This allows the rehabilitation program to commence more rapidly. It also allows for delayed decision making regarding the need for surgery.

The disadvantage of the halo device is that pressure and friction from the vest or jacket may lead to altered skin integrity.⁷ Special attention must be given to ensure the skin remains intact. During more active phases of the rehabilitation process, the halo device may slow functional progress because of added weight and interference with the middle to end range of upper-extremity movement. In a small percentage of patients, there are complications of dysphagia and temporomandibular joint dysfunctions associated with wearing the halo device.⁷

Thoracolumbar Spine

Internal fixation of the thoracolumbar region is necessary when stability and distraction cannot be maintained by other means.³⁹ Common thoracic stabilization procedures include transpedicular screws (Figure 16-7) and a hybrid type of instrumentation.

Figure 16-3 ■ A, Radiograph of person who had an anterior cervical fusion at C3-C4. B, Lateral radiologic view of anterior fusion C3-C4.

Figure 16-4 ■ Philadelphia collar. It is fabricated of polyethylene foam with rigid anterior and posterior plastic strips, it is easily applied via Velcro closures, and it limits flexion, extension, and rotary movements of the cervical spine.

Figure 16-5 ■ The Aspen collar (formerly known as the Newport collar) encircles the neck, is somewhat open, and provides cervical motion restriction. It is rigid yet flexible at its edges to conform to each patient's anatomy. Pads and shells are removable and washable.

Figure 16-6 ■ Halo vest. Basic components are the halo ring, distraction rods, and jacket (jacket not pictured).

Postoperatively, an external trunk support may be necessary to limit excessive vertebral motion and to maintain proper thoracic and lumbar alignment.³⁹ This may be achieved by a custom thoracolumbosacral orthosis (Figure 16-8) or a Jewett brace (Figure 16-9). Initially the client's activity may be limited to allow for a complete fusion to take place and to minimize the possibility of rod displacement. All spinal limitations should be discussed with the surgeon postoperatively.

The goals of the operative procedures at any spinal level discussed are to reverse the deforming forces, to restore proper spinal alignment, and to stabilize the spine.⁴⁰ All these procedures have advantages and disadvantages. The surgeon, client, and family must be involved in the decision-making process to select the most appropriate method of treatment. This will allow the therapeutic rehabilitation process to begin.

Pharmacological Management Immediately after Traumatic Spinal Cord Injury

Neurological damage from SCI may be a result of (1) physical disruption of axons traversing the injury site, or (2) as described earlier, cellular events that follow the primary injury. Investigators believe that secondary injuries to surrounding tissues can be lessened by pharmacological agents, specifically methylprednisolone and monosialotetrahexosylganglioside

Figure 16-7 ■ Radiograph of transpedicular screws. (Courtesy Dr. H. Herndon Murray, Assistant Medical Director, Shepherd Spinal Center, Atlanta, Georgia.)

(GM1). To date, two major pharmacological clinical trials have been completed.

The National Acute Spinal Cord Injury Study⁴¹ (NASCIS-2) used high doses of methylprednisolone and showed significant improvements in sensory and motor function 6 months after injury.⁴² Young and Flamm⁴³ showed that methylprednisolone enhanced the flow of blood to the injured spinal cord, preventing the typical decline in white matter, extracellular calcium levels, and evoked potentials, thus preventing progressive posttraumatic ischemia.⁴⁴⁻⁴⁷ The dosage recommended by the NASCIS-2 study is 30 mg/kg of methylprednisolone followed by an infusion of 5.4 mg/kg/hr for 23 hours.⁴¹ The therapist must be aware of side effects that may occur with such high doses of steroids, including gastric ulcers, decreased wound-healing time, hypertension, cardiac arrhythmias, and alteration in mental status.⁴²

THERAPEUTIC REHABILITATION CONTINUUM OF CARE

Therapeutic rehabilitation can be effectively delivered beginning in an acute-care setting at the time of injury and continuing on through a lifetime of care. Rehabilitation teams may use one of three models: multidisciplinary, interdisciplinary, and transdisciplinary.³ The standards set forth by the Commission on Accreditation of Rehabilitation Facilities (CARF) suggest that the interdisciplinary model of team structure is optimal in the rehabilitation setting.³¹

The continuum of care may be divided into several phases that include medical management (previously described),

Figure 16-8 ■ Custom thoracolumbosacral orthosis. This molded plastic body orthosis has a soft lining. It controls flexion, extension, and rotary movements until healing of the bone has occurred.

inpatient rehabilitation, outpatient rehabilitation, and home health. The continuum also includes returning the patient into wellness programs and community reentry outreach programs. The progression of a patient through the rehabilitation process will vary greatly from one person to the next. The patient may also move back and forth throughout the continuum of care.

Inpatient Rehabilitation

Inpatient rehabilitation begins during the critical and acute-care stages after an SCI. The primary emphasis of early rehabilitation is to lessen the adverse effects of neurotrauma and immobilization. This focus may last from a few days to several weeks, depending on the severity and level of injury and other associated injuries. Although therapeutic intensity may be limited, clients may begin participating in early therapy that should include, but should not be limited to, out-of-bed activities, gaining upright tolerance, range-of-motion (ROM) exercises, early strength training, and skin-management education. Goals during this phase should focus on prevention of secondary complications and preparing the client for full rehabilitation participation. The treatment team must begin discharge planning and family training in this phase.

Figure 16-9 ■ Jewett hyperextension brace. A single three-point force system is provided by sternal pad, suprapubic pad, and thoracolumbar pad. Forward flexion is restricted in the thoracolumbar area.

As the acute phase progresses, out-of-bed activities are tolerated for longer periods of time and the patient begins to work toward specific long-term goals. In accordance with Medicare guidelines for inpatient rehabilitation, the client is able to participate in therapeutic programs a minimum of 3 hours a day.^{48,49} The intensity of therapy may continue to be limited according to unresolved medical issues.

As medical issues resolve and endurance improves, the patient will progress to a higher and more active level of participation. During inpatient rehabilitation, the patient gains varying levels of independence in specific skills. The patient may be taught advanced skills to perform activities of daily living (ADLs), transfers, and mobility. Community outings may be scheduled to refine advanced skills, identify further needs, and foster community reintegration and participation. In addition, the following will be completed unless otherwise indicated by the rehabilitation team: (1) family training, (2) home and school or work evaluation, (3) delivery and fitting of discharge equipment, (4) instruction in home management, (5) instruction in home exercise programs, (6) dependent passenger driving evaluations, (7) assistive technology (AT) referrals for devices to enable computer access and other electronic aids to daily living (EADLs), (8) referrals for continued services, and (9) driving evaluation. Discharge planning largely encompasses activities aimed at a smooth transition back into the community whenever possible.

Outpatient Rehabilitation and Community Reentry

Discharge from an inpatient rehabilitation program marks only the beginning of the lifelong process of adjustment to changes in physical abilities, community reintegration, and participation in life activities. Inpatient rehabilitation provides an environment best suited for learning self-care skills, yet “the implications of living in the community with SCI can scarcely be anticipated accurately by the newly injured individual or the able-bodied staff.”⁵⁰ Because of the shortened lengths of hospitalization, services provided after discharge are becoming increasingly important. A direct consequence of this shift results in outpatient treatment of patients who have more acuity, greater care needs, and fewer skills attained in the inpatient rehabilitation program before entry into the outpatient arena. Common outpatient therapy treatment programs have included advanced transfer training, advanced wheelchair mobility training, locomotor training, upgraded ADL training, and upgraded home exercise program instruction. This is a shift in the typical program structure because these skills were traditionally a part of the inpatient rehabilitation.

Services provided after inpatient discharge may include day programs, single-service outpatient visits, wellness programs, and routine follow-up visits and services. The “day program” concept has emerged to meet the demand for more comprehensive rehabilitation services. The primary purpose of these services is to provide a coordinated effort for the client to return to full reintegration into the community. There is a variety of day program options for individuals, with each program offering various levels of care that range from two coordinated disciplines to services like those of an inpatient rehabilitation program. One common thread for virtually all day program settings is that the clients are medically stable, do not require skilled nursing services during the night, and need a coordinated approach for two or more services with the focus on performance of functional skills and on the transference of these skills into the community.

EXAMINATION AND EVALUATION OF BODY FUNCTION AND STRUCTURE

Regardless of where the patient begins the rehabilitation process, an examination is completed on admission. The examination and evaluation will assist in establishing the diagnosis and the prognosis of each patient as well as determining the appropriate therapeutic interventions. The client and caregivers participate by reporting activity performance and functional ability.⁵¹ Any pertinent additions to the history stated by the client should be described. The client’s statement of goals, problems, and concerns should be included. The main areas of the examination are outlined here.

History

A review of the medical record is the first step toward the examination because it provides the background information and identifies medical precautions. The history should include general demographics, social history, occupation or employment, pertinent growth and development, living environment, history of current condition, functional status and activity level, completed tests and measures, medications,

history of current condition if applicable, medical and surgical history, family history, reported patient and family health status, and social habits.⁵² If the history suggests a loss of consciousness or brain injury, the clinician should consider the possibility of compromised cognition and should include tests and measures during the examination and assessment appropriate to that impairment.

Systems Review

The physiological and anatomical status should be reviewed for the cardiopulmonary, integumentary, musculoskeletal, and neuromuscular systems. In addition, communication, affect, cognition, language, and learning style should be reviewed.⁵¹

Tests and Measures

Depending on the data generated during the history and systems review, the clinician performs tests and measures to help identify impairments, activity limitations, and participation restrictions and to establish the diagnosis and prognosis of each client. Tests and measures that are often used for persons with SCI are included in [Box 16-1](#). For more detail related to specific tools, refer to the *Guide to Physical Therapist Practice*.⁵²

Neurological Examination

American Spinal Cord Injury Association Examination

It is recommended that the international standards of ASIA be used for the specific neurological examination after an SCI.⁵³ See [Figure 16-10](#) for the ASIA motor and sensory examination form. Assessment of muscle performance allows for specific diagnosis of the level and completeness of injury. The examination of muscle performance includes each specific muscle and identifies substitutions from other muscles.

BOX 16-1 ■ TESTS AND MEASURES⁵²

- Aerobic capacity and endurance
- Anthropometric characteristics
- Assistive and adaptive devices assessment
- Community and work integration or reintegration
- Environmental home and work barriers examination
- Gait, locomotion, and balance
- Integumentary integrity
- Joint integrity and mobility
- Motor function

Along with the strength of each muscle, the presence, absence, and location of muscle tone should be described. The Modified Ashworth Scale is a common tool used to describe hypertonicity.⁵⁴ The client's sensation is described by dermatome. The recommended tests include (1) sharp-dull discrimination or temperature sensitivity to test the lateral spinothalamic tract, (2) light touch to test the anterior spinothalamic tract, and (3) proprioception or vibration to test the posterior columns of the spinal cord. Sensation is indicated as intact, impaired, or absent per dermatome. A dermatomal map is helpful and recommended for ease of documentation.

Functional Examination

It is recommended that a complete functional assessment be performed on initial examination and thereafter as appropriate. Myriad tools exist to assess functional skills. Many institutions develop functional assessments that address home, community, and institutional mobility and ADL functional skills. The Functional Independence Measure (FIM) is one of the more commonly used tools that is currently applied for many impairment diagnostic groups, including SCI.⁵⁵

Another tool that is recognized as a primary outcome measure to assess functional recovery for the client with SCI is the Spinal Cord Injury Independence Measure III (SCIM III).⁵⁶ This tool was specifically designed for the functional assessment of individuals with SCI. The SCIM III has been shown to be valid, reliable, and easily administered.⁵⁷⁻⁵⁹ Other tools, such as the Quadriplegia Index of Function (QIF)⁶⁰ and the Craig Handicap Assessment and Reporting Technique (CHART),⁶¹ are options. Additional assessments for patients with SCI are described in Table 16-3.

GOAL SETTING FOR ACTIVITY AND PARTICIPATION SKILLS

Goal setting is a dynamic process that directly follows the examination. Each activity limitation identified should be addressed with specific short- and long-term goals. The clinician must interpret new information continuously, which leads to continuing reevaluation and revision of goals.⁶² Goals are always individualized and should be established in collaboration with the treatment team, the client, and the caregiver, and with realistic consideration of anticipated

TABLE 16-3 ■ ASSESSMENT OF FUNCTION SUMMARY TABLE

OVERALL FUNCTIONAL ASSESSMENTS	DESCRIPTION
SPINAL CORD INJURY (SCI) FUNCTIONAL ASSESSMENTS	
Spinal Cord Injury Independence Measure (SCIM) ²³⁹	Designed for the functional assessment of individuals with spinal cord injury in the categories of self-care, respiratory, sphincter management, and mobility skills
Quadriplegia Index of Function (QIF) ⁶⁰	Assesses function for individuals with tetraplegia in the categories of transfers, grooming, bathing, feeding, dressing, wheelchair mobility, bed activities, bowel, bladder, and knowledge of personal care
Capabilities of Upper Extremity (CUE) instrument ²⁴⁰	Assesses the action of grasp, release, and reaching in individuals with tetraplegia by measuring reaching and lifting, pulling and pushing, wrist action, hand and finger actions, and bilateral action
WALKING FUNCTION ASSESSMENTS	
Spinal Cord Injury Functional Ambulation Inventory (SCI-FAI) ²⁴¹	Observational gait assessment that assesses gait, assistive device use, and walking mobility
Walking Index for Spinal Cord Injury (WISCI) ²⁴²	An ordinal scale describing walking function that takes into consideration level of independence, assistive device use, and lower-extremity orthotic use
Six-minute walk test ²⁴³	An endurance walking test that measures the distance walked over a 6-min period of time
Ten-meter walk test ²⁴⁴	Measures walking speed by measuring how fast an individual walks a distance of 10 m
Timed Up-and-Go Test ²⁴⁴	Assesses standing, walking, turning, and sitting
WHEELCHAIR FUNCTION ASSESSMENTS	
Wheelchair Circuit ²⁴⁵	Assesses the performance of various wheelchair propulsion skills by measuring ability, performance time, and physical strain for eight standardized skills
Wheelchair Assessment Tool ²⁴⁶	Measures the ability and time to perform six mobility and wheelchair skills for individuals with paraplegia
Wheelchair Skills Test ²⁴⁷	Assesses the ability to perform 50 separate skills in the areas of wheelchair handling, transfers, maneuvering the wheelchair, and negotiating obstacles
Obstacle Course Assessment of Wheelchair User Performance ²⁴⁸	Assesses the wheelchair user's performance in 10 difficult environmental situations
Wheelchair Users Functional Assessment (WUFA) ²⁴⁹	A 13-item assessment of wheelchair skills in individuals who primarily use a manual wheelchair for their mobility
Wheelchair Physical Functional Performance (WC-PFP) ²⁵⁰	Assesses the ability to complete various tasks from the wheelchair by measuring upper body strength, upper body flexibility, balance, coordination, and endurance
Functional Evaluation in a Wheelchair ²⁵¹	Assesses functional performance from a manual and/or power wheelchair via a self-administered questionnaire

needs on return to the home environment. Factors to consider in the goal-setting process include age, body type, associated injuries, premorbid medical conditions, additional orthopedic injury, cognitive ability, psychosocial issues, spasticity, endurance, strength, ROM, funding sources, and motivation.

Long-term goals for the rehabilitation of patients with SCI reflect functional outcomes and are based on the strength of the remaining innervated or partially innervated musculature. Short-term goals identify components that interfere with functional ability and are designed to “address these limiting factors while building component skills”⁷ of the desired long-term goals.⁶³

Functionally based goals are established in the following areas: bathing, bed mobility, bladder and bowel control, communication, environmental control and access, feeding, dressing, gait, grooming, home management, ROM and

positioning, skin care management, transfers, transportation and driving, wheelchair management, and wheelchair mobility. Refer to Table 16-4 for anticipated goals for each level of injury. Information presented in this table should be recognized as general guidelines because variability exists. These guidelines are most usefully applied to patients with complete SCI. Goal setting for individuals with incomplete SCI is often more challenging, given the greater variability of client presentations and the uncertainty of neurological recovery. As with any patient, continual reevaluations provide additional insight into functional limitations or progression and potential and thereby direct the goal-setting process. In addition to specific functional goals and expectations, family training; home, work, or school modifications; and community reentry should be considered.

Rehabilitation teams may elect to hold a goal-setting or interim conference for each patient, during which team

members, including the client, have the opportunity to discuss the long-term goals that have been established. It may be useful to request that the patient sign a statement acknowledging understanding of, and agreement to, all long-term goals.

EARLY REHABILITATION AND COMPLICATION PREVENTION

Early rehabilitation of the patient with SCI begins with prevention. Preventing secondary complications speeds entry into the rehabilitation phase and improves the possibility that the patient will become a productive member of society.

Table 16-5 describes an overview of the primary complications that can arise after an SCI. In this table, known causes and common management activities are reviewed. Tests and measures commonly used to determine the complication and the recommended medical and/or therapeutic interventions are listed in the table. Although various reports of incidences are published, the largest database is the Model Spinal Cord Injury Care Systems report.^{41,64} Because of their high incidence and potential effect on long-term outcomes, the following complications require further discussion: skin compromise, loss of ROM or joint contractures, and respiratory compromise after SCI.

Preventing and Managing Pressure Ulcers and Skin Compromise

After SCI and during the period of spinal shock, patients are at greater risk for development of pressure ulcers.^{65,66} The use of backboards at the emergency scene and during radiographic procedures contributes to potential skin compromise; therefore, immediate concern for tissue death,

especially at the sacrum, should be taken into account. Recently, padded spine boards have become available and are recommended to reduce the risk of skin complications.

Preventive skin care begins with careful inspection. Soft tissue areas over a bony prominence are at greatest risk for acquiring a pressure sore.⁶⁷ Key areas to evaluate include the sacrum, ischia, greater trochanters, heels, malleoli, knees, occiput, scapulae, elbows, and prominent spinous processes. A turning schedule should be initiated immediately. Even if the patient has unstable fractures or is in traction, he or she can be turned and positioned with flat pillows using the logroll technique. Even small changes off the sacrum and coccyx are helpful. The patient's position in bed should be initially established for turns to occur every 2 to 3 hours.⁶⁶ This interval can be gradually increased to 6 hours with careful monitoring for evidence of skin compromise. A reddened round area over the bone that does not disappear after 15 to 30 minutes is the hallmark start of a pressure sore, and action to avoid or minimize pressure in the area must be taken immediately to avoid progression. Turning positions include prone, supine, right and left side-lying, semiprone, and semisupine positions.^{68,69} Secondary injuries such as fractures and the presence of vital equipment, such as ventilator tubing, chest tubes, and arterial lines, should be considered when choosing turning positions. The prone position is the safest position for maintaining skin integrity but may not always be feasible.

Pillows or rectangular foam pads may be used to bridge off the bony prominences and relieve potential pressure. This is especially helpful above the heels. Padding directly over a prominent area with a firm pillow or pad may only increase pressure and should be avoided. Great care should

TABLE 16-5 ■ COMPLICATIONS AFTER SPINAL CORD INJURY

COMPLICATION	CAUSE	DIAGNOSTIC TESTS AND MEASURES	MEDICAL TREATMENT OR INTERVENTION	THERAPEUTIC INTERVENTION
CARDIOPULMONARY				
Pneumonia Atelectasis	Bacterial or viral infection, prolonged immobilization, prolonged artificial ventilation, general anesthesia	Radiographic studies, diagnostic bronchoscopy	Antibiotics, bronchodilator therapy, therapeutic bronchoscopy, suctioning	Chest physical therapy: percussion, vibration, postural drainage, mobilization, inspiratory breathing exercises
Ventilatory failure	Weakness or paralysis of the inspiratory muscles, unchecked bronchospasm	Pulmonary function tests (PFTs), arterial blood gases (ABGs), end-tidal CO ₂ monitoring, pulse oximetry	Artificial ventilation and supportive therapy, management of underlying cause (e.g., pneumonia), oxygen therapy	Airway and secretion management treatment as above, early mobilization once stabilized, biofeedback to assist with ventilator weaning as appropriate
Deep vein thrombosis (DVT)*	Venous stasis, activation of blood coagulation, pressure on immobilized lower extremity, and endothelial damage ⁶⁵⁻⁶⁷	Doppler studies, leg measurements, extremity visual observation and palpation, low-grade fever of unknown origin	Subcutaneous heparin ^{3,252} Prophylactic anticoagulation can decrease incidence to 1.3% ⁵ Vena cava filter for failed anticoagulant prophylaxis	Early mobilization and range of motion (ROM) for prevention, centripetal massage for prevention, compression garments, education about smoking cessation, weight loss, and exercise; avoid constricting garments and monitor overly tight leg bag straps and pressure garments (Paralyzed Veterans of America DVT guidelines)
Pulmonary embolus	Dislodging of DVT	Ventilation-perfusion lung scan, signs and symptoms including chest pain, breathlessness, apprehension, fever, and cough	Vena cava filter Anticoagulation therapy	None
Orthostatic hypotension	Vasodilation and decreased venous return, loss of muscle pump action in dependent lower extremities and trunk ²⁵³	Monitor blood pressure with activity and changes in position, observation for signs and symptoms	Medications to increase blood pressure, fluids in the presence of hypovolemia	Gradient compression garments: Ace wraps, abdominal binders, appropriate wheelchair selection to prevent rapid changes in position early in rehabilitation
Apneic bradycardia	True origin unknown; believed to be caused by sympathetic disruption resulting in vagal dominance in response to a noxious stimulus or hypoxia ²⁵⁴	Electrocardiogram Heart rate Respiratory rate	Hyperventilation	Remove noxious stimulus
INTEGUMENTARY SYSTEM				
Pressure ulcers	Prolonged external skin pressure exceeding the average arterial or capillary pressure ²⁵⁵	Wound measurements, staging classification, nutritional assessment ⁷¹	Nutritional support as needed, surgical or enzymatic debridement, surgical closure, muscle flap, skin flap or graft, antibiotics as appropriate	Irrigation and hydrotherapy, dressing management, electrotherapy ⁷¹
Shearing	Stretching and tearing of the blood vessels that pass between the layers of the skin ⁷	See pressure ulcers	See pressure ulcers	Add protective padding during functional activities, skill perfection, correct handling techniques
Moisture	Excessive sweating below the level of injury, urinary and bowel incontinence, poor hygiene	See pressure ulcers	See pressure ulcers, treat possible urinary tract infection, medications for bladder incontinence	Protective barrier ointments and powders, establish effective bowel and bladder programs, educate for improved hygiene, and refine activity of daily living (ADL) skills

TABLE 16-5 ■ COMPLICATIONS AFTER SPINAL CORD INJURY—cont'd

COMPLICATION	CAUSE	DIAGNOSTIC TESTS AND MEASURES	MEDICAL TREATMENT OR INTERVENTION	THERAPEUTIC INTERVENTION
NEUROMUSCULAR				
Spasticity	Upper motor neuron lesion ⁷³ Deep tendon reflex spasticity scale evaluation	Ashworth or Modified Ashworth Scale Baclofen pump insertion ⁷⁵	Antispastic pharmacological agents: baclofen, diazepam (Valium), dantrolene Surgical intervention: myelotomy, rhizotomy, peripheral neurotomy ⁷³ Botox injection	Prolonged stretching; inhibitive positioning or casting Cryotherapy, weight-bearing exercise, and aquatic therapy
Flaccidity	Lower motor neuron lesion ^{7,256} Most often in injuries at L1 level and below	Deep tendon reflexes (would be absent)	None	None for treating flaccidity; however, secondary treatments that need to be considered include positioning to improve postural support, education for skin protection, and bracing and splinting to maintain joint integrity
Neurogenic bowel [†]	Refer to bowel management	Positive bulbocavernosus reflex: indicates reflexic bowel	Oral laxative, suppositories, and enemas	Establish comprehensive bowel program
Autonomic dysreflexia	Triggering of an uncontrolled hyperactive response from the sympathetic nervous system by a noxious stimulus ⁷ ; noxious stimuli may include bowel or bladder distention, urinary tract infection, ingrown toenail, tight clothing, and pressure sore	Sudden rise in systolic blood pressure of 20-40 mm Hg above baseline ²⁵⁴ Observation of signs and symptoms: Sweating above level of injury Goose bumps Severe headache Flushing of skin from vasodilation above level of injury ²⁵⁴	Catheterization of the bladder, irrigation of indwelling catheter, pharmacological management if systolic blood pressure is greater than 150 mm Hg Remove ingrown toenail if present	Immediately position the client in upright position, identify and remove noxious stimuli, check clothing and catheter tubing for constriction, and perform bowel program if fecal impaction is suspected
Ulcers, gastrointestinal	Venous status, activation of blood	Radiographic studies, diagnostic	Medications to increase blood pressure	Gradient compression garments; Ace wrap
OTHER				
Thermoregulation problems	Interruption between communication with autonomic nervous system and hypothalamus Lack of vasoconstriction and inability to shiver or perspire ²⁵⁴	Body temperature	Cooling or warming blanket if extreme	Education about risk and proper protection from elements; behavior modification, education for proper hydration and appropriate clothing
Pain	Radicular pain originating from the injury, ^{7,257,258} kinematic or mechanical pain, direct trauma, referred pain ^{258,259}	Pain scales, functional assessment, ²⁶⁰ taxonomy	Immobilization and rest, pain medications, injections for pain or antiinflammatory measures	Restore ideal alignment and posture; thermal modalities and electromodalities; manual therapy, improve movement patterns
Urinary tract infections	Presence of excessive bacteria in urine	Urinalysis, urine culture and sensitivity, temperature	Antibiotics	Monitor fluid intake and educate for proper technique during bladder care
Contractures	Muscle imbalance around joint; prolonged immobilization, unchecked spasticity, pain	Goniometric measurements	Tendon release; Botox injection for isolated spasticity	ROM functional use of extremity, casting or splinting, achieving and maintaining optimal postural alignment

Continued

TABLE 16-5 ■ COMPLICATIONS AFTER SPINAL CORD INJURY—cont'd

COMPLICATION	CAUSE	DIAGNOSTIC TESTS AND MEASURES	MEDICAL TREATMENT OR INTERVENTION	THERAPEUTIC INTERVENTION
Heterotopic ossification (HO)	Unknown	Alkaline phosphatase levels (increase after 6 weeks) ^{261,262} ; observation for sudden loss of ROM, local edema, heat, erythema, nonseptic fever	Etidronate disodium (Didronel): use prophylactically or during inflammatory stage Surgical resection	Maintain available ROM; avoid vigorous stretching during inflammatory stage; achieve and maintain optimal wheelchair positioning
Osteoporosis and joint changes degenerative	Bone demineralization ²⁶³	Bone scan	None; calcium supplement for prevention	Weight-bearing techniques: amount and type unknown, specific to spinal cord injury
Spinal deformities	Muscle imbalance or weakness around spinal column; poor postural support, asymmetrical functional activities	Posture evaluation, seating evaluation	If severe: surgical fixation, thoracic orthosis	Restore postural alignment, avoid repetitive asymmetrical activities, control spasticity
Gastroduodenal ulcers, gastrointestinal bleeding	Acute: disruption of central nervous system, abdominal trauma or stress response to neuroendocrine system ²⁶⁴ Chronic: impairment of autonomic nervous system ⁷	Hematocrit and hemoglobin; observation of gastrointestinal fluids	Surgical intervention; restore normal gastrointestinal function	Establish effective bowel program, establish high-fiber diet, provide education and stress management
Metabolic, endocrine	Impairment of autonomic nervous system	Observe for fatigue, malaise; undesirable weight gain ⁶²	None known	Education, exercise, and weight control

*Consortium for Spinal Cord Medicine Clinical Practice Guidelines: *Prevention of thromboembolism in spinal cord injury*, Washington, D.C., February 1997, Paralyzed Veterans of America.

†Consortium for Spinal Cord Medicine Clinical Practice Guidelines: *Neurogenic bowel management in adults with spinal cord injury*, Washington, D.C., March 1998, Paralyzed Veterans of America.

be taken for regular checks if this bridging technique is used in the trunk or buttocks region while the patient is in bed, owing to eventual shifting of the foam.

Keeping the head of the bed as low as tolerated minimizes the risk for shearing and excessive sacral pressure. For patients who are not appropriate for rigorous turning schedules (e.g., patients with unstabilized fractures), specialty alternating pressure mattresses are available. Low air loss, alternating pressure, or even air-fluidized mattresses are available for those who require the head of the bed to be elevated more than 30 degrees for prolonged periods and also have other extenuating conditions such as respiratory distress, diabetes, and/or low prealbumin.⁷⁰

While the patient is sitting, an appropriate pressure redistribution (relief) cushion is recommended and a pressure relief (weight shift) schedule is established and strictly enforced.

Although pressure is one of the most prevalent causes of skin compromise, other forces may lead to problems, including friction, shearing, excessive moisture or dryness, infection, and bruising or bumping during activities. This is especially true of clients with SCI because of altered thermoregulation, changes in mobility, decreased or absent sensation, and incontinence of bowel and bladder. In addition, as patients begin to learn functional skills, they may

have poor motor control and impaired balance and must be carefully monitored to avoid injury.

Should skin compromise occur, the first intervention is to identify and remove the source of the compromise. Modifications to the seating system or changing to a more pressure-reducing mattress system or cushion may be necessary. Examination and treatment will then need to focus on healing the wound and preventing other secondary complications that may occur as a result of potential immobility and delayed physical rehabilitation. The reader is encouraged to refer to *Pressure Ulcer Treatment: Clinical Practice Guideline*, developed by the Agency for Health Care Research and Quality, for examination tools, including the classification of pressure ulcers.^{71,72}

Treatment interventions may include hydrotherapy, specialty wound dressings, electro-modalities, and thermal modalities to increase circulation.⁷¹ Mechanical, autolytic, enzymatic, or surgical debridement may be necessary to obtain and maintain a viable wound bed. If the wound does not heal, surgical interventions with myocutaneous or muscle flaps may be necessary for closure. Coordinated return-to-sit programs or protocols after such medical interventions are necessary to prevent opening of the surgical site. Such surgical procedures are costly and significantly delay functional rehabilitation.

After closure and healing of the wound, education becomes a priority to maintain skin integrity. The client must adhere to a more rigorous skin check program as rehabilitation continues, giving special attention to the affected area. Teaching patients to advocate for themselves and to problem solve equipment and lifestyle issues that may affect their skin condition will reduce the recurrence rate. Alcohol, tobacco, and drug use (both recreational and prescription) should be managed for long-term success. Prevention of skin compromise is critical and cannot be stressed enough to health care providers, patients, and caregivers.

Prevention and Management of Joint Contractures

The development of a contracture may result in postural misalignment or impede potential function. Daily ROM exercises, proper positioning, and adequate spasticity control may help prevent contractures.⁶⁶ Contracture prevention includes the use of splints for proper joint alignment, techniques such as weight bearing, ADLs, and functional exercises. Patients exhibiting spasticity may require more frequent ROM intervention.^{66,73}

Adaptive Shortening or Adaptive Lengthening of Muscles

Although isolated joint ROM should be normal for all patients, allowing adaptive shortening or adaptive lengthening of particular muscles is recommended to enhance the achievement of certain functional skills.^{69,74} Likewise, unwanted shortening or lengthening of muscles should be prevented. The following section reviews a few examples of these concepts as they relate to SCI.

Tenodesis is described as the passive shortening of the two-joint finger flexors as the wrist is extended. This action creates a grasp, which assists performance of ADLs (Figure 16-11).^{69,75} A patient with mid to low tetraplegia may rely on adaptive shortening of these long finger flexors to replace active grip.⁶⁹ If the finger flexors are stretched across all joints during ROM exercises, the achievement of some functional goals may be limited. ROM to the finger flexors should be applied only while the wrist is in a neutral position. There is controversy over

Figure 16-11 ■ Tenodesis grasp.

shortening of the flexor tendons. Some clinicians argue that the client can develop a fixed flexion contracture of the proximal interphalangeal joints, interfering with future surgical attempts to restore finger function.³⁸ It is recommended to promote tenodesis functioning via adaptive shortening while maintaining joint suppleness.

In the presence of weakened or paralyzed elbow extensors, shortening of the elbow flexors should be prevented because it will impair ADL function and transfer skills.^{7,69} Contracted elbow flexors or pronator muscles in a client with an SCI level of C6 can cost this client his or her independence. Likewise, the rotator cuff and the other scapular muscles should be assessed for their length-tension relationships and their ability to generate force. Normal length of these muscles should be maintained. For example, achieving external rotation of the shoulder (active and passive) is critical for clients with low-level tetraplegia. Shortening of the subscapularis and other structures can quickly result in a decrease in motion, limiting bed mobility, transfers, feeding, and grooming skills. Patients with complete paraplegia who are candidates for ambulation require normal ROM in the lower extremities. If the hip flexors or knee flexors are allowed to shorten, achieving standing and ambulation goals will be more difficult.

The combination of lengthened hamstrings and tight back extensor muscles provides stability for balance in the short- and long-sitting positions. This aids in the efficiency of transfers and bowel and bladder management. Balance in long sitting assists with lower-extremity dressing and other ADLs. Hamstrings should be lengthened to allow 110 to 120 degrees of straight leg raising without overstretching back extensor muscles.

Splinting to Prevent Joint Deformity

Deformity prevention is the first goal of splinting.⁷⁶ Patients with cervical spinal cord injuries may have lost normal neural input to musculature in their wrists and hands. Other clients may have partial motor control, which may lead to muscle imbalances and loss of ROM. In the absence or weakness of elbow extensors, a bivalve cast or an elbow extension splint at night may be beneficial to prevent joint contractures. At the wrists, a volar wrist support is commonly used initially and may be progressed to a longer-term option of a definitive wrist orthosis. Other splints often used for deformity prevention of the hands include resting hand splints with proper positioning to maintain the support of the wrist and web space (Figure 16-12, A).⁷⁷ Another hand-based option is the intrinsic plus splint (Figure 16-12, B), which places the metacarpophalangeal joints closer to 90 degrees of flexion and decreases intrinsic hand muscle tightness.

Another goal of splinting in the SCI population is to increase function. Patients with tetraplegia at the C5 level rely on an orthosis to be independent with communication, feeding, and hygiene. They must have joint stability and support at the wrist and the hand to perform these skills. The splint is often adapted with a utensil slot or cuff so that the client can effectively perform the skills mentioned previously.

Patients who are not strong enough to use their wrists for tenodesis may require splinting to support their wrists until they can perform wrist extension against gravity. Long opponens splints can be used to position the thumb for

Figure 16-12 ■ A, Resting hand splint. B, Volar intrinsic plus splint maintains alignment of the wrist and fingers to promote metacarpophalangeal flexion for tenodesis grasp.

function but support the weak wrist (Figure 16-13). Once the wrist muscles strengthen, the long opponens splint can be cut down to a hand-based short opponens to maintain proper web space and thumb positioning while maximizing tenodesis.

As mentioned previously, clients with injuries at the C6 level can use their wrists for a tenodesis grasp.^{75,78,79} Critical components of the splint assessment for these clients are the positioning of the thumb, web space, and index finger observed during the grasp. It is recommended that the client's hand be positioned with the thumb in a lateral pinch position because this is the most commonly used prehension pattern to pick up objects. Clients who are not splinted may not have the proper positioning to pick up objects because their tenodesis is "too tight" or "too loose."

Clients with C8 to T1 injuries or clients who have incomplete injuries may have "clawing" or hyperextension of the metacarpophalangeal joints. This is caused by finger extensor musculature that is stronger than finger flexor musculature.^{75,80} To prevent this, a splint can be made to block the metacarpophalangeal joints and promote weak intrinsic muscle function. Depending on the extent of the imbalance, these splints can be used during function or worn only at night. Cost, time, material, and clinician experience are important considerations when deciding between custom

and prefabricated splints. A well fitting, prefabricated splint can be as effective as a custom-fabricated splint in certain situations. Custom splints require additional resources and clinician expertise. One way to minimize time spent in fabrication of splints is to use a good pattern and premade straps. Finally, educating the client on the splint-wearing schedule, skin checks, and splint care is important for preventing skin breakdown.

Treatment for Joint Deformity

If a joint contracture occurs despite preventive measures, more aggressive treatments are necessary. This may include more aggressive use of splinting, plaster or fiberglass casting techniques, or botulinum toxin type A (Botox) injections.⁸¹⁻⁸³ When splinting is not effective, fabrication of serial or bivalve casts may be indicated. The client with minimal ROM limitations may require only one cast. Most commonly, the client has a significant limitation and requires serial casts, in which several casts are applied and then removed over a period of weeks to increase extensibility in the soft tissues surrounding the casted joint.⁸⁴ The involved joint is placed at submaximal ROM.⁸⁵ Once the cast is removed, the joint should have an increase of approximately 7 degrees of ROM.⁸⁵ This process continues until the deformity is minimized or resolved. The final cast is a bivalve so that the cast can act as a positioning device that can be easily removed. Casting contraindications are skin compromise over the area to be casted, heterotopic ossification, edema, decreased circulation, severe fluctuating tone, and inconsistent monitoring systems. The elbow, wrist and hand, and finger joints are the most common joints casted for clients with SCI. Casting for most of these clients may be the last resort to regain increased ROM before a client can begin using feeding, grooming, or communication skills. Long-arm casts are used when elbow and wrist contractures must be managed simultaneously. If evaluation of the upper extremity reveals a pronation or supination contracture, a long-arm cast would also be the cast of choice. Dropout casts are used with severe elbow flexor or extensor contractures, but the patient should be in a position in which gravity can assist. Wrist-hand and finger casts are indicated for contractures that prevent distal upper-extremity function. Most commonly, a client will have a wrist flexion-extension contracture or have finger flexor-extensor tone and will require a cast to use the tenodesis or individual fingers for fine motor skills. Sometimes wrist casts with finger shells or resting hand extensions on casts are needed to ensure that the hand, fingers, and web space

Figure 16-13 ■ Long opponens splint with fabricated utensil holder.

are maintained in a position of optimal function. Casting is an expensive and labor-intensive treatment modality, but if indicated and used appropriately it can assist a client in regaining lost joint ROM needed for increased independence and function.

Botox may be used in conjunction with casting. In a study conducted by Corry and colleagues⁸³ tone reduction was evident when botulinum toxin type A was used; however, ROM and functional improvement varied among subjects. Pierson and co-workers⁸² found that, with careful selection, subjects who received botulinum toxin type A had significant improvements in active and passive ROM. Research indicates that patients who have flexor spasticity without fixed contracture will benefit the most.

Surgical intervention may be recommended by an orthopedic physician in severe cases of joint contracture.⁸⁶ Some of the more commonly used surgical options include joint manipulation under anesthesia, arthroscopic surgical releases, open surgical releases, and rotational osteotomy.

Prevention and Management of Respiratory Complications

Early management must focus heavily on preventing pulmonary complications and maximizing pulmonary function so the patient may perform physical activities. The clinician should first determine which ventilatory muscles are impaired. The primary ventilatory muscles of inspiration are the diaphragm and the intercostals. The diaphragm is innervated by the phrenic nerve at C3 through C5. The intercostals are innervated by the intercostal nerves positioned between the ribs. If the diaphragm is weak or paralyzed, its descent will be lessened, reducing the patient's ability to ventilate.⁸⁷⁻⁹⁰

Accessory muscles of ventilation are primarily located in the cervical region.⁹¹ The accessory muscles are used to augment ventilation when the demand for oxygen increases, as during exercise. Accessory muscles may also be recruited to generate an improved cough effort.⁶⁶ The most commonly cited accessory muscles are the sternocleidomastoids, the scalenes, the levatores scapulae, and the trapezius muscles.^{88,89} The erector spinae group may also assist by extending the spine, thus improving the potential depth of inspiration.⁸⁹

The abdominals are the primary muscles used for forced expiration in such maneuvers as coughing or sneezing. The latissimus dorsi, the teres major, and the clavicular portion of the pectoralis major are also active during forced expiration and cough in the client with tetraplegia.⁹² Alterations in the function of these muscles will have an impact on the patient's ability to clear secretions and produce loud vocalization. Gravity plays a crucial role in the function of all ventilatory muscles.⁸⁹ Neural input to the diaphragm increases in the upright position in persons with intact nervous systems. As one moves into an upright position, the resting position of the diaphragm drops as the abdominal contents fall.⁸⁹ The diaphragm is effectively shortened, which makes generating a strong contraction more difficult. With intact abdominal musculature, however, a counter pressure is produced and adequate intraabdominal pressure is maintained, allowing the diaphragm to perform work. If weakness or paralysis of the abdominal wall is present, the client may need a binder or corset to maintain the normal pressure relationship.^{69,87,93-95} Unless the SCI has affected only the lowest sacral and lumbar areas, some degree of ventilatory impairment is present and should be addressed in therapeutic sessions.

Many treatment techniques are available to address the myriad causes of ventilatory impairment. Decreased chest wall mobility and the inability to clear secretions should always be addressed. Interventions may include inspiratory muscle training, chest wall mobility exercises, and chest physical therapy.^{69,74,90,96,97}

Inspiratory Muscle Training

Inspiratory muscle training may be used to train the diaphragm and the accessory muscles that are weakened by partial paralysis, disuse from prolonged artificial ventilation, or prolonged bed rest. In the presence of significant impairments, it is generally recommended that training be initiated in the supine or side-lying position and progressed to the sitting position when tolerated. When training a moderately weak diaphragm, gentle pressure during inspiration may be used to facilitate the muscle (Figure 16-14). Accessory muscle training may be facilitated with the client in the

Figure 16-14 ■ Diaphragm facilitation. **A**, Hand placement and patient positioning to facilitate the diaphragm and inhibit accessory muscle activity. **B**, Firm contact is maintained throughout inspiration. The lower extremities are placed over a pillow in flexion to prevent stretching of the abdominal wall.

supine position while a slight stretch is placed on these muscles.⁷⁴ The stretch is accomplished by shoulder abduction and external rotation, elbow extension, forearm supination, and neutral alignment of the head and neck. A more challenging position incorporates upper thoracic extension. The clinician's hands are placed directly over the muscle to be facilitated. The patient is instructed to breathe into the upper chest (Figure 16-15). As the treatment progresses, the diaphragm may be inhibited for short training periods by applying pressure over the abdomen in an upward direction. Care must be taken to avoid excessive pressure to prevent occlusion of vital arteries.

As the inspiratory muscles strengthen, resistive inspiratory devices may be used. Inspiratory devices are relatively inexpensive and most function similarly. Most devices have a one-way valve that closes when the patient inspires, forcing him or her to breathe either through a small aperture or against a spring-loaded resistance. Although evidence fully supporting this intervention remains inconclusive,⁹⁸ some researchers have shown improvements in total lung capacity⁹⁹ and improved endurance measures.¹⁰⁰ The diaphragm may also be trained by using weights on the abdominal wall with the client positioned supine. Derrickson and colleagues¹⁰¹ concluded that both inspiratory muscle training devices and abdominal weights are effective in improving ventilatory mechanics. Muscle trainers, however, appear to promote more of an endurance effect than the use of abdominal weights.

Diaphragm and Phrenic Nerve Pacing

When the primary inspiratory muscles are no longer volitionally active as a result of SCI, diaphragm or phrenic nerve pacing may be used to cause the diaphragm to contract. These interventions are most commonly indicated when the lesion is at or above the C3 level.¹⁰¹⁻¹⁰⁶ Electrical stimulation may be applied directly or indirectly through a vein wall or the skin or directly to the phrenic nerve via thoracotomy. Transdiaphragmatic pacing, in which electrodes are placed laparoscopically on the diaphragm, is also an option.¹⁰⁷ Transdiaphragmatic pacing is less invasive than direct phrenic nerve pacing, may be implanted and initiated on an outpatient basis, and may result in improved outcomes. Both of these procedures require a reconditioning program that involves extensive caregiver and client training. Many clients

Figure 16-15 ■ Accessory muscle facilitation. Hand placement and patient positioning.

require some residual use of mechanical ventilation even after maximal tolerance has been achieved so as not to over-fatigue the phrenic nerve. Other researchers are considering also pacing intercostal muscles¹⁰⁸ or using a combination of diaphragmatic and intercostal pacing. There is limited evidence comparing the outcomes associated with these devices in isolation or in combination therapies.

Glossopharyngeal Breathing

Glossopharyngeal breathing is another way of increasing vital capacity in the presence of weak inspiratory muscles.^{90,94,97} Moving the jaw forward and upward in a circular opening and closing manner traps air in the buccal cavity. A series of swallowing-like maneuvers forces air into the lungs, increasing the vital capacity. This technique has been reported to increase vital capacity by as much as 1 L.⁷⁴ Although this technique is rarely used to sustain ventilation for long periods of time,¹⁰⁹ it may be used in emergency situations and to enhance cough function. The client with high tetraplegia should attempt to master this skill.

Secretion Clearance

Ventilatory impairment occurs when the client is unable to clear secretions.^{87,110} Factors such as artificial ventilation and general anesthesia hamper secretion mobilization. With artificial ventilation, clients may require an artificial airway.^{110,111} The presence of this airway in the trachea is an irritant, and the client subsequently produces more secretions.⁸⁷ A description of various types and parameters of ventilation is beyond the scope of this chapter. Clinicians working with clients requiring artificial ventilation are referred to other publications.^{110,112}

Secretions are most commonly removed by tracheal suctioning, unassisted coughing, or assisted coughing. Recently there has been a resurgence of previously used technologies that provide rapidly alternating pressures through a mouthpiece or an endotracheal tube to remove secretions. This is commonly referred to as insufflation-exsufflation.¹¹³ To date, conclusive research determining which single technique or combination of techniques achieves the best outcome is not available. Insufflation-exsufflation may result in fewer complications and is reported to be more comfortable to the client. Barriers to implementation of these techniques may include expense of the equipment and competency barriers in that training is required. Postural drainage, percussion or clapping, and shaking or vibration are used to assist with moving secretions toward larger airways for expectoration.^{17,69,79}

Assisted coughing is typically used with people who are unable to generate sufficient effort.⁹⁷ The assistant places both hands firmly on the abdominal wall. After a maximal inspiratory effort, the patient coughs and the assistant simply supports the weakened wall. A gentle upward and inward force may be used to increase the intraabdominal pressure, yielding a more forceful cough (Figure 16-16).^{84,97} Excessive pressure over the xiphoid process should be avoided to prevent severe injury.

Patients may learn independent coughing techniques. In preparation for a cough, the patient positions an arm around the push handle of the wheelchair, opening the chest wall to enhance inspiratory effort. The other arm is raised over the head and chest during inspiration. This procedure is followed by a breath hold, strong trunk flexion, and then a

Figure 16-16 ■ Quad coughing. **A**, Hand placement for the Heimlich-like technique. **B**, Anterior chest wall quad coughing. The inferior forearm supination promotes an upward and inward force during the cough.

cough (Figure 16-17).⁹⁷ Another technique for independent coughing is accomplished by placing the forearms over the abdomen and delivering a manual thrust during cough. This technique is more difficult and may not provide an inspiratory advantage.

Early Mobilization

Getting the patient upright as soon as possible promotes self-mobility and should be planned carefully. An appropriate seating system for pressure relief and support should be chosen. Most patients require a reclining wheelchair with

elevating footrests or tilt-in-space wheelchairs when they are first acclimating to the upright position.^{69,74,97}

The client is transferred initially to a reclining or tilting back position and progressed to an upright position as signs and symptoms of medical stability allow. The client should be monitored for evidence of orthostatic hypotension. Dizziness or lightheadedness is most common. Ringing in the ears and visual changes also may occur. Changes in mental function may indicate more serious hypotension, and the client should be reclined immediately. Assessing blood pressure before and during

Figure 16-17 ■ Self-produced quad coughing. **A**, Full inspiratory position. **B**, Expiratory or cough position.

Figure 16-18 ■ Abdominal binder. Correct placement is over the anterior-superior iliac spine and at the level of lower rib cage. Custom corsets may be used if an elastic binder does not provide adequate support to enhance vital capacity.

activities provides an objective measurement of the client's status.

Because of paralysis, the abdominal wall may not support the internal organs and viscera. In these cases an abdominal binder or corset should be applied to all clients with lesions above T12 to assist in venous return^{74,95,97}; as discussed, this will enhance ventilatory function. If the client has a history of vascular insufficiency or prolonged bed rest, wrapping the lower extremities with elastic bandages while applying the greatest pressure distally may be beneficial.

Abdominal binders and corsets are fitted so that the top of the corset lies just over the lower two ribs.⁹⁵ The bottom portion is placed over the anterior iliac spine and iliac crest (Figure 16-18). The corset or binder should be adjusted slightly more tightly at the bottom to assist in elevating the abdominal contents.^{69,74,97} Properly fitting the abdominal binder is essential. If it is placed too high or allowed to ride up, ventilation may be impaired by restriction of chest wall excursion. If placed too low, it will not provide the necessary abdominal support.

The client can be transferred initially with a manual or mechanical lift. Lift systems may be advantageous because they allow total control of the client and give the assistant more time to ensure that monitoring devices, lines, or tubes attached to the client remain intact. Lift systems may be freestanding hydraulic lifts or electronic devices or may be mounted on the ceiling.

Once the client is out of bed, a weight shift or pressure relief schedule is immediately established. Initially, weight shifts are performed at 30-minute intervals and modified according to skin tolerance.⁶⁷ A timer may be issued to ensure reminders for weight shifts. This is particularly important if the client has cognitive deficits. The skin is inspected thoroughly before and immediately after out-of-bed activities. Total sitting time is progressed according to tolerance.

REHABILITATION: ACHIEVING FUNCTIONAL OUTCOMES

Once secondary complications are managed and the client is able to tolerate out-of-bed activities, more aggressive functional training begins. The following information will

address special considerations for functional progression related to SCI.

Optimal neck, shoulder, and upper-extremity strength and ROM are important factors to consider in order to maximize functional outcomes. Neck musculature is typically painful and restricted in cervical injuries, especially after surgical procedures. Most clients will have a cervical orthosis in place postoperatively to prevent rotation and flexion and extension. Cervical spine mobility may be so limited that correcting a forward head posture is the first goal. Soft tissue massage, manual therapy, and other modalities may be beneficial. When cleared by the physician, the client can begin more aggressive neck exercises.

Key muscle groups in the shoulder to consider are the scapular stabilizers and movers, which allow for humeral flexion, adduction and abduction, shoulder internal and external rotation, and scapular movements. Clients with high cervical injuries have the potential for development of tight upper trapezius muscles. Upper trapezius inhibitory or scapular taping to relax the tight muscles and facilitate the weak scapular musculature is often beneficial. In the injury levels above C7, the scapular musculature may not be fully innervated, and thus positioning in the proper alignment and strengthening the innervated musculature are essential. The clinician will use findings from manual muscle testing and the goniometric examination to determine the appropriate stretching and strengthening programs. Patients may need to begin with gravity-eliminated exercises using air splints, bilateral slings, skateboards, and functional electrical stimulation (FES).

Activities of Daily Living and Instrumental Activities of Daily Living

ADLs include skills such as communication, feeding, grooming, bathing, dressing, bladder and bowel management, home management, and community reentry. Instrumental activities of daily living (IADLs) encompass multistep activities to care for self and others,¹¹⁴ such as parenting, household management, and financial management. Depending on the level and severity of the SCI, patients will achieve varying levels of independence. Most of the ADL areas discussed in this section will address skill levels with a complete injury. Activities should be graded differently for an incomplete injury after completion of ASIA and manual muscle testing. For purposes of this discussion we will use terms used in the FIM.

Patients with high-level tetraplegia (C1 to C4) will be dependent in most ADLs as well as IADLs but will be able to verbalize how to safely perform all skills. Patients with low-level tetraplegia (C5 to C8) may achieve some level of independence, but this will vary according to the amount of intact musculature and the patient's body shape and weight, age, and motivation level. The ability of these patients to achieve maximum independence in all areas of ADLs may be accomplished only through the use of appropriate orthoses or adaptive equipment. See Table 16-4 for functional expectations and Table 16-6 for orthotic indications.

Patients with injuries at the C5 or C6 level are especially challenging in this area of rehabilitation. These patients must have biceps function and adequate elbow ROM before any ADL goals can be achieved. To achieve these goals, patients also need to work toward supporting their body

TABLE 16-6 ■ UPPER-EXTREMITY ORTHOTICS

SPLINT	LEVEL OF SPINAL CORD INJURY	RATIONALE
DYNAMIC ORTHOTICS		
Mobile arm support (ball-bearing feeder)	Weak C5 Incomplete injuries Also indicated with shoulder weakness (internal-external rotator muscle grades 2– to 3/5; bicep-supinator muscle grades 2–/5)	Function Assists in reaching in horizontal and vertical planes Increases functional ROM and strength Independence with feeding and hygiene after setup Provides support to allow correct movement patterns
Overhead rod and sling	Weak C5 Incomplete injuries Also indicated with shoulder weakness (internal-external rotator muscle grades 3 to 3+/5; bicep/supinator muscle grades 3/5)	Function Increases functional ROM and strength Independence with wheelchair driving after setup Independence with feeding and hygiene after setup Provides support to allow correct movement patterns
STATIC SPLINTS, CASTS, AND ORTHOTICS		
Resting hand splint	C1-C7	Position Prevent joint deformity Preserves web space Preserves balance with intrinsic and extrinsic musculature
Intrinsic plus splint	C1-C7	Position Same as resting hand splint but places finger MP joint in more flexion Long term, allows better tenodesis alignment of first digit and thumb
Elbow extension splints, bivalve cast	C5-C6	Position Prevents elbow contracture from muscle imbalance and/or hypertonicity
Rolyan TAP splint (prefabricated)	C5-C6	Position Provides constant low stretch Use with muscle imbalance and/or mild hypertonicity
Dorsal wrist support splints	C5	Function (e.g., slot for utensils) and position Prevents severe wrist drop and ulnar deviation If positioning is needed long term, may consider permanent splint fabricated by orthotist
Long opponens splint	C5	Position and function Can be dorsal or volar Prevents wrist drop and ulnar deviation Preserves web space and supports thumb, reducing subluxation Slot may be fabricated for function
Wrist cock-up splint	C5 Incomplete injuries	Position and function Supports wrist in slight extension Allows finger movement for incomplete injuries
Short opponens splint	C6-C7	Position and function Supports thumb to prevent subluxation Improves tenodesis and prehension
Tenodesis brace or splint	C6-C7	Function Enhances natural tenodesis in either tip-pinch or lateral pinch May consider permanent splint fabricated by orthotist
MP block splint	C8-T1	Position Prevents “claw hand” or hyperextension of the MP joints Protects weak intrinsic musculature

MP, Metacarpophalangeal; ROM, range of motion.

weight with simultaneous extension of the shoulder, elbow, and wrist, otherwise known as *propping* (see Figure 16-35, A to C). Elbow positioning devices such as pillow splints, casts, or resting splints enhance alignment. Other orthotics to consider for maximizing function include definitive wrist supports and mobile arm supports (MASs)¹¹⁵ or short opponens splints if the patient has wrist extension. Appropriate

wheelchair positioning with lap trays, armrests, wedges, or lateral trunk supports is important to maximize function for persons with C5 or C6 injuries.

Patients with a C7 or C8 level of injury generally will not prove to be as challenging for the rehabilitation therapist. With the presence of triceps, the ADL skills are easier to achieve. Most patients, given the right body type, will be

able to achieve these goals with only minimal assistance from a caregiver.

Patients with paraplegia usually achieve total independence with communication, feeding, and grooming. These patients may need adaptive equipment to perform some of these IADL and ADL skills; however, they should be able to be performed without assistance from another person. Endurance is a major concern for the patient's independence while performing ADLs. Some skills require a considerable amount of time and effort. If endurance becomes a factor, patients should choose to perform some activities while receiving assistance for other skills that are too challenging or time-consuming.

Feeding

Patients with C1 to C4 tetraplegia are dependent in feeding but can verbalize this skill. Patients with C5 SCI with weak shoulders and biceps musculature require a dynamic orthosis to support the upper extremity during feeding. The most common orthoses used are the MAS^{115,116} (Figure 16-19) and the offset feeder (Figure 16-20). Patients with low-level tetraplegia may not have weakness in the shoulder

Figure 16-19 ■ Mobile arm support (MAS) used during feeding.

Figure 16-20 ■ Offset feeder orthosis.

that would affect feeding, but they may have weak wrist function. Some of the dorsal wrist supports have a cuff built in that can be functional. The patient with no finger function can use a wrist-driven tenodesis brace for managing objects or to hold a feeding utensil (Figure 16-21). A universal cuff can be worn on the hand to hold feeding utensils (Figure 16-22, A). The patient with weak finger function can use built-up handles on the utensils. There are also commercially available and esthetically pleasing utensils such as those in Figure 16-22, B. Cutting can be difficult for patients without finger function.

Grooming

The basic components of grooming are washing the face, combing or brushing the hair, performing oral care, shaving, and applying makeup. More advanced grooming activities may include nail care, donning and doffing of contact lenses, or other hygiene tasks specific to the individual. Individuals with C1 to C4 tetraplegia are dependent but can verbalize these skills. Patients with C5 injuries perform these skills with some assistance but may require orthotic devices, such as an MAS or offset feeder for shoulder support and a splint for wrist support. Patients with low-level tetraplegia may need cuffs or built-up grips on razors, brushes, and toothpaste to be independent (Figure 16-23). A proper bathroom setup for optimal wheelchair positioning is important for all patients. Patients with tetraplegia often rely on the support of the elbows as an assist, so sink height should be considered. The proper positioning and adaptive equipment will be the difference between independence and dependence in these skills (Figures 16-24 and 16-25).

Bathing

Bathing includes washing and rinsing the upper and lower extremities and the trunk. Patients with C1 to C4 tetraplegia are dependent in bathing but are instructed to verbalize this skill. Patients with C5 injury can range from requiring maximal assistance to being dependent in bathing. Patients with low-level tetraplegia bathe with moderate assistance to total independence with use of adaptive devices. Patients with paraplegia are typically independent in bathing but may need

Figure 16-21 ■ Tenodesis braces have varying grasps. The largest grasp position allows the client to hold a soft drink can.

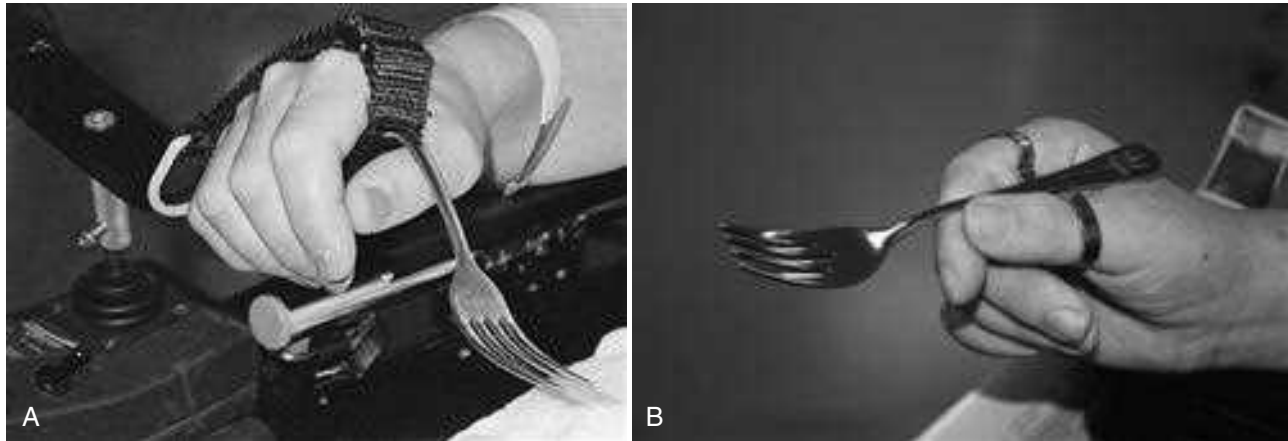

Figure 16-22 ■ **A**, Universal cuff used for feeding. **B**, Dining with Dignity is one commercially available type of flatware for individuals with impaired grip.

Figure 16-23 ■ Simple razor adaptation that helps turn razor on and off with a grosser motor movement.

adaptive devices. After examination of the patient's upper-extremity strength, balance, spasticity, body type, endurance, and home accessibility, the therapy team can determine the appropriate bathing equipment and setup for the patient (Figure 16-26). Patients with limited upper-extremity and trunk strength may need straps to assist with trunk support and adaptive cuffs to control the hand-held shower head. Basic bathing safety should be taught to all patients. Bathing safety includes checking the water temperature with a known area of intact sensation, skin checks before and after bathing, and skin protection during the transfers. These precautions are necessary to prevent burns and skin breakdown during the bathing process.

Dressing

Dressing includes dressing and undressing the upper and lower extremities with clothing that fits the patient's premorbid lifestyle. Patients with C1 to C5 tetraplegia are dependent,

Figure 16-24 ■ **A**, A client with a C5 spinal cord injury is able to brush his teeth with use of a cuff, adapted long straw, and proper wheelchair positioning at the sink. **B**, Client with C6 spinal cord injury uses bilateral tenodesis to support toothpaste while holding a toothbrush in his mouth.

Figure 16-25 ■ Sink height can be important in assisting this client with C6 spinal cord injury to brush his hair.

Figure 16-26 ■ Bathroom setup with shower or commode chair and hand-held shower head.

but they can verbalize safe techniques to perform all the dressing skills. Independence in this skill for patients with low tetraplegic and paraplegic injuries may depend on where the skill is performed (e.g., mat, bed, or wheelchair). Patients with low-level tetraplegia can perform upper body dressing and undressing independently with equipment such as a button hook, hook and loop fasteners (Velcro), or adapted loops. Lower-body dressing is usually performed in bed (Figure 16-27) versus the wheelchair because of endurance, strength, and body type issues. Patients with paraplegia are expected to dress with total independence in the bed, but they may need equipment such as a leg lifter or a long-handled shoehorn for dressing in the wheelchair (Figure 16-28). This should be encouraged, if possible, for independence in the community.

Bladder Management

Bladder management includes determining and performing the bladder program, clothing management, body positioning, setup and cleanup of equipment, disposal of urine, and

Figure 16-27 ■ Client with low-level tetraplegia maintains balance while performing lower-extremity dressing in bed.

Figure 16-28 ■ Early practice when dressing in the wheelchair may involve leaning on a surface to assist with this skill.

cleanup of self. Water or video urodynamic studies are performed to determine the patient's bladder status and the most optimal bladder training program. Patients often enter the rehabilitation program with an indwelling catheter as their bladder management program. The indwelling catheter should be removed as soon as possible because it puts the patient at risk for chronic urinary tract infections.¹¹⁷

On the basis of injury level, patients have either a reflexive bladder (upper motor neuron lesions) or an areflexive bladder (lower motor neuron lesions).⁶⁹ The reflexive bladder reflexively empties when the bladder is full. The therapeutic goals for managing the reflexive bladder include low-pressure voiding and low residual urine volumes. The nonreflexive bladder will not empty reflexively and needs to be manually emptied at regular intervals. The goals for managing the areflexive bladder include establishing a regular emptying schedule and continence between emptying. Management of an areflexive bladder includes performance of intermittent catheterizations.

Patients with C1 to C5 tetraplegia are typically dependent in their bladder programs. An automatic leg-bag emptier can assist with just the elimination component of the bladder skill; however, the patient will still be dependent in all of the other components of bladder management. Male patients with injuries at C6 level and below may be able to complete portions of the bladder management. Patients with limited hand function may need adaptive devices such as orthoses to assist with catheter insertion, adaptive scissors to open bladder packages, leg bags with flip-top openers, and leg bag loops (Figure 16-29). Female patients with paraplegia will most likely need to begin their training in bed with a mirror to obtain the most ideal position. Touch technique can be taught so they will not be reliant on a mirror if they have good finger sensation and use, and they may progress to using the touch technique in a wheelchair. Some people with SCI may decide to have a suprapubic catheter placed or a bladder augmentation procedure as a lifestyle choice.

Bowel Management

The goal of bowel management is to have the patient able to predictably induce regular elimination. As described under bladder management, the level of injury will assist in telling if the patient will have either a reflexive bowel or a nonreflexive bowel.⁶⁹ The bulbocavernosus reflex (BCR) is elicited by pinching the dorsal glans penis or by pressing the clitoris and palpating for bulbocavernosus and external anal sphincter contraction.¹¹⁸ If the patient has a positive BCR, this is indicative of a reflexive bowel. With a reflexive bowel, tone of the internal and external anal sphincter is present although the patient will not feel the need to have a bowel movement. Voluntary anal contraction and relaxation are not possible, but the nerve connection between the colon and the spinal cord are still intact, allowing the patient to reflexively eliminate stool. This can be done with chemical or mechanical stimulation.¹¹⁸

Flaccid bowel programs are much more difficult to regulate because there is no internal or external anal sphincter tone. Timing and diet are critical for the success of this program. A suppository may be required to assist with the

Figure 16-29 ■ Bladder management supplies may include knee spreader with mirror, sterile catheter kit, catheter inserter, leg bag with tubing and adapter, catheter, “HouseHold” for positioning, bungee cord to hold pants, pants holder, small prelubricated female catheter.

process, and in this situation the rectum should be emptied before suppository insertion.¹¹⁹ If the established bowel program is not followed consistently, involuntary bowel movements or impaction may occur.

Bowel management training must begin as soon as the patient is medically stable. The components of bowel management include clothing management, body positioning, setup and cleanup of equipment, performance of the bowel program, disposal of feces, and cleanup of self. To establish the most effective bowel training program, the interdisciplinary team must work together. The team will need to discuss patient medications that may affect the bowels, the time of day when the patient plans to perform the program, the physical appropriateness related to scapular strength and endurance, and all equipment that will be used.

Patients with injury above the C6 level will be dependent in performing the bowel program; however, they should be independent in the verbalization of the technique. Patients with limited hand function (C6 to C7) may require a digital bowel stimulator and a suppository inserter with an adapted cuff or splint (Figure 16-30). In addition, a roll-in shower chair or upright shower or commode chair with a padded cutout in the seat will allow the patient to reach the buttock area to perform the stimulation. For this level of injury, it may be advantageous to perform the bowel program in conjunction with the shower to conserve energy with transfers. For individuals with paraplegia, full independence is expected for completion of all bowel management skills. These programs are typically performed on appropriate bathroom equipment or the bed.

To increase the effectiveness of the bowel program the patient should follow the guidelines identified in Box 16-2.

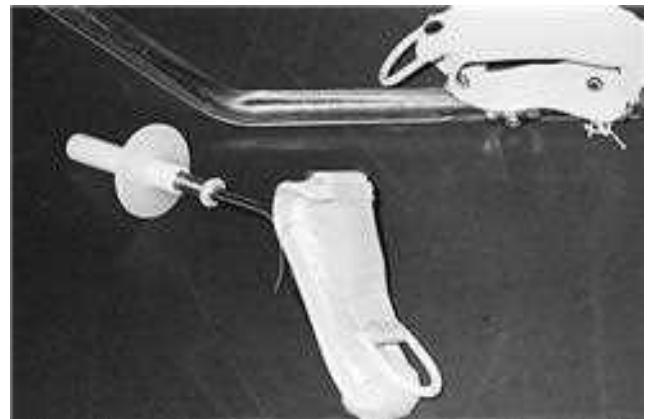

Figure 16-30 ■ Dil stick and suppository inserter with adaptive cuffs.

BOX 16-2 ■ GUIDELINES FOR BOWEL PROGRAM

1. Perform the bowel program at the same time each day.
2. Follow a diet high in fiber (25 to 35 g recommended).
3. Drink at least eight glasses of water per day.
4. Drink a hot liquid 30 minutes before initiating the bowel program.
5. Perform the bowel program in an upright position.
6. Consider premorbid bowel schedule.

Home Management

Home management may be divided into two components: light home management and heavy home management. Light home management includes managing money, preparing a snack in the kitchen, doing laundry, and making the bed. Heavy home management includes shopping for groceries, preparing a complex meal in the kitchen, dusting, and vacuuming. The clinician should discuss the role the patient would like to assume at home. The patient may want to resume previous home management roles or may want to discuss changing roles with a family member or caregiver to have energy for other skills.

Patients with C1 to C5 tetraplegia will be dependent in home management. Patients with limited or no hand function will need adaptive kitchen devices, adapted utensils, and adapted cleaning equipment. Preplanning activities may be essential for independent function with patients at all levels of injury. Patients with hand function may require extended handles on equipment and must incorporate energy conservation techniques.

Parenting

Research has shown the importance of parenting behavior and attitude on children's ability to adjust to various circumstances. This adjustment is not, however, affected by the disability status of a parent.^{120,121} Patients with C1 to C5 tetraplegia may be dependent in the physical aspects of parenting. Patients with low-level tetraplegia may be able to participate in the more physical aspects of parenting with some level of adaptations such as a wheelchair-accessible table with sides to change an infant.¹²² Parenting skills for a patient with paraplegia would depend on the environment and the specific activity being performed as well as the mobility of the individual. Therapists can provide advice and ideas to assist with selection of parenting and baby equipment as well as be a resource in discussing and adapting equipment options such as slide-down cribs, adjustable-height high chairs, carrying slings or supports, and baby strollers that can be more easily pushed with one hand.^{122,123}

Assistive Technology

AT can be helpful in letting people resume more independent lives in areas of self-care, work, and recreation. AT is defined by the 1998 Technology-Related Assistance for Individuals with Disabilities Act (Public Law 105-394). It defines AT devices as "any item, piece of equipment, or product system, whether acquired commercially, modified, or customized, that is used to increase, maintain, or improve functional capabilities of individuals with disabilities." Hedrick and colleagues¹²⁴ found that in both civilians and veterans the most frequently used AT devices were (1) manual mobility and independent living devices (e.g., manual wheelchairs, manual exercise equipment, manual motor vehicle control devices such as a steering knob, walkers, reachers); (2) powered mobility and independent living devices (e.g., power lifts, power doors, motorized wheelchairs, power-assisted motor vehicle operation devices); (3) prosthetics and orthotics (static and dynamic, such as splints, mentioned earlier); (4) alternative computer access devices, which may be as simple as a typing splint to as complex as brain control; and (5) speech-generating devices

(SGDs) formerly known as *augmentative and alternative communication devices*.

Many specialty facilities that treat large numbers of SCI patients will have specialized therapists called Assistive Technology Practitioners (ATPs) and/or AT departments to specifically assess, select, and train in the use of device(s)—specifically seating, driving, and electronic access. Seating departments will evaluate and prescribe customized manual or powered mobility seating systems. This is essential as professionals struggle to assist the patient with reimbursement for the mobility devices as well as the always-changing technology. Not everyone has access to someone with this specialized certification; thus consideration should be given by the therapist in the evaluation phase to include where the patient will use the chair and how it will get there, looking at the "big picture" rather than only the mobility device. For example, how will the wheelchair be transported? Can the wheelchair be locked down so the patient may drive in a van or be a dependent passenger? Can the patient load the manual chair into his or her car (Figure 16-31)? There are specially trained practitioners called *driving rehabilitation specialists* who specialize in recommending equipment and transportation of the patient as a passenger in addition to providing driver education and driver training. They help to evaluate and to assist with making correct vehicle modifications and adaptive equipment choices for the patient as a driver. There are over 600 specialists in the United States represented in each of the 50 states. A professional can be found on the Association for Driver Rehabilitation Specialists (ADED) website (www.drivers-ed.org).¹²⁵ When considering a sedan, these specialists will evaluate the patient to see how he or she operates primary and secondary vehicle controls, opens and closes the door, transfers into the vehicle, and stores, secures, and retrieves the wheelchair. If the patient is unable to perform any of those tasks then a van may be an option. Modifications can allow a person to transfer to the van's driver seat or to drive from the wheelchair. The driving control technology that is available to compensate for reduced strength or ROM includes steering systems, hand controls, and reduced effort and zero effort steering and braking. The rehabilitation specialist will provide a comprehensive evaluation to determine the patient's ability to drive. That evaluation will consider visual, perceptual, and functional abilities as well as reaction time and behind-the-wheel assessment. In both sedan and van selection, it is always best to recommend that the patient consult the driving rehabilitation specialist before purchasing and modifying the vehicle.

In this day of ever-changing technology, the patient may need assistance to access many electronic devices, such as computers, televisions, lights, call systems, personal digital assistants (PDAs), cell phones, music systems, or digital readers or the not-yet-invented device that will be coming on the market in the future. Dexterity is required to operate many standard devices such as computers. There are many "off-the-shelf" adaptations using universal designs to enable persons with limited dexterity to use a computer. A person with a higher tetraplegic level of injury can use alternative methods to access a computer, such as a microphone with speech recognition software, pneumatic controls (sip-and-puff devices), or an eye gaze system. The most popular and inexpensive way to access a computer is speech recognition

Figure 16-31 ■ Car transfer. Most patients with a paraplegic level of injury are modified independent (FIM level 6) in the performance of a car transfer. The patient approaches the car on the driver's side and opens the door. **A**, After stabilizing the wheelchair, he may place his foot or feet into the car or leave them on the footrest or the ground. **B**, He performs a depression-style transfer onto the seat of the car; **C**, positions his lower extremities appropriately inside the car; and **D**, prepares to get the wheelchair into the car by removing the wheels (quick release) and cushion and placing these on the floor in the front passenger area or in the back seat. **E to G**, The rigid model of wheelchair is folded and transferred across the patient onto the passenger seat. Transferring out of the car is the reverse process, beginning with getting the wheelchair out of the car and reassembling it.

software. However, the computer-brain interface is a newer technology currently in clinical trials and uses intact brain function to address these needs. In recent years computer companies have been more sensitive to the population with disabilities. The operating systems have adjustments that make the keyboard easier to use, referred to as *Ease of Access* or *Universal Access features*. These are very helpful for someone who may be entering commands with a single point such as a mouth stick or a pointer on only one hand. This adjustment can change how the keyboard works or can provide an on-screen keyboard. There are shortcuts that allow the patient to do everything with the keyboard, thus eliminating a mouse, which may be difficult for a mouth stick user. Many of these keyboard commands are not needed if the individual uses an already built-in speech recognition program or purchases one. There are detailed

tutorials on both the Microsoft and the Apple websites. Manufacturers do not always consider how persons needing adaptations will access their device. Cell phones and all commercial Bluetooth technology still requires some touch to activate; however, some vendors have made modifications available, although they are expensive. Surface touch screens are not disability friendly, and many phones and music systems use that technology. The therapist's role is to help assess, decide, and adapt how the access should be achieved for the patient, taking advantage of whatever the patient has to use. EADLs such as call systems or computer systems can be adapted using pneumatic controls (sip-and-puff devices) or voice-activated controls for independence from the bed and the wheelchair. There are switches that can be activated with head or eye control, allowing patients with little movement the

ability to communicate. Patients with C3 to C4 injuries, depending on neck strength and ROM, can use lower-tech equipment such as mouth sticks for pushing cell phone buttons from the wheelchair in addition to the head rest buttons or a sip-and-puff switch (Figure 16-32). Patients with C5 injuries begin to use their biceps, deltoids, and internal and external rotator strength to interact with their environment. Positioning of the buttons, devices, or mounts for devices is important for these patients, who may or may not be using an MAS. Adaptive splinting for support at the wrist can allow these patients to use their upper arms in writing, typing, turning pages, and using computers (Figure 16-33). Patients with wrist function but no finger function can use utensil holders with a pointer to “dial” a phone number, for example, or can use their natural tenodesis to grasp and manipulate objects (Figure 16-34). For injuries at the T1 level and below, interaction with the environment in all areas should be independent.

Figure 16-32 ■ Mouth stick writing can be accomplished with the client upright in the wheelchair and with the support of a bedside table and bookstand.

Figure 16-33 ■ Long Wanchick writing device.

Figure 16-34 ■ Tenodesis brace writing by use of a pen with a built-up grip.

Mobility

Bed Mobility and Coming to Sit

The components of bed mobility include rolling side to side, rolling supine to prone, coming to sit, and scooting in all directions while either long or short sitting. Initial training for bed mobility is usually conducted on the mat, as it is easier to learn on the firmer surface. When skills on the mat are mastered, the patient can be progressed to a less firm surface, such as the bed. Bed mobility is a challenging skill for clients with tetraplegia to learn because of their limited upper-extremity strength (Figure 16-35, A to C).^{7,62} To accommodate for the loss of upper-extremity musculature, compensatory strategies and assistive devices, such as bed loops, may be used (Figure 16-35, F to I). Clients with paraplegia often master bed mobility skills quickly and much more easily than clients with tetraplegia because of their intact upper-extremity musculature.

Pressure Relief in the Upright Position

The client with high tetraplegia achieves independent pressure relief in the wheelchair through appropriately prescribed specialty controls. For example, a pneumatic control switch may be used to activate the recline mode of a power wheelchair (Figure 16-36). When the client is unable to operate a specialty switch, an attendant control may be used. When powered options are not feasible because of cognitive deficits, financial limitations, or other reasons, a manual recliner (Figure 16-37) or tilt wheelchair is used. When clients are dependent in performing pressure relief, they can be taught to instruct others in this skill. Clients with mid- and low-level tetraplegia are taught to perform a side or forward lean technique for pressure relief if the strength of the shoulder musculature is appropriate (Figure 16-38). The client with paraplegia is usually taught to perform a pushup (depression) for pressure relief (Figure 16-39).

The appropriate time to maintain the change in position is usually 60 seconds at intervals of 30 to 60 minutes. The treatment plan should include instructing the client in ways to ensure that the schedule for pressure relief is maintained in all settings. The use of watches, clocks, timers, and attendant care may be necessary.

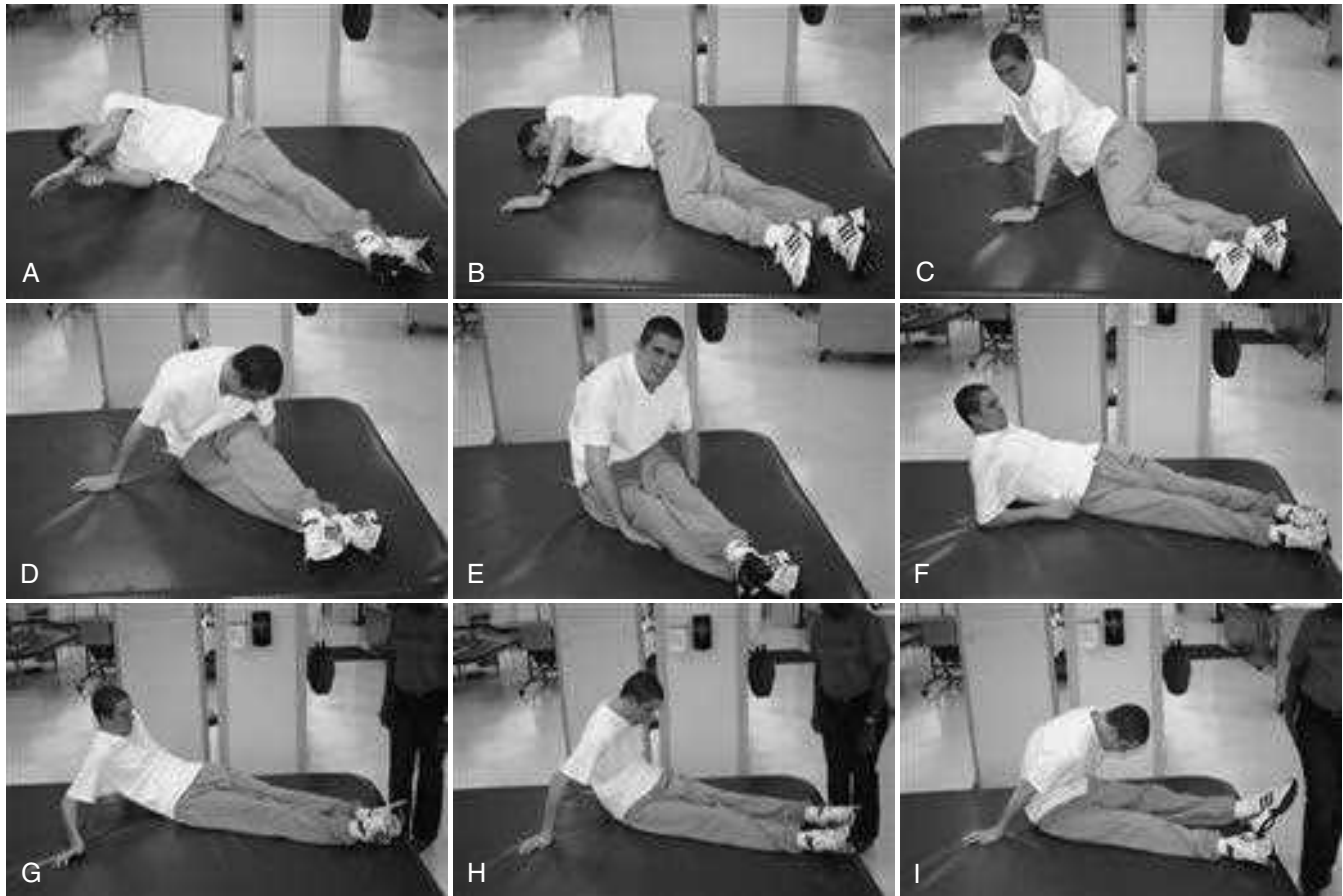

Figure 16-35 ■ Bed mobility and coming to sit. **A**, The patient rolls from supine to side-lying position. **B**, He progresses to supporting his weight through the downside elbow and shoulder. **C**, He pushes up onto extended arms. **D**, While shifting his weight onto the left arm, he unweights the right arm and hooks his right hand behind his right knee, gaining enough leverage to push and pull himself toward upright in a long sitting position. **E**, He continues to shift his weight to the right until he gains a balanced sitting position with his weight forward over his extended legs. Supine to sitting: **F** and **G**, Starting from a supine position on a bed or a mat, the arms are extended and the hands positioned under the buttock or in the curve of the back (lumbar spine); the head is lifted; and leverage is used to pull up until the upper body weight is supported on bilateral elbows. **H**, The weight is shifted from right to left or vice versa, and the elbows are extended to support the upper body weight. **I**, While the elbows are kept extended, the hands are carefully walked forward until balanced long sitting has been achieved.

Wheelchair Transfers

The physical act of moving oneself from one surface to another is described as a *transfer*. Wheelchair transfers may be accomplished in many different ways. The type of transfer used by a client is determined by the injury level, assistance needed, client preference, and safety of the transfer. When performing transfers, both the client and the person assisting must give attention to the use of appropriate body mechanics.

Dependent transfers may be accomplished with an electric (power) lift, hydraulic lift, manual pivot, transfer board, or manual lifts, which may require two or three people. A transfer with an overhead power lift is the least physically challenging on the part of the caregiver; however, these lifts are costly and are not easily transportable. The use of a hydraulic lift may be desirable if funding is not available for a power lift or the transfer needs to be done in an outdoor

environment (i.e., car transfer). However, the hydraulic lift may not be the method of choice because the lift is bulky, difficult to store, and awkward to transport. Pivot transfers or manual lifts may be used because of client or caregiver preference or when clients are smaller in stature and when other, more costly lift systems are not available to the individuals.

Transfers can be performed with the use of a transfer board, depression-style, or via the stand or squat and pivot method. The mechanics of teaching an assisted transfer to a client with C7 tetraplegia is depicted in [Figure 16-40](#). The client is taught to position the wheelchair, position the transfer board, use correct body mechanics to get the best leverage to effect movement in the desired direction, remove the board, and position his or her body appropriately.^{7,62}

Wheelchair transfers are performed on many different surfaces. The training procedure begins with the easiest transfer and progresses to the more difficult transfer. Instructions

Figure 16-36 ■ The pneumatic control (sip-and-puff straw) is usually ordered on a power reclining or tilt-in-space wheelchair for patients with injury levels above C6. The straw is removable, and several are supplied with the wheelchair. The straw is attached to a flexible arm, and it is adjustable to different heights and angles to fit the needs of the patient.

Figure 16-37 ■ The manual reclining wheelchair is a piece of durable medical equipment that is prescribed on a temporary or a permanent basis. The back of the wheelchair fully reclines, and the legrests elevate to allow for effective pressure relief while the client is out of bed. Other features of the wheelchair are desk armrests, which may be adjustable in height; a removable headrest; and removable legrests. The wheelchair folds and may be transported in a vehicle.

A

B

Figure 16-38 ■ **A**, Pressure relief: side lean. The tetraplegic patient with C6- to C7-level injury may use a side lean to achieve pressure relief over the ischial tuberosities. The patient hooks one upper extremity around the push handle of the wheelchair on one side and leans away from the hooked upper extremity until the ischium on the hooked side is clear of the wheelchair cushion. The position is maintained for 1 minute and repeated on the other side. **B**, Pressure relief: forward lean. The forward lean method of pressure relief is used for many different injury levels. The subject must have adequate range of motion at the hips and in the lumbosacral spine to allow the ischia to clear the wheelchair cushion at the end range position.

for wheelchair transfers usually begin on level surfaces and progress to uneven surfaces as individual strength and skill allow.^{7,62} Given these two principles, the following list is an example of how one might proceed with transfer training:

1. Mat transfer (see [Figure 16-40](#))
2. Bed transfer

Figure 16-39 ■ Pressure relief: depression. This method of pressure relief is consistent with a full pushup in the wheelchair. Most patients with a paraplegic level of injury and some patients with a low tetraplegic injury level are able to perform this method of pressure relief.

3. Toilet transfer
4. Bath transfer
5. Car transfer (see [Figure 16-31](#))
6. Floor transfer ([Figures 16-41 to 16-43](#))
7. Other surfaces (e.g., armchair, sofa, theater seat, pool)

Wheelchair Mobility Skills

Instructions in the safe and appropriate use of the wheelchair may begin before getting the client out of bed by orienting the client to the wheelchair and its component parts.

Ideally, a power reclining or tilt wheelchair is supplied for clients with C1 to C5 tetraplegia to promote maximal independence. The most common drive-system options available for these clients include, but is not limited to, chin drive, pneumatic systems (see [Figure 16-36](#)), and head control ([Figure 16-44](#)). A client with mid- to low-level tetraplegia may be instructed in the use of both power and manual upright wheelchairs. The client with paraplegia is instructed in the use of a manual upright wheelchair unless there are extenuating circumstances. For example, a power wheelchair is appropriate for a client who is 50 years old and has severe rheumatoid arthritis.

A newer wheelchair that combines the benefits of a manual wheelchair with a power wheelchair is the pushrim-assisted power assist wheelchair ([Figure 16-45](#)).¹²⁶ This wheelchair may be best suited for clients who have some upper-extremity weakness, joint degeneration, upper-extremity pain from propelling a manual wheelchair, or reduced exercise capacity or endurance. This type of wheelchair could potentially delay secondary injuries of manual wheelchair users.¹²⁷ Both power and manual wheelchair mobility training begins on level surfaces. When a client is instructed on how to propel a manual wheelchair, it is suggested that a semicircular pattern be used to reduce the trauma to the upper extremities.¹²⁷ Wheelchair gloves are beneficial in reducing friction over the palms of the hands during propulsion ([Figure 16-46](#)). Research evidence is available that demonstrates the safety and superior efficacy of a formal approach to wheelchair skills training of wheelchair users and their caregivers. The Wheelchair Skills Program (WSP) is one example of such a program and is available free on the Internet.¹²⁸ This program includes useful evaluation and training tools to help practitioners translate this research evidence into clinical practice.¹²⁹

Training progresses toward more difficult skills as follows:

1. Mobility on level surfaces in open areas
2. Setup for transfers
3. Mobility in tight spaces
4. Mobility in crowded areas
5. On and off elevators
6. Up and down ramps
7. Through doors
8. Wheelies ([Figure 16-47](#))
9. Negotiation of rough terrain
10. Up and down curbs and steps ([Figures 16-48 and 16-49](#))

Ambulation Considerations—Orthotic Disposition

“Will I ever walk again?” is a question often asked during SCI rehabilitation. The team must be empathetic toward and acknowledge the client’s goals for ambulation, and the subject should be discussed openly. The professionals involved in the care of the patient must be careful not to take hope away from the client. Hope is important to maintain positive survival skills in SCI rehabilitation.

When ambulation is an appropriate goal, the treatment program may be short and relatively uncomplicated for some and extremely laborious for others. Treatment techniques may include therapeutic exercise, biofeedback, neuromuscular stimulation, locomotor training (discussed later in this chapter), balance training, standing, and various other pre-gait and gait activities. The clinician must consider the postdischarge environment and include those surfaces in training.

The walking disposition of patients with incomplete SCI is challenging owing to the complexity of problems and varying degrees of impairment. These patients may have pain, ROM limitations, ventilator pump dysfunction, weakness, and spasticity, as well as sensory and balance dysfunction. In addition, their pre-morbid physical condition must be considered. Musculoskeletal asymmetries, such as muscle shortening on the stronger side and lengthening on the weaker side, may lead to pelvic obliquity and scoliosis. A team approach to orthotic prescription is desirable to meet the needs of patients with incomplete SCI. Even if

Figure 16-40 ■ Wheelchair to mat transfer using a transfer board. **A**, The patient positions the wheelchair at a 20- to 30-degree angle to the surface to which he is transferring and positions the board with or without assistance. **B**, The patient moves forward in the wheelchair to clear the tire in preparation for lateral movement on the transfer board. **C**, To achieve the appropriate mechanical leverage, the patient is instructed to twist the upper body and look over the trailing shoulder (**D**). He pushes and lifts to effect movement across the board. **E**, When the client has achieved a safe position on the transferring surface, the transfer board is removed. **F** and **G**, The patient is helped to get his feet onto the surface.

Figure 16-41 ■ Floor transfer. The independent performance of a floor transfer is a goal for most patients who have a paraplegic level of injury. The patient may use different techniques to get onto the floor. Forward floor transfer: **A**, The patient positions his feet off the footrest and moves forward onto the front edge of his cushion. **B**, He reaches for the floor, first with one hand then with both, and

Figure 16-41, cont'd C, lowers his knees to the floor. D, He advances his hands forward until his body is clear of the wheelchair.

Figure 16-42 ■ Floor transfer sideways. After moving to the front of the wheelchair seat, (A) the patient leans to the left and reaches for the floor and (B) shifts his weight toward the left arm. C and D, He balances his weight between both arms and in a very controlled manner lowers his body to the floor.

Figure 16-43 ■ Forward lowering floor transfer. **A**, This transfer method begins from a balanced position on the front edge of the wheelchair seat with feet on the floor. **B**, Hips are lifted off the seat forward enough to (**C**) lower the buttocks to the footrest. Note that this requires significant strength and control through the upper body as well as (**D**) excellent range of motion in shoulder extension and a reasonably loose anterior shoulder capsule. **E**, Legs are moved forward for balance. Also, a small pillow or cushion (not shown here) can be used to pad the footrest to protect the patient's skin.

orthotic devices enable these patients to become independent with standing or walking, the energy costs, joint deterioration, and muscle stresses over the life expectancy of each individual need to be considered. Orthotic prescription should be approached systematically. The patient's goals, funding, premorbid and current health status, social support, and the environment to which they are returning should be considered. A basic clinical algorithm for the selection of orthoses for persons with neurological impairment has been proposed by researchers at Rancho Los Amigos Medical Center. This algorithm is referred to as the Rancho ROADMAP (Recommendations for Orthotic Assessment, Decision-Making, and Prescription).¹³⁰ Successful brace prescription uses the minimum amount of

bracing to achieve the maximum amount of function. It also anticipates changes in each patient's clinical picture. For example, braces may be manufactured with joints built into the plastic, or joints that begin as fixed, and are later cut to allow articulation. Some models of knee-ankle-foot orthoses (KAFOs) can be altered to become ankle-foot orthoses (AFOs).¹³¹

The philosophy regarding the use of orthoses for ambulation for individuals with complete paraplegia varies greatly among rehabilitation centers. Some facilities encourage ambulation for these individuals, whereas others strongly discourage it, given that only a small percentage of these clients continue to use orthotics after training has been completed.^{132,133}

Figure 16-44 ■ Head array is a headrest and head control for driving wherein the position of the head activates the drive control of the wheelchair. It is appropriate for persons with high cervical injuries. The head array switches can be adjusted to the individual's specific needs relative to their active range of motion and control of their head. The switches are embedded in the headrest panels and not only control driving but can also control activation of other devices for environmental control. The side panels of the headrest can be straight or curved depending on the needs of the patient. Additionally, the head array can be sized for either adult or pediatric patient.

Figure 16-45 ■ Power assist system. The Xtender by Sunrise Medical is one of three power assist systems available. The motors are in the wheels. The battery extends off the back of the wheelchair. There is a connection between the motors in the wheels. The system is added to a manual wheelchair. There are two power assist levels.

Figure 16-46 ■ Para Push gloves. Wheelchair gloves, mesh back, open fingers, and leather-padded palm. Usually appropriate for patients with paraplegia-level injuries. Available from multiple suppliers.

Figure 16-47 ■ A wheelie is a functional mobility skill that enhances functional independence. The performance of a wheelie is a precursor to negotiating steep ramps, curbs, steps, and rough terrain.

Figure 16-48 ■ **A**, Descending a curb is an advanced wheelchair mobility skill. This man with AIS A, T12 paraplegia assumes the balanced wheelie position and approaches the curb in a forward position. The wheelie position is maintained as he rolls off the curb. **B**, Climbing a curb with assistance is also an advanced skill. This is the same man as in **A**. He “pops” into a wheelie and advances his wheelchair to move his casters up onto the curb. He then reaches back to his wheel, leans forward, and pushes as the helper assists by lifting the back of the chair. A more advanced skill would be to perform this activity by approaching the curb with speeds fast enough to gain momentum, “pop” a wheelie, and advance up and over the curb in one continuous movement (not shown). The curb height, strength, level of injury, and body composition of the patient are determining factors for speed requirements.

Figure 16-49 ■ Descending steps using one handrail. This patient with AIS A, level T12 approaches the steps backward, using the handrail on his right with both hands, and lowers himself down three steps. This is one of several methods that may be used to negotiate steps.

When the philosophy of the rehabilitation center is to use orthoses for clients who do not have functional motor control below their level of injury, criteria should be established so that both the client and the professional staff are consistent in their approach to ambulation. This gives the client specific information and clarifies goals to be attained, ensuring the most positive outcome (**Box 16-3**).

The ambulation trial gives the client and the team an opportunity to simulate orthotic use. If the decision is made to order orthoses, specific goals should be set. Goals range from standing and exercise ambulation to community ambulation. Most persons with complete injuries above the L2 level achieve only exercise ambulation because of the energy necessary for functional ambulation.

Research has demonstrated that the energy cost of ambulation for individuals with complete lesions at T12 or higher is above the anaerobic threshold and cannot be maintained over time. This study also concluded that ambulation for these individuals using a swing-through gait pattern is equivalent to “heavy work” or a variety of recreational and

BOX 16-3 ■ CRITERIA FOR AMBULATION TRIAL FOR COMPLETE INJURIES

Expressed desire for ambulation with appropriate goals
 Body weight not to exceed 10% of ideal
 Range of motion: Hip extension 5 degrees, full knee extension, ankle dorsiflexion 5 to 15 degrees, passive straight leg raise 110 degrees
 Intact skin
 Stable cardiovascular system
 Controlled spasticity
 Independent function at the wheelchair level

sporting activities.¹³²⁻¹³⁶ Consequently, it is easy to understand why lower-extremity orthoses may end up in the closet unused.

The energy cost for ambulation is highest for persons with complete paraplegia who use a swing-through gait pattern and lowest for persons who use bilateral AFOs or a combination of an AFO and a KAFO. Even individuals requiring only bilateral AFOs have a gait efficiency of less than 50% of normal, underscoring the importance of the hip extensor and abductor muscles required for normal ambulation. These muscles are severely or completely paralyzed in this population.^{134,135}

Assuming that a patient has upper extremities with intact function, the energy cost of ambulation is progressively reduced when more residual motor function is present in the lower extremities. Conversely, the person with incomplete tetraplegia has higher energy costs for ambulation despite spared lower-extremity function because of upper- and lower-extremity weakness (Boxes 16-4 and 16-5 and Figures 16-50 to 16-54).¹³²⁻¹³⁶

Factors that affect orthotic selection are cost, injury level, residual motor function, experience bias of the clinician, patient's medical status, skin and cardiovascular integrity, and patient's acceptance. Generally, the hip, knee, ankle, and foot orthosis (HKAFO) is used when selected motions of the hip need control or the benefits of the reciprocating gait orthosis (RGO) are desired, as is the case with the pediatric population. The use of a KAFO is indicated when the quadriceps muscle strength is less than 3/5. AFOs are indicated in the presence of ankle instability and weakness and to control hyperextension of the knee joint.¹³⁴⁻¹³⁷

Materials and components of bracing continue to evolve. Carbon fiber is becoming more common in bracing, including in low-profile AFOs, either customized or off the shelf.

BOX 16-4 ■ FOUR CATEGORIES OF AMBULATION¹³¹

1. Standing only
2. Exercise—ambulates short distances
3. Household—ambulates inside home or work, uses wheelchair much of the time
4. Community-independent on all surfaces; does not use wheelchair

BOX 16-5 ■ LOWER-EXTREMITY ORTHOSES¹³⁷**HIP-KNEE-ANKLE-FOOT ORTHOSES**

Reciprocating gait orthosis (RGO) (see Figure 16-50)

University of California Biomechanics Lab (UCBL) orthotic (see Figure 16-54)

Figure 16-50 ■ The reciprocating gait orthosis (RGO), although generally used with children, is also used with adults. Its main components are a molded pelvic band, thoracic extensions, bilateral hip and knee joints, and lower limb segments that may be of polypropylene construction with a solid ankle. The RGO uses a dual cable system to couple flexion of one hip with extension of the other.

Figure 16-51 ■ Scott-Craig knee-ankle-foot orthosis (KAFO) is a special design for spinal cord injury. The orthosis consists of double uprights, offset knee joints with pawl locks and bail control, one posterior thigh band, a hinged anterior tibial band, an ankle joint with anterior and posterior adjustable pin stops, a cushion heel, and specially designed longitudinal and transverse foot plates made of steel.

There is a trade-off with carbon fiber, however. The benefits of using carbon fiber are that it is lightweight and rigid. However, it is not easily modified after it is manufactured (Figure 16-55, A).

Components have advanced quickly in the last 10 years. A recently introduced new joint, Sensor Walk, allows persons with no quadriceps function to stand with control from the joint and then swing the limb freely. Multiple sensors in the footplate of this KAFO signal to the knee joint the position and weight-bearing status of the leg. The joint does not require full knee extension for position of the knee to be maintained, an advantage over other types of stance-control mechanisms. If the patient has gluteal function, this device also allows the individual to ascend and descend stairs using a step-over-step gait pattern (Sensor Walk Electronic KAFO).¹³⁸ Other, similar joints in the category of stance-control knee joints are now available from several different manufacturers and include the E-MAG and Horton knee joints. These devices use a knee locking mechanism that is either mechanically or electronically controlled and is triggered by heel contact. During stance the knee is locked and with unweighting the limb is allowed to swing through in a normal reciprocal pattern. The advantages of this technology are obvious from a functional perspective. However, the experience of orthotists and clinicians are that these devices are costly and insurance companies are hesitant to cover the additional expense.¹³⁹⁻¹⁴¹

A new system for ambulation that has undergone clinical trials in the United States is the ReWalk system. This exoskeleton uses motion sensors, onboard computers, and robotics to assist persons with paraplegia in walking and ascending

Figure 16-52 ■ **A**, Polypropylene knee-ankle-foot orthosis (KAFO) and combination plastic and metal KAFO. **B**, Stance-control KAFO knee joint. This joint combines the stability of a locked knee during the stance phase of walking but allows flexion of the limb for the swing phase of gait. A locked knee makes it much harder to clear the leg over the ground. Some long leg brace users are perfect candidates for the stance-control KAFOs. These devices, through a few different types of joint mechanisms, create a locked knee when the leg is supporting the weight of the body but unlock when the leg is lifted to allow for easy advancement of the leg as it is allowed to bend. For the right patients, this allows them as much mobility to get around as it does stability.

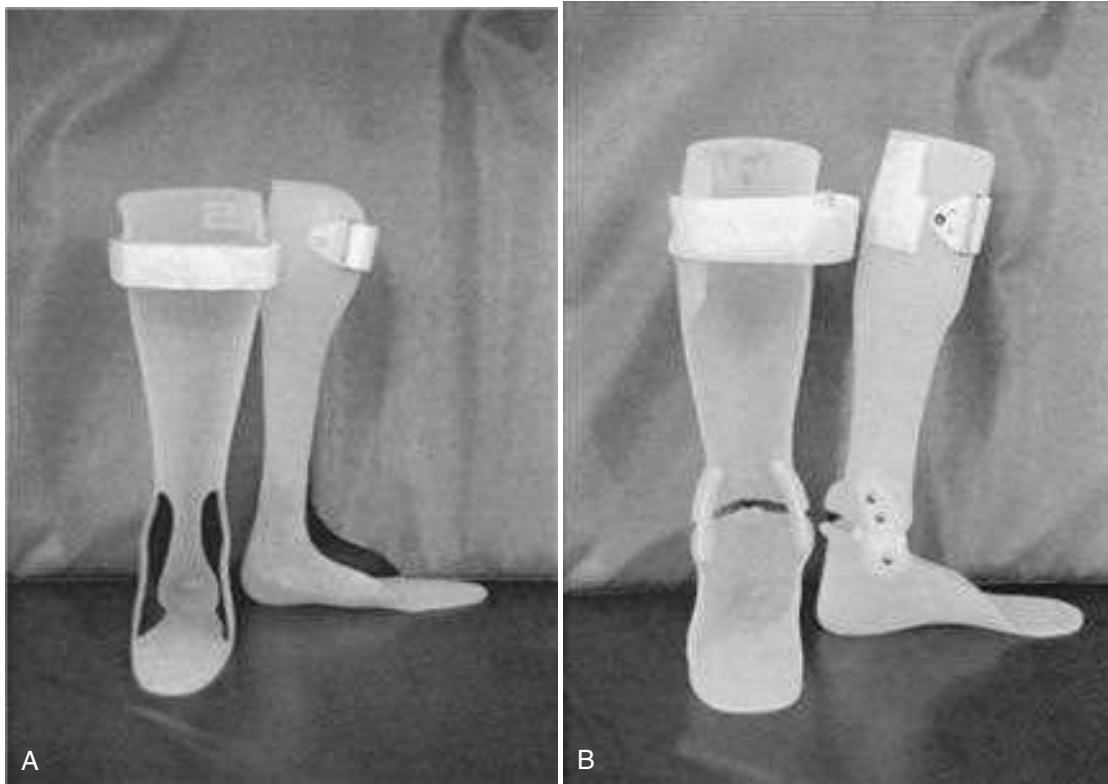

Figure 16-53 ■ **A**, Custom-made solid ankle-foot orthoses (AFOs) in 5 degrees of dorsiflexion with full footplates. **B**, Custom-articulated AFOs with adjustable Oklahoma ankle joints.

Figure 16-54 ■ University of California Biomechanics Laboratory (UCBL) orthosis. This orthosis is designed with a deep heel cup that holds the calcaneus securely. In addition, the high medial and lateral trimlines support the joints of the midfoot and allow more optimal subtalar joint function. The orthosis also supports the longitudinal arch of the foot. (From Lusardi MM, Nielsen CC: *Orthotics and prosthetics in rehabilitation*, Woburn, MA, 2000, Butterworth Heinemann.)

and descending curbs, ramps, and stairs. Individuals wearing this exoskeleton have reportedly been able to come from sitting to standing, to ambulate using forearm crutches, to walk community distances, as well as negotiating environmental obstacles. Clinical trials have been performed at MossRehab in Philadelphia as well as internationally. The parent company, Argo Medical Technologies, began full production and distribution in early 2011 (Figure 16-55, B). Other companies are now in the developmental stages and performing clinical trials with similar exoskeletal devices in preparation for Food and Drug Administration (FDA) approval. Among these are Ekso Bionics, Berkeley, California, and Vanderbilt University research department, Nashville, Tennessee.

Ideally, each patient's neurological recovery potential is maximized before or while brace prescription takes place. Advances in rehabilitation strategies that facilitate neural plasticity and recovery of function (i.e., walking) include the use of body-weight support during locomotor training. This technique of training may employ aquatics, a robot to assist with movement of the extremities, or manual facilitation of stepping performed by physical therapists and their rehabilitation teams using a body-weight suspension system. The principles of locomotor training are discussed later in this chapter.

Equipment

In SCI rehabilitation, the use of equipment is necessary to achieve the expected outcomes. Clinicians work closely with the physician and other team members, including the rehabilitation technology supplier, to determine the most

Figure 16-55 ■ A, Allard braces. The Allard family of ankle-foot orthoses (AFOs) include a prefabricated shell that can be customized by the trained orthotist to the specific needs of the patients. These dynamic orthoses are constructed of carbon composites, which accounts for their strength as well as their light weight. There are three different AFOs in the series: Ypsilon, ToeOFF, and BlueRocker. The AFOs are intended to be used with a custom foot orthotic. **B**, ReWalk is a wearable, motorized, quasi-robotic suit. Partially concealable under clothing, ReWalk provides user-initiated mobility-leveraging advanced motion sensors, sophisticated robotic control algorithms, on-board computers, real-time software, actuation motors, tailored rechargeable batteries, and composite materials.

appropriate equipment to meet individual needs. It is important to have access to trial equipment so the client has the opportunity to practice with equipment similar to what will be prescribed. Ideally the rehabilitation technology supplier should be accessible to the rehabilitation team to allow for necessary adjustments to the equipment. In addition, rehabilitation technology suppliers should be knowledgeable and responsible for educating rehabilitation professionals regarding new products. When possible, all equipment should be ordered from a single supplier to reduce confusion when the need for repairs arises. To ensure that the most appropriate piece of equipment is prescribed, the following must be considered: durability, function, transportability, comfort, cost, safety, cosmesis, and acceptance by the user.⁶² Generally, the higher the injury level, the more costly the equipment owing to the technology involved. [Table 16-7](#) lists equipment according to injury level.

Ideally, equipment should be ordered as soon as possible so the client can be fitted before discharge. Shorter lengths of stay make early equipment ordering difficult. For example, a client may not have 3/5 wrist extension to be fitted with a tenodesis brace but with strengthening over time would be an excellent candidate. Clinicians need to negotiate with the funding source so that equipment may be ordered in the outpatient setting. Equipment required for the SCI population is costly, requiring extensive review by third-party payers before funding is approved or denied. Many health care policies do not cover the funding of needed equipment. As a result of these factors, many clients are discharged without the equipment they need. Lack of appropriate equipment may result in (1) a feeling of loss of control, (2) contractures and postural deformities, (3) skin breakdown, (4) a loss of skills learned in rehabilitation, (5) poor self-image, and (6) increased dependence on others.

Seating Principles

Many individuals spend 8 hours or more per day in their wheelchairs after an SCI. Consequently, proper seating of these clients may be the most important intervention clinicians provide. The seating process should be addressed on admission, continually throughout the rehabilitation program, and regularly after discharge to help prevent and minimize complications.^{77,142} The wheelchair is an integral part of the client's self-image and in many ways will help define personal lifestyle.⁶² Goals for seating the client with an SCI are identified in [Box 16-6](#).

Every seating session begins with a thorough examination, as described earlier. Trial simulations are essential to determine how the patient will function and maintain posture over time in the seating system. Simulations help to avoid costly mistakes. The patient must be involved in the decision-making process to ensure that the seating system will work.

Individuals with SCI are at high risk of pressure ulcers owing to lack of mobility and impaired sensation. Great care must be taken to reduce pressure over bony prominences and to distribute pressure over as large an area as possible.¹⁴³ Pressure-distributing cushions should be evaluated clinically and with pressure-sensing devices to determine the optimal wheelchair cushion for each individual.^{142,144} Many patients with muscle paralysis of the trunk find that the effects of gravity in a sitting position pull the head and upper torso forward and over the pelvis, resulting in a long kyphosis or a C-curved posture ([Figure 16-56](#)).¹⁴⁴ Two resulting problems are increased weight bearing on the sacrum and development of a thoracic kyphosis, leading to neck hyperextension in an effort to maintain a horizontal gaze.¹⁴² This position is also assumed by patients to improve their balance. This occurs when the seat-to-back angle is closed and the client feels as if he or she is falling forward. Unfortunately, this poor seating posture is

TABLE 16-7 ■ EQUIPMENT NEEDS CORRELATED TO INJURY LEVEL

INJURY LEVEL	EQUIPMENT	COST (IN DOLLARS)	INJURY LEVEL	EQUIPMENT	COST (IN DOLLARS)	
C1 to C3	Ventilator (bedside)	14,700	C7 to C8	Wheelchair cushion	450-600	
	Ventilator (portable for wheelchair)	14,700		Bedside table	225

quickly learned and difficult to correct.¹⁴² This posture can often be prevented by tilting the wheelchair slightly backward while maintaining a fixed seat-to-back angle (Figure 16-57).¹⁴² In this position, the effects of gravity augment sitting balance and facilitate good spinal alignment. Education regarding proper positioning, the use of a sacral block, a firm wheelchair seat and back, and properly applied pelvic positioning devices also aid in preventing the kyphotic posture.¹⁴²

Asymmetrical muscle strength, asymmetrical spasticity, and preferential use of one upper extremity over another often result in poor trunk alignment. The use of lateral trunk supports, lateral pelvic supports, and properly applied seat belts may aid in maintaining symmetrical trunk posture.

Strong muscle spasms, combined with the effects of gravity, may cause the person with severely impaired mobility to slide down in the wheelchair, resulting in increased

pressure on the sacrum and shearing of the skin. For these patients, a manual wheelchair with adjustable seat and back angles can be used to improve stability. Power wheelchairs with power tilt systems allow users to reposition themselves and use the power tilt for improved stability.

Optimal pressure distribution is achieved by maximizing the surface area, allowing immersion into the seat cushion, and promoting a symmetrical posture. The width of the seat should be slightly more than that of the widest body part. The seat depth should come to approximately within 1 to 2 inches of the popliteal fossae, except when it interferes with lower extremity (LE) management. The height of the back should reflect the client's motor function and seated stability. If the back is too high, it can restrict functional activities such as wheelchair propulsion and wheelies. Patients with tetraplegia who use the push handles of the wheelchair to hook while

BOX 16-6 ■ GOALS FOR SEATING THE CLIENT WITH SPINAL CORD INJURY

1. Maximize functional independence
2. Improve pressure distribution and relief of pressure
3. Optimize comfort
4. Enhance the quality of life
5. Optimize good postural alignment and sitting balance
6. Compensate for fixed deformities
7. Allow for transportation of the mobility system

The following are basic seating concepts of proper postural alignment:

- Neutral pelvic alignment
- Symmetrical alignment of the trunk and neck
- Neutral head positioning over the pelvis
- Maintenance of a horizontal gaze
- Maintenance of ankle in neutral alignment with full support of the foot
- Maintenance of the thighs in neutral abduction and adduction with full contact with the cushion
- Neutral shoulder positioning to avoid shoulder elevation, protraction, or retraction and to provide adequate upper-extremity support^{142,144}
- Elbow angle that approximates 100 to 120 degrees when the hand is resting at the top of the wheel or pushrim¹²⁶

Figure 16-57 ■ Example of corrected C-curve posture.

Figure 16-56 ■ Example of typical kyphotic C-curve posture in the patient with tetraplegia.

performing functional activities may require custom modification of the wheelchair back (Figure 16-58).

The size, weight, and portability of the wheelchair seating system affect the individual's lifestyle. The client's home or work environment must be evaluated closely for accessibility so that the wheelchair seating system can be used effectively in those environments. The buildings must be structurally sound and spacious to accommodate heavy-power wheelchair systems. The means of transportation of the wheelchair (car versus van) may determine whether a rigid or folding wheelchair frame is indicated. Transit options and tie-down systems must be considered for safe transportation. The wheelchair must be adjusted to make it as efficient as possible to propel to reduce stress on upper-extremity joints. Many manual wheelchairs are lightweight (less than 35 pounds) and have multiple adjustments and choices of tires and casters that make manual wheelchair propulsion more efficient. Reducing rolling resistance, positioning the rear axle for maximum propulsion stroke efficiency, and teaching efficient propulsion techniques reduce shoulder musculature fatigue and upper-extremity injury. Rear wheel size should be selected so that when the wheelchair user is seated, he or she is able to touch the rear axle with the middle finger. This position increases the range of contact during propulsion. In addition, shifting the distribution of the user's weight back over the rear axle (usually accomplished by moving the rear wheel axle forward) reduces the percentage of weight on the front casters, making propulsion more efficient.¹⁴⁵ This adjustment reduces the rear stability of the wheelchair, so the use of

Figure 16-58 ■ Example of custom modification of a wheelchair back to allow a patient with tetraplegia to hook the push handle with one upper extremity.

anti-tip bars and/or training in wheelie maneuvers is essential. Finally, along with wheelchair fit, the esthetics of the wheelchair can affect the individual's self-image and therefore the community reentry. This should be considered when assisting the patient to make wheelchair seating decisions.

Education

Education of the client and caregivers is an integral part of the rehabilitation process. Formal education includes group and individual instruction and family and caregiver training. Clients and caregivers are taught preventive skin care, bowel and bladder programs, safe ways to perform all ADL tasks, nutritional guidelines, thermoregulation precautions, pulmonary management, cardiopulmonary resuscitation, management of autonomic dysreflexia, equipment management and maintenance, transfer techniques, wheelchair mobility, ambulation, proper body positioning, ROM exercises, ADL basics, and leisure skills. Home programs are taught to maintain or increase strength, endurance, ROM, and function. Energy conservation techniques and proper body mechanics are incorporated into all aspects of training.

Clients are formally tested on their knowledge, and remedial instruction should be provided in deficient areas. During family training, caregivers are formally evaluated on their abilities to safely provide care to the client. Supervised therapeutic outings and passes allow the client, caregivers,

and the team to identify problem areas and provide additional education in those areas.

Psychosocial Issues

The immediate reaction to the onset of SCI is physical shock accompanied by anxiety, pain, and fear of dying. The response to such an injury varies greatly and depends on the extent of the injury, the premorbid activity level, the style of coping with stress, and family and financial resources. There may be great sensory deprivation from immobilization, neurological impairment, and the monotony of the hospital routine. Several psychological theories have been proposed to describe responses and coping mechanisms.⁶⁵ The process of coping with these changes is referred to as *adjustment* (see Chapter 6)

Rehabilitation personnel are becoming more aware of the need not only to teach functional skills but also to teach psychosocial and coping skills to the client and significant others. Education in the following areas facilitates the adjustment process: creative recreation, financial planning, negotiating community barriers, social skills, managing an attendant, creative problem solving, accessing community resources, fertility and child care options, assertiveness, sexual expression, vocational planning and training, and the use of community transportation. These skills may be introduced in the inpatient rehabilitation setting but will be developed further in the home and community environments. True adjustment and adaptation begin after discharge from rehabilitation.^{146,147}

Sexual Issues

Sexuality is how people experience and express themselves as sexual beings and is a normal part of being human,¹⁴⁸ so it is not surprising that persons with SCI place a high priority on resuming sexual functions after their injury.¹⁴⁹ After SCI, men may experience impairments in penile erection, ejaculation, orgasm, and fertility. Women with SCI may experience impairments in the ability to become aroused or achieve orgasm and/or may have decreased vaginal lubrication.¹⁵⁰ Improving sexual functions is a high priority for both men and women after SCI.¹⁴⁹ Table 16-8 lists the relationship of the level of spinal injury to sexual function. Treatment of sexual dysfunction should be a coordinated effort among the patient, significant other, and appropriate health care professionals. Sexual counseling, educational programs, and medical management provide opportunities to address the areas of sexual dysfunction, alternative behaviors, precautions, and other related areas.¹⁵⁰

Depending on the level and completeness of the SCI, most men can attain an erection either through psychogenic (via T11 to L2 pathways) or reflexogenic pathways (S2 to S4)¹⁵¹; however, these erections are often not reliable or adequate for sexual intercourse. The first-line treatment for erectile dysfunction after SCI is the use of phosphodiesterase type V inhibitors such as sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra). Other treatments include intracavernosal (penile injectable) medications, mechanical methods such as vacuum devices and penile rings, and, as a last resort, surgical penile implants.¹⁴⁸

Male orgasm and ejaculation are likely to occur together; however, after SCI an orgasm may not always lead to ejaculation, or there may be retrograde ejaculation into the bladder.¹⁵² A study by Sipski and colleagues showed that 78.9%

TABLE 16-8 ■ RELATION OF LEVEL OF SPINAL INJURY TO SEXUAL FUNCTION

INJURY LEVEL	SEXUAL FUNCTION
Cauda equina/conus	Males Usually no reflex erections Rare psychogenic erection Ejaculation occasionally occurs
	Females Vaginal secretions often absent Patients generally fertile
Thoracic/cervical	Males Reflex erections predominate (usually short duration) Psychogenic erections generally absent Ejaculation occasional
	Females Vaginal secretions present as part of genital reflex Fertility preserved Sensation of labor pain absent

of men with incomplete upper motor neuron SCI achieved orgasm as compared with 28% of men with complete upper motor neuron injuries ($P < .001$), whereas 0% of men with lower motor neuron injuries affecting their sacral cord achieved orgasm.¹⁵²

“Will I ever be able to become a father?” is a common question of men after SCI. Pregnancy rates in partners of men with SCI are lower than in the general population, but there is a good chance (greater than 50%) that men with SCI can become biological fathers with advances in reproductive assisted technology. Roughly 2 weeks after an SCI, semen quality declines¹⁵³ to levels approaching those observed in males with chronic SCI.¹⁵⁴ There is evidence that bladder management with clean intermittent catheterization may improve semen quality over other methods of bladder management.¹⁵⁵ The two most common methods of sperm retrieval are vibrostimulation (less invasive) and electroejaculation. These methods are successful for persons with lesions above T10. If these methods are not successful, there is an option of surgical aspiration. Depending on the semen quality, a progression from intravaginal insemination, intrauterine insemination, in vitro fertilization (IVF), to IVF plus intracytoplasmic sperm injection is recommended.¹⁴⁸

Women with SCI may have impairment in arousal and orgasm. The vagus nerves are thought to facilitate the presence of vaginal-cervical perception of orgasm. Preservation of T11 to L2 sensory dermatomes is associated with psychogenically mediated genital vasocongestion and lubrication.¹⁵⁶ There is some evidence that supports the use of sildenafil in women to partially reverse subjective sexual arousal difficulties.¹⁴⁸ For women who have a lower motor neuron lesion, vaginal secretions are often absent, and an artificial lubricant is recommended.

Amenorrhea may occur immediately after SCI and last up to 4 to 5 months. Despite this delay, it is believed that fertility in women is unaffected by SCI.¹⁵⁷ Women are able

to conceive; however, there are increased risks to pregnancy, which may include bladder problems, spasticity, pressure sores, autonomic dysreflexia, and problems with mobility.¹⁵⁸

Discharge Planning

Discharge planning begins from the time the client is being considered for admission and continues through the rehabilitation program. It is a continuous process that includes the client, family, treatment team, and community resources, with the goal being successful community reintegration and a perceived good quality of life. The rehabilitation team must identify the specific needs of the client and must structure the program to enhance the chance of success. Lengths of stay are getting shorter in response to pressure from third-party payers to contain costs. This requires the discharge planning process to be expedited so that procurement of needed equipment, completion of architectural modifications, and referrals to outpatient and community resources occur in a timely manner.

Architectural Modifications

Architectural barriers in the home, transportation system, workplace, or school may prevent access to opportunities. The architectural changes required by the person with SCI for independence in the home and community depend on the degree of impairment, financial resources, and client and family acceptance of modifications or equipment. The clinician should discuss equipment options with the client and family on the basis of the degree of modification they plan to make to their home. Thinking creatively about low-tech adaptations should be considered part of the therapist's role. Problem solving with and by the client is vital to the process of identifying alternatives as ideas for the future (Figure 16-59).

Many available resources describe the dimensions of the basic wheelchair and specifications for making homes and facilities accessible to wheelchair users. See Appendix 16-A at the end of this chapter for resources on architectural modification.

Return to Work or School

Successful community reintegration after SCI includes returning to preinjury social roles and, more specifically, returning to work, school, and/or leisure interests. Public school systems have a legal obligation to provide an appropriate school setting for a child with a disability. Rehabilitation teams may assist with school reentry by adding school visitations and education for faculty or peers. School accessibility can be assessed and the patient and therapists can have an opportunity to share appropriate information about the new impairments before reentry into the school system. Also, rehabilitation programs that are CARF accredited must offer academic programs. School reentry programs may enhance communication between academic rehabilitation faculty and school, bridging the gap for return. Students returning to college may need assistance developing problem-solving skills related to campus accessibility, Americans with Disabilities Act (ADA) rights, campus transportation options, and self-advocacy for sports adaptations.

Rehabilitation programs must also emphasize returning to work throughout the process. For patients who have

Figure 16-59 ■ Low-tech home adaptations. **A**, A strap is added to make a clothes dryer door accessible. **B**, A hole is drilled and a handle added to a screen door knob.

sustained a traumatic SCI and are included in SCI model systems data,¹³ 57.5% report being employed at the time of the accident. Only 11.6% are employed at the 1-year anniversary, but by year 20 35.4% are employed. At year 10 after injury, people with paraplegia (31.7%) have a slightly better employment outcome versus those with tetraplegia, of whom 26.4% are employed.⁴¹ Many individuals can return to their previous jobs after SCI.^{159,160} The Americans with Disabilities Act of 1990 (PL 101-336) prohibits businesses with 15 or more employees from discriminating against “qualified individuals with disabilities” with respect to the terms, conditions, or privileges of employment.¹⁶¹ Job site and job responsibilities may need to change to accommodate the new impairments, allowing the patient to fully participate. For those who are unable to perform previous jobs or who were unemployed before injury, many programs exist for training in vocational skills. The Department of Rehabilitation Services (DRS) evaluates clients for skills and functional abilities and provides funding for those qualifying for job training, job site modification, and the purchase of essential equipment that may include transportation. Services offered by the DRS vary from state to state. Each state agency has a list of resources available in the

community, such as rehabilitation technology, independent living centers, and job training and placement programs. Individuals should refer to their state DRS for assistance with employment.

Engaging in sports and other leisure skills can open doors for patients returning to the community. Participating in sports and leisure, whether learning a new skill or adapting something previously enjoyed, may boost physical capacity and enhance self-worth. Adapted sporting activities found in the United States include power soccer, quad rugby, wheelchair basketball, tennis, swimming, and snow skiing, to name a few. The Paralympics provide competitive venues for elite athletes, and many road races across the United States have opened the roads for wheelchair athletes to compete alongside able-bodied runners. A handful of colleges and universities have developed adapted sports teams and are beginning to offer student scholarships.

Health Promotion and Wellness

Individuals with spinal cord injuries are living longer owing to improvements in medical management, but this has also led to increased incidence of chronic diseases, such as cardiovascular disease (CVD) and diabetes mellitus, in this population.¹⁶²⁻¹⁶⁴ The Surgeon General’s Report on Physical Activity and Health identifies persons with disabilities as among the most inactive subgroup in the United States.¹⁶⁵ Cardiopulmonary disease has been identified as a primary source of morbidity for persons with aging spinal cord injuries,^{32,166} and nearly all cardiovascular risk factors are increased in individuals with SCI. Increased rates of diabetes, impaired glucose tolerance, metabolic syndrome, and obesity—all conditions that are exacerbated by physical inactivity—contribute to the development of CVD.¹⁶⁷ Muscle atrophy is common in people with complete and incomplete SCIs, with an associated increase in fat mass resulting from the imposed immobility caused by the neurological impairment. These are all key factors when considering the impact of resting energy expenditure (REE) on metabolism in people with SCIs¹⁶⁸ and in evaluating the risk of obesity in this population.

Key components of a health and wellness program for persons with SCI are exercise, prevention of secondary complications, injury prevention, good nutrition, and good psychological support. Physical activity after SCI has been shown to improve muscle strength, endurance, mobility, the ability to fall asleep, self-image, and blood lipid profiles and decrease the risk of premature death. In addition, exercise has been shown to decrease anxiety, loneliness, depression, stress, heart disease, blood pressure, respiratory illness, diabetes, obesity, and other medical complications.¹⁶⁹

Exercise programs for individuals with SCIs must take into consideration the musculoskeletal, respiratory, cardiovascular, and autonomic nervous system changes that occur after SCI. Components of an exercise program should include flexibility, muscular strength, and cardiovascular endurance, and an appropriate exercise prescription should address exercise mode, intensity, duration, and frequency. It is important to find a type of exercise that is enjoyable for each individual so that it can be easily integrated into his or her lifestyle. Required exercise intensity to improve cardiovascular fitness and reduce the risk of CVD is 50% to 80% of peak oxygen uptake.¹⁷⁰ American College of Sports

Medicine (ACSM) guidelines suggest that able-bodied individuals exercise 30 to 60 minutes most days of the week, and these guidelines are often extrapolated to the disabled population as well.¹⁷¹ However, they do not take into account that individuals with SCIs are also using their upper extremities to complete many of their ADLs and mobility tasks, so 30 minutes of exercise two or three times per week may be sufficient for them to maintain their fitness.¹⁷⁰ Circuit resistance training programs using alternating resistance maneuvers and high-speed, low-resistance arm exercise have been shown to be beneficial in improving muscle strength, endurance, and anaerobic power of middle-aged men with paraplegia while also significantly reducing their shoulder pain.¹⁷² Circuit resistance training has also been shown to increase peak oxygen consumption and cardiorespiratory endurance in patients with chronic paraplegia.^{173,174}

Exercise programs, both in the clinic and home, may incorporate specialized equipment. The types of equipment available for exercise testing or training in persons with SCI are well documented in the literature. Arm crank ergometers, wheelchair ergometers, wheelchair treadmills, lower-extremity cycling with FES, suspended ambulation protocols, and field test protocols are among the more widely used equipment in the clinic.^{175,176} Exercise equipment varies in expense, and each clinic must choose the method that best fits its treatment setting and budget. Home exercise programs may be established with equipment such as weights and cuff weights, elastic bands and tubing, and hand cycles.

Overuse syndromes are common among long-term wheelchair users. When any type of exercise program is established, factors that are specific to SCI should be considered.¹⁷² Long-term wheelchair use can lead to an increased incidence of carpal tunnel syndrome, elbow or shoulder tendonitis, early onset of osteoarthritis, and rotator cuff injuries. The motion and resistance of the upper-extremity muscles during wheelchair propulsion can lead to an overdevelopment of anterior shoulder muscles, scapular protraction, and posterior shoulder weakness. This musculature imbalance may lead to elevation and internal rotation of the humeral head that may cause pain as a result of impingement. Injuries can be prevented or slowed if clients perform a proper warmup with stretching and flexibility exercises, wear protective equipment (e.g., helmet and padded gloves), alternate modes of exercise, and get proper rest between exercise sessions.

Through an established health and wellness program, a person with SCI has the potential to increase quality of life, improve ADLs, decrease secondary complications, decrease depression, and decrease the number of related hospitalizations. It is a goal that integration to wellness programs for individuals with SCIs will become a standard in all facilities.

RESTORATION AND RECOVERY

Upper-Extremity Restoration

Improving hand and upper-extremity function plays a critical role in achieving independence with ADLs.^{177,178} Surgical restoration of hand grasp, lateral pinch, or elbow extension in a patient with tetraplegia can be an option

through tendon transfers.^{179,180} Typically, before individuals are considered for surgery, their neurological function has reached a plateau, they are psychologically stable, and they have functional goals.¹⁸⁰ Individuals seeking restorative surgery to the upper extremity undergo a preoperative evaluation using the International Classification for Surgery of the Hand in Tetraplegia (ICSHT).¹⁸¹ Before any surgical interventions, therapy may be recommended to ensure that the individual is a candidate for tendon transfer procedures.¹⁸⁰ Postoperative rehabilitation varies on the basis of specific procedures and may consist of 2 months or more, with strength improvements continuing for up to 1 year postoperatively.^{182,183} Tendon transfer procedures may be an option to improve upper-extremity function.¹⁸³

Activity-Based Therapy

The terms *activity-based restorative therapies*, *activity-based therapies*, and *activity-based rehabilitation* have been coined in the last 10 years to describe a new fundamental approach for treating deficits induced by neurological paralysis. The goal of this approach is to achieve activation of the neurological levels located both above and below the injury level using rehabilitation therapies in order to facilitate recovery after a debilitating neurological incident.¹⁸⁴ The theory behind the achievement of recovery from participation in intense therapy programs, often called *activity-based therapy programs*, involves plasticity of the nervous system. Dunlop defines *plasticity* as the ability of neurons to rearrange their anatomical and functional connectivity in response to environmental input, thereby achieving new or modified outputs.¹⁸⁵ Several lines of evidence suggest that the central nervous system is capable of synaptic plasticity and anatomical reorganization occurring at both cortical and subcortical levels, including the spinal cord, after SCI.¹⁸⁶⁻¹⁸⁸ Facilitating reorganization of the injured nervous system is the goal of these types of intensive therapy programs, and rehabilitative interventions are thought to affect plasticity in several ways, including behaviorally, physiologically, structurally or neuroanatomically, cellularly, and molecularly.¹⁸⁹

For clinicians, this “emerging paradigm shift” in the practice of SCI rehabilitation has recently been described as a transfer from therapy that focuses on teaching compensatory strategies such as learning to use the upper extremities for mobility when the lower extremities are impaired, toward intensive recovery programs specifically designed to improve locomotor abilities in people with incomplete spinal cord injuries.¹⁹⁰ Traditional therapy for the treatment of these types of injuries is designed to improve a client’s independence using techniques that promote the use of assistive devices to compensate for lost function, such as using a wheelchair for mobility. In contrast, intensive therapy programs for people with SCI focus on recovering the ability to use their trunk and limbs to stand and walk as they did before their injury along with promoting lifelong health and wellness in this population. Although not clearly defined, activity-based therapy often involves intensive practice and repetition of task-specific mobility training to promote recovery and facilitates revitalization of the central nervous system. (Refer to Chapter 4 for additional discussion.)

Specialized rehabilitation technology is often used in this type of therapy approach, including but not limited to

body-weight–supported treadmill (BWST) systems, robotic BWST systems, FES bikes, and LE FES systems designed to improve overground walking ability. (Refer to Chapters 9 and 38 for further discussion of rehabilitation technologies.)

Improving Walking Function

Research on locomotor training through the use of BWST systems first began with spinalized cats in the 1980s¹⁹¹⁻¹⁹⁵ and then progressed to human subjects with increasing popularity in the 1990s and 2000s (Figure 16-60, A).^{190,196-200} Much of the theory behind this rehabilitation approach is based on activating intrinsic connections of spinal cord circuitry to elicit the appropriate patterns of muscle activation for walking called *central pattern generators* (CPGs).²⁰¹ Research involving the cat model has provided the most conclusive and descriptive evidence for the presence and activity of CPGs,²⁰² including the ability to produce locomotor output in spinalized animals.²⁰³ However, the evidence in humans has been less conclusive and is mainly based on the presence of alternating flexor and extensor activity seen in fetuses in utero and the presence of “locomotor-type patterns” seen in patients with complete SCIs through tonic epidural stimulation.²⁰⁴

Although many locomotor training studies have demonstrated improved walking function in response to training in patients with incomplete SCIs, questions remain regarding

the efficacy of this type of training over more traditional gait training approaches. However, as interest in locomotor training interventions continued to grow, so did concern over the amount and intensity of labor required by therapists to complete this rehabilitation technique. The advent of robotic-assisted locomotor training devices offered a less burdensome alternative to facilitate walking in persons with incomplete SCIs while reducing therapist strain (Figure 16-60, B).^{198,205,206} Over the last several years various types of locomotor training approaches have been studied with regard to incomplete SCIs; however, many questions still remain regarding efficacy of specific intervention choices and timing for this population. In a randomized controlled trial, Dobkin and colleagues reported that after 12 weeks of equal administration of locomotor training using manual assistance and conventional overground gait training, no differences in walking abilities were reported in patients with incomplete SCIs with either intervention.¹⁹⁷ Field-Fote and co-workers¹⁹⁸ randomly assigned 27 patients with motor incomplete SCIs into one of four different stepping groups using body-weight support including treadmill training with manual assistance, treadmill training with electrical stimulation, overground training with stimulation, and treadmill training with robotic assistance. After 12 weeks of training, all subject groups demonstrated a significant effect of training on walking speed, but differences among the four groups

Figure 16-60 ■ **A**, Manual treadmill. Treadmill training with body-weight–supported and manual assistance is being completed on the TheraStride Innoventor, which combines a treadmill and support harness system with software that measures variables of gait training, including speed, weight supported, and amount of time walked. Two or three therapists are needed to provide assistance at the trunk and lower limbs to facilitate an appropriate gait pattern. **B**, Robotic treadmill. The Lokomat by Hocoma is a robotic-assisted treadmill that provides adjustable body-weight support and gives clinicians the ability to adjust gait-specific parameters when completing training with patients who have mobility deficits.

were not statistically significant.¹⁹⁸ Finally, two systematic reviews have also concluded that there is insufficient evidence at this time to conclude that any one locomotor training strategy is superior to any other to improve walking function in people with incomplete SCIs.^{207,208} However, Lam and colleagues did suggest that patients with chronic SCIs might benefit more from the combined approach of locomotor training with electrical stimulation.²⁰⁷

Upper-Extremity Neuroprosthetics

The first developments in upper-extremity FES began in the 1960s with use of a flexor hinge orthosis, much like a tenodesis brace.²¹⁰ Later developments focused on improving hand function, primarily palmar grasp and lateral pinch.²¹¹ The use of surface electrodes then led to the development of implantable FES systems. The NeuroControl Freehand System is an implanted medical device that uses electrical stimulation electrodes that are attached to muscles in the hands and forearms and a pacemaker-type stimulator that is surgically implanted in the chest. Signals come from the external controller to the electrodes and cause muscles to contract and the hand to open and close. The system was approved by the FDA in 1997, but marketing was stopped in 2001. The future of upper-extremity implantable neuroprosthetics is currently uncertain, with no systems having been made commercially available since the NeuroControl Freehand.

More recent development of upper-extremity neuroprosthetics has been focused around external neuroprosthetics with products such as the Bioness H200 (Handmaster) or the bionic glove by Hanger Orthopedic. The Bioness H200 system enables appropriately selected clients with midcervical injuries to flex and extend the thumb and fingers, allowing a useful pinch and grasp, by hitting a switch or a trigger (Figure 16-61). The bionic glove uses three channels to activate and flex the thumb and extend or flex the fingers by using wrist extensors or flexors to control the neuroprosthesis.²¹²

Lower-Extremity Neuroprosthetics

The first system for standing and stepping to gain FDA approval was the Parastep II system, developed by Sigmedics (Northfield, Illinois).²¹³ This type of system generally uses two to 12 channels of stimulation. The system in its simplest form uses one set of electrodes placed over the quadriceps muscle and another set over the sural, saphenous, or peroneal nerve. This system consists of a computer control box, lead wire, electrodes, and a cable connected to a walking device that houses the command switch(es) for step function. Other walking systems that use implanted electrodes are being investigated at this time, but none are FDA approved. Both FES systems, the surface electrode system and the implanted system, in their present state show promise for the future. However, these systems currently do not present a viable alternative to wheelchair use because of the high energy requirement.^{214,215} In addition, there is limited research in the use of epidural spinal cord stimulation to facilitate ambulation.^{143,216}

Hybrid FES orthosis systems are orthotic systems that incorporate FES. Usually the FES is a simple configuration of approximately four channels and uses surface stimulation. One such system, used with the RGO, was developed by Douglass and colleagues at Louisiana State University Medical School. Systems such as this offer the advantage of increased energy efficiency compared with the use of only orthoses or only FES. Conversely, the bulkiness of the systems impedes the completion of some ADLs, and donning and doffing is more difficult.^{80,217,218}

FES devices have also been designed to address foot drop dysfunction to improve overground locomotion in patients with incomplete SCIs. Promising results have been demonstrated in all outcome measures of walking, such as functional mobility, speed, spatiotemporal parameters, and the physiological cost of walking.²¹⁹⁻²²¹ Improvements in walking function could be associated with plasticity in central nervous system organization, as seen by the modification of the stretch reflex and modifications

Figure 16-61 ■ The Bioness H200 system enables appropriately selected patients with midcervical injuries to flex (A) and extend (B) the thumb and fingers, allowing a useful pinch and grasp, by hitting a switch or a trigger.

in the corticospinal activation of lower leg muscles.²²² Commercially available products designed to improve overground walking in people with neurological injuries with foot drop include the Bioness L300 (Figure 16-62) and the WalkAide by Innovative Neurotronics (Figure 16-63). Both devices are single-channel foot drop stimulators that synchronize the electrical impulses to the dorsiflexors with gait. Overcoming many of the technical shortcomings of conventional FES units, these units have increased compliance and community use of this technology. Several studies have reported the immediate effects and short-term gains; however, long-term benefit of foot drop stimulation for people with SCI is yet to be sufficiently established in the literature.^{219-221,223}

Functional Electrical Stimulation Cycling

FES cycling has gained acceptance in recent years in treatment of patients with spinal cord injuries. Many authors have reported significant health and wellness benefits that are both physiological and psychological when treating patients with SCIs with this technology.²⁰⁹ During this intervention, electrodes are applied to various muscle groups of the lower extremities including the quadriceps, hamstrings, gluteal muscles, tibialis anterior, and gastrocnemius and soleus. The bike then electrically stimulates the selected muscle groups at the appropriate intervals to produce the torque that turns the ergometer at a preset speed. The FES-driven workload can be supplemented by an internal motor within the ergometer. Currently there are three commercially available products, including the RT300 by Restorative Therapies (Figure 16-64), ERGYS 2 by Therapeutic

Figure 16-62 ■ Bioness L300 system is a neuroprosthetic device that contains an orthotic cuff and electrodes. It fits just below the knee to supply functional electrical stimulation (FES) to the lower leg, stimulating the appropriate muscles and causing dorsiflexion. A gait sensor is placed in the client's shoe, and as he or she shifts weight off of the affected limb, FES is triggered to assist with foot drop.

Figure 16-63 ■ The WalkAide System is a neuroprosthetic device that contains an orthotic cuff and electrodes. It fits just below the knee to supply functional electrical stimulation (FES) to the lower leg, stimulating the appropriate muscles and causing dorsiflexion. It is activated by a tilt sensor mechanism and relies on the angle of the tibia for appropriate timing of the FES to assist with foot drop.

Figure 16-64 ■ RT300-SL leg FES system is a portable functional electrical stimulation (FES) bike that can be easily accessed from the patient's wheelchair. Adhesive electrodes can be applied to a variety of lower-extremity muscles including the quadriceps, hamstrings, gluteals, tibialis anterior, and gastrocnemius. These muscles are stimulated at the appropriate time to facilitate a cycling motion using a lower-extremity ergometer. FES bike software has the capability to store patient-specific parameters between sessions and patients.

Alliances, and the RehaMove by Hasomed. The following benefits from FES cycling have been reported in patients with spinal cord injuries: improved cardiorespiratory fitness, increased leg circulation, increased metabolic enzymes or hormones, greater muscle volume and fiber size, enhanced functional exercise capacity, decreased spasticity, decreased blood glucose and insulin levels, and improved bone mineral density.^{209,224-230}

Newer technology also may include upper-extremity FES (Figure 16-65) cycling in which the electrodes may be applied to various muscle groups of the arm and scapula. The most commonly used muscle groups are the anterior deltoids, biceps, and triceps. Use caution in the presence of unresolved glenohumeral subluxation. There has been less research directly looking at the benefits of the upper-extremity FES cycle systems, but clinicians in the field suggest that it may yield many of the same benefits as lower-extremity FES cycling.

Whole Body Vibration

Whole body vibration (WBV) training has become increasingly accessible and popular for training individuals with and without disabilities in recent years. Vibration is used as a mechanical stimulus to increase motor unit recruitment through the feet when standing on a vibration platform (vertical or oscillating) or via the tendon of a muscle belly when a hand-held unit is used.²³¹ In a meta-analysis looking at the effects of vibration on muscular development in the able-bodied population, Pedro and Rhea determined that vibration exercise can be effective at eliciting chronic

muscle strength adaptations and can be used by professionals to improve muscular strength in individuals. It was also determined that vertical platforms elicit a significantly larger effect for chronic adaptations than oscillating platforms, but oscillating platforms elicit a greater treatment effect for acute effects than vertical platforms.²³² A variety of literature has recently been published demonstrating the benefits of using this modality in people with a variety of clinical conditions including cerebral palsy,²³³ Parkinson disease,²³⁴ stroke,²³⁵ and SCI.²³⁶ However, there is still only a small body of evidence describing the effects of WBV on individuals with SCIs.²³⁷ Ness and colleague²³⁷ found a statistically significant improvement in cadence when treating individuals with chronic SCIs with WBV that was comparable to improvements seen in individuals who have undergone locomotor training. In a follow-up study²³⁶ these authors also reported a decrease in quadriceps spasticity after individuals with chronic SCIs completed 12 sessions of WBV training. Overall, further research needs to be completed on this intervention to determine the most efficacious use of parameters with patients who have sustained SCIs, but early research supports that this may be a useful intervention to improve walking speed and decrease spasticity in individuals with chronic SCIs (Figure 16-66).

Figure 16-65 ■ RT300 SA Arm system is a functional electrical stimulation (FES) upper body ergometer designed to stimulate muscles of the upper extremities. Adhesive electrodes can be applied to a variety of muscle groups over the trunk, shoulders, and arm muscles and are stimulated at the appropriate time to facilitate a cycling motion using the upper-extremity ergometer. FES bike software has the capability to store patient-specific parameters between sessions and clients.

Figure 16-66 ■ The Wave vibration plate is used in the clinical setting to facilitate upright standing posture and can also be used to facilitate upper- and lower-extremity strengthening exercises.

In conclusion, recovery of walking is an increasing possibility for a large number of people with SCI. New modalities of treatment have become available for this population, but most still need to be evaluated for their efficacy.

CONCLUSION

Comprehensive treatment of the individual with SCI can be very challenging. Health care reform issues force the rehabilitation team to explore new cost-efficient options to continue to provide high-quality rehabilitation. New medical and rehabilitation interventions provide the clinician with a plethora of interventions to improve functional recovery as well as promote neurological recovery after SCI (Table 16-9). Scientists continue to research ways to prevent and/or cure paralysis and loss of function after SCI; however, until those goals have been achieved the

best defense against SCI is to prevent the injury from occurring. Programs such as ThinkFirst are aimed at helping individuals of all ages learn to reduce their risk of SCI by educating them to make safe choices. Key concepts include “Buckle up. Drive safe and sober. Avoid violent situations. Lower your risk to fall. Wear a helmet. Check the water before you dive.”²³⁸

References

To enhance this text and add value for the reader, all references are included on the companion Evolve site that accompanies this textbook. This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 264 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

TABLE 16-9 ■ SUMMARY OF SPINAL CORD REGENERATION EFFORTS

AGENT/ INTERVENTION	MECHANISM	SPONSOR	TRIAL STATUS/RESULTS
Methylprednisolone (MP)	Antiinflammatory, blocks glutamate receptors, reduces accumulation of free radicals.	Pharmacia	Standard trauma protocol; effective in high dosages if given 1st 48 hours post-injury. Celebrex may be as effective.
Monosialic ganglioside (GM-1)	Neurotrophic factor limits cell death by buffering excitotoxicity and preventing apoptosis	Sygen	May accelerate recovery in 1st 6 weeks but no difference @ 6-12 mos.
Activated macrophages	Bolsters immune response, introduces nerve growth factors.	Proneuron	Phase II 2003-06; early termination due to \$\$; results not released.
Cell matrix modifiers - Cordaneurin (acute) Corda-Chron (chronic)	Modify inhibitory glial scar matrix, allowing axon sprouting, growth, and functional plasticity.	Neuraxo	Preclinical studies completed; no Phase I announced at present.
Minocycline	Synthetic tetracycline antibiotic that inhibits activity of inflammatory cytokines, free radicals, etc. causing excitotoxicity.	NACTN	Promising preclinical work and human trials likely in Canada.
Decorin	Naturally occurring protein molecule that suppresses scar tissue formation.	Baylor College of Medicine and Integra Life-sciences	Preclinical
4-Aminopyridine (Fampridine or 4-AP)	Potassium channel blocker restores action potential conduction in de- or poorly-myelinated nerves; enhances synaptic transmission.	Acorda	Chronic SCI; Two Phase II studies (spasticity, bladder control) 2003-05; moderately effective. FDA may approve in 2010 for MS.
HP-184	Synthetic protein that functions as a potassium channel blocker to improve nerve conduction.	Aventis	Chronic SCI; Phase II completed; limited efficacy; no further development planned.
Riluzole	Sodium channel blocker and antiexcitotoxic drug marketed for treatment of ALS.	NACTN	Phase II trial in acute SCI likely to be funded by NACTN.
Glial growth factors (Neuregulin)	NGF stimulates myelin production from remaining oligodendrocytes.	Acorda	Preclinical; may initiate Phase I in MS; no date projected.
Monoclonal antibodies	Several antibodies have been identified with potential to repair CNS myelin and restore neurological function in MS and SCI.	Acorda, Biogen Idec, Amgen	Preclinical studies
AIT-082 (Neotrofin)	NGF promotes axonal sprouting.	Neurotherapeutics	Clinical trial completed but no results released.
Inosine + Axiogenesis Factor (AF-1)	NGFs that promote axon growth in the corticospinal tract.	Boston Life Science	Phase I trial pending with stroke patients.
Glial derived neurotrophic factor (GDNF)	Neurotrophic effect on sensory neurons superior to other nerve growth factors (NGF, NT-3, NT-4/5)	Amgen	Phase II trial with advanced Parkinson's; terminated early due to lack of efficacy.
Oscillating Field Stimulator (OFS) Andara	Implanted electrodes above and below lesion deliver OFS, which promotes axonal growth.	Cyberkinetics	Small Phase I in acute SCI; humanitarian device exemption requested.

PREVENT SECONDARY INJURY EFFECTS		COMPENSATE FOR LOSS OF MYELIN		ENCOURAGE AXONS TO GROW		REPLACE DEAD CELLS				
BLOCK EXCITOTOXICITY	LIMIT APOPTOSIS	BOLSTER IMMUNE RESPONSE	PREVENT GLIAL SCARRING	STIMULATE MYELIN PRODUCTION	PREVENT DISSIPATION OF NERVE IMPULSES	INTRODUCE TROPHIC FACTORS	BLOCK GROWTH INHIBITORY FACTORS	GUIDE AXON GROWTH	IMPLANT REPLACEMENT NERVE CELLS	INDUCE DIFFERENTIATION OF PROGENITOR CELLS

TABLE 16-9 ■ SUMMARY OF SPINAL CORD REGENERATION EFFORTS—cont'd

AGENT/ INTERVENTION	MECHANISM	SPONSOR	TRIAL STATUS/RESULTS
Neurotrophic factor (NT-3)	NGF improves bowel function in chronic SCI.	Regenereon	Phase II trial completed; no further development planned.
IN-1 antibody	Binds to Nogo, a myelin-growth inhibitor, thereby stimulating axonal growth and remyelination.	Novartis	Phase I in Europe; Phase II in US considered but no estimated start date.
Nogo-66 nogo receptor blocker	anti-NgR1 antibody that blocks uptake of Nogo.	Biogen Idec	Preclinical studies in MS and SCI.
Chondroitinase ABC	Enzyme that breaks down chondroitin-6-sulfate proteoglycans (CSPG), a growth inhibitor, to promote axonal growth.	Acorda	Preclinical studies
Recombinant C3 toxin (Cethrin)	Blocks rho signaling protein, which mediates inhibitory Nogo and may be responsible for apoptosis; stimulates axon regeneration.	Alseres	Phase I/IIa completed in '07; promising results; Phase IIb trials pending but funding appears to be an issue.
Schwann cell transplants	Myelin producers in peripheral nerves cross into CNS at dorsal root; may be used to deliver trophic factors and as bridges to support axonal growth.		Clinical evaluation.
Olfactory ensheathing glial (OEG) cells	Cells may function in 3 ways: encourage cell migration, guide direction of axon growth, provide a bridge or scaffold over cord damage.	Portugal, China, Russia, Australia	Several uncontrolled treatments offered overseas - one safety review article; no published efficacy findings.
Fetal spinal cord transplants	Experimental procedure for treatment of syringomyelia.	Univ. of Florida	Phase I trial completed; cells survived and filled syrxn. No further studies - Replaced by hESC studies (Geron).
Fetal pig neural stem cells	Replace neural cells and promote differentiation.	Diacrin	Appears to be safe in Phase I trial; no effectiveness results released.
Bone marrow stromal stem cells	Autologous bone marrow-derived cells differentiate into neuron and glial cells and improve functioning in preclinical studies.	Brazil, Ukraine	No US trials planned.
Fetal neural stem cells	Cultured neural stem cells derived from a single 8-week fetus.	NeuralStem	US Phase I trial for ALS at Emory in 2010.
Human embryonic neural stem cells	Embryonic stem cells that have been differentiated into precursors of neuron-support cells. Source is H1 cell line "approved" human embryonic stem cell line.	Geron	Phase I trial on FDA hold as of August 2009. Expect restart in late 2010.
Umbilical cord blood stem cells	Cells used in treatment of leukemia, autoimmune diseases (lupus), and sickle cell anemia.	Stemcyte, China, India	China conducting CB + Lithium trial. Possibility of US trial in >2011?

CHAPTER 17 Neuromuscular Diseases

ANN HALLUM, PT, PhD, and DIANE D. ALLEN, PT, PhD

KEY TERMS

amyotrophic lateral sclerosis
disuse atrophy
Duchenne muscular dystrophy
Guillain-Barré syndrome
overwork damage
polyradiculoneuropathy

OBJECTIVES

After reviewing this chapter the student or therapist will be able to:

1. Describe the basic pathology and medical treatment of amyotrophic lateral sclerosis, Guillain-Barré syndrome, and Duchenne muscular dystrophy.
2. Describe the current goals and interventions for each condition.
3. Describe the “safe” exercise windows related to disuse atrophy and exercise (overwork) damage.
4. Be able to apply intervention concepts discussed in this chapter to other neuromuscular diseases.

Neuromuscular diseases encompass disorders of upper or lower motor nerves or the muscles they innervate. This chapter traces the connections among the central nervous system (CNS), peripheral nervous system (PNS), and musculoskeletal system through the disordered functioning associated with three neuromuscular diseases: amyotrophic lateral sclerosis (ALS), which damages upper and lower motor neurons; Guillain-Barré syndrome (GBS), which compromises lower motor neurons and the PNS; and Duchenne muscular dystrophy (DMD), which affects the muscles themselves. To review the normal connections, upper motor neurons originate in the motor cortex of the brain (Betz cells). Axons from these upper motor neurons descend by means of the corticobulbar and corticospinal tracts to synapse with lower motor neurons in the brain stem (neurons of the cranial nerves with motor functions) and spinal cord (anterior horn cells or alpha motor neurons). Simultaneously, corticobulbar tract fibers innervate neurons originating within the brain stem and descending through the spinal cord to provide additional input to lower (alpha) motor neurons. Axons from the lower motor neurons within both the brain stem and spinal cord run within the peripheral nerves, which include motor and sensory fibers, to synapse with muscle fibers. The muscle fibers respond to excitation by contracting. Depending on the site of the pathology, neuromuscular diseases can be classified as neurogenic or myopathic. ALS and GBS are neurogenic disorders; DMD is a primary myopathy (Figure 17-1).

In considering the movement dysfunction associated with these diseases, strength and endurance are most affected, with flexibility deficits resulting from these.¹ All three disorders decrease a person’s ability to generate force in the affected muscles, with weakness as a primary symptom. Loss of muscle strength can lead to speech, swallowing, and respiratory difficulties along with functional limitations. Fatigue is another primary deficit, although the neurogenic disorders tend to result in central fatigue (deficit in ability to recruit motor units) as opposed to the peripheral fatigue of

the myopathies (deficit in ability of muscle fibers to contract forcefully).² Secondary movement problems include loss of range of motion (ROM) in immobile muscles and joints, and pain or muscle spasms. Adaptability, the ability to sense obstacles or changes in the environment and change the course of a movement in response,¹ may be affected with the sensory loss in GBS but is not typically a problem in ALS or DMD.

AMYOTROPHIC LATERAL SCLEROSIS

Pathology and Medical Diagnosis

ALS, commonly known in the United States as *Lou Gehrig disease*, is a relentless, degenerative, terminal disease affecting both upper and lower motor neurons. Massive loss of anterior horn cells of the spinal cord and the motor cranial nerve nuclei in the lower brain stem results in muscle atrophy and weakness (amyotrophy). Demyelination and gliosis of the corticospinal tracts and corticobulbar tracts caused by degeneration of the Betz cells in the motor cortex result in upper motor neuron symptoms (lateral sclerosis).

The cause of ALS is unknown; however, numerous theories have been proposed. Ninety percent of the cases of ALS are sporadic without a known genetic component; however, most neurodegenerative diseases are now thought to be related to complex protein misfolding disorders. The latest research suggests that ALS and other neurodegenerative disorders are related to TDP-43 proteinopathy.³ Approximately 5% to 10% of the cases seem to have a complex genetic basis coded on *ALS1* through *ALS8* and other mutations that are associated with frontal lobe dementias. Twenty percent of genetic causes of ALS are thought to be related to mendelian mutations in the superoxide dismutase-1 (SOD1) gene (*ALS1*). Other factors considered in the genesis of ALS are vascular endothelial growth factors, toxicity leading to motor neuron death, oxidative stress and mitochondrial dysfunction related to microglial inflammation,^{4,5} and environmental factors.⁶

Neuromuscular diseases

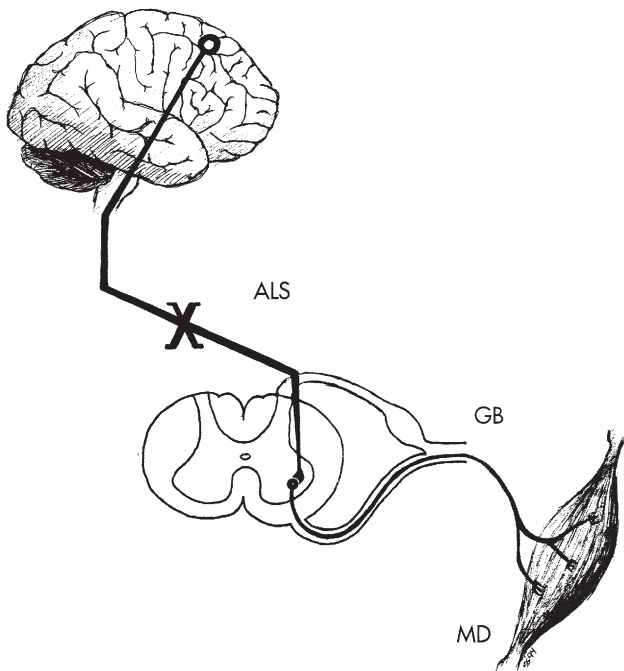

Figure 17-1 ■ Primary sites of pathological features of amyotrophic lateral sclerosis (ALS), Guillain-Barré syndrome (GBS), and Duchenne muscular dystrophy (DMD).

The differential diagnosis for ALS is extensive. The possibility of cervical or lumbar spondylosis, syringomyelia, multiple sclerosis, primary lateral sclerosis, and diseases associated with lower motor neuron pathology, among other diagnoses, needs to be excluded before the diagnosis of ALS is made.⁷ Currently, no single laboratory test is available to confirm a diagnosis of ALS, although creatine phosphokinase levels are elevated in approximately 70% of patients and tend to be higher in patients with limb onset ALS rather than bulbar onset.⁸ Genetic testing to identify the mutations in the Cu,Zn SOD1 gene is available when a family history of ALS is present. Other laboratory tests, such as identification of biochemical markers in the blood and cerebrospinal fluid, are used to exclude other neurological diseases. Electromyography (EMG) and nerve conduction studies can be helpful to confirm the presence of widespread lower motor neuron disease without peripheral neuropathy or polyradiculopathy. Neuroimaging studies are used to rule out conditions that may have clinical signs similar to those of ALS.⁹

Because of the absence of clear laboratory markers of ALS, the clinical diagnosis must be made on the basis of recognition of a pattern of observed and reported symptoms of both upper and lower motor neuron disease and persistent declines in physical functions supported by inclusionary and exclusionary diagnostic testing. Because of the overlap of symptoms with other neuromuscular disorders, misdiagnosis is not uncommon.¹⁰

ALS is the most common form of motor neuron disease, with an incidence of approximately three to five cases per 100,000 persons. Mean age at onset is 57 years, with two thirds of patients aged 50 to 70 years old at time of onset.¹¹

Men are affected approximately 1.3 to two times more frequently than are women, although the differences are less with late onset of disease (ages 70+).¹²

Clinical Presentation

The World Federation of Neurology (WFN) has developed suggested diagnostic criteria (suspected, possible, probable, and definite) for patients with ALS entering clinical research trials. Essentially, a patient with “definite” ALS must show concomitant upper motor neuron and lower motor neuron signs in three spinal regions or in two spinal regions with bulbar signs. Either upper or lower motor signs must also be evident in other regions of the body.¹³ Exclusionary criteria are oculomotor nerve pathway abnormalities (the oculomotor nerve is spared in ALS), significant movement disorder patterns, sphincter control problems, the presence of sensory and autonomic nervous system (ANS) dysfunction, and cognitive deterioration.¹⁴ (Refer to the WFN ALS website [www.wfnals.org] section on ALS education for up-to-date criteria used for clinical studies.)

Although a consistent diagnostic criterion for ALS has been the absence of sensory involvement, some evidence exists that there is a progressive functional deficit in sensation, perhaps related to ongoing immobility.¹⁵

Similarly, cognitive deficits are considered exclusionary criteria for an ALS diagnosis. However, a small subgroup of patients with both familial and sporadic forms of ALS has been identified as having concomitant evidence of frontotemporal dementia (FTD), showing lower scores on executive cognitive functions, word finding, and phrase length.¹⁶ A combination of ALS and FTD suggests a common cause may be possible.¹⁷ Because of these findings, therapists should be aware of the possibility of cognitive deficits in their patients with ALS, manifested as a decrement in executive skills such as planning and organization and language problems. Such patients may have more difficulty following through on medication and therapeutic recommendations, and their families may need more support. Unassociated with overall cognitive impairment, some deficits in action knowledge as opposed to object knowledge have been noted in patients with ALS, correlating with atrophy in the motor and premotor cortex.¹⁸ Specific cognitive deficits, therefore, may be more common than previously noted.

The earliest clinical markers heralding ALS are fasciculations (especially unequivocal fasciculation in the tongue), muscle cramps, fatigue, weakness, and atrophy.^{13,19} During initial diagnostic visits, patients frequently report to their physicians a profound sense of fatigue or the loss of exercise tolerance.¹⁹ Ninety percent of patients report weakness occurring in a striated muscle or group of muscles. Because the onset of ALS is insidious, most patients are not aware of the strength changes, or they have adjusted to the changes until they have difficulty with a functional activity such as tying shoes or climbing stairs. Physical examination usually demonstrates more widespread weakness and atrophy than reported by the patient. By the time most patients report weakness, they have lost approximately 80% of their motor neurons in the areas of weakness. This demonstrates the plasticity of the nervous system and its drive to adapt to meet functional goals. The weakness spreads over time to include musculature throughout the body. Succeeding symptoms of weakness in other muscles depends on the continued

loss of motor neurons to the 20% threshold needed for perception of weakness.^{20,21} A typical, but not absolute, pattern of motor progression is early distal involvement followed by proximal limb involvement. In some cases bulbar symptoms herald the onset of ALS, but bulbar symptoms more commonly occur later in the disease. Flexor muscles tend to be weaker than extensor muscles.²²

Although the atrophy and weakness component of ALS is most obvious, 80% or more of patients show early clinical evidence of pyramidal tract dysfunction (e.g., hyperreflexia in the presence of weakness and atrophy, spasticity, and Babinski and Hoffmann reflexes).¹³ Although in some cases the upper motor neuron signs may be absent clinically, Chou²³ has shown on autopsy that significant involvement may be present despite the lack of clinical evidence.

The pattern of ALS onset is highly varied, with several patterns identified by primary area of onset. Lower-extremity onset is slightly more common than upper-extremity onset, which is more common than bulbar onset. Some patients show initial symptoms in distal musculature of upper and lower extremities. A significant diagnostic feature of the pattern of disease is the asymmetry of the weakness and the sparing of some muscle fibers even in highly atrophied muscles. For example, a patient may have weakness of the right intrinsic and shoulder musculature or weakness of the left anterior tibial muscles. Bulbar symptoms are presaged by tongue fasciculations and weakness, facial and palatal weakness, and swallowing difficulties, which result in dysphagia and dysarthria. Pseudobulbar palsy is sometimes present in ALS, manifested by spontaneous laughing or crying unrelated to the situation.²⁴ Despite the pattern of onset, however, the eventual course of the illness is similar in most patients, with an unremitting spread of weakness to other muscle groups leading to total paralysis of spinal musculature and muscles innervated by the cranial nerves. Death is usually related to respiratory failure.²⁵

In a longitudinal study using monthly questionnaires, direct patient interviews, record reviews, physician interviews, and family member interviews, Brooks and colleagues²⁰ followed 702 patients with ALS. Their findings suggest that spread of neuronal degeneration occurred more quickly to adjacent areas than to noncontiguous areas. The spread to adjacent areas was more rapid at the brain stem, cervical, and lumbar regions. Limb involvement after bulbar onset was more aggressive in men than in women.²⁰

One study focused on developing methods to assess the natural history of the progression of ALS so that medical and supportive treatment planning and interventions could be instituted.²⁶ Hillel and colleagues²⁷ have developed the ALS severity scale for rapid functional assessment of disease stage. Their 10-point ordinal scale allows clinicians and therapists to score patients in four categories: speech, swallowing, and lower-extremity and upper-extremity function (Box 17-1).

A five-point scale of severity is currently being used in ALS clinical drug trials. Patients in stage 1 (mild disease) have a recent diagnosis and are functionally independent in ambulation, activities of daily living (ADLs), and speech. Stage 2 (moderate) identifies patients with mild deficits in function in three regions or a moderate to severe deficit in one region and mild or normal function in two other regions. Stage 3 (severe) defines patients who need assistance because of deficits in two or three regions; for example, the patient needs assistance to walk or transfer, needs help

with upper-extremity activities, and/or is dysarthric or dysphasic. Stage 4 identifies patients with nonfunctional movement of at least two regions and moderate or nonfunctional movement of a third area. Stage 5 is death.²² (See Brooks and colleagues¹⁴ and Pradas and colleagues²⁸ for information on the natural history of ALS and its importance in the design of clinical treatment trials.)

Along with the primary impairments of weakness and fatigue affecting body structure and function in ALS, patients also have progressive limitations in activity and participation.²⁹ Activity limitations result in gradual loss of independence in community and then household tasks. Mechanical and electronic adaptive devices can help extend independence in some ADLs past the initial strength losses. Participation limitations result in progressive isolation from the community and family unless extraordinary efforts persist to retain a communication system at home and through electronic media.

Medical Prognosis

In almost all cases ALS progresses relentlessly and leads to death from respiratory failure. The rate of progression seems to be consistent for each patient but varies considerably among patients. Patients with an initial onset of bulbar weakness (dysarthria, dysphagia) and respiratory weakness (dyspnea) tend to have a more rapid progression to death than patients whose weakness begins in the distal extremities.³⁰ Death usually follows within 2 to 4 years after diagnosis, with a small number of patients living for 15 to 20 years.¹⁰

Years of survival after diagnosis may change as drug therapies are developed.³¹ In addition, increasing numbers of patients are electing to prolong life with home-based mechanical ventilation as opposed to palliative or comfort care only.

Medical Management

ALS has no known cure and minimal effective disease-slowing treatments. Mitchell and Borasio²⁴ have created a table (see Table 2 in their study) that summarizes the results of trials of the many putative ALS-modifying pharmaceuticals. Only riluzole has been approved for treatment of ALS. Riluzole provides very modest improvement over a placebo in both bulbar and limb function, but not in actual strength of muscles.³² The drug extended lifespan an average of 2 to 3 months. The side effects were minimal in some studies, but fatigue and weakness have been noted in 26% and 18% of patients taking riluzole compared with a placebo.³³

The popular press has reported on nutritional cures for ALS, including regular use of vitamin E. However, Orrell and colleagues³⁴ found insufficient evidence to support clinical use of vitamin E supplements in ALS as an additive to riluzole treatment or as adjunctive therapy, although no apparent contraindication was found to taking the supplement. Other nutritional and nonpharmaceutical supplements have had some success in animal models of ALS, but this has not yet been confirmed in humans.³⁵

Cannabis has been studied for its effect on spasticity in patients with multiple sclerosis and spinal cord injury. In a study of 131 people with ALS, 13 used cannabis, with reports of reduction in spasticity, pain, and depression.³⁶ Because of the apparent hopelessness of the diagnosis, many physicians,

BOX 17-1 ■ AMYOTROPHIC LATERAL SCLEROSIS SEVERITY SCALE: LOWER EXTREMITY, UPPER EXTREMITY, SPEECH, SWALLOWING**LOWER EXTREMITIES (WALKING)****Normal**

- | | | |
|----|-------------------|--|
| 10 | Normal ambulation | Patient denies any weakness or fatigue; examination reveals no abnormality. |
| 9 | Fatigue suspected | Patient experiences sense of weakness or fatigue in lower extremities during exertion. |

Early Ambulation Difficulties

- | | | |
|---|--------------------------------|--|
| 8 | Difficulty with uneven terrain | Difficulty and fatigue when walking long distances, climbing stairs, and walking over uneven ground (even thick carpet). |
| 7 | Observed changes in gait | Noticeable change in gait; pulls on railings when climbing stairs; may use leg brace. |

Walks with Assistance

- | | | |
|---|--|---|
| 6 | Walks with mechanical device | Needs or uses cane, walker, or assistant to walk; probably uses wheelchair away from home. |
| 5 | Walks with mechanical device and assistant | Does not attempt to walk without attendant; ambulation limited to less than 50 ft; avoids stairs. |

Functional Movement Only

- | | | |
|---|--------------------------|---|
| 4 | Able to support | At best, can shuffle a few steps with the help of an attendant for transfers. |
| 3 | Purposeful leg movements | Unable to take steps but can position legs to assist attendant in transfers; moves legs purposefully to maintain mobility in bed. |

No Purposeful Leg Movement

- | | | |
|---|------------------|--|
| 2 | Minimal movement | Minimal movement of one or both legs; cannot reposition legs independently. |
| 1 | Paralysis | Flaccid paralysis; cannot move lower extremities (except, perhaps, to close inspection). |

UPPER EXTREMITIES (DRESSING AND HYGIENE)**Normal Function**

- | | | |
|----|-------------------|---|
| 10 | Normal function | Patient denies any weakness or unusual fatigue of upper extremities; examination demonstrates no abnormality. |
| 9 | Suspected fatigue | Patient experiences sense of fatigue in upper extremities during exertion; cannot sustain work for as long as normal; atrophy not evident on examination. |

Independent and Complete Self-Care

- | | | |
|---|---------------------------------|--|
| 8 | Slow self-care | Dressing and hygiene performed more slowly than usual. |
| 7 | Effortful self-care performance | Requires significantly more time (usually double or more) and effort to accomplish self-care; weakness is apparent on examination. |

Intermittent Assistance

- | | | |
|---|----------------------|---|
| 6 | Mostly independent | Handles most aspects of dressing and hygiene alone; adapts by resting, modifying (e.g., use of electric razor), or avoiding some tasks; requires assistance for fine motor tasks (e.g., buttons, ties). |
| 5 | Partial independence | Handles some aspects of dressing and hygiene alone; however, routinely requires assistance for many tasks such as applying makeup, combing, and shaving. |

Needs Attendant for Self-Care

- | | | |
|---|---------------------------|--|
| 4 | Attendant assists patient | Attendant must be present for dressing and hygiene; patient performs the majority of each task with the assistance of the attendant. |
| 3 | Patient assists attendant | The attendant directs the patient for almost all tasks; the patient moves in a purposeful manner to assist the attendant; does not initiate self-care. |

Total Dependence

- | | | |
|---|------------------|---|
| 2 | Minimal movement | Minimal movement of one or both arms; cannot reposition arms. |
| 1 | Paralysis | Flaccid paralysis; unable to move upper extremities (except, perhaps, to close inspection). |

SPEECH**Normal Speech Processes**

- | | | |
|----|------------------------------|--|
| 10 | Normal speech | Patient denies any difficulty speaking; examination demonstrates no abnormality. |
| 9 | Nominal speech abnormalities | Only the patient or spouse notices speech has changed; maintains normal rate and volume. |

Detectable Speech Disturbance

- | | | |
|---|------------------------------|---|
| 8 | Perceived speech changes | Speech changes are noted by others, especially during fatigue or stress; rate of speech remains essentially normal. |
| 7 | Obvious speech abnormalities | Speech is consistently impaired; rate, articulation, and resonance are affected; remains easily understood. |

BOX 17-1 ■ AMYOTROPHIC LATERAL SCLEROSIS SEVERITY SCALE: LOWER EXTREMITY, UPPER EXTREMITY, SPEECH, SWALLOWING—cont'd**Intelligible with Repeating**

- | | | |
|---|-----------------------------|--|
| 6 | Repeats message on occasion | Rate is much slower, repeats specific words in adverse listening situation; does not limit complexity or length of messages. |
| 5 | Frequent repeating required | Speech is slow and labored; extensive repetition or a “translator” is commonly used; patient probably limits the complexity or length of messages. |

Speech Combined with Nonvocal Communication

- | | | |
|---|-------------------------------------|--|
| 4 | Speech plus nonverbal communication | Speech is used in response to questions; intelligibility problems need to be resolved by writing or a spokesperson. |
| 3 | Limits speech to one-word responses | Vocalizes one-word responses beyond yes and no; otherwise writes or uses a spokesperson; initiates communication nonvocally. |

Loss of Useful Speech

- | | | |
|---|------------------------------------|--|
| 2 | Vocalizes for emotional expression | Uses vocal inflection to express emotion, affirmation, and negation. |
| 1 | Nonvocal | Vocalization is effortful, limited in duration, and rarely attempted; may vocalize for crying or pain. |
- X Tracheostomy

SWALLOWING**Normal Eating Habits**

- | | | |
|----|---------------------|---|
| 10 | Normal swallowing | Patient denies any difficulty chewing or swallowing; examination demonstrates no abnormality. |
| 9 | Nominal abnormality | Only patient notices slight indicators such as food lodging in the recesses of the mouth or sticking in the throat. |

Early Eating Problems

- | | | |
|---|------------------------------------|--|
| 8 | Minor swallowing problems | Reports some swallowing difficulties; maintains essentially a regular diet; isolated choking episodes. |
| 7 | Prolonged times, smaller bite size | Meal time has significantly increased and smaller bite sizes are necessary; must concentrate on swallowing thin liquids. |

Dietary Consistency Changes

- | | | |
|---|----------------|--|
| 6 | Soft diet | Diet is limited primarily to soft foods; requires some special meal preparation. |
| 5 | Liquefied diet | Oral intake adequate; nutrition limited primarily to liquefied diet; adequate thin liquid intake usually a problem; may force self to eat. |

Needs Tube Feeding

- | | | |
|---|---|---|
| 4 | Supplemental tube feedings | Oral intake alone no longer adequate; patient uses or needs a tube to supplement intake; patient continues to take significant (greater than 50%) nutrition orally. |
| 3 | Tube feeding with occasional oral nutrition | Primary nutrition and hydration accomplished by tube; receives less than 50% of nutrition orally. |

No Oral Feeding

- | | | |
|---|--|---|
| 2 | Secretions managed with aspirator and/or medications | Cannot safely manage any oral intake; secretions managed with aspirator and/or medications; swallows reflexively. |
| 1 | Aspiration of secretions | Secretions cannot be managed noninvasively; rarely swallows. |

Adapted with permission from Hillel AD, Miller RM, Yorkston K, et al: Amyotrophic lateral sclerosis severity scale. *Neuroepidemiology* 8:142, 1989.

especially those not associated with major medical centers having neuromuscular disease units, do not refer patients with ALS for services, yet few primary care physicians or neurologists have extensive experience in the care of patients and families coping with ALS because of the low incidence of the disease. Yet, referral of patients with ALS to a multidisciplinary clinic typically extends the patient's lifespan, especially patients with bulbar onset of ALS.^{25,37}

Muscle Spasms and Pain

Some patients experience muscle cramps and spasms related to upper motor neuron pathology, and up to 73% of patients complain of pain, typically in the later stages.²⁴ Although most spasms can be relieved with stretching or increased

movement, some patients require medications such as quinine or baclofen to relieve symptoms (see Chapter 36 for information on drug therapies). In a review of studies on the treatment of spasticity in ALS, Ashworth and colleagues³⁸ found only one randomized study addressing spasticity: a moderate-endurance exercise regimen decreased spasticity at 3 months after initiation of the program. Stretching and massage may prove helpful for nocturnal muscle cramps.²⁵ Kesiktas and colleagues³⁹ report that in a controlled study of spasticity in patients after spinal cord injury, adding hydrotherapy to a program of medication and exercise decreased severity of spasms and decreased the amount of medication required. A similar response could be hypothesized in patients with ALS. In addition to muscle spasms, patients

report nonspecific aching and muscle soreness, probably related to immobility and trauma to paralyzed muscles during caregiving procedures. However, many patients do not receive adequate pain medication, or the pain is not controlled by the medication taken.⁴⁰ A Cochrane review in 2008 found no randomized or quasi-randomized controlled trials of drug therapy for pain in ALS, although several case series reported the use of acetaminophen, nonsteroidal antiinflammatory drugs (NSAIDs), or opioids.⁴¹ Careful administration of medications such as baclofen, tizanidine, dantrolene sodium, and diazepam is useful for some patients with spasticity. Because each has a different action and side effects, the medications may have to be adjusted to find the right dosage and combination. In some patients with severe cramping, botulinum toxin injections might be helpful, but they must be carefully administered to prevent further weakness. Because many patients have compromised respiratory function, the physician must take great care when prescribing pain medication, especially opiates, which are often used when antispasmodics or antiinflammatory pain medications no longer work.²⁵ Patients should be instructed to keep a daily reporting log of the effectiveness of the medication so that the dosage can be adjusted if necessary.

Dysphagia

Dysphagia, a difficulty swallowing liquids, foods, or saliva, accounts for considerable misery in the patient with advanced ALS, and it must be dealt with aggressively. Patients with dysphagia have both nutritional and swallowing problems associated with weakness of the lips, tongue, palate, and mastication muscles.⁴² As the progressive loss of swallowing develops, patients are also at extreme risk for aspiration. Most patients with dysphagia also have severe problems with management of their saliva (sialorrhoea). If a patient has difficulty transporting saliva back to the oropharynx for swallowing, choking and drooling are common.⁴³ This condition is disconcerting to the affected person, who must constantly wipe the mouth or have someone do it for him or her.

In addition, secretions are often thickened because of dehydration. With pooling of the thickened saliva, the possibility of aspiration is increased. Viscosity of saliva can best be treated by hydration and, in some cases, pharmaceuticals. Drugs, such as decongestants, antidepressant drugs with anticholinergic side effects, and atropine-type drugs, can help control the amount of saliva, provided the patient is well hydrated.⁴⁴ In extreme cases, various surgical procedures such as ligation of the salivary gland ducts, severing the parasympathetic supply to the salivary glands, and excision of the salivary glands have been used effectively.⁴⁵ Newer treatments to decrease excessive secretions are radiotherapy and botulinum A toxin injections into salivary glands.⁴⁶

Although dietary treatment is not known to be effective in changing the course of the disease, a nutritious diet to meet caloric, fluid, vitamin, and mineral needs must be maintained. Seventy-three percent of patients with ALS have difficulty bringing food to the mouth, making them dependent on others for their dietary needs. Because of the time it takes to be fed, many patients decrease their intake. All patients with dysphagia should be referred for a dietary consultation to determine the choice and progression of solid and liquid foods and supplements.⁴⁷ Appel and colleagues⁴⁷ describe

nutritional plans to maintain nutrition and hydration in patients with motor neuron diseases. Patients with bulbar symptoms and severe dysphagia who are no longer able to consume nutrients orally because of motor control problems and recurrent aspiration may need a percutaneous endoscopic gastrostomy (PEG) for feeding, depending on the patient's wishes for long-term care. Some evidence exists that the PEG should be performed early in the disease process to prevent severe weight loss and aspiration.⁴⁸ Although a PEG does not appreciably lengthen survival time,⁴⁹ patients may have less fear of choking or aspiration. Receiving nourishment from a PEG does not prevent the person from taking food orally if desired.

Dysarthria

Dysarthria, impairment in speech production, is the result of abnormal function of the muscles and nerves associated with coordinated functions of the tongue and lips, larynx, soft palate, and respiratory system. Speech impairments are the initial symptom in most patients with bulbar involvement. Speech intelligibility is compromised by hypernasality, abnormalities of speed and cadence of speech, and reduced vocal volume. Speech is further compromised by inadequate breath volumes for normal phrasing. A possible option to help patients with severe hypernasality is a palatal lift prosthesis to augment velopharyngeal function.^{50,51} Because little can be done medically to delay the loss of speech control, early referral to a speech therapist is essential. Numerous augmentative and alternative communication systems are now available, the simplest being voice amplification systems or homemade point boards and computer-based head or eye tracking text-to-speech systems that can be modified as the patient status changes. The type of communication system should be chosen with awareness of the patient-caregiver environment.⁵²

Respiratory Management

Progressive respiratory failure is the primary cause of death in ALS patients. Respiratory failure is related to primary diaphragmatic, intercostal, and accessory respiratory muscle weakness.⁵³ Respiratory failure should be anticipated and discussed early following the diagnosis of ALS so that patients and their caregivers can express their wishes and develop an advanced directive for care in the terminal phase of the disease.⁵⁴

Physiological tests used to indicate respiratory dysfunction include vital capacity, sniff nasal pressure, and nocturnal oximetry.¹⁰ Clinical signs of increased respiratory dysfunction are dyspnea with exertion or lying supine; hypoventilation; weak or ineffective cough; increased use of auxiliary respiratory muscles; tachycardia (also a sign of pulmonary infection with fever and tachypnea); changes in sleep pattern; daytime sleepiness and concentration problems; mood changes; and morning headaches.⁵⁵

In early stages of patient care, physical therapists (PTs) may help manage respiratory dysfunction by providing postural drainage with cough facilitation (suctioning if necessary), especially during acute respiratory illnesses. The patient and care providers should also be taught breathing exercises, chest stretching, and incentive spirometry techniques, as well as postural drainage techniques if the caregivers are prepared to provide such support. Although

breathing exercises consisting of resisted inspiratory muscle training can facilitate functional respiration, even practicing unresisted breathing for 10 minutes three times a day has been shown to result in improved function.⁵⁶ An assessment of the home environment is imperative to identify sleeping positions and energy conservation techniques that can be incorporated into the patient's daily life.

As respiratory symptoms increase, oxygen at 2 L/min or less can be used intermittently at home. When hypoventilation with a decline in oxygen saturation becomes common during sleep, resulting in morning confusion and irritability, patients have the option to initiate noninvasive, positive-pressure ventilation (NIV) such as bilevel positive airway pressure (BiPAP). BiPAP, which provides greater inspiratory pressure than expiratory pressure to decrease the effort of breathing, can be administered by either mask or contoured nasal delivery systems. Some evidence indicates that early use of NIV can increase survival time by several months and increase quality of life.⁵⁷ When a patient can no longer benefit from NIV, a decision must be made about initiating ventilation by tracheostomy or palliative care.⁵⁸ (See also Miller and colleagues⁵⁹ for an excellent discussion of practice parameters in the decision-making process related to ventilatory support.) Although in the initial stages of ALS most patients indicate they would not want prolonged respirator dependence at home, patients may change their minds as they adapt to the disease restrictions.⁶⁰ A small study of patients who started tracheostomy intermittent positive-pressure ventilation (TIPPV) demonstrated increased long-term survival (2 to 64 months).⁵⁴ In another series of 70 patients on long-term TIPPV, 50% of the patients were living after 5 years; however, 11.4% of these patients had entered a "locked-in state in which they were unable to communicate in any manner."⁶¹ Decisions about long-term respirator use should be made by the patient and involved family members or partners, with input from the interdisciplinary team caring for the patient. Discussions of preferred long-term care options should be revisited as the patient's condition changes.

If a patient decides that home ventilation is a reasonable option, those involved in the decision should visit another patient who is using in-home mechanical ventilation, if possible. Because the decision for home mechanical ventilation (HMV, NIV, or TIPPV) also affects the life of the patient's spouse, children, and extended family who may be responsible for some aspects of home care, or whose lives may be affected by the presence of in-home nurses or attendants, the decision for HMV should not be taken lightly. Extensive preparation, ongoing support, and respite options for caregivers are necessary if HMV is to be successful. Success of HMV also depends on such variables as third-party payment for home care equipment and nurse or attendant staffing, working status of the partner or spouse, age and physical fitness of the spouse and children, pre-ALS family psychosocial interactions, and financial factors. HMV should be viewed as long term, often extending for more than 1 year. Initiation of HMV results in a reasonable perceived quality of life for the patient, yet caregivers report that their quality of life may be lower than the patient's because of the burden of care that must be provided.⁶²

With chronic respiratory insufficiency, the patient and family must be involved in the long-term care decisions

related to instituting mechanical assistance under either emergency situations or in response to gradual deterioration. This discussion should occur before the patient develops respiratory failure. Acute respiratory failure can be frightening, and few patients or family members are prepared to forego intubation and artificial ventilation during the emergency. Patients and caregivers should understand that not making a decision about mechanical ventilation, noninvasive or invasive, is a decision to support mechanical ventilation.⁶³

Physicians and health care workers who work with the patient and family must be aware of their own feelings and beliefs about prolonging life. For example, a healthy physician or therapist who values control and an active lifestyle may envision a life on a ventilator as intolerable and pass that value on to the patient, who may or may not have the same needs. The patient's decision, or change in decision, must be respected by the medical team involved in care.⁶⁴ In medical centers that use a team approach, patients and families may find support by meeting with counselors or peers with ALS who are making or have made decisions about long-term ventilator care.

Therapeutic Management of Movement Dysfunction Associated with ALS

Perhaps because of the multitude of issues to consider when managing the impairments and limitations associated with ALS, evidence suggests that patients treated by a specialized ALS multidisciplinary team fare better than do those treated by single-source providers,⁶⁵ or in general neurology clinics.³³ A Cochrane review of the evidence for multidisciplinary care advantages in this population concluded that the evidence is of low quality, so far, with no controlled trials identified.⁶⁶ Whether administered through an ALS-specific team or not, therapeutic management will necessitate examination of the patient's current status, evaluation of the deficits in relation to patient preferences and needs, and establishment of a plan based on mutually determined and realistic goals. The rate of the patient's disease progression, the areas and extent of involvement, and the stage of illness must be considered. A patient at the initial stages will have different needs than a patient at later stages who has chosen NIV or tracheostomy ventilation that may extend life span at a markedly reduced mobility level. The goal at all stages is to optimize health and increase the quality of life. With guidance and environmental adaptations, patients with slowly progressing weakness may be able to continue many of their ADLs for an extended number of years. In the final stages of the disease, when the patient is bedridden, programs to increase strength or endurance are not appropriate, and interventions such as stretching may not effectively control contracture development. However, patients may still benefit from positioning and range-of-motion (ROM) exercises to decrease muscle and joint pain related to immobility. The prescription of assistive devices and training of caregivers will also be needed. The efficacy of therapeutic interventions will be related to the timing of interventions, the motivation and persistence of the patient in carrying out the program, and support from family members or caregivers.⁶⁷ Objective documentation of outcome measures will help justify the usefulness of therapeutic interventions at all stages of this disease.

Examination

The extent of the therapeutic examination of a patient with ALS will depend on whether the therapist is working as a member of a rehabilitative team or as an independent or clinic-based therapist receiving a referral to evaluate and treat. PTs and OTs working as team members may have a more circumscribed role related to gross motor function and ADLs, with other consultants focusing on bulbar, respiratory, and environmental adjustments. The therapist working in a facility without a neuromuscular disease clinic or in a community or rural environment, however, should be aware of the need to carry out a broad-based assessment. In addition to the standard neuromuscular, musculoskeletal, and functional-level examinations, the therapist should also evaluate the patient's stated or observed functional problems relative to bulbar and respiratory impairments, environmental blocks to independence, and caregiving demands.

If possible, before the patient's initial visit, the therapist should contact the patient and request that he or she keep an activity log for several days. If an early contact is not possible, the therapist can assign that task during the initial session. The log should include 15-minute time increments in which the patient or caregiver can record what she or he was doing during a specific period. The log should also indicate whether the patient was experiencing fatigue or pain during the activity and how the patient perceived her or his respiratory status. An example of an activity log and how it is used is shown in Figure 17-2. The sense of fatigue with repetitive muscle activity or functional activity should be specifically tracked by the patient.

Weakness will be the primary deficit, with other problems following depending on the location of strength loss. Muscle weakness and the experience of fatigue may be independent measures of ALS pathology, however.⁶⁸ Although weakness may affect balance during gait, patients with ALS have not shown deficits in postural control during quiet stance despite significant paresis or tone changes, possibly because sensation is relatively preserved.⁶⁹

The therapist's examination will vary depending on the patient's situation²⁹; however, a typical initial assessment may include the following:

- Review of the patient's medical and activity records, especially time since diagnosis, time course of disease progression to date, current medications, concurrent medical issues, current activities and participation and tolerance for them.
- History should focus on current and recent activities and participation signifying patient's lifestyle, ADL tasks, hobbies or interests, and work focus; primary complaints, including weakness, fatigue, pain, respiratory status, safety, or speech and swallowing issues; psychosocial support issues (family, caregivers, and agencies); patient's and family members' understanding of ALS and the likely progression and prognosis; and patient's current concerns and goals.
- Screening for multisystem involvement should include checking vital signs at rest, skin integrity, bony abnormalities, sensory integrity, communication ability, and ability to follow multistep commands. More extensive examination of systems showing deficits may be indicated, or the patient may be referred to appropriate health care professionals.
- Baseline testing of muscle strength (manual muscle testing [MMT] or electronic handheld dynamometer testing if standards are clear and can be replicated), ROM, spasticity, and endurance; documentation of any areas of atrophy.
- Assessment of functional activity level (using a standardized test or assessment tool whenever possible) to include, as appropriate: transfers, gait, upper-extremity function, postural control, and assistive devices; suggested tools include the ALS functional rating scale (ALSFRS),⁷⁰ the ALS severity scale (ALSSS),²⁷ timed walk test, or Purdue Pegboard.⁷⁰
- Documentation of pain (type, site, and intensity; use body chart and subjective pain scale); identify what makes pain worse or better.
- Assessment of bulbar and respiratory function. (For an in-depth evaluation of bulbar function, the patient should be referred to an ear, nose, and throat clinic or communications disorders clinic unless full evaluation is available in a comprehensive ALS clinic. See Table 17-1 for bulbar and respiratory evaluation suggestions.)
- Environmental assessment with a focus on energy conservation and safety at current and future functional capabilities.

Brinkmann and colleagues⁷⁰ identify standards for assessment of patients with ALS in clinical trials. The review and description of standardized methods for performing recommended tests and measurements is extremely valuable for any therapist assessing and treating patients with ALS.

In evaluating the results of the examination, the therapist should synthesize data to define the following, all of which are necessary for developing goals with the patient.

- Rate of the patient's disease progression
- Distribution of weakness and spasticity, respiratory factors leading to hypoxemia, and ease of fatigability and bulbar involvement
- Phase of the disease
- Any preexisting impairments and/or activity limitations (see Chapter 8)

Goals of Therapeutic Intervention

Intervention goals and the recommended exercise and activity program designed by PTs or OTs must be based on the patient's personal goals. Goals are often a difficult area for therapists to discuss with the patient because the disease is progressive despite intervention. Patients, therapists, and physicians commonly assume that because nothing can be done to "cure" the disease, not making additional demands on a patient who is already coping with daily loss is somehow kinder. Some believe that exercise programs may create false hopes that exercise will delay progression. Others believe that exercise will hasten progression.⁷¹ The literature on rehabilitation in neuromuscular disorders, however, suggests that patients with ALS can benefit from carefully designed exercise and activity programs. Active participation in determining goals for therapy can provide the patient and the family with some sense of control over a difficult situation.⁷

The general, broad goals for both patient and therapist are related to maintaining maximal independence in daily living and a positive quality of life for as long as possible.

Name: J. Costello

DATE: 5-10-00
 DAY: Saturday

DAILY ACTIVITY LOG

- Instructions:
- 1) In column I write in what you are doing during the 24 hour period. You may draw a line or an arrow to indicate when the activity occurs for more than one 15 minute time period.
 - 2) In column II indicate whether you are lying down, sitting, standing, or moving actively (walking, etc.) during the activity.
 - 3) In column III on a 10 point scale, indicate how fatigued you feel while performing the activity (No fatigue = 0, extreme fatigue = 10.)
 - 4) In column IV indicate where you feel pain if any and score the intensity on a 10 point scale (No pain = 0, extreme pain = 10.)

Try to fill out your log three or four times a day so you don't forget what you have been doing. An example is shown below.

	I	II	III	IV	
	What are you doing? Type of activity	What position are you in (lying, sitting, standing, moving)	Fatigue level 0 - 10	Location	Intensity 0 - 10
5:30 AM	sleep	lying	0		
45					
6:00					
15					
30	Bathroom	standing	2	neck	3
45	shave, etc				
7:00					
15	Breakfast	sitting	3	neck	3
30

Rights were not granted to include this table in electronic media.
Please refer to the printed publication.

More specific therapeutic goals are (1) maintenance of mobility and independent functioning, to include safe mobility for patient and caregiver; (2) maintenance of maximal muscle strength and endurance within limits imposed by ALS; (3) prevention and minimization of secondary consequences of the disease, such as contractures, thrombophlebitis, decubitus ulcers, and respiratory infections^{7,67}; (4) management of energy conservation techniques and respiratory comfort; (5) determination of adaptive equipment needs to include mobility, self-help and feeding devices, augmentative communication units, and hygiene equipment that supports both patient and caregiver⁷; and (6) eliminating or preventing pain.⁷²

Therapeutic Considerations

To prevent more rapid functional loss than expected from the natural history of the disease, both the patient and therapist must delicately balance the level of activity between the extremes of inadequate exercise and excessive exercise. Exercise has been recommended for the general public for its many benefits.⁷³ Inadequate exercise may result in loss of strength and endurance from disuse, as well as secondary problems such as loss of ROM, muscle cramping, and pain. Excessive exercise may result in excessive fatigue and consequent inability to perform ADLs during recovery periods. Overuse injury with excessive strengthening exercise may also lead to unnecessary pain and loss of strength. The next two sections review the evidence for the optimum amount of activity or exercise.

Disuse Atrophy. Because ALS is a disease of older adults, patients may not have maintained their aerobic fitness or muscle strength before the onset of their neuromuscular problem. Newly diagnosed patients also commonly report that they had markedly decreased their activity level in the months before diagnosis because of a sense of fatigue or increasing clumsiness from increasing weakness. If the patient had led a sedentary lifestyle before diagnosis, the additional

decrease in activity level after the onset of ALS can lead quickly to marked cardiovascular deconditioning and disuse weakness. The disuse weakness lowers muscle force production and reduces muscle endurance.⁷⁴

Exercise or Overwork Damage. Anecdotal evidence that muscle activity or overwork exercise can lead to a loss of muscle strength has been reported since the poliomyelitis epidemic of the 1940s and 1950s.⁷⁵ During that epidemic, physicians and therapists noted that patients with poor- and fair-grade muscles who exercised repeatedly or with heavy resistance after reinnervation often lost the ability to contract the muscle at all⁷⁶ (see Chapter 35). Controlled testing of this observation suggests that overwork damage occurs in mostly denervated muscles, not in all muscles. Reitsma⁷⁷ noted that vigorous exercise damaged muscles in rats if less than one third of motor units were functional. If more than one third of the motor units remained, exercise led to hypertrophy. An additional mechanism of potential overwork damage is inhibition of the collateral sprouting of intact axons to innervate “orphaned” muscle fibers when other axons degenerate. Yuen and Olney⁷⁸ provided evidence that collateral sprouting of intact axons can partially reinnervate orphaned muscle fibers in ALS. In a rat model, highly intensive activity reduced the ability of adjacent axons to sprout after fewer than 20% of intact motor units remained.⁷⁹ In contrast, vigorous exercise in a mouse model had no adverse effect on the course of ALS.⁸⁰ Lui and Byl⁸¹ systematically reviewed the literature reporting exercise effects in animal models of ALS and calculated an effective size of 1.39 (where numbers over 0.8 are considered large) in favor of exercise. The few negative effects they noted were associated with either very-high-intensity exercise or a slow rate of exercise (slower than usual activity for animals when unrestricted in activity). In addition to generic overwork, evidence exists that repeated maximal eccentric contractions may specifically damage even normal muscle fibers, resulting in muscle weakness of several weeks’ duration.⁸² Although

normal muscle eventually adapts to repeated eccentric exercise, whether the reparative effect is possible in patients with neuromuscular diseases is uncertain. Aboussouan⁵⁵ reviews some of the specific mechanisms of exercise intolerance in neuromuscular diseases, including mitochondrial dysfunction, abnormal muscle metabolism, impaired muscle activation, and central activation failure.

Many researchers have expressed concern about the possible relation between high-resistance exercise and muscle fiber degeneration in humans with motor neuron disease.^{83,84} Because of the concerns about damage from stressing substantially denervated muscles, Sinaki and Mulder⁸⁵ published recommendations in 1978 that patients with ALS not engage in any vigorous exercise and focus instead on exercise associated with walking and daily activities. On the other hand, McCrate and Kaspar⁸⁶ review the possible mechanisms by which exercise protects nerves from more rapid degeneration. Evidence regarding the positive benefits of exercise in ALS has been accumulating, with fewer adverse effects than some expected.

Sanjak and colleagues⁸⁷ reported that muscle damage does not necessarily result from resistance exercise testing or training, although fatigue occurs more easily during both anaerobic and aerobic exercise. Milner-Brown and Miller⁸⁸ found that mild progressive resistance exercise was helpful in neuromuscular disorders if the patient had muscle strength in the good (4/5) to normal (5/5) range. They determined that patients should begin their exercise program early because strength training of muscles with less than 10% of normal function was generally not effective. Aitkens and colleagues⁸⁹ noted strength gains of 4% to 20% without deleterious effects after a 12-week program of moderate-resistance (30% of maximum isometric force) exercises in patients with slowly progressive neuromuscular diseases. Kilmer and colleagues⁹⁰ in the same population, found no additional advantage to high-resistance training (12 weeks of exercise using the maximum isometric force the individual was able to lift 12 times) and noted evidence of overwork in some subjects. In a case report of a patient with ALS, strengthening 6 days a week for 10 weeks with proprioceptive neuromuscular facilitation (PNF) patterns using maximal resistance applied manually or with tubing resulted in strengthening of 14 muscle groups out of 18 with no adverse effects.⁹¹ Aksu and colleagues⁹² compared a supervised versus home exercise protocol in 26 ambulatory ALS patients. They noted that supervised breathing exercises, stretching, manually applied resistance exercise with PNF, and functional mobility training 3 days a week for 8 weeks resulted in small gains in function in the first 4 weeks and a slower decline over the subsequent 10 months compared with home-based breathing, stretching, and active ROM exercises. The groups were not randomly allocated but were not significantly different in the measured variables at baseline.⁹² In a randomized controlled trial, Drory and colleagues⁹³ assigned 25 patients with ALS to a group continuing their normal daily activities or a group participating in a moderate daily program of exercise individualized for each patient. The primary exercise focus was to have muscles of the trunk and limbs work against “modest” loads while undergoing significant shortening (not lengthening or eccentric contractions). The exercises were completed twice daily for 15 minutes at home with phone contact by

the treating therapist every 14 days. Data were evaluated for 3 and 6 months after initial assessment. All patients showed continued disease progression; however, in all cases, at the 6-month assessment patients who exercised showed positive effects in maintenance of muscle strength, less fatigue, less spasticity, less pain, and higher functional ratings.⁹³ In another randomized controlled trial, moderate load and moderate-intensity resistance exercises prescribed individually to patients with ALS in the early stages resulted in significantly less decline in function, small improvements in strength, and no reported adverse effects, compared with patients who performed stretching exercises alone.⁹⁴ A Cochrane review designated the quality of the Drory and colleagues (2001) study as “fair” and the Dal Bello-Haas and colleagues⁹⁴ study as “adequate.”⁹⁵ Table 17-2 summarizes some of the studies of strength training in neuromuscular diseases.

Fewer researchers have considered endurance in neuromuscular disorders.⁷³ Sanjak and colleagues⁸⁷ noted that exercise energy requirements during bicycle ergometry testing were greater than expected, possibly because of motor inefficiency caused by weakness. Work capacity and maximal oxygen consumption were decreased, but heart rate, respiratory responses, and blood pressure were within normal limits. Wright and colleagues⁹⁶ found small positive physiological effects from an aerobic walking program in patients with slowly progressive neuromuscular disorders. Pinto and colleagues⁹⁷ provided eight ALS patients with NIV during exercise to compensate for respiratory insufficiency. Patients walked on a treadmill for 10 to 15 minutes to the point of subjective fatigue, leg pain, heart rate above 75% of resting value, or desaturation of oxygen not correctable with NIV. In comparison to a nonexercising control group, the exercising group had a significant reduction in the rate of decline of respiratory function test results, strength, and function over the 1-year training period.⁹⁷

Endurance training for longer than 10 to 15 minutes in patients with ALS may be restricted by central fatigue, the decreased ability to recruit all motor units or develop high discharge rates,⁹⁸ and not merely respiratory function. Sharma and colleagues⁹⁹ explored the mechanism of fatigue in ALS. Both maximum voluntary contraction and tetanic force decreased in patients with ALS compared with controls following a 25-minute low-intensity intermittent exercise, but with similar recovery. Fatigue may thus be a consequence of chronic denervation resulting in secondary muscle changes such as altered muscle metabolism and impaired calcium kinetics along with the loss of motor unit activation.⁹⁹

In addition to strength and endurance gains from exercise, ongoing, gentle exercise programs may also help decrease persistent pain and muscle stiffness that often accompany weakened, overtaxed muscle groups.¹⁰⁰ A case study of a patient with ALS undergoing a focused exercise program revealed a positive psychological effect on the patient’s coping strategies.¹⁰¹ Besides exercise programs, some preliminary evidence exists to suggest that creatine supplementation may increase isometric power in patients with ALS over the short term.¹⁰² Modafinil has been noted to have potential in helping with severe fatigue in ALS.¹⁰³

Many studies focus on the impact of exercise on muscle strength; however, knowledge of impairments does not necessarily correlate directly with functional status.

TABLE 17-2 ■ SUMMARY OF STRENGTH TRAINING STUDIES IN NEUROMUSCULAR DISEASES

AUTHOR	STUDY POPULATION AND SAMPLE SIZE	DURATION OF TRAINING	TRAINING MODALITY	TRAINING PROTOCOL	RESPONSE(S)
Vignos and Watkins, 1966 ²⁹¹	Various neuromuscular diseases (NMDs) (24)	12 months	Weight training (multiple muscle groups)	Unspecified, but based on 10-repetition maximum (RM)	Strength increased; percentage increase correlated with initial strength
Milner-Brown and Miller, 1988 ⁸⁸	Various NMDs (12)	>12 months (variable)	Weight training (elbow flexion and knee extension)	Initially one set of 10 reps based on 15 RM performed on alternate days; gradually increased to a maximum of five sets 4 days/week; protocol individualized	Strength increased significantly when the initial degree of strength loss was not severe (<10%)
McCartney et al, 1988 ²⁹⁷	Various NMDs (12)	9 weeks	Weight training (arm curl and leg press)	3 days/week; initially two sets of 10-12 reps at 40% of 1 RM; gradually progressed to three sets of 10-12 reps (one set at 50%, 60%, and 70% of 1 RM); contralateral arm control	Strength and muscular endurance increased; considerable inter-subject variability
Aitkens et al, 1993 ⁸⁹	Slowly progressive NMD (27) and able-bodied controls (14)	12 weeks	Weight training (elbow flexion, knee extension, grip one side only)	3 days/week; resistance at 30% of 1 RM; work increased commensurate with ability	Significant improvement in most isokinetic strength measures (not grip) in both groups; cross-training effect
Kilmer et al, 1994 ⁹⁰	Slowly progressive NMD (10) and able-bodied controls (6)	12 weeks	Weight training (elbow flexion, knee extension, one side only)	3-4 days/week; high-resistance exercise (resistance based on 12 RM; progressed from one to five sets of 10 reps)	Results mixed; increase in leg strength but decrease in arm strength in NMD
Lindeman et al, 1995 ³²⁵	MD (33) and HMSN (29); nonexercise control group	24 weeks	Weight training (knee extension and flexion, hip extension and flexion)	3 days/week; initially three sets of 25 reps at 60% of 1 RM; progressed to three sets of 10 reps at 80% of 1 RM	In MD group, no change in strength In HMSN group, increased strength of knee extensors; no adverse effects
Drory et al, 2001 ⁹³	ALS (25): randomly assigned to treatment or control groups	24 weeks	Moderate load, trunk and limbs, concentric contractions	Twice daily, 15 min per session	Treatment group: maintenance of strength, less fatigue, less spasticity, less pain, higher function
Aksu et al, 2002 ⁹²	ALS (26): convenience assignment to treatment and control groups	8 weeks	Breathing exercises, PNF, stretching, vs stretching and ROM and breathing exercises	3 days/week supervised vs home	Increased ROM, strength in treatment group; function sustained better in treatment group
Dawes et al, 2006 ³²⁶	Various NMDs: 11 randomly allocated to control group, nine to treatment group	8 weeks	Walking and strengthening exercises	Walking for 20 min at light to moderate intensity alternating days with progressive resistance and repetitions in strength	Treatment group had increase in leg muscle strength; no change either group in 2-min walk test

TABLE 17-2 ■ SUMMARY OF STRENGTH TRAINING STUDIES IN NEUROMUSCULAR DISEASES—cont'd

AUTHOR	STUDY POPULATION AND SAMPLE SIZE	DURATION OF TRAINING	TRAINING MODALITY	TRAINING PROTOCOL	RESPONSE(S)
Dal Bello-Haas et al., 2007 ⁹⁴	ALS (27 early stage): randomly allocated to resistance exercises plus stretch or just stretch groups	24 weeks	PT-prescribed resistance exercises performed at home to patient tolerance	3 days/week resisted exercise plus stretch vs just stretch group	Slowed decline in treatment group and small strength gains

HMSN, Hereditary motor and sensory neuropathy; MD, myotonic dystrophy; PNF, proprioceptive neuromuscular facilitation; PT, physical therapist; ROM, range of motion.

Although some research has shown improvements in muscle force production with strengthening and endurance training, associated functional improvements were evident in some studies⁹² but not others.¹⁰⁴ Jette and colleagues⁸² calculated the percentage of predicted normal maximal isometric force (%PMF) relative to four walking levels in patients with ALS: unable to walk, walking within the home only, walking in the community with assistance, and independent walking in the community. Although they found great variation in muscle force production between and within the different levels of walking for each patient, they demonstrated that relatively small changes in force production were associated with losses of functional levels. For example, on average, when an independent ambulator began to need assistance in the community, the lower-extremity strength dropped to less than 54%PMF. When the patient became an in-home ambulator only, the average strength dropped to approximately 37%PMF, and it was approximately 19%PMF when the patient was no longer able to walk. Jette and colleagues⁸² acknowledge that many factors need to be considered when interpreting their work; however, their study relates functional skills to isometric muscle force production in a concrete way. Factors such as spasticity, age at onset of ALS, prior levels of fitness and activity, and psychological factors, including past responses to extremely challenging situations and satisfaction with social support, must also be considered.

Based on the evidence and current practice, exercise prescription in the early stages of ALS should address the following⁷²:

1. To improve compliance, include both a formal exercise program and enjoyable physical activities.
2. Include activities with opportunities for social development and personal accomplishment.
3. Strengthening programs should emphasize concentric rather than eccentric muscle contractions; use moderate resistance rather than high resistance; and focus on muscles that have at least antigravity strength.
4. Endurance programs should be monitored for signs of fatigue, more so when continuous activity lasts longer than about 15 minutes. Activity programs should include rest periods.
5. Patients should ensure that they have adequate oxygenation, aeration, and carbohydrate loads⁷³ as well as adequate fluids before exercising.
6. Muscle strength must be monitored to assess for possible overwork weakness; in unsupervised programs,

patients must be instructed about signs and symptoms that indicate overwork, including feeling weaker within 30 minutes after exercise, having excessive soreness 24 to 48 hours after exercise, and experiencing severe muscle cramping, heaviness in the extremities, or prolonged shortness of breath¹⁰⁵; and therapists should check with an independently exercising patient regularly to assess whether any deterioration in strength may be from progression of the disease or overwork weakness.

If a patient shows evidence of significant, persistent weakness after institution of an exercise program or persistent morning fatigue after exercise on the previous day, the therapist must carefully redesign the patient's exercise program and activity level and increase the frequency of monitoring the patient's program. The program must be adjusted as the disease progresses. Figure 17-3 is a diagram showing the appropriate exercise "window" for use in working with a patient with a neuromuscular disorder.

Therapeutic Interventions

Maintenance of strength and endurance requires daily activity and repetitive muscle contractions. In normal persons, absence of muscle contraction can result in decreases of 3% to 5% in muscle strength per day. If the patient's exercise level requires less than 20% of the maximal voluntary contraction of the muscles, a decrease in strength will occur; yet overwork must be avoided.¹⁰⁶

Sinaki¹⁰⁷ has described three phases and six substages of ALS with recommended exercise levels (Box 17-2). Although therapists should not assume that all patients will fit precisely within the stages as described, the stages do provide sugges-

Figure 17-3 ■ Exercise window for normal and damaged or denervated muscles. (From Coble NO, Maloney FP: Effects of exercise on neuromuscular disease. In Maloney FP, Burks JS, Ringel SP, editors: *Interdisciplinary rehabilitation of multiple sclerosis and neuromuscular disorders*, New York, 1985, JB Lippincott.)

BOX 17-2 ■ EXERCISE AND REHABILITATION PROGRAMS FOR PATIENTS WITH AMYOTROPHIC LATERAL SCLEROSIS ACCORDING TO STAGE OF DISEASE**PHASE I (INDEPENDENT)****Stage 1****Patient Characteristics**

Mild weakness
Clumsiness
Ambulatory
Independent in activities of daily living (ADLs)

Treatment

Continue normal activities or increase activities if sedentary to prevent disuse atrophy
Begin program of range-of-motion (ROM) exercises (stretching, yoga, tai chi)
Add strengthening program of gentle resistance exercises to all musculature with caution not to cause overwork fatigue
Provide psychological support as needed

Stage 2**Patient Characteristics**

Moderate, selective weakness
Slightly decreased independence in ADLs, such as:

- difficulty climbing stairs
- difficulty raising arms
- difficulty buttoning clothing

Ambulatory

Treatment

Continue stretching to avoid contractures
Continue cautious strengthening of muscles with manual muscle testing (MMT) grades above F+ (3+); monitor for overwork fatigue
Consider orthotic support (e.g., ankle-foot, wrist, thumb splints)
Use adaptive equipment to facilitate ADLs

Stage 3**Patient Characteristics**

Severe selective weakness in ankles, wrists, and hands
Moderately decreased independence in ADLs
Easily fatigability with long-distance ambulation
Ambulatory
Slightly increased respiratory effort

Treatment

Continue stage 2 program as tolerated; use caution not to fatigue to point of decreasing patient's ADL independence
Keep patient physically independent as long as possible through pleasurable activities such as walking
Encourage deep breathing exercises, chest stretching, postural drainage if needed
Prescribe wheelchair, standard or motorized, with modifications to allow eventual reclining back with head rest, elevating legs

PHASE II (PARTIALLY INDEPENDENT)**Stage 4****Patient Characteristics**

Hanging-arm syndrome with shoulder pain and sometimes edema in the hand
Wheelchair dependent
Severe lower-extremity weakness (with or without spasticity)
Able to perform ADLs but fatigues easily

Treatment

Heat, massage as indicated to control spasm
Preventive antiedema measures
Active assisted passive ROM exercises to the weakly supported joints; caution to support, rotate shoulder during abduction and joint accessory motions
Encourage isometric contractions of all musculature to tolerance
Try arm slings, overhead slings, or wheelchair arm supports
Motorized chair if patient wants to be independently mobile; adapt controls as needed

Stage 5**Patient Characteristics**

Severe lower-extremity weakness
Moderate to severe upper-extremity weakness
Wheelchair dependent
Increasingly dependent in ADLs
Possible skin breakdown as a result of poor mobility

Treatment

Encourage family to learn proper transfer, positioning principles, and turning techniques
Encourage modifications at home to aid patient's mobility and independence
Electric hospital bed with antipressure mattress
If patient elects home mechanical ventilation (HMV), adapt chair to hold respirator unit

PHASE III (DEPENDENT)**Stage 6****Patient Characteristics**

Bedridden
Completely dependent in ADLs

Treatment

For dysphagia: soft diet, long spoons, tube feeding, percutaneous gastrostomy
To decrease flow of accumulated saliva: medication, suction, surgery
For dysarthria: palatal lifts, electronic speech amplification, eye-pointing electronics
For breathing difficulty: clear airway, tracheostomy, respirator if patient elects HMV
Medications to decrease impact of dyspnea

Modified with permission from Sinaki M: Exercise and rehabilitation measures in amyotrophic lateral sclerosis. In Yase Y, Tsubaki T, editors: *Amyotrophic lateral sclerosis: recent advances in research and treatment*, Amsterdam, 1988, Elsevier Science.

tions for interventions on the basis of degree of impairment, functional limitations, and level of disability. In the following section, staging patterns are used as the framework for therapy interventions. Staging information is particularly helpful to therapists who do not have the opportunity to work with large numbers of patients with ALS.

Most patients need specific guidance about what type of activities and exercises they should do.⁶¹ Although many physicians may suggest to patients that they increase their activity level, their suggestions are seldom specific. Examples of exercise advice that patients have recalled are “Try to move around as much as possible,” “Walk some more,” and “Be active, but don’t overdo it.” Because changing their typical exercise pattern is difficult for most patients, even when they know doing so is important, referral for a physical therapy consultation can be helpful.¹⁰⁸

Phase I (Independent): Stages 1 to 3. A program to increase activity must be specifically designed, with input from the patient about willingness to participate and knowledge of the patient’s environmental situations and social support systems. In the early stages of the disease, patients should be encouraged to continue as many prediagnosis activities as tolerated. For example, a golfer should continue to golf for as long as possible. Walking the course should be encouraged if it is not too fatiguing. When walking or balance becomes difficult on uneven terrain, the golfer can use a golf cart, decrease the number of holes played, move to a par 3 course, or hit balls at a driving range. If upper-extremity weakness is a major problem that interferes with swinging the club for distance shots, the player can continue playing the greens or on putting courses. Some golfers may need adaptations to club handles with nonskid material such as Dycem (Dycem Non-Slip products, www.dycem.com) or Scoot-Gard (Vantage Industries Product) to prevent the club from rotating on impact.

Patients with newly diagnosed ALS who had a sedentary lifestyle before diagnosis should be encouraged to increase their activity level. This may include activities that require muscular effort within or around the home, such as sharing household and gardening tasks or beginning a walking program around the neighborhood. After diagnosis, some patients begin searching for in-home exercise devices such as bicycles and rowing machines. As with healthy persons who start an exercise program after the purchase of exercise equipment, patients with ALS are not likely to use the equipment consistently if they did not before a diagnosis. The search for a “perfect” exercise machine may reflect the patient’s desperation to do something tangible. Without taking away the patient’s motivation to exercise, therapists can encourage participation in exercise programs that do not require expensive equipment, such as walking or working out to specific exercise routines. A clever therapist can make a video for each patient that includes stretching and gentle exercise programs that elicit muscle contractions from all functional muscle groups (by using inexpensive elastic bands or small weights) with follow-up breathing, “warm down,” and relaxation exercises. Patients could follow a program of six maximal isometric contractions held for 6 seconds and isotonic elastic band exercises at submaximal levels to maintain and improve muscle strength.¹⁰⁹ Patients should exercise for short periods several times a day rather than attempting to exercise all muscle groups in one session.

For most patients in the early stages of ALS, pleasurable, natural activities such as swimming, bowling (can gradually decrease weight of ball if shoulder strength is a problem), walking, bicycling (three-wheeler may be needed or in-home stationary bicycle, either of which must be evaluated for easy mounting and dismounting), or tai chi should be recommended. Some patients prefer to exercise alone, whereas others will gain confidence and companionship by joining a group activity. Listening to the patient’s desires related to group activities is important. The dropout rate is high among those who have been pressured to participate. Some spouses or family members are supportive of the patient’s activity needs and will join the patient in his or her regimen. If possible, the spouse and family members should be engaged in the treatment planning process.¹¹⁰

The therapist must observe the patient completing her or his entire recommended activity program. The patient’s response to the program must be monitored because fatigue from exercise sessions can interfere with the ability to carry out other normal daily activities. If the patient becomes too exhausted at the end of a session, he or she may learn to fear exercise and may become depressed about the decreased activity status. This depression may lead to decreased activity and further deconditioning (see Chapter 6).

Phase II (Partially Independent): Stages 4 and 5. During phase II, the goal of physical and occupational therapy intervention should be to help the patient adapt to limitations imposed by weakness and spasticity, an increasingly compromised cardiorespiratory status, and possible pain from stress related to weakness or muscle imbalance. This transition stage is often frightening for patients because the decrease in function and independence becomes clear; therapists should accentuate what the person can do and how accommodations can be made to help maintain independence. After a full physical assessment of the patient’s motor status similar to the initial evaluation, the patient, family members, and therapists (including PT, OT, and speech therapist if a team approach is possible) should discuss treatment options and adaptive devices that can help the patient remain as independent as possible.

During late phase I and through phase II, many patients show significant weakness of both upper- and lower-extremity musculature, but each patient has his or her own pattern and rate of progression of weakness and onset of spasticity, bulbar, and respiratory symptoms. A typical patient at this time may have marked weakness of the intrinsic muscles, shoulder muscle weakness (in some cases “hanging arm” syndrome) with shoulder pain, and generalized lower-extremity weakness (in some cases more severe distally). Patients may be able to walk within the home environment, but many patients have precarious balance and fall easily because of muscle weakness. At this stage, most patients report fatigue with minimal work and have to rest frequently when carrying out ADLs. ROM can deteriorate quickly in this phase of the disease, requiring daily stretching to end range for the calf, quadriceps, hip adductors, trunk lateral flexors, and long finger flexors.²⁹ Moderate exercise can have a modest effect in reducing spasticity.⁹³

Patients at this point, even if ambulatory, should consider using a wheelchair outside the home to conserve energy.⁷² Factors to consider in choosing a wheelchair include extent of insurance coverage or financial assistance

programs for purchase of wheelchair (some policies or programs may provide only one type of wheelchair or only one wheelchair, either motorized or manual); transportability of motorized chair from home to community and work (few motorized wheelchair brands fold for stowing in car trunk, and few families can afford to purchase a van that will allow the patient to drive or be driven while in a motor chair); reclining potential of chair back and headrest (preferably electric) to allow the patient to shift weight and rest while in the chair during later stages of the disease; removable arm rests for ease of transfer; potential for headrest attachment or extension; potential mounting area for portable respirator equipment if needed; and ease with which caregiver can help patient with chair mobility transfers.⁷² Chairs should have lumbar support and appropriate cushioning to prevent pressure ulcers.¹⁰⁵

At this stage, patients with more advanced bulbar symptoms begin to experience dysarthria and may need guidance in dealing with communication issues. Murphy¹¹¹ indicated four major reasons for communication: to identify needs or request help, share information, respond politely in social situations, and maintain social closeness. The primary focus of communication for the study participants was to maintain social closeness. Although few patients had any instruction in ways to deal with communication problems, most patients and caregivers created ways to make themselves understood, such as giving cues about the topic and context, creating a “shorthand” language, and checking with the dysarthric speaker to ensure that the listener understands the patient correctly. A number of patients in the study who had significant dysarthria commented that attempting to communicate socially was extremely tiring. Therapists who are guiding patients with

energy conservation techniques should be aware of the exhaustion that can be associated with communication. A number of strategies recommended by the American Speech-Language-Hearing Association¹¹² can be used by the person with ALS to deal with the effects of dysarthria, including the following:

- Reduce background noise in the room.
- Face the person while talking.
- Use short, simple phrases rather than long, complicated ones.
- Take the time to say what needs to be said; do not allow people to rush conversation.
- Make extra use of body language, such as gestures and facial expressions, and use writing to supplement speech, if possible.
- Do not worry about saying things correctly; if the basic message being conveyed is understood, then that is enough.

Also in this stage, some patients and families may need support to identify adapted feeding systems (special utensils, adapted plates, adjustable tables) and hygiene equipment if transfers within the family bathroom are problematic.¹¹³

Because Mr. Turner in [Case Study 17-1](#) was cared for in a neuromuscular disease clinic, he benefited from input from multiple specialists working as a team to help him maintain his independence. Unfortunately, many patients do not have the benefit of such a coordinated treatment environment. Therefore, when necessary, the therapist must be in a position to provide input on adaptive and safety devices and bulbar issues if other specialist input is not available. Therapists working in smaller communities and rural areas most likely need to be chameleon-like to play many therapeutic roles when working with the patient with ALS.

CASE STUDY 17-1 ■ MR. TURNER

Mr. Turner is a 45-year-old man diagnosed 2 years ago with ALS. He lives at home with his wife, who works full time, and two teenaged children. Mr. Turner is a computer programmer for an engineering firm in the area. Since his diagnosis, Mr. Turner has been able to continue his full-time work schedule, although he states that he is no longer able to touch type and can type with the index fingers only. He has noticed that his shoulders and neck hurt (4 out of 10 on a numerical pain rating scale) after an hour at the computer. In the last 2 weeks he has found it fatiguing to walk to the cafeteria for lunch (approximately 100 meters), and he fears that he will be knocked down when walking in crowds. He dropped his tray last week, which was embarrassing, so he decided to eat in his office even though he misses the socialization and opportunity to discuss work issues with his colleagues.

Mr. Turner has been able to continue most of his nonwork activities, although he is no longer able to operate his sailboat independently and is having trouble maintaining his balance when golfing. Also when golfing, he now uses a cart and plays only nine holes. He states that his wife and children are supportive and that they have made some changes in the home environment to accommodate his increasing weakness. He also revealed, however, that his children seem frustrated with him because he is so much slower than he was before the illness.

On assessment, Mr. Turner showed marked wasting of hand intrinsics. He was unable to abduct or flex either shoulder past 90 degrees. His right shoulder showed considerable atrophy, especially of the deltoid and supraspinatus muscles. All other upper-extremity movements were weakened but in the G- (4-) range. His neck posture was forward: neck extension is F+ (3+), neck flexion is G- (4-). Scapular winging was noted bilaterally. No spasticity or loss of passive ROM was evident in the upper extremities. Lower-extremity musculature showed generalized weakness at the F (3) to F+ (3+) range, with left musculature weaker than right, marked wasting of the foot intrinsics, and a cavus foot position bilaterally. Spasticity of the hip adductors and hamstrings was noted (Modified Ashworth Scale grade 2), but no passive ROM loss was detected in the lower extremities. Most obvious during gait was inadequate dorsiflexion for heel strike and no propulsion during heel-off. He showed a bilateral corrected gluteus medius pattern on weight bearing. He needed to pause to lock each knee during weight bearing and at times he pushed his knee into extension with his hand. He had great difficulty ascending and descending the four steps to enter his home. There were no stairs to negotiate at work.

Until this appointment, Mr. Turner had not been willing to discuss the use of adaptive equipment or a wheelchair. During

Continued

CASE STUDY 17-1 ■ MR. TURNER—cont'd

prior clinic visits his decisions were supported and he was told that when he was ready, therapists would work with him and his family to help with equipment decisions.

Mr. Turner also showed some early bulbar signs. He noted that he sometimes had to catch drool when working intensely, and that his pillow was moist in the morning. Food sometimes got stuck in his cheek area and he could not move it out with his tongue. Swallowing was still adequate for eating all foods; however, he had had a few coughing episodes when drinking coffee and wine. He showed increased use of accessory musculature when breathing but had no reports of respiratory distress. His cough was adequate to clear secretions.

With input from the therapist, Mr. Turner and his wife identified the following general goals:

1. Increase mobility while conserving energy
2. Control fatigue and pain of upper extremities and neck during computer work
3. Maintain maximal muscle strength and ROM (patient reported that he felt stiff)
4. Identify safety issues within the home and work environment and adjust household and work environment to prepare for the time when Mr. Turner could not ascend and descend stairs safely

A treatment plan was discussed to achieve the following:

1. Increase mobility. Because of his increased walking difficulties, Mr. Turner decided to use a front-wheeled walker with a seat attachment at home. Because of his hand grip weakness, he felt most stable using attached forearm troughs. For his worksite, he selected a motorized wheelchair so that he could maintain his independence at work. Although he found that he could push an ultralight manual chair, his upper-extremity strength was clearly decreasing. Mr. Turner decided that he preferred the motorized chair to an electric scooter because of the financial cost of switching devices when the scooter no longer provided adequate postural support.

Because Mr. Turner's insurance and Medicare would not fund an additional manual chair and because the family had no way to transport the electric wheelchair, the ALS Society loaned the family a manual wheelchair for home use. Although not ideal, it was functional. Mr. Turner's son made some inexpensive adjustments to adapt the chair for a headrest, and his daughter and grandchildren repainted the chair to his specifications.

Because Mr. Turner wanted to keep as active as possible and use his walker within the home, he was fitted with bilateral ankle-foot orthoses (AFOs) with a flexible ankle joint and pretibial shell to facilitate knee extension. Straps were simple overlap style because Mr. Turner had poor thumb and grasp control.

2. Decrease fatigue and pain of upper extremities. Mr. Turner was taught some simple ROM exercises of the neck and arms to perform every half hour while working at the computer. In a simulated work environment the therapist noted that Mr. Turner had a forward head position when working at a computer similar to his workstation. The height of the computer was adjusted to decrease his neck strain, and the desk height was adjusted to allow his wheelchair to fit under the desk so that his arms could rest fully on the surface.

He felt immediate relief with the adaptations. He was also fitted for a soft neck collar to wear when he felt he needed more neck support. (As his condition worsened, he learned to rest his head on the headrest of his chair and recline slightly for a few minutes every 15 minutes.)

3. Maintain maximal muscle strength and ROM. Mr. Turner was taught as many self-ranging maneuvers as possible, which he was encouraged to do in small segments frequently throughout the day. For example, his series of motions included neck rotations, side bends, and flexion and extension within strength limits; upper-extremity motions with the exception of shoulder flexion and abduction past 90 degrees; hip flexion, abduction, and rotations; full knee extension; and all ankle motions. When using the walker, Mr. Turner was encouraged to extend each hip fully and to stretch his heel cords. Mrs. Turner and their adult children were taught to administer full ROM exercises, including trunk rotations, with special attention to ranging of the shoulder to prevent impingement. Simple massage techniques were also taught to all family members who felt comfortable with the task.

Mr. Turner had been active before the onset of ALS and he liked to exercise. He rented a portable pedaling unit to attach to a chair at home. He pedaled two to four times a day, with no additional resistance, to the point at which he felt fatigue (usually 3 to 5 minutes at this stage). He carefully monitored his soreness and fatigue level after exercise and increased and decreased his pedaling depending on how he felt immediately and several days after exercise. Mr. Turner felt invigorated by this exercise, which he usually did while watching television. He was also taught a series of simple elastic band exercises, with tensile strength adjusted according to his ability to contract his muscles without fatigue. Mr. Turner was also shown a series of isometric exercises for all muscle groups to do throughout the work day. Because he had some foot and ankle edema, he was encouraged to wear lightweight pressure stockings while sitting. Mr. Turner also had access to a swimming pool, and he was encouraged to carry out walking and upper-extremity exercises as long as another adult was with him in the water at all times.

4. Assess environment of home and work. Occupational therapy input was requested to help with ADL aids such as reachers, utensil adaptors to facilitate grip, rubber pen grippers, key adaptors to permit turning, and thumb abduction splints to assist in pincer grasp. Mr. Turner's OT made several visits to his worksite and home to identify adaptations of the environment for safety and independence. His wheelchair was eventually adapted with universal joint arm troughs to decrease his effort during self-feeding and basic upper-body hygiene. Ramps were recommended for home entry, and nonpermanent safety rails were placed in the bathroom. Mr. Turner was able to assist with transfer to a shower chair, and the shower head was replaced with a handheld unit.

A speech pathology consultation was also requested. Using information from the PT's manual muscle testing, the speech pathologist carried out a thorough bulbar evaluation and provided information about swallowing

CASE STUDY 17-1 ■ MR. TURNER—cont'd

techniques. The speech therapist focused on ways to decrease drooling and ways to cope with food pocketing (tongue mobility was impaired) by using techniques such as hand pressure on the cheek to push food back to the center of the mouth. The therapist also instructed Mr. Turner and his wife how to prepare foods with textures that were easily swallowed and manipulated. Mr. Turner had lost 5 pounds during the last 6 months, so he was also referred to the dietician for information about how to maintain nutritious calorie intake.

PROGRESSION OF THE DISEASE

Within 3 to 4 months after initial examination, Mr. Turner was no longer able to continue working despite workplace adaptations. At home, he became more dependent. Mr. Turner had great difficulty adjusting to his physical dependence. Because of his slow onset of dysphagia and his augmented communication system, he was able to continue control over his expressive, cognitive, and emotional life for another few months. Initially Mr. Turner angrily resisted his wife's attempts to help him with eating and dressing tasks. This began to alienate her and the children until a family meeting was held with their medical social worker and PTs and OTs. All family members had the opportunity to express their frustrations. A major irritation to the children was what they perceived to be their constant waiting for their father to complete a task. Mrs. Turner was most irritated when Mr. Turner yelled at her when she attempted to help even though he frequently expressed anger about his clumsiness. Mr. Turner sadly admitted that he was having increasing difficulty with his ADLs and was sometimes too tired after dressing to participate in family activities. At the end of the meeting, the family had worked out a compromise plan. Mr. Turner would continue to do as much as possible for himself. He would specifically ask for help from Mrs. Turner when he wanted it so she did not get caught in his anger about needing help. He preferred that the children not have to take any role in his care at this point but realized that he might need their help later. Visiting nurse support was requested twice a week to help with bathing, and the OT was requested to make another home visit to help with toileting needs. Mr. Turner felt comfortable with his wife and children carrying out ROM exercises. A therapy home visit was arranged to review the exercise and positioning program as well as respiratory exercises and postural drainage techniques.

As Mr. Turner became totally dependent, he needed 24-hour care. Professional nurses were provided through his insurance contract 14 hours a day from 6:30 AM to 8:30 PM. Family members provided care until midnight. Initially Mr. Turner was able to activate a bell at night to call for help. His wife and children followed a schedule to turn him every 3 hours throughout the night. When Mr. Turner became respirator dependent and was no longer able to call for help, it became clear that the nighttime responsibilities were taking a heavy toll on his wife, who worked full time, and the children, who were in high school and college. Fortunately the family was able to pay for a nurse assistant to remain at Mr. Turner's bedside throughout the night, although the family members all felt that they had no privacy. Although the family was committed to having Mr. Turner remain at home until his death, all agreed that they needed respite. Thus several week-long hospitalizations were made to give the family a break in the constant care needs.

Although Mr. Turner had elected HMV, he also had signed a durable power of attorney for health care, indicating that he did not want treatment for infections and that palliative care for comfort should direct his treatment. He had a strong lust for life, but he had come to accept his impending death. He did not have strong religious views, but he had talked with all his caregivers and therapists about his concerns related to death. He freely expressed his fear of "nonbeing." Because his caregivers and therapists were willing to talk about his and their own feelings, Mr. Turner came to believe that he would live on in the minds, hearts, and behaviors of those he had known. This idea seemed to give him great comfort. He particularly liked to talk to others about special times they had had together and how their interactions had affected each other. To help Mr. Turner process his death, his family, friends, and medical team put together an album of pictures and statements about their time together. Mr. Turner frequently liked to have his wife read through the book with him. His family continued to carry out his ROM exercises and massage because Mr. Turner had indicated that the treatments provided him physical comfort and the spiritual closeness he needed with his family. His primary treatment during the last few days consisted of morphine to decrease his respiratory discomfort. After 5 to 6 months of being totally dependent for all care and respiratory function, Mr. Turner died at home in his sleep after a respiratory illness.

Phase III (Dependent): Stage 6. PTs and OTs are usually less involved in the care of the patient in phase III, and nursing personnel become more active. During this phase, therapists make home visits to support caregivers and respond to questions about pain control, bed mobility, positioning to prevent pressure ulcers, ROM, and equipment adaptations.^{29,72,105} Therapists should be sure to teach all caregivers some basic body mechanics to use during lifting and patient care activities. If possible, caregivers should be taught how to safely move the person with ALS from the bed to a reclining wheelchair or other reclining chair during specific times of the day so that the person can continue to be part of the family activities. However, the ease of caregivers in transferring and caring for the person in the wheelchair must also be considered. Although some patients want

to be in the midst of family activities even when dependent on HMV, other patients feel uncomfortable with their dependency and appearance and are reasonably content to stay in their room with television and visits from family members. This highly personal decision by patients must be respected. The therapist should review ROM procedures with family and professional caregivers and provide splinting or positioning devices if spasticity or paralysis leads to caregiving difficulties (e.g., excessive adductor tone and contractures interfering with hygiene and bowel care) or tissue damage and pain. If nursing care providers do not give advice on pressure relief beds or mattresses of air or foam,¹⁰⁵ therapists should be prepared to do so. Unfortunately, many insurance providers and Medicare may not fund special mattresses, and they can be costly. Therapists

may also need to review postural drainage techniques with caregivers.

Of greatest importance in phase III, and sometimes in earlier stages, is the patient's ability to communicate. In the earliest manifestation of dysarthria, therapists train patients to slow the speech rate and cadence, exaggerate lip and tongue movements, and manage phrasing through breath control.⁸³ Although spouses and caregivers can often interpret their partner's or patient's severely dysarthric speech (see earlier discussion of phase II), most patients who use NIV or invasive ventilation for a prolonged period need to find nonverbal methods to communicate. If severe bulbar impairments precede extremity paralysis, paper and pencil, alphabet and word boards, and adapted computer keyboards can be used with minimal upper-extremity or finger strength for pointing. The American Speech-Language-Hearing Association provides suggestions for developing communication boards with the specific language most appropriate for the patient's situation.¹¹² For example, the board may be designed with commonly needed sentences, words used in the person's daily life, and the alphabet. As the person's ability to finger point decreases, the language board can be redesigned. When no extremity movement is possible, subtle neck movements or pressures, eye gaze, eye blink, upper facial movements, and electroencephalographic activity can be harnessed to operate communication devices.^{114,115} Learning to use electroencephalographic interfaces, however, takes months of intense training and may not provide a reasonable system for communication for most patients with ALS.¹¹⁶

Some patients with hypernasality benefit from using an orthodontic palatal appliance. Patients with a tracheostomy may benefit from use of a Passy-Muir (Irvine, Calif) speaking valve tracheostomy tube. These devices require recommendation by communication specialists. As speech quality deteriorates and sound projection wanes, the spouse or caregiver can use an electronic speech amplifier to magnify the patient's speech. Speech pathologists and therapists have information on commercially available amplifying devices that are often used by persons with hearing problems but can be used by hearing people to amplify the speech of a person with severe weakness of phonation.

When selecting a communication device, therapists must work closely with the patient and family members to ensure that the system is compatible with patient skills and communication needs and preferences. Expensive systems commonly lie unused because of simple factors such as lack of proximity to the patient, interference of the unit with personal care, increased caregiver workload to manage the unit, and slowness of communication processing. The best systems are tailored to the precise needs of the patient; however, many patients do not have the financial or insurance support to purchase the device, and many patients in the end stages of ALS do not have the time to wait for systems designed for their specific needs. Therefore commercially manufactured systems may be most appropriate. (See Cook and Hussey¹¹⁴ for a comprehensive list of communication devices and control interfaces.)

Some patients and caregivers learn to communicate effectively with simple eye gaze, eye blinking, and clicking techniques with Morse code or self-developed codes. At minimum, patients with no ability to communicate or move

and their caregivers must have some system to communicate emergency needs; for example, looking to the right means "help" and looking to the left means "pain." Therapists should help patients develop alternative modes of communication before intelligible speech becomes impossible. (See also Cobble¹¹⁷ for information on language impairments.)

In addition to communication systems, environmental control systems can be programmed to turn on and off television, lights, and other electronic units with the same type of switching units used for communication (e.g., eye blink, infrared beam, head movement pressure). Unfortunately, these devices are often expensive and may not be available to all patients. (See Cook and Hussey¹¹⁴ for a comprehensive review of environmental control systems.) Financial support is often not extended for high-tech equipment by third-party payers because of the patient's limited life expectancy. The ability to communicate and call for help, however, is of paramount importance with completely dependent patients.

By phase III most patients have significant problems eating and maintaining nutrition, although these problems may manifest in earlier stages. Patients often report choking or coughing after swallowing liquids or problems moving food around in the mouth or to the back of the throat for swallowing. These problems are best handled medically and can be assessed with videofluoroscopy or videoendoscopy. The aggressiveness of treatment intervention depends on the patient's preference and whether she or he still wants to attempt any oral feeding (e.g., syringe feeding, oral gastric tubes) or wishes to have a PEG or another alternative to oral feedings implemented. Therapists, however, can help patients and caregivers develop strategies that improve eating and nutrition, such as adjusting eating position, changing head and neck alignments, adding thickeners to liquids, and adjusting portion sizes and texture of foods.⁷

Psychosocial Issues

Giving the bad news of a terminal diagnosis is difficult for even the most experienced clinician. In dealing with the diagnosis of ALS, most physicians now believe that the diagnosis, prognosis, and possible patterns of progression should be shared with the patient and family or partners and caregiving friends. Only by knowing the truth can patients and families deal openly with one another and make plans for the future.¹¹⁸ McCluskey and colleagues¹¹⁹ suggest that those giving the medical or therapeutic diagnosis should attend to good practice parameters when giving bad news, such as creating the appropriate setting, identifying patient and caregiver needs, asking what patients and caregivers want to know, providing knowledge, exploring feelings of the patients and caregivers, and formulating a strategy for dealing with the situation. Patients and family members seldom remember what they are told when first given a terminal diagnosis. They do, however, remember how the information was given. Therefore information should be given honestly but with a sense of hope. All information need not be given at the time of diagnosis. Rather, the patient and family can be exposed to more in-depth information over a number of sessions when they have the opportunity to ask questions that occur during the assimilation process. Therapists, especially those working in isolation from a comprehensive clinic, should also follow these guidelines by

providing information, helping the patient and family identify goals, and establishing a plan for intervention. Patients should know that the goals will have to be adjusted and plans reset as the disease process continues. If patients and families know that they can contact the therapist for support and advice, many of the negative aspects of the illness can be confronted in a positive manner. Preferably, an appointment for a follow-up visit will be set so patients and family members feel that contact with the care provider is expected.

Information about transitions related to nutrition, communication, and respiratory functions should be delivered to patients and families in time to make thoughtful decisions rather than just before a time of crisis, such as after a choking episode or during a respiratory arrest. Care should also be taken to respect the cultural and spiritual views of the patient and family.⁵⁸ Preferably, patients and family members will prepare an advance medical directive that should be reviewed with the physician at least every 6 months.¹²⁰

Therapists treating patients who do not have access to a multidisciplinary ALS clinic should remember that they are often the person who works most closely with the patient, and they should plan on spending enough time with the family to respond to concerns and help with problem solving. Patients will progress through the diagnostic process with different responses and at different rates on a continuum from taking a cognitive approach by asking many questions and reviewing the most current research to the extreme of marked denial and disinterest in participating in any medical or therapeutic recommendations.

Purtilo and Haddad¹²¹ identified four major fears of the patient who has a terminal condition: fear of isolation, fear of pain, fear of dependence, and fear of death itself. Patients with progressive diseases often see their social contacts decrease. Mr. Turner in Case Study 17-1 was concerned when he was no longer able to join his colleagues in the company cafeteria. After he received his motorized wheelchair he was able to continue his social contacts until his bulbar symptoms progressed to a point that he chose not to eat in public. When Mr. Turner lost the ability to speak and had to use his computerized speech system, he noticed that fewer colleagues stopped by his office to talk because of the slowness of the communication process. Although he understood the problem, Mr. Turner mourned the loss of friendship and his loss of standing as a competent computer expert. Because of his need for social contact, Mr. Turner continued to work until he could no longer tolerate the sitting position. His fear of isolation increased when he became homebound. Although colleagues came for visits regularly at first, as Mr. Turner progressed to a near locked-in state only a few close friends came by for brief visits. Mr. Turner's greatest fear was being separated from his family and abandoned to hospital care with inconsistent staffing patterns. Fortunately, in his community, Mrs. Turner was able to set up visitations from several church members, clerics, and hospice volunteers.

Fear of uncontrolled pain is common among people with terminal diseases. Patients need assurance that their pain will be controlled. Fortunately, today pain medications can be administered in many forms, dosages, and frequencies that can be tailored to the patient's specific needs. In a study of the final month of life with ALS, caregivers reported that a major emphasis of care was to eliminate as much pain and discomfort as possible, even if it shortened the patient's

life.¹²² Keeping a pain log of intensity, type, location, and time of pain may provide the physician with information necessary to best prescribe dosages. Many patients with ALS do experience significant pain from musculoskeletal sources, persistent spasms, or spasticity and pressure sores. Most of these problems can be handled with appropriate pain medications, muscle relaxants, careful positioning, frequent ROM exercises, and tissue massage. Undertreated and uncontrolled pain is associated with a patient's seeking information on assisted suicide.¹²³ Some patients who expressed interest in assisted suicide options did not follow up because of religious beliefs and concerns about possible loss of life insurance coverage for surviving family members.¹²⁴

A major concern of patients with ALS is the dependence necessary for ADLs associated with late phase II and phase III of the disease. Because the process is gradual, most patients have the opportunity to make adjustments. The dependency issues and resulting privacy issues are more uncomfortable for some patients than for others, especially for the person who has always valued self-control and independence. Some patients are concerned about their increasing dependence because of the consequences of increasing burden of care on spouses or other caregivers.¹²⁵ That concern for others sometimes causes patients to choose hospital, nursing home, or in-patient hospice care over home care during the terminal stage of the disease. Not all patients with terminal illness react the same way during the dying process. Throughout the process, patients and family members may cycle back and forth through a range of different emotional and coping reactions: depression, anger, hostility, bargaining, and acceptance and adaptation (order is not implied).¹²¹ How the patient coped with life's difficulties before the illness and her or his prior relationship patterns often direct how the patient will deal with the terminal illness. In one study, patients adjusted most successfully to the changes in their functional status if they did not look back to the past and compare their losses to their future.¹²⁶

Health care providers and family members often have great difficulty coping with a patient who is depressed; they may make repeated efforts to "talk the person out of" the depression. Medical professions must be able to distinguish between depression that can be destructive and the mourning or grieving that is a necessary and vital response to dealing with loss. In both states the person may feel a level of withdrawal, sadness, apathy, loss of interest in activities, and cognitive distortions. In a depressive state, however, the patient experiences an accompanying loss of self-esteem. A person in mourning rarely experiences that loss of self-esteem essential to a diagnosis of depression. The grieving person's feelings are congruent with the degree of loss experienced.¹²⁷ A person who grieves for what is lost but who has adapted to the prognosis may make plans for the impending death. Such behaviors are positive coping strategies. However, depressive symptoms related to hopelessness, uncontrolled suffering, and perceived burden on caregivers are more related to a choice for treatment discontinuance of feeding or ventilatory support.¹²⁴

The issue of depression is complicated by the pseudobulbar effect of emotional lability (inappropriate laughing and crying), which is manifested by approximately 50% of patients with ALS. This emotional lability is not under complete control of the patient and is often misunderstood by family members and caregivers. Although current treatment is antidepressant,

sant medications, underlying clinical depression may or may not be present that would respond to higher doses of antidepressant medication and counseling.¹²⁰

Yet, pressuring a patient who appears depressed to see a mental health clinician can lead to loss of trust if the patient is not comfortable talking about feelings or confiding in a counselor. Therefore, OTs and PTs and other persons involved in the direct care of a dying patient may find that their patients feel safer talking with nonprofessional counselors or psychotherapists about the burden of their care on family members or their own impending death. Rehabilitation personnel should, therefore, be aware of local options for in-home support services, palliative care, and end-of-life options and services and be prepared to listen to the patient's concerns if the patient expresses the need for emotional support.

Caregiver Issues

Often in the concern for the patient's needs, health care professionals pay little attention to the effect a person's degenerative illness has on other members of the family. ALS significantly affects the person's extended family because the patient gradually becomes increasingly dependent on family members, partners, or caregiving friends for physical care, social arrangements, cognitive stimulation, and emotional support. For some families, the spouse may have to take on additional work, return to work, or, in the case of some older women, join the workforce for the first time to deal with the financial stresses that occur when chronic illness invades the family unit. Family members must absorb the former family duties of the dependent person. For example, a spouse or child may have to handle all the cooking, cleaning, or other household chores or work to help support the family. Once the patient becomes dependent, the caregiver may need to reduce or discontinue employment to take care of the patient. All family members may have to become involved in the physical care of the increasingly dependent person with ALS.

Children of patients with ALS also have to deal with major changes in their lifestyle. Although they may love their parent who is sick, at some level most are frustrated with factors such as the need to provide physical care to parents. This is a difficult problem for children who have not had a positive relationship with that parent. Children living in the home of a parent who is dying of ALS also express frustration about the lack of privacy in their home when nursing personnel and attendants are present, interruptions in family and personal life plans, embarrassment because of the parent's appearance and dependency, lack of attention from the caregiving and working parent, and fear of financial crises (e.g., possible loss of home, no financial support for college).

The entire family is affected by the sick person's increasing dependency and impending death. In a small study of 11 family caregivers, many caregivers felt frustrated and resentful because their lives were consumed with the caregiving responsibilities. Most caregivers had adjusted to some degree after 2 to 4 years. Caregivers who adjusted most successfully learned to take time for themselves without guilt and to tap their social support systems for help.^{126,128} Similarly, 40 caregivers of young adults with severe disabilities reported being overwhelmed by the physical requirements of daily care and felt a severe loss of spontaneity in their lives.¹²⁹ They also reported a sense of isolation from everyday social interactions. Although they highly valued their

social support systems, they expressed frustration that few people offered instrumental or direct service support, such as respite care or help with medical appointments, housekeeping, or shopping. Despite the stresses of caregiving, the caregivers felt positive about their roles in helping the dependent adult by finding meaning in their acts of caregiving.¹²⁹ Fortunately, most families manage to cope with the process—the major contributing factor being the coping ability of families before the illness. To be really effective, the therapist working with the patient with ALS must be prepared to help families and caregivers find appropriate ways of coping with the emotional, social, and physical stress of caregiving. For example, therapists should present, without pressing, adaptive equipment options to patients when they first start to show impairment in functional ability. If shown how the equipment will help them maintain independence, most patients are receptive to its use. Even when presented in a positive way, however, a wheelchair or adaptive devices may be resisted long after the adaptations would facilitate mobility and ADLs. Therapists must be attentive to patients' feelings and fears at this time because use of a wheelchair heralds to many patients the beginning of the end.

Other factors that affect the family of a patient with ALS include medical insurance and differing levels of long-term care coverage. Some families are fortunate to have excellent coverage that provides extensive home nursing support, whereas other families are unable to cope with the financial stresses and must accept public assistance during the final stages of the disease. As opposed to Germany and Japan, which provide long-term nursing care insurance, in the United States financial stress on patients with ALS can reach more than \$150,000 per year for ventilation support at home.⁶³ Financial burden significantly impacts patient and caregiver decisions. (See [Case Study 17-1](#) and end-of-life issues resources at www.nlm.nih.gov/medlineplus/endof-lifeissues.html#cat1.)

GUILLAIN-BARRÉ Syndrome

Pathology and Medical Diagnosis

In the past 15 years a broad spectrum of inflammatory demyelinating polyradiculoneuropathies has been identified. GBS, or acute inflammatory demyelinating immune-mediated polyneuropathy, is the most common form of the disease. GBS affects nerve roots and peripheral nerves, leading to motor neuropathy and flaccid paralysis with possible sensory and ANS effects.¹³⁰ Purely motor forms and mixed motor and sensory forms of GBS have been identified.¹³¹ Unlike ALS, GBS usually has a good prognosis, with most patients returning to their prior functional status by 1 year after onset.

The incidence of GBS is approximately one to four cases per 100,000 persons. A variant form is acute motor axonal neuropathy, which, like GBS, has a good prognosis. Less common forms are acute motor and sensory axonal neuropathy, which has a less positive prognosis (and which some consider to be a distinct type of peripheral neuropathy); Miller-Fisher syndrome, with primarily cranial nerve symptoms, ataxia, and areflexia¹³²; and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), which causes progressive or relapsing and remitting numbness and weakness.¹³³ Epidemiological studies show that males are affected by GBS twice as often as are females.¹³⁴

Approximately 27% of patients with GBS have no identified preceding illness; however, more than two thirds had symptoms of an infectious disease 2 weeks before the onset of GBS symptoms. Although no consistent predisposing factors are known, evidence exists to support connections with *Campylobacter jejuni*, *Mycoplasma pneumoniae*, cytomegalovirus, and Epstein-Barr virus. In GBS the spinal roots and peripheral nerves are infiltrated with macrophages and T lymphocytes. Macrophages then attack and strip the myelin sheaths. In milder cases of GBS the axons are left intact and the nerves are remyelinated, typically in a matter of weeks.¹³⁵ However, in some cases, the axons also degenerate, with recovery dependent on axonal regeneration from intact elements, which takes months and may be incomplete.¹³⁵ In acute axonal motor neuropathy, macrophages invade the axon directly, leaving the myelin intact.¹³⁶ Some evidence exists in a substantial number of patients with GBS that axonal loss is related to long-lasting or permanent muscle weakness.^{137,138}

Because of damage to the myelin sheath, saltatory propagation of the action potential is disturbed, resulting in slowed conduction velocity, dyssynchrony of conduction, disturbed conduction of higher frequency impulses, or complete conduction block.¹³⁹ Partial conduction block is most often seen in the early stages of GBS, and the conduction block increases as the patient reaches a plateau. The most common conduction block findings are in the peroneal nerve, followed by the tibial nerve. Proximal conduction block is evident more often than distal conduction block. In axonal neuropathy, conduction block is more severe, and the number of functional motor units is decreased (Figure 17-4).¹⁴⁰ The diagnostic criteria for GBS are detailed in Box 17-3.

Clinical Presentation

GBS in both children and adults is characterized by a rapidly evolving, relatively symmetrical ascending weakness or flaccid paralysis. Motor impairment may vary from mild weakness of distal lower-extremity musculature to total paralysis of the peripheral, axial, facial, and extraocular musculature. Severe fatigue is present in 38% to 86% of patients with GBS, depending on the cutoff point used to define severity and the age of the sample, with a positive correlation between severe fatigue and age.¹⁴¹ Tendon reflexes are usually diminished or absent. Twenty percent to 38% of patients may require assisted ventilation because of paralysis or weakness of the intercostal and diaphragm musculature.^{142,143} Impaired respiratory muscle strength may lead to an inability to cough or handle secretions and to decreased vital capacity, tidal volume, and oxygen saturation. Secondary complications such as infections or organ system failure lead to death in approximately 5% of patients with GBS.¹⁴⁴ Approximately 35% to 50% of patients develop some cranial nerve involvement, primarily facial muscle weakness, although patients may also develop oropharyngeal and oculomotor involvement.^{143,145}

ANS symptoms are noted in approximately 50% of patients. Low cardiac output, cardiac dysrhythmias, and marked fluctuations in blood pressure may compromise management of respiratory function and can lead to sudden death. Other typical ANS symptoms may result in peripheral pooling of blood, poor venous return, ileus, and urinary retention.¹⁴⁶

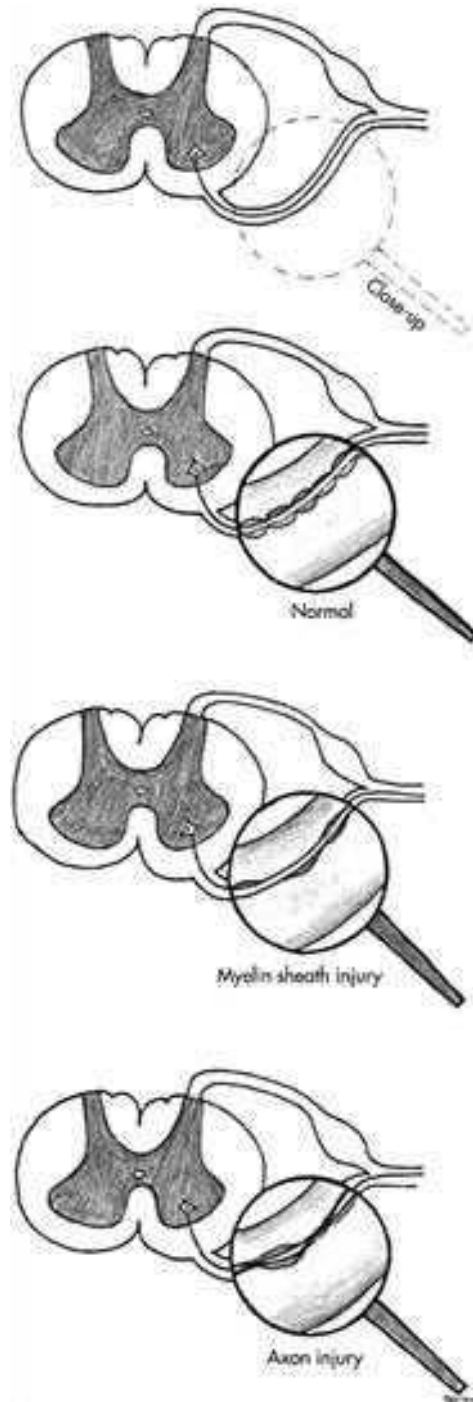

Figure 17-4 ■ Peripheral nerve showing axonal degeneration and demyelination.

Sensory symptoms such as distal hyperesthesias, paresthesias (tingling, burning), numbness, and decreased vibratory or position sense are common. The sensory disturbances often have a stocking-and-glove pattern rather than the dermatomal distribution of loss. Although the sensory problems are seldom disabling, they can be disconcerting and upsetting to patients, especially during the acute stage.^{147,148}

Pain was identified as a significant presenting symptom reported in the original articles describing GBS. When

BOX 17-3 ■ COMMON DIAGNOSTIC FEATURES OF GUILLAIN-BARRÉ SYNDROME

- A. Motor weakness
 - 1. Progressive symptoms and signs of motor weakness that develop rapidly
 - a. Relative symmetry of motor involvement
 - b. Usual progression of weakness from distal to proximal; self-limiting to distal limbs of upper and/or lower extremities or may extend to full quadriplegia with respiratory and cranial nerve involvement
 - 2. Areflexia of at least distal tendon responses
- B. Mild sensory symptoms or signs, particularly paresthesias and hypesthesias
- C. Autonomic dysfunction such as tachycardia and arrhythmias, vasomotor symptoms
- D. Absence of fever at onset of symptoms; history of flulike illness common
- E. Laboratory test results nonspecific but may show elevation of cerebrospinal fluid protein; cerebrospinal fluid cells at 10 or fewer mononuclear leukocytes per cubic millimeter of cerebrospinal fluid
- F. Electrodiagnostic testing, nerve conduction velocities usually abnormal
- G. Recovery usually begins 2 to 4 weeks after plateau of disease process

pain was prominent, patients spontaneously revealed its presence during a medical history. Therefore therapists who may be working with patients with an onset of low back pain not associated with known injury or stress and reports of paresthesias (pins and needles) and vibratory or decreased tendon reflexes should evaluate or monitor for possible GBS.^{149,150}

The most common description of presenting pain was of muscle aching typically associated with vigorous or excessive exercise. Pain was usually symmetrical and reported most frequently in the large-bulk muscles such as the gluteals, quadriceps, and hamstrings and less often in the lower leg and upper-extremity muscles. Some pain reported during late stages of the illness was described as “stiffness.” Pain was consistently more disturbing at night.¹⁵⁰ As the disease progresses, some patients experience severe burning or hypersensitivity to touch or even air movement, which can interfere with nursing care and limit therapy interventions. The types of pain reported include paresthesias, dysesthesias, axial and radicular pain, joint pain, and myalgias.¹⁵¹ Dysautonomia (orthostatic hypotension, blood pressure instability, cardiac arrhythmias and sometimes bowel and bladder dysfunction) is relatively common in patients with GBS requiring ventilatory support; in one prospective study of 297 patients, cardiac arrest associated with dysautonomia was the leading cause of death.¹³⁷ In patients with paraplegia or quadriplegia, approximately one fourth had problems with urinary retention caused by detrusor areflexia or overactivity, overactive urethral sphincter, and disturbed bladder sensation.¹³⁴ The possibility of deep vein thrombosis (DVT) and pulmonary embolus must also be monitored and prophylactic treatment used.¹⁵²

Medical Prognosis

Although some patients have a fulminating course of progress with maximal paralysis within 1 to 2 days of onset, 50% of patients reach the nadir (the point of greatest severity) of the disease within 1 week, 70% by 2 weeks, and 80% by 3 weeks.¹⁴⁵ In some cases the process of increasing weakness continues for 1 to 2 months. Onset of recovery is varied, with most patients showing gradual recovery of muscle strength 2 to 4 weeks after progression has stopped or the condition has plateaued. Although 50% of the patients may show minor neurological deficits (e.g., diminished or absent tendon reflexes) and 15% may show persistent residual deficits in function, approximately 80% become ambulatory within 6 months of onset of symptoms. The most common long-term deficits are weakness of the anterior tibial musculature and, less often, weakness of the foot and hand intrinsics, quadriceps, and gluteal musculature. Three percent to 5% of patients die of secondary cardiac, respiratory, or other systemic organ failure.^{134,151} Fatigue or poor endurance was also noted as a long-term consequence of GBS, possibly attributable to deconditioning and peripheral fatigue related to muscle fatigue during the healing process.^{141,153} Vasjar and colleagues¹⁵⁴ also report that fatigue and poor exercise tolerance were common persisting symptoms in children who appeared to have fully recovered from acute GBS.

Although often not the focus of most studies on the long-term impact of GBS, sensory deficits (impaired response to pinprick, light touch, and vibration and proprioception in combination with other sensory losses) are an ongoing problem for patients 3 to 6 years after recovery from acute GBS. In a study of 122 subjects, 38% showed sensory deficits in the upper extremities¹⁵⁵ and 66% had ongoing sensory deficits of the lower extremities.¹⁵¹ The muscle aches and cramps experienced by some of these patients appeared to be related to sensory rather than persistent motor dysfunctions as usually thought.

Overall, factors associated with a poor prognosis are severity of muscle weakness (especially quadriplegia), the need for respiratory support, cranial nerve involvement associated with loss of eye movement and swallowing, rapid rate of progression from onset, length of time to nadir, older age at onset, history of gastrointestinal illness, and recent cytomegalovirus infections.^{134,142} In a prospective study of 297 patients with GBS in Italy, disease severity was not associated with time to clinical recovery, but it did predict ultimate outcome, along with shorter length of time to nadir, older age at onset, evidence of axon damage, and recent gastroenteritis.¹³⁷

Medical Management

Medical treatment depends on the rate and degree of ascending paralysis. Because most patients return to their prior functional status, excellent supportive care during the acute stage is imperative. Respiratory compromise should be expected, and all patients, including those with limited paralysis and sensory dysfunction, must be closely monitored for the rapid onset of pulmonary and cardiac decompensation or cardiac arrhythmias, paroxysmal or orthostatic hypotension, urinary retention, and paralytic ileus caused by dysautonomia.¹⁵² Because of the possibility of sudden respiratory failure, patients with evidence of GBS must be hospitalized so that immediate cardiorespiratory support can be given if functional vital capacity (FVC) falls below 20 mL/kg or

oxygen saturation falls below 75%.¹⁴⁴ Patients who progress to respiratory paralysis must be treated in an intensive care environment where adequate respiratory function can be maintained, secondary infections can be prevented or limited, and metabolic functions can be carefully monitored. The patient should be intubated if the FVC falls below 12 mL/kg or if the patient is increasingly dyspneic even if FVC is above the cutoff level.^{145,156} Twenty-five percent of patients who experience respiratory failure will develop pneumonia.¹⁵¹ Even if daytime respiration seems adequate, night-time respiratory insufficiency (sleep-disordered breathing) should be ruled out if patients have persistent sleepiness or fatigue.¹⁴¹

Patients with GBS in the intensive care unit (ICU) on ventilation and with varying levels of paralysis and sensory dysfunction feel trapped and out of control because they cannot express their needs. These patients can usually hear well and most can see what is happening around them. They benefit from being oriented to time, having the personnel explain all procedures, and having some means of obtaining help. Therapists can work with the ICU staff to provide the patient with alternative forms of communication, such as eye blink, clicking, and communication boards designed for their needs. Having some form of communication and knowing that they will not be left alone will help prevent traumatic stress reactions.¹⁵²

In addition to the intensive monitoring of progression and supportive care required for patients with GBS, two specific immunotherapy-based treatments—plasma exchange (removal of plasma from withdrawn blood with retransfusion of the formed elements back into the blood) and intravenous immunoglobulin (IVIg) (taking blood from a vein, separating plasma, and returning the blood cells with a plasma substitute)—have been under investigation for their ability to decrease the duration of respirator dependence and the time to onset of improvement. Systematic reviews of these interventions as of 2010 have found that plasma exchange decreases recovery time and is most beneficial if begun within the first week of diagnosis and can be beneficial up to 30 days after diagnosis.¹⁵⁷ Plasma exchange is also cost-effective as used in patients with mild, moderate, or severe courses of GBS.¹⁵⁸ IVIg is somewhat safer and easier to administer than plasma exchange; IVIg speeds recovery by the same amount of time as plasma exchange and is more effective than supportive care only. Adding IVIg to plasma exchange did not improve time to recovery any more than either treatment alone.¹⁵⁹ High-quality evidence is available to support IVIg use in adults with GBS; the quality of evidence is slightly less high to support its use in children with GBS.¹⁶⁰

Although corticosteroids have been used to decrease the inflammatory process in GBS since the 1960s, a review of clinical studies of corticosteroid effectiveness showed that corticosteroid treatment alone does not hasten recovery from GBS.¹⁶¹ Hughes and colleagues have developed practice parameters associated with these findings.¹⁶²

Therapeutic Management of Movement Dysfunction Associated with Guillain-Barré Syndrome

Therapeutic management of the movement deficits associated with GBS includes supportive management during the acute phase, prevention of long-term medical comorbidities during

the acute through early recovery stages, and rehabilitation throughout recovery.¹⁶³ With the assumption that the patient will have significant return of function within months, therapists must help maintain the integrity of functioning systems, address pain, teach compensatory strategies, and appropriately promote increasing activity after the plateau. The immediate needs of the patient will change as the patient moves through the acute stage, the plateau at the nadir, and the recovery stage of GBS before and after muscles attain antigravity strength. Transitioning between the changes in immediate therapeutic goals necessitates careful examination of the current status, progression of disease, and needs of the patient.

Examination

A comprehensive examination of the patient's movement and function includes factors shown in [Box 17-4](#). The extent of the examination in any one session depends on the patient's condition and ability to participate. History taking should include the course of the disease, along with any recent illness, preexisting neuromotor or other medical conditions, current concerns, and the patient's immediate goals. Screening tests can help determine whether sensory and autonomic systems are involved along with motor systems. Checking vital signs at rest and immediately after activity, assessing skin integrity especially in immobile patients, screening cranial nerve performance, and noting communication ability are all important components. Additional testing of sensation (and documentation on a body chart, for example) or autonomic systems may be required if the screening tests indicate.

In GBS, assessment of muscle strength and ROM as specifically as possible is important so the patient's course of progression or improvement can be tracked, possible patterns leading to contractures can be predicted and prevented, and the appropriate level of exercise can be implemented. MMT, dynamometry, or isokinetic testing could be useful in various stages; goniometry is typically used for ROM testing. Full MMT and joint ROM may require several sessions in the initial stages, and a few specific muscles and joints may be selected (e.g., sternocleidomastoids, deltoids, triceps, flexor carpi ulnaris, lumbricals, iliopsoas, gluteus medius, anterior tibialis, flexor hallucis longus; shoulders, fingers, ankles) to test for changes weekly.

Several factors may interfere with complete assessment in the initial stage. Patients who report considerable pain during handling or active movement may not tolerate or may be unwilling or unable to cooperate with testing. The therapist should track the patient's level of pain, for example, on a numerical rating of pain scale, to help distinguish between weakness and loss of ROM related to pathological condition, immobility, or pain.

Fatigue and respiratory difficulties may also preclude complete strength assessment in a single session. Fatigue may result from deconditioning, increased effort required to perform similarly with weakened muscles, and inability to recruit sufficient motor units to maintain contractions.¹⁶⁴ Fatigue can be documented in relation to amount of activity tolerated (with specific symptoms noted before rest is required) or with a questionnaire such as the Fatigue Severity Scale (FSS), Fatigue Impact Scale (FIS), or the Visual Analogue Scale for Fatigue (VAS-F).¹⁴¹ Functional tests may include standardized scales of independence in ADLs or balance, tests of manual dexterity, and temporal measures

BOX 17-4 ■ FACTORS TO CONSIDER IN THE EXAMINATION OF PATIENTS WITH GUILLAIN-BARRÉ SYNDROME

HISTORY

Patterns and sequence of symptom onset
Recent illness or injury, prior episodes of sensorimotor problems

MOTOR FUNCTION

Visual inspection to identify symmetry of muscle bulk and function
Myotatic reflexes, rule out tonic reflexes
Manual muscle testing, carefully identifying pattern of weakness (testing should be as muscle specific as possible rather than assessing muscle groups only; use form for serial recording)
Presence of muscle fasciculations
Cranial nerves
Range of motion (use form for serial recording)
Equilibrium reactions sitting and standing (if testable)
Current functional status (activities of daily living, including bowel and bladder function, ambulation)
Endurance and experienced fatigue

SENSORY SYSTEM

Identify pattern of sensory loss or changes (use body chart)
Identify specific type of sensory change (e.g., paresthesias, anesthesia, hypesthesias) (use body chart)

Identify pain type and location (use body chart): what makes it better, what makes it worse?

Identify pressure points or areas that might lead to pressure sores

AUTONOMIC SYSTEM

Blood pressure resting and immediately after activity (prone, sitting, standing, if possible)
Heart rate resting and immediately after activity, dysrhythmias
Body temperature stability
Bowel and bladder control

PSYCHOSOCIAL SYSTEMS

Identify patient and family concerns in acute circumstances and concerns about long-term issues that may affect patient and family. Assessment need not be extensive if referral can be made for social service evaluation of patient and family financial concerns, day-to-day living problems (e.g., transportation, child care), support systems, and coping strategies.

ELECTRODIAGNOSTIC TESTING

Nerve conduction velocity. (Physician will order these studies to be performed by a clinician skilled in the procedures. This may be a physical therapist, physician, or technician depending on facility.)

of gait. Chehebar and colleagues¹⁶³ review some of the pros and cons of standardized tests such as the Barthel Index, modified Hughes scale of GBS disability, and the Functional Independence Measure. Health-related quality-of-life measures used in related populations include the Nottingham Health Profile and the SF-36.¹⁶⁴ Forsberg and colleagues¹⁶⁵ provide a comprehensive list of tests they administered in a prospective study of 42 patients followed for 2 years after the onset of GBS. At 2 weeks postonset, 40 of 42 patients had submaximal scores on total muscle strength, grip strength, balance, and gait speed testing. At 2 months, total muscle strength was still most affected, whereas 25% of the patients had regained maximal grip strength, balance, and gait speed (designated as 1.4 to 1.5 m/sec). By 2 years, over half of the subjects still lacked the maximum total muscle score, and 40% claimed fatigue. Sensory deficits were claimed by up to 36% of patients at 2 years.¹⁶⁵

Changes in the patient's condition should be monitored with serial MMT, ROM assessments, sensory testing, and functional status examinations. See Kami and colleagues¹⁶⁶ for suggestions on serial functional assessments. Before the patient is discharged from the hospital or rehabilitation unit, therapists should complete an assessment of the patient's home environment so that appropriate safety and adaptive equipment can be in place in time for the patient's return home.

Respiratory and Dysphagia Examination

Therapists are usually involved early in the care of patients with GBS. For patients with respiratory or bulbar paralysis, the therapist's initial contact may be in the ICU. Although most hospitals have fully equipped ICUs, a therapist working

in a rural or smaller community hospital may be the first person to note a patient's changing respiratory status during an evaluation and treatment session for muscle weakness or back pain. Therefore the therapist must be prepared to advise nursing and medical staff about the need to test oxygen saturation levels and FVC. Therapist attention to respiratory complications is particularly important in the managed care environment, which discourages hospitalization if presenting symptoms are not life endangering.¹⁴⁵ A simple estimate of FVC can be done at bedside. If after taking a large breath the patient can count out loud only to 10, the forced vital capacity is approximately 1 L and intubation should be considered. Complete information on the PT's evaluation of patients in acute respiratory failure is provided by Irwin and Tecklin.¹⁶⁷

Patients who have been intubated or who have cranial nerve involvement with oral motor weakness commonly have a high incidence of aspiration. Patients with severe oral-motor problems and dysphagia should be evaluated thoroughly and treated by a therapist skilled in oral-motor dysfunction and feeding. This may be a speech therapist, OT, or PT depending on the facility. Patients with a feeding tube (PEG) should receive their feedings in a relatively upright position and should remain in that position for 30 to 60 minutes after feeding to decrease the chance of aspiration. According to Logemann,¹⁶⁸ approximately 40% of patients receiving bedside swallowing assessments have undetected aspiration. Therefore the bedside evaluation should be considered only a preliminary step in the diagnostic process. In addition to careful assessment of oral-motor control, some clinicians recommend cervical auscultation to listen to swallowing sounds, particularly during the acute phase of the illness.

With evidence of swallowing difficulties and possible aspiration, the patient should be referred for comprehensive testing with videofluoroscopy. Swallowing also can be assessed by techniques such as fiberoptic endoscopy, ultrasound, electroglottography to determine laryngeal movement, and scintigraphy, which involves scanning a radioactive bolus during swallowing.¹⁶⁹ (Refer to section on medical management of ALS for suggestions for dealing with dysphagia.)

Intervention Goals

General goals for the care of the patient with GBS, to be specified with reference to the patient's preferences, include the following:

- Facilitate resolution of respiratory problems and dysphagia
- Minimize pain
- Prevent contractures, decubitus ulcers, and injury to weakened or denervated muscles
- Introduce a graduated program of active exercise while monitoring overuse and fatigue
- Resume psychosocial roles and improve quality of life

Therapeutic Interventions

In a Cochrane review of exercise in people with peripheral neuropathies, no randomized or quasi-randomized controlled trials were identified for patients with GBS as of September 2009.¹³⁵ However, some treatment programs used for patients with other neuromotor dysfunctions can be adapted for use with patients with GBS.

Respiratory and Cranial Nerve Dysfunction

Depending on the facility, PTs may be involved in the respiratory care of patients with GBS. PTs may conduct chest percussion, breathing exercises, resistive inspiratory training, or strict protocols to prevent overfatigue of respiratory muscles while weaning patients from mechanical ventilation.¹⁷⁰ Goals of treatment are related to increasing ventilation or oxygenation, decreasing oxygen consumption, controlling secretions, and improving exercise tolerance. See Irwin and Tecklin¹⁶⁷ for coverage of treatment programs and techniques appropriate for the GBS patient with acute or residual respiratory dysfunction.

When patients are placed on mechanical ventilators, communication can be difficult and frustrating.¹⁷¹ The rehabilitation team can help develop and execute alternative means of communication.

In the more severe cases of GBS, cranial nerve involvement can lead to multiple complications such as dysphagia and vocal cord paralysis. In many facilities, speech pathologists or OTs are responsible for establishing a dysphagia treatment program. Therapists responsible for treatment of patients with dysphagia and swallowing problems should refer to Logemann's classic text on the evaluation and treatment of swallowing disorders.¹⁶⁸ Therapeutic goals are the prevention of choking and aspiration and the stimulation of effective swallowing and eating. The act of chewing and swallowing is complex and requires coordinated reflexive and conscious action. Intervention is focused on positioning (upright with head tilted slightly forward),¹⁷¹ head control, and oral-motor coordination (e.g., sucking an ice cube, stimulating the gag response, facilitating swallowing with

quick pressure on the neck and thyroid notch timed with intent to swallow). A conscious swallowing technique is introduced with thick liquids and progressed to thinner liquids after the patient's oral-motor coordination response is enough to control movement of fluids. Once the patient has good lip closure, fluids should be introduced one sip at a time from a straw cut to a short length to minimize effort. Semisoft, moist foods are gradually introduced (pasta, mashed potatoes, squash, gelatin). Any crumbly or stringy foods (coffee cakes, cookies, snack chips, celery, cheeses) should be avoided, and the patient should not attempt to talk or be interrupted during eating until choking does not occur and swallowing is comfortable and consistent.¹⁷² Feeding training should occur during frequent, short sessions to prevent fatigue. Therapists should be prepared to use the Heimlich maneuver if choking occurs or have a suction machine available at bedside.

Pain

If pain seems to be a major factor limiting the patient's passive or active motion, the treatment team should determine the best approach to alleviate pain. According to one study, patients with GBS did not seem to show a consistent response to any specific pain medication, although six of the 13 patients seemed to have a positive response to codeine, oxycodone plus acetaminophen (Percocet), and oxycodone plus aspirin (Percodan).¹⁴⁷ Some patients may find relief with medications used to treat neurogenic pain, such as the tricyclic antidepressants, carbamazepine, or gabapentin (anticonvulsants).¹⁵¹ For patients who do not respond to conventional analgesics or tricyclic antidepressants, a short course of high-dose corticosteroids can lead to pain relief.¹⁴⁴

Some patients with neuropathy have noted decreased pain after using transcutaneous electrical nerve stimulation (TENS).^{173,174} Although no study has examined the effect of TENS specifically on pain associated with GBS, it might be a treatment option to help with desensitization in patients whose pain is not controlled with passive movement or pain medications.

Another option is capsaicin, the active ingredient in chili peppers, which when applied topically interacts with the sensory neurons to relieve pain from peripheral neuropathies.¹⁵¹ Therapists, wearing gloves, apply a topical anesthetic until the area is numb. The capsaicin is then applied topically. The capsaicin remains on the skin until the patient starts to feel the heat, at which point it is promptly removed. Because the nerves are overstimulated by the burning sensation, the sensory gateway is unable to report pain for an extended period.¹⁷⁵

Some patients who experience extreme sensitivity to light touch, such as from movement of sheets, air flow, and intermittent touch contact, benefit from a "cradle" that holds sheets away from the body. Some find relief if the limbs are wrapped snugly with elastic bandages, which provide continuous low pressure while warding off light and intermittent stimuli. Alternatively, the patient's pain response can be desensitized through methodical stimulation with frequent, consistent stimuli to the affected area for short durations to allow acclimatization.¹⁷⁰

Contractures, Decubitus Ulcers, and Injury to Weakened or Denervated Muscles

Positioning. In the acute stage of GBS, rehabilitation will focus on positioning and passive ROM to prevent contractures and decubitus ulcers.¹⁷⁶ Preventing pressure sores

starts within the first few days of hospitalization, especially for the patient who has complete or nearly complete paralysis. A positioning program for the dependent patient is the first line of defense, with turning at least every 2 hours for both pressure relief and lung drainage.¹⁷¹ In addition, the patient should have a special mattress or unit that constantly changes the pressure within the mattress to shift the patient's position or is designed to spread pressure over wide surfaces. Patients who are slender or who have lost significant muscle mass from GBS-induced atrophy will have prominent bony surfaces; the therapist may need to fashion foam "doughnuts" or pads or use sheepskin-type protection for pressure relief. Patients who have muscle pain may prefer to have their hips and knees flexed. If so, the patient must be taken out of the flexed position for part of each hour to avoid muscle shortening.

As part of a complete positioning program, therapists should consider how best to maintain the physiological position of the hands and feet. Research has shown that mild continuous stretch maintained for at least 20 minutes is more beneficial than stronger, brief stretching exercises.¹⁷⁷ Thus the use of splints for prolonged positioning is superior to the use of short bursts of intermittent, manually applied passive stretching for maintaining functional range. Although some facilities still use a footboard to control passive ankle plantarflexion, most therapists now use moldable plastic splints that can be worn when the patient is in any position. Because ankle-foot splints often prevent visual inspection of the heel position, care must be taken to ensure that the heel is firmly down in the orthosis and that the strapping pattern is adequate to secure the foot. The strap system must be simple enough to be positioned properly by all staff and family members caring for the patient. The ankle-foot splint should extend slightly beyond the end of the toes to prevent toe flexion and skin breakdown from the toes rubbing on sheeting. Care should be taken not to compress the peroneal nerve with the splint as it crosses the fibula,¹⁴⁸ a particularly vulnerable area after the loss of muscle mass in the lower legs from the GBS.¹³⁹ Wrist and hand splints may be prefabricated, resting-style splints, or molded to meet the patient's specific needs. Because spasticity is not a problem in the patient with GBS, a simple cone or rolled cloth may be adequate to maintain good wrist, thumb, and finger alignment for short-term immobility.

Range of Motion. To be effective, the ROM program must start within the first couple of days of hospitalization and include both accessory and physiological motions to increase circulation; provide lubrication of the joints; and maintain extensibility of capsular, muscle, and tendon tissue. Passive ROM exercises to the ends of normal range for all extremity joints, fingers and toes, neck, and trunk should be performed twice daily—more frequently if the patient has no active movement. Patients can be instructed to perform the ROM exercises themselves if they can move actively without pain or fatigue; during the acute stage of declining strength, they should be observed during ROM activities to ensure adequacy of the range and any changes in quality of movement. If the patient cannot complete movement through full range independently, a therapist or well-instructed and monitored caregiver can assist the patient in moving to the end of range. This may not be easy if the patient has pain with motion. Knowing whether to "push through the pain" or stay within the limits of pain is often a great dilemma for the therapist. The therapist

needs to find a balance between working for full joint range and reacting to the patient's reports of pain. If the ends of ranges start to become stiff, stretch should be slow and sustained at the end point for 10 to 30 seconds.

Denervated or weakened muscles can be injured easily; therefore the therapist is responsible for ensuring that joint structures are not damaged and that ROM activities are done with appropriate support of the limb to prevent sudden overstretching. Instruction to caregivers regarding passive ROM activities must include details such as externally rotating the shoulder during abduction to prevent impingement and ensuring that the subtalar joint is in the neutral position during dorsiflexion to avoid overstretching of the midfoot. In hospitals where the patient is treated by a changing therapy or nursing staff or by family members, a positioning schedule with diagrams, a splinting plan, and ROM recommendations should be presented in poster format at the patient's bedside to facilitate consistent treatment.

ROM can usually be maintained with standard positioning and ROM programs. Nevertheless, some patients, especially those who have reported severe extremity and axial pain early during the disease process and those who have been quadriplegic and respirator dependent for prolonged periods, may develop significant joint contractures despite preventive interventions. As with patients with spinal cord or severe head injuries, heterotopic ossification has been reported in patients with GBS.¹⁷⁸ Meythaler and colleagues¹⁷⁹ note that early mobilization was related to therapeutic decreases in serum calcium levels and suggest that aggressive ROM (but not hard or abrupt movements that may injure the muscle) may impede the effects of heterotopic bone overgrowth, which can have a severe impact on ROM. Once heterotopic ossification has been identified, treatment includes modification of ROM exercise to use only active and passive motion within the pain-free arc.¹⁷⁰

Soryal and colleagues¹⁸⁰ reported on three patients with GBS who had marked residual contractures that limited function after strength improved. None of the patients had radiological signs of erosive arthropathy or inflammatory joint disease. Soryal hypothesized a number of possible mechanisms for the limitations in ROM: (1) therapists and nurses may have been reluctant to take patients who reported marked pain during passive movement through the full ROM; (2) the contractures may have been a result of pain or damage caused by inappropriate excessive passive movement of hypotonic and sensory-impaired joints and muscles (often caused by poor movement of the patient in bed or by poorly trained staff or family members moving limbs); (3) the paralysis may have resulted in lymphatic stasis with accumulation of fluid in tissue spaces and nutritional disturbances; and (4) vasomotor disturbances resulting from autonomic neuropathy may have led to adhesions and fibrosis. Although the authors found few reports describing contractures as a significant residual problem, they suggested that ROM programs must be defined precisely as to frequency and duration, particularly for patients reporting early joint pain.¹⁸⁰

Some patients will prefer to position their limbs so muscle and tendons are in the shortened range in an attempt to decrease muscle pain. This may lead to capsular contractures. The therapist should be aware of changes in "end feel" over time when testing ROM of each joint to determine if capsular and ligamentous structures are also becoming more restricted as the muscle and tendon tissue shortens. Patients

who have intact sensation of pain and temperature may respond positively to the use of heat (up to approximately 45° C or 113° F) before stretching to decrease muscle pain and facilitate tissue elongation before stretching. Several basic studies of rat tail tendon and the relation between load and heat have shown that attaining permanent length increases in collagenous tissue is possible with a combination of heat and stretch.¹⁸¹⁻¹⁸⁴ (Caution: Heat should not be used on a patient with a sensory deficit that inhibits ability to distinguish differences in temperature.)

On the basis of evidence that continuous passive motion (CPM) is effective in maintaining joint range in both rabbits and human beings,¹⁸⁵ Mays¹⁸⁶ described a case study of a patient with GBS (quadriplegia with 7 days of mechanical ventilation) who had persistent pain and stiffness of the upper extremities and fingers approximately 3 months after the onset of GBS. CPM of the hands and fingers was added to a program of occupational therapy that included ROM, splinting, and ADLs. The author reported an increase in the rate of recovery of finger range and a decrease in pain after use of CPM. Numerous other studies have reported the value of CPM in maintaining or increasing ROM after hip and knee surgery. It may be a useful adjunct to traditional therapy for patients with GBS, especially those who continue to develop contractures with standard, intermittent ROM programs. Patients with severe paresthesias or dysesthesias may not be able to tolerate CPM equipment.

Massage also may play a positive role in maintaining muscle tissue mobility and tissue nutrition while limiting the amount of intramuscular fibrosis development. The use of massage in patients with GBS has not been reported; however, it makes intuitive sense that it may be a useful adjunct to ROM exercises in patients who do not have marked hypersensitivity to touch, significant muscle pain, or a history of DVT. Patients with or without a history of DVT who are immobile for long periods or who have concomitant cardiac illnesses may have marked swelling of the distal limbs. After medical clearance, edema-specific massage and limb-elevation techniques may be useful if tolerated by the patient. Early active ROM exercises creating “muscle pumping” contractions in muscles with at least fair strength can help prevent uncomfortable edema.

Progressive Program of Active Exercise while Monitoring for Overuse and Fatigue

Although most patients with GBS recover from the paralysis, the course and rate of recovery may vary significantly among patients. The decline of strength may take 2 days to 4 weeks, with a plateau of a few days to a few weeks after the nadir. Strength returns over the course of weeks to months, depending on whether the disease process affected only myelin or the axons themselves. Strength usually returns in a descending pattern—opposite to the pattern noted during onset of the disease. No evidence exists to indicate that active exercise can change the rate of progression of the disease or regrowth of myelin or axons, although it may improve function through increased strength and aerobic capacity once muscles are reinnervated. The major goal of therapeutic management throughout the course of GBS must be to maintain the patient’s musculoskeletal system in an optimal ready state, prevent overwork, enhance circulation and cardiorespiratory endurance within the limits of active movement, and pace the recovery process to obtain maximal function as reinnervation occurs.

In the acute stage of GBS, active exercise is limited to whatever the patient can move without pain or excessive fatigue. Slings or adaptive devices may help support the weight of a limb to continue active movement in a gravity-eliminated plane for those muscles that have lost antigravity strength. As the disease reaches its nadir, activity remains limited. Once weakness stops progressing, passive maintenance of ROM may be the only activity possible for immobile patients. As strength begins to return after the plateau, therapists must prescribe limited amounts of low-resistance activities, with strict avoidance of antigravity strain on the muscles until strength reaches the 3/5 (Fair) range of MMT. Active exercise can be added very slowly, with frequent rest periods and monitoring to avoid fatigue.^{177,187} Activity should be halted at the first point of fatigue or muscle ache; abnormal sensations (tingling, paresthesias) that persist for prolonged periods after exercise may also indicate that the exercise or activity level was excessive. Any progression of resistance or repetitions of strengthening exercises should be monitored for 3 to 7 days for increase in weakness, muscle spasms, or soreness before exercises are progressed further.¹⁸⁸ If additional weakness or soreness ensues, the additional activity must be eliminated for several days, with reinitiation at a lower level of resistance or number of repetitions and more gradual increase. Work simplification and energy conservation strategies may be useful to improve function in the recovery stage of GBS.¹⁷⁰ As strength increases, additional resistance may be applied to those muscles showing good recovery while avoiding strain on muscles that have not yet reached the same level, frequently the most distal musculature. Even when strength has returned throughout, rehabilitation and exercise may need to continue to address fatigue that may persist at each of the International Classification of Functioning, Disability and Health (ICF) levels: body function and structure, activity, and participation.¹⁴¹ For an example of treatment progression during the acute stage from week 1 through week 12, see Table 17-3.

In the initial stages of upright activity after any period of bed rest, therapists must progress patients with GBS very carefully because 19% to 50% of this population show orthostatic hypotension along with dysautonomia.^{139,146} A program to improve tolerance to upright position can be started in the ICU if the patient is on a circle electric or Nelson standing bed. If a standing bed is not available, a sitting program can be initiated as soon as it is tolerated. A progressive standing program can be instituted when the patient’s respiratory system and ANS are no longer unstable and the patient can be moved to a tilt table. Caution should be taken to stabilize the patient fully to maintain alignment and to limit activity in muscles having strength below the fair range. When beginning training, some patients benefit from using an abdominal binder or foot-to-thigh compression stockings if tolerated. Because of the relation between poor hydration and hypotension, therapists must ensure the patient is well hydrated before beginning upright or standing tolerance programs.¹³⁹

As was discussed in the section on therapeutic considerations for patients with ALS, a muscle that has significant denervation is more likely to respond to exercise with overwork fatigue (see Figure 17-3 for the therapeutic window for exercise). Studying the effect of exercise on rat muscle after nerve injury, Herbison and colleagues¹⁸⁷ identified a loss of contractile proteins during initial reinnervation. After reinnervation the same amount of exercise resulted in muscle

TABLE 17-3 ■ MEDICAL STATUS OF PATIENTS WITH GULLAIN-BARRÉ SYNDROME AND POSSIBLE TREATMENT OUTLINE

MEDICAL STATUS	TREATMENT*
Tracheostomy	Week 1:
Respirator dependent	Postural drainage every 3 hours around the clock
Complete cranial nerve paralysis	Passive ROM exercises to all joints
Quadriplegia	Splinting (molded plastic) of hands and feet to maintain functional position
	Positioning, splinting, and ROM program schedule posted at bedside
	Weeks 2-5:
	Postural drainage decreased to two times each shift (every 8 hours)
	Passive ROM exercises, physiological and accessory motions, gentle stretching of intercostal musculature, trunk rotations
	Continue splinting and positioning program
	Family education: family members taught gentle physiological ROM techniques, with attention to correct shoulder patterns and simple massage techniques
Respirator set on intermittent mandatory ventilation	Weeks 6-7:
Weaning to respirator at night by end of week 7	Postural drainage two times each shift (every 8 hours)
No active muscle contractions except eye opening and lip movements	Continue ROM program, splinting, and positioning
Dysphagia	Begin to build tolerance of upright sitting with good trunk alignment
	Begin facilitation of active facial and tongue muscle activity in patterns necessary for swallowing, eating, and speaking; speech pathology, occupational therapy consultation for dysphagia training
	Family members active in care, helping with ROM, splinting, and positioning schedule as they choose
Palpable muscle activity in neck, trunk, proximal musculature of upper and lower extremities	Weeks 8-12:
	Postural drainage one time each shift
	Chest stretching, breathing exercises
	Dysphagia program in collaboration with speech consultant
	Muscle reeducation program with electromyographic biofeedback progressing to gravity-eliminated exercises using suspension slings attached to bed
	Tilt-table standing program to increase tolerance to upright (wearing positioning splints if necessary)
	Collaborate with occupational therapist for treatment in wheelchair with suspension slings to facilitate active arm motion in gravity-limited position
	Exercise, rest, positioning schedule posted
	Family, patient educated about stimulating activity level to prevent fatigue, overuse of reinnervating muscles

ROM, Range of motion.

*Treatment depends on rate of recovery.

hypertrophy. Bensman¹⁸⁸ reported on eight patients who had stabilized after acute polyradiculoneuritis (among them patients with GBS). All eight patients had a temporary loss of function after strenuous physical exercise. Three patients apparently had significant decreases in strength. All patients were then placed on a program of passive ROM exercises, and an increase in muscle strength was noted. Recurring episodes of a temporary loss of function appeared to be related to strenuous exercise and fatigue. The current position for patients with GBS, then, is that excessive exercise during early reinnervation when only a few functioning motor units are present can lead to further damage rather than to the expected exercise-induced hypertrophy of muscle.

During the initial stages of exercise, the repetitions per exercise period should be low and the frequency of short periods of exercise should be high.¹⁷⁷ As reinnervation occurs and motor units become responsive, the early process of muscle reeducation exercise used by the therapist may be similar to that used after polio. To encourage active contraction of the muscle the therapist should carefully demonstrate to the

patient the expected movement. The therapist then passively moves the patient's limb while the patient observes. After gaining a clear picture of what movement is expected, the patient is encouraged to contract muscles. Facilitatory techniques such as skin stroking, brushing, vibration, icing, and tapping may be used in conjunction with the muscle reeducation process if the sensory and pain status of the patient permits. The patient is taught to reassess his or her movements and make corrective responses. As the patient gains strength, the movements are translated into functional activities.¹⁸⁷

Functional activities should be appropriate for the muscle grade of that muscle or muscle group. For example, if the patient's deltoid muscle has a poor (2/5) grade on MMT (full ROM with gravity eliminated), the patient should be cautioned not to attempt to elevate her or his arm against gravity (e.g., to shave or do one's hair). Patients may exercise when the limb weight is supported (using overhead slings, powder boards, pool exercises) to allow the patient to move actively through a full range until he or she can take resistance in the gravity-eliminated position. Children, teenagers, or adults

with impaired judgment often need a strict schedule of rest and activity. Patients and staff also need to be reminded that prolonged sitting in bed or in a wheelchair, even when supported, may tax the axial musculature. A program of gradual sitting should be instituted, with the final goal being independent, unsupported sitting with functional equilibrium reactions. In busy hospitals a schedule of sitting and activity should be posted in clear view at the patient's bedside.

As reinnervation progresses and strength and exercise tolerance increases, the therapist may choose to use facilitative exercise techniques such as neurodevelopmental sequencing¹⁸⁹ or PNF^{190,191} to recruit maximal desired contraction of specific muscle groups. Although PNF techniques are excellent for eliciting maximal contraction, care must be taken not to overwork the weaker components of the movement pattern. A positive aspect of PNF techniques is that they can be tied in with functional patterns such as rolling, which is necessary for bed mobility, transitions to quadruped, kneeling, sitting, standing, and gait.

Because patients with GBS are transferred from acute care facilities to rehabilitation, skilled nursing, or home environments more quickly than in the past, therapists must be careful to document any serial negative changes or plateaus in motor, sensory, or respiratory impairments or functional status that may herald a relapse.¹³⁹ Although 65% to 75% or more of patients with GBS show a return to clinically normal motor function, 2% to 5% of patients have a recurrence of symptoms similar in onset and pattern to the original illness.¹⁹² Recurrence of symptoms should trigger immediate cessation of activity and possibly medical reassessment in case of respiratory insufficiency.

Anecdotal and empirical evidence shows that patients with GBS can continue to show deficits during strenuous exercises that require maximal endurance. Four soldiers who were considered clinically recovered from GBS (normal motor power with or without reappearance of reflexes and the absence of sensory impairment) were unable to pass the Army Physical Fitness Test (APFT), which is designed to measure a minimal acceptable age-related level of physical fitness for military duty (maximal effort to challenge respiratory and muscular endurance, strength, and flexibility). Before onset of GBS, the four patients had all exceeded the APFT standards. None was able to pass the APFT as long as 4 years after the illness, indicating that the persistent deficit interfered with their ability to continue their military careers.¹⁹³ The possibility of long-term endurance deficits should be considered when patients appear to have reached full recovery but report difficulty when returning to work or activities that require sustained maximal effort.^{194,195}

So far, no pharmaceutical agents have been helpful in alleviating fatigue in this population. In a study of the use of amantadine to relieve severe fatigue in 74 patients with GBS randomly allocated to treatment or placebo groups, the groups showed no difference in any of the primary or secondary measures recorded.¹⁹⁶ Determining the effectiveness of interventions to affect fatigue may be complicated by differences in measures of experienced fatigue (subjectively reported) versus physiological fatigue (central or peripheral reduction in voluntary muscle force production) and the weak relationship between these in many neuromuscular disorders.¹⁹⁷

Cardiovascular fitness may also be compromised after recovery from GBS. This may be caused by altered muscle function, but it is also related to deconditioning from an

imposed sedentary lifestyle.¹⁵⁴ Several studies have reported the effect of endurance exercise training after GBS. In one case study a 23-year-old woman with a chronic-relapsing form of GBS with onset at age 15 years was placed on a walking and cycling program at 45% or less of her predicted maximal heart rate reserve. The low-intensity exercise program was selected to prevent possible fatigue-related relapse. After the program, the subject had improved her walking time 37%, walking distance approximately 88%, and cycle ride time more than 100%. Although no standardized or formalized recording of functional level was recorded before and after the exercise program, the patient reported that her energy level for ADLs was a "little higher" and that stair walking was easier.¹⁹⁴ In another single-subject study of a 54-year-old man 3 years after onset of GBS with residual weakness, the authors demonstrated similar improvements in cardiopulmonary and work capacities as well as leg strength after a 16-week course of a thrice-weekly aerobic exercise program. The subject also reported expanded ADL capabilities. The authors suggested that their training regimen may disrupt the cycle of inactivity after recovery from GBS that leads to disuse atrophy and further deconditioning in patients with mild residual weakness.¹⁹⁸ Fehlings and colleagues¹⁹⁹ tested muscle strength and endurance in a group of children at least 2 years after acute onset of GBS. Although the children appeared essentially recovered, endurance of the arm muscles was lower than that of the lower extremities. They hypothesize that the typical walking, running, and cycling activities that the children participated in were sufficient to improve strength and endurance of lower-extremity muscles, and they recommended that children be encouraged to participate in activities such as swimming to improve upper-extremity endurance. Controlled tetherball and volleyball activities are also appropriate. Tuckey and Greenwood²⁰⁰ reported positive results of treatment with partial body-weight support (PBWS) treadmill exercise for a patient with severe GBS. Garssen and colleagues²⁰¹ reported a 20% reduction in fatigue levels, along with improved physical condition and strength, after a 12-week intensive bicycling exercise program for patients several years after the onset of GBS.

Improvements in strength and endurance after GBS may continue for months to years. A prospective study following 6 patients for 18 months after onset of GBS recorded continuing improvement of muscle strength on average throughout the assessment period, and yet the average strength of major muscle groups had not yet reached that of healthy controls.²⁰² Although the traditional thought has been that little clinical improvement occurs after 2 to 3 years, Bernsen and colleagues²⁰³ found that 21% of the patients in a study of 150 patients after recovery from acute GBS reported improvement after 2.5 to 6.5 years, although the authors thought the perception of improvement was related to improved sensory function. Of future research and clinical interest are the long-term consequences of GBS and how the normal aging process will affect patients who have some mild residual effects—for example, whether some patients will develop increasing weakness over time similar to persons with postpolio syndrome.¹³⁹

For those patients who experience significant losses in proprioception after GBS, sensory reintegration activities and high repetitions of task practice may help to redevelop motor engrams that are based on the altered sensory perception.¹³⁹

Patients with GBS have a significantly reduced health-related quality of life compared with control subjects at

approximately 1 year after onset, associated with decreased functional scores and changes in work status.²⁰⁴ Although physical training may be expected to improve functional scores and work capabilities, Bussmann and colleagues²⁰⁵ found little correlation between physical fitness and other domains. They hypothesized that training has psychological components, such as positive effect on mood and self-confidence, that influence quality of life in addition to physical changes.

Adaptive Equipment and Orthoses

Judicious use of orthotic devices and adaptive equipment should be considered an integral part of the rehabilitation process. The purpose of the orthotic and adaptive devices is twofold: (1) to protect weakened structures from overstretch and overuse and (2) to facilitate ADLs within the limits of the patient's current ability. Orthotic devices and adaptive equipment should be introduced and discontinued on the basis of serial evaluations of strength, ROM, and functional needs. For example, a hospitalized patient who has poor (2/5) middle deltoid strength may practice upper-extremity activities such as eating while using suspension slings. A thumb position splint may be used temporarily to aid thumb control in grasping tasks.

Most patients will need a wheelchair for several months until strength and endurance improve. As strength returns, patients recovering from severe paralysis may need to change from use of a wheelchair with a high, reclining back with a head rest to use of a lightweight, easily maneuverable chair. A quandary for the therapist is to predict how long a wheelchair will be necessary and whether it should be rented or purchased as the patient progresses through different stages of recovery. While moving from wheelchair mobility to independent ambulation, patients will usually progress from parallel bars to a walker with a seat to allow frequent resting, and then to crutches or a cane. Because wheelchairs, walkers, crutches, and canes, especially custom appliances, are expensive and not always covered by insurance, the therapist should carefully consider the cost to the patient during the recovery process.

Although most patients with GBS are able to walk within 8 months of onset, many show a prolonged residual weakness of calf and, most commonly, anterior compartment musculature, requiring the use of an AFO. The decision whether to use a prefabricated orthosis or custom appliance is not always simple. Several temporary orthotic measures can be considered. For example, if the patient shows good gastrocnemius-soleus strength with mild weakness of the dorsiflexors, a simple

elastic strap attached to the shoelaces and a calf band may be sufficient to prevent overuse of the anterior compartment muscles. An old-fashioned, relatively inexpensive spring wire brace, which can be attached to the patient's shoes to facilitate dorsiflexion, is a good choice for patients who report sensory hypersensitivity when wearing a plastic orthosis.

Most therapy units today have access to varied sizes of plastic, fixed-ankle AFOs that can be used until a decision is made to have the patient fitted with custom AFOs. A newer system of prefabricated AFOs with adjustable ankle motion cams has been developed that allows the therapist to limit plantar flexion and dorsiflexion to the specific needs of the patient. For patients with reasonable control of plantar flexion and dorsiflexion but with lateral instability because of peroneal weakness, a simple ankle stirrup device such as the AirCast Air-Stirrup Ankle Brace (AirCast, Summit, NJ) can be used temporarily to provide lateral ankle stability. Although few patients with GBS need knee-ankle-foot orthoses (KAFOs) on a long-term basis, inexpensive air splints or adjustable long-leg metal splints to control knee position are sometimes helpful when working on standing weight bearing and during initial gait training. See Chapter 34 for additional information on orthotics.

Psychosocial Issues

Although most patients with GBS have a good recovery over a period of 2 or more years, the acute stage of the disease can be frightening, especially to patients who progress to complete paralysis and respiratory failure. Nancy, in [Case Study 17-2](#), reported that she was terrified during the time she was totally paralyzed (including eyelid movement) and on a respirator. She said that nurses, doctors, and hospital staff seemed to assume she could not hear because she was unable to respond in any manner. In her words,

“They acted like I was already dead, and I thought I would be from the way they were talking. The thing I hated the most was when the night nurses from the registry would come in and ask how to make the ventilator work! I felt panicked. Can you imagine having your life depend on a machine and knowing that the person who was supposed to make it work had no idea what to do if a tube came unconnected? They were always worried about my blood pressure. Who wouldn't have high blood pressure in that situation! The thing I liked about my therapists was that they told me what they were going to do even when I couldn't respond. They didn't just start doing things or pulling on me like other people did.”

CASE STUDY 17-2 ■ NANCY

Nancy, a 16-year-old girl with a history of repeated hospitalizations for asthma, was admitted to the hospital with tingling in the hands and feet and mild respiratory distress. Because staff thought her asthma attacks had a significant emotional component, her repeated complaints of paresthesias, muscle pain, and weakness were largely ignored or attributed to anxiety attacks. The day after admission, Nancy began staggering while walking and became extremely agitated and hysterical, screaming that she was dying and could not breathe. A medical assessment showed evidence of wheezing with a normal chest radiograph

and decreased FVC. She was uncooperative during strength testing, although strength was estimated to be within normal limits except for approximately Fair (3/5) strength of the dorsiflexors and everters and Good (4/5) strength of the plantar flexors. She became extremely upset when her feet were touched.

Because of her psychological history, she was referred for psychiatric assessment and was placed on an anxiolytic medication. Two hours later she had a full respiratory arrest and was intubated and maintained on mechanical ventilation. Over the

CASE STUDY 17-2 ■ NANCY—cont'd

next 3 days she developed flaccid quadriplegia and within 5 days she had complete cranial nerve involvement. She was weaned from the respirator after 29 days after several episodes of pneumonia. After extubation, she had swallowing and speech problems that resolved by discharge at 3 months after onset. During the acute stage, she was catheterized because of urinary retention and was treated for a bowel obstruction. Sensation was normal for perception of temperature changes and deep pressure.

Proprioception was diminished at the ankle, knee, and fingers. Paresthesias and hypesthesias, aggravated by light touch, were present in a glove-like pattern in both hands and a stocking pattern in both feet.

Nancy's physical therapy treatment began in the ICU. Formal strength testing was inappropriate; passive ROM was full but felt stiff at ends of ranges in the wrist, fingers, and ankles. The goals were to assist in respiratory care, prevent joint contractures, and prevent stasis ulcers during the period of immobility. Although her postural drainage treatment was performed by using respiratory therapy techniques in conjunction with aerosol medication by intermittent positive-pressure ventilation (IPPV), PTs began a course of chest stretching techniques in coordination with a fastidious ROM program performed twice a day by a therapist and on the evening and night shifts by a nurse. A pressure relief mattress was ordered for her bed. To prevent contracture development, an OT fabricated bilateral wrist and finger splints; a PT molded ankle splints to maintain 90 degrees of dorsiflexion with neutral eversion-inversion. A positioning and ROM schedule in poster form with pictures of positions and ROM patterns was posted at Nancy's bedside.

Because Nancy reported severe hypersensitivity to light touch or to any passive movement of her limbs, a cradle was placed on the bed to prevent sheets from touching her and to prevent air flow changes from irritating her skin. She was fitted for above-knee light pressure stockings, which seemed to decrease her sensitivity to light touch.

Progression of the GBS process seemed to plateau at approximately 15 days after onset with a gradual return of respiratory function complicated by infections. Weaning from the respirator was difficult, and the PT played a major role in instructing Nancy, the staff, and her family in appropriate breathing exercises to be performed every 1 or 2 hours. Because her parents wanted to be involved with her care, they were taught ROM techniques with special attention to correct shoulder ROM techniques. The PTs continued to follow Nancy twice a day to ensure that accessory motions were completed with the physiological motions. Moist hot packs were used effectively before ROM exercises for 1 week to minimize severe muscle pain.

As part of her positioning program, Nancy was placed in a supported semisitting position while on the respirator. As muscle control returned, a muscle reeducation program was initiated that focused initially on the head and trunk and then on the upper and lower extremities. Exercise periods were limited to 15 minutes twice a day. She would have benefited from more frequent short sessions; however, this was not possible. Her parents were shown how to guide her active exercise program cautiously so that she was able to exercise more frequently at low repetitions. When each muscle group reached an

MMT grade of Fair (3) or greater, Nancy was allowed to use the muscles in functional activities with specified limitations in activity duration. When she was able to tolerate upright sitting and had some bed mobility, Nancy was transferred to a Nelson bed in which she could begin a gradual standing weight-bearing program.

A speech therapist worked with Nancy in the ICU to help her relearn safe swallowing patterns and to reintroduce her to different-textured foods. A dietician had been working with Nancy throughout her hospitalization to ensure adequate nutrition while intubated, and she worked closely with the speech therapist to progress Nancy's diet as she became able to handle liquids and solids.

After being weaned from the respirator and transferred to the general floor, Nancy was brought to the physical therapy department for treatment, which was frequently done in conjunction with occupational therapy. As strength increased, she began a program of resisted exercise. Trunk and upper- and lower-extremity PNF patterns were used as the primary exercise technique; however, great caution was used to avoid overworking weak muscle groups evoked during use of the PNF pattern. A full mat program with rolling and coming to sitting was also instituted. OTs focused on graduated use of Nancy's upper extremities, first using overhead slings attached to a wheelchair and later using a lap board to support her weakened shoulder musculature while practicing hand activities.

After 2 months of hospitalization, Nancy was discharged home to return for daily outpatient rehabilitation. Because Nancy appeared to be regaining strength well, she was provided with an ultralight rental wheelchair through her insurance for use until a final determination was made for long-term need. Nancy was also fitted with prefabricated adjustable AFOs, which were purchased through the physical therapy department. After 4 to 6 months a determination would be made about expected recovery of her persistently weakened dorsiflexors. If Nancy appeared to need AFOs for a prolonged period, a set of specifically molded AFOs would be ordered. At discharge, both the PT and OT made a home visit with the hospital social worker and parents to determine what home adaptations and support services would be necessary.

Follow-up of Nancy's outpatient therapy showed that she continued to make gradual recovery over the next 1.5 years. She returned to school 3 months after rehabilitation discharge using a wheelchair. She graduated to a walker, then to forearm crutches, and finally to independent ambulation. She refused to be seen using a walker at school, so she continued to use the wheelchair at school until she was independent on crutches. She continued to wear bilateral AFOs but was weaned from full-time use approximately 14 months after discharge. During the weaning process, Nancy wore her AFOs at school while walking and for any walking distance over four city blocks or if she heard her feet begin to slap from fatigued dorsiflexors. By 14 months, Nancy showed no evidence of overuse weakness after her regular activities, although she had difficulty with endurance activities in her physical education classes. When hiking, she carried her AFOs to use when she expected a long downhill trek to prevent overwork from eccentric muscle activity. By age 19 years—3 years postonset—Nancy had returned fully to her normal activity level.

Skirrow and colleagues²⁰⁶ remind clinicians that the “intensive care patient is plunged into a world of machines that flash and beep; of tubes and wires that seem to spring from almost every orifice; and of mind-numbing sedative and analgesic medications.” Needless to say, evidence is increasing that patients treated in acute trauma rooms or ICUs can have posttraumatic stress disorder (PTSD). Particularly vulnerable are patients who have had previous traumatic experiences. PTSD places patients at marked risk for increased startle responses, extreme vigilance or anticipation of painful events, sleep disorders, terrifying dreams, and dissociative flashbacks after leaving the ICU; sometimes these symptoms are left untreated for years after the experience.^{152,207} Patients discharged from prolonged ICU experiences, especially those who had respiratory failure, have an increased incidence of anxiety, depression, and panic disorders years after discharge.

In a nursing study of patient experiences in the ICU, researchers found that patients often felt anxious, apprehensive, and fearful. The patients expected ICU nurses to be experienced and technically adept, but those who felt most secure despite the traumatic ICU experiences felt that the nurses were vigilant to their needs and offered personalized care,^{152,208} a point clearly made by Nancy in the case study. Although one might expect ICU staff to be carefully tuned in to patient needs, the highly technical nature of modern ICUs may attract personnel less focused on individual patient care, or it may prevent caring staff from attending to the little kindnesses that are so comforting to critically ill patients. Baxter²⁰⁷ suggests that caregivers in the ICU try to orient patients to what is being done, to approach the patients within their field of vision, and to minimize unexpected noises and sudden touching.

Although most patients recover well from GBS, 3 to 6 years after onset of GBS 38% of patients in a Dutch study had to make a job change to accommodate their physical status, 44% had to alter their leisure activities, and nearly 50% described ongoing psychosocial changes.²⁰³ Similar findings were reported in a study of Japanese patients recovering from GBS.^{209,210}

In summary, the rehabilitation program for a person with GBS must be graded carefully according to the stage of illness. In the acute care environment when respiratory deficits are present, the initial emphasis is directed toward support of maximal respiratory status through postural drainage, chest stretching, and breathing exercises. Because of prolonged bed rest and immobility related to weakness, accessory and physiological ROM must be maintained with around-the-clock efforts. Splinting or positioning devices are recommended to maintain functional positions during prolonged periods of immobility. A gradual program to increase upright tolerance is begun when respiratory and autonomic functions have stabilized. Therapists must keep in mind the potential to damage denervated muscles with aggressive strengthening programs when developing a rehabilitation plan and a home-based conditioning program. Perhaps as a result of cautious exercise programs, cardiovascular conditioning appears to lag significantly behind strengthening, so endurance training should specifically follow the return of strength. Adaptive equipment and orthoses should be used as needed to protect weakened muscles, facilitate normal movement, and prevent fatigue during the

reinnervation process. Although a rehabilitation program has been found to make a measurable difference in patient long-term recovery, many patients are being discharged without follow-up care.²¹¹ Therefore therapists should be assertive in ensuring that their patients with GBS have ongoing contact with rehabilitation specialists who can guide the recovery process (see *Case Study 17-2*).

DUCHENNE MUSCULAR DYSTROPHY

Pathology and Medical Diagnosis

Muscular dystrophy refers to forms of hereditary myopathy characterized by progressive muscle weakness associated with deterioration, destruction, and regeneration of muscle fibers. During the process, muscle fibers are gradually replaced with fibrous and fatty tissue. Each of the inherited forms of myopathy (e.g., Becker dystrophy, myotonic dystrophy, limb-girdle dystrophy, and facioscapulohumeral dystrophy) has its own unique genetic and phenotypic characteristics. (For a comprehensive review of the forms of muscular dystrophy and myopathy, see Dubowitz.²¹²) Because Duchenne (pseudohypertrophic) muscular dystrophy (DMD) is one of the most commonly known forms of muscular dystrophy, it is used as a model for discussion of treatment implications for therapists. DMD is a disease of progressive muscle weakness leading to total paralysis and early death in the late teens or young adulthood. It has an incidence of 13 to 33 cases per 100,000 live births and a new mutation rate of approximately 1 in 10,000 (i.e., one third or more of cases occur in families without a history of DMD). The abnormal gene for DMD has been detected on the X chromosome at band Xp21.2, which encodes for dystrophin, a 427-kD cytoskeleton protein in the membrane. Because it has an X-linked recessive pattern, the disease affects males almost exclusively.²¹³ However, in nearly one third of DMD cases, DNA analysis is normal and diagnosis must be confirmed by protein analysis or immunohistology tests.²¹⁴

In almost 100% of patients with DMD there is a complete absence of dystrophin from muscle tissue. This loss of dystrophin results in a weakened cell membrane that is easily damaged in muscle contraction.²¹³ However, loss of dystrophin alone is not considered the sole explanation of the severity and lethality of muscular dystrophy.²¹⁵

Laboratory studies show serum creatine kinase (CK) elevated more than 100 times normal in early stages of the disease. These CK levels decrease over time with loss of muscle mass. Elevated CK level is evident at birth long before symptoms are evident. Muscle biopsy specimens show degeneration with gradual loss of fiber, variation in fiber size, and a proliferation of connective and adipose tissue. Histochemical studies indicate loss of subdivision into fiber types, with a tendency toward type I fiber predominance. Electromyographic studies show patterns of low-amplitude, short-duration, polyphasic motor unit action potentials.

Although the absence of dystrophin is usually discussed relative to skeletal muscle, dystrophin is also evident on the membrane surfaces of the cardiac Purkinje fibers and is thought to contribute to the cardiac conduction problems seen in DMD. Cardiac involvement is present in more than 60% of boys with DMD across all ages; however, the common electrocardiogram and electrocardiographic abnormalities are reflected early in clinical complications in 30% of

boys until late stages of the disease, when more than 95% of boys have significant cardiomyopathy. Because of the increased life span secondary to in-home ventilation for respiratory failure, nearly 20% to 30% of deaths can be attributed to cardiac disease.²¹⁶

The average IQ of boys with DMD is approximately 85, with one third of the boys testing below 75, as reflected in delayed developmental milestones. A specific deficit in verbal intelligence and verbal memory that leads to significant impairment in later cognitive development has been identified.^{217,218}

Clinical Presentation

Although histological studies have indicated that DMD may be identified in the fetus as early as the first trimester, symptoms are seldom noted until the child is 2 to 5 years of age. When recalling the child's early development, parents often state that the affected child was more placid and less physically active than expected.²¹⁹ The earliest obvious manifestations of DMD, however, may be the delay of early developmental milestones, particularly crawling and walking. In many cases the onset is gradual. Parents or teachers may first identify a problem because the boy is noted to have difficulty keeping up with peers during normal play activities and to be somewhat clumsy, with frequent falling when attempting to run, jump, climb structures, or negotiate uneven terrain. By age 5 years, symmetrical muscle weakness can usually be clearly identified by MMT. Deep tendon reflexes may be absent by 8 to 10 years or earlier. Sensation is normal.²²⁰

The typical progression of weakness is symmetrical from proximal to distal, with marked weakness of the pelvic and shoulder girdle musculature preceding weakness of the trunk and more distal extremity muscles. Bowel and bladder function is usually spared. Progression of weakness is slow but persistent. Weakness of trunk and lower-extremity musculature typically leads to changes in gait at 3 to 6 years of age. Muscle mass continues to decline, with increasing weakness of the trunk, anterior neck, and upper-extremity musculature affecting functional activities. A typical child will continue walking until about age 12 or 13 years, at which time the process of transition to a wheelchair becomes imperative. A rapid decrease in strength may occur after prolonged periods of immobilization caused by illness, injury, or surgery.²²¹

Progression of Lower-Extremity Weakness

Before age 5 years, hypertrophy of the calf muscles is frequently noted. Pseudohypertrophy is evident as the muscle tissue is replaced by fat and fibrous tissue. Even in the early stages of the disease, few boys with DMD walk with a normal gait pattern. Because of early pelvic girdle muscle weakness, most young boys retain a developmentally immature, wide-based gait pattern. An early distinctive feature of DMD is the Gowers maneuver, in which the child gets up from the floor by using his arms to crawl up his own legs (Figure 17-5).²¹⁹

Muscle imbalance occurs in typical patterns as a result of weakness and contractures. As the posterior hip muscles weaken, the child must arch his back when standing and retract his shoulder girdle to maintain the center of gravity behind the hip joint. This creates a pattern of lumbar lordosis with protrusion of the abdomen. As the quadriceps

weaken, the child must maintain his knees in hyperextension to place the axis of rotation posterior to the line of gravity. At this point, mild equinus contractures caused by a muscle imbalance between the plantar and dorsiflexors may help the child maintain knee control because the gastrocnemius-soleus group provides a torque that opposes knee flexion. If plantar flexion contractures become severe, however, the child will not be able to maintain standing balance because his base of support is too small and his ankle adaptive strategies are nonfunctional.

Once the child stops weight bearing, development of severe equinovarus deformities is common. Figure 17-6 shows a pattern of progression of muscle imbalance affecting the trunk and lower extremities in stance. Note the increasing lordosis and plantar flexion as the boys attempt to maintain their center of gravity posterior to the hip joint and anterior to the knee joint.

Progression of Gait Pattern Changes

The typical changes in gait pattern over time are identified in Figure 17-7; however, age alone is not an adequate index of predicted gait pattern. Many factors influence how long a child will be able to ambulate. Contributing factors are rate of progression of weakness; severity of contractures (hip flexion, external rotation, abduction, knee flexion, and plantar flexion—inversion contractures occur as disease progresses); influence of body weight; degree of respiratory compromise; type of treatment interventions such as bracing, surgery, and exercise; extent of family support; and the child's personal motivation to ambulate. When the child can no longer ambulate functionally, a wheelchair must be ordered to fit the specific needs of that child within his home and community environment. (For an extensive analysis of changes in gait pattern see Sutherland and colleagues.²²²)

Progression of Upper-Extremity Weakness

The upper-extremity pattern of weakness is similar to that in the lower extremities, with proximal musculature being affected before distal musculature. Functional changes related to weakness of upper-extremity musculature, however, usually lag behind those in the lower extremities by 2 to 3 years. The early weakness of the scapular stabilization muscles interferes with controlled movement of the arms and hands during reaching. The child gradually loses biceps and brachioradialis function, followed by continued deterioration of triceps and more distal musculature. The marked instability of scapular musculature is clearly evident when the child tries to elevate his trunk with his arms (e.g., when attempting to use crutches) or when he is lifted from under the shoulders.^{220,223} A classic test of scapular stability is the test for the Meryon sign, in which the child slips from the examiner's grip as the child is being lifted from under the arms (Figure 17-8). Typical progression of upper-extremity weakness is shown by use of the reaching test (Figure 17-9).

By the time the child reaches stage 3 of the reaching test, he needs considerable help with eating, hair care, and oral hygiene. Because of major trunk involvement and marked lower-extremity weakness, the child will also be dependent for most ADLs, such as hygiene, dressing, and transferring. Weakness of the respiratory muscles (diaphragm, chest wall, and abdominal musculature) is usually evident by the tenth or twelfth year, although the diaphragm remains functional

Figure 17-5 ■ Child demonstrating Gowers maneuver necessary to achieve upright posture because of pelvic and trunk weakness caused by Duchenne muscular dystrophy.

longer than do the intercostal and accessory muscles. A progressive, sometimes severe scoliosis may contribute to respiratory compromise. Pure respiratory failure, restrictive lung disease, or respiratory failure caused by infection is the usual cause of death, most commonly at age 18 to 25 years.²²⁴ Typical functional stages in DMD are identified in [Box 17-5](#). See Emery and Muntoni²¹³ for a comprehensive review of the clinical process of DMD.

Medical Intervention

Treatment of Primary Pathology

DMD has no cure. Some clinicians suggest that until an effective treatment can be found, the best way to decrease the number of children with DMD is through genetic counseling.

Serum CK is elevated in the female carriers, and genetic molecular probes of possible carriers are now available to identify deletions within the Xp21 region (the short arm of the X chromosome) at a 95% accuracy level. Of course, some families may have belief systems that do not allow consideration of pregnancy termination to prevent having a boy with possible DMD. Those views must be respected. Prenatal diagnosis of DMD for women without a family history of the disease is not yet practical.²²⁵

Despite much effort, an effective pharmaceutical agent has not been identified to treat DMD. In a Cochrane review, Manzur and colleagues²²⁶ concluded that glucocorticoid corticosteroid therapy improves muscle strength in the short term of 6 months to 2 years; however, adverse effects such as weight gain, excessive hair growth, osteoporosis, and behavioral problems were noted. Researchers have also attempted to implant the normal precursor muscle cells or myoblasts directly into dystrophic mice and, in several cases, into children with DMD to precipitate the proliferation of normal donor muscle cells into the host muscles of dystrophic subjects, but results have not led to significant improvement.²²⁷ Animal studies using helper-dependent adenoviral vectors for dystrophin gene transfer to muscles in dystrophic mice show promise for patients with DMD.²²⁸

Although no cure for DMD is on the horizon despite the positive research on gene transfer, the functional status of the patient, quality of life, and life expectancy can be influenced with thoughtful, functionally based treatment and supportive care. [Figure 17-10](#) provides an overall scheme for the management of DMD.

Figure 17-9 ■ Method of evaluating the working hand as demonstrated by the reaching test.

BOX 17-5 ■ FUNCTIONAL TRANSITIONS IN PATIENTS WITH MUSCULAR DYSTROPHY

1. Ambulates with mild waddling gait and lordosis. Can run with marked effort, gait problems magnified. Can ascend, descend steps, curbs.
2. Ambulates with moderate waddling gait and lordosis. Cannot run. Difficulty with stairs and curbs. Rises from floor using Gowers maneuver. Rises from chair independently.
3. Ambulates with moderately severe waddling gait and lordosis. Rises from chair independently but cannot ascend or descend curbs or stairs or rise from floor independently.
4. Ambulates with assistance or in some cases with bilateral knee-ankle-foot orthoses. May have had surgical release of contractures. May need assistance with balance. Needs wheelchair for community mobility. Propels manual chair slowly. Independent in bed and self-care, although may need help with some aspects of dressing and bathing because of time constraints.
5. Transfers independently from wheelchair. Unable to walk independently but can bear and shift weight to walk with orthoses if supported. Can propel self in manual chair but has limited endurance. Motorized chair more functional. Independent in self-care with transfer assist for bath or shower.
6. Wheelchair independence in motorized chair. May need trunk support or orthosis. Needs assistance in bed and with major dressing. Can perform self-grooming but is dependent for toileting and bathing. May need alternating pressure relief mattress.
7. Wheelchair independence in motorized chair but may need to recline intermittently while in chair. Dependent in hygiene and most self-care requiring proximal upper-extremity control.
8. As previous stages; will also use two hands for single-hand activities—one hand supports working arm. May perform simple table-level hand activities, some self-feeding with arm support.
9. Sits in wheelchair only with trunk support and intermittent reclining or transfer to a supine position. Boys attending school may need to be on gurney for part of day. May benefit from nighttime ventilatory support or intermittent daytime positive-pressure ventilation. (Some patients may have had an elective tracheostomy and need ventilatory support unit attached to wheelchair.) May have some hand control if arms supported. Will need help with turning at night.
10. Totally dependent. Unable to tolerate upright position, may elect home ventilatory support. Tracheostomy necessary for prolonged ventilation. Tracheostomy may be adapted for speech if oral musculature adequate. Needs 24-hour care. If around-the-clock home care cannot be arranged, patient must be hospitalized.

Treatment of Cardiopulmonary Factors

Respiratory failure is the cause of death in 70% to 80% of patients with DMD. Cardiac and other causes account for the remaining deaths. Although cardiac involvement is evident early, because of limited physical activity the clinical impact of heart disease is not a significant problem until the adolescent years. Even while ambulatory, children with DMD have a lower exercise performance than age-matched healthy children, with higher resting heart rates and diminished cardiopulmonary response to submaximal and maximal exercise.²²⁹ Once the child becomes wheelchair dependent, his cardiorespiratory fitness deteriorates markedly. With increasing weakness of the respiratory musculature and the development of scoliosis, physicians must be vigilant in their treatment of respiratory infections.²³⁰ The American Thoracic Society consensus statement on the respiratory care of boys with DMD suggests the following:

- A child should be seen at age 4 to 6 years for baseline pulmonary function testing.
- Patients should be seen by a pediatric respiratory physician twice a year after becoming wheelchair dependent if the FVC falls below 80% or the child is older than 12 years.
- Patients who need mechanically assisted airway clearance or mechanically assisted ventilation should be seen by a pulmonary specialist every 3 to 6 months.
- All patients should undergo cardiac and pulmonary assessments before any surgery.²¹⁴

Assistance in respiration progresses in steps.²²¹ In the first step, a self-inflating manual ventilation bag may be sufficient. Step two is associated with manual and mechanically assisted cough techniques. Steps three and four consist of the institution of nocturnal and daytime ventilation, respectively. Step five consists of tracheostomy, if the patient and family prefer.

Sleep-disordered breathing and hypoventilation are common in the later stages of DMD, and the onset is often subtle. Early symptoms include repeated nighttime awakenings, early morning headache, and daytime sleepiness. Inexpensive oximetry can be used in the home to identify nighttime oxygen desaturation if polysomnography with continuous carbon dioxide monitoring is not available.²³¹

Because sleep hypoxia is common in the later stages of DMD, IPPV or noninvasive ventilation by nasal mask or mouthpiece is recommended to control oxygen desaturation at night. Eventually most boys with DMD enter a stage of constant hypoventilation throughout the day and night, and a decision needs to be made about the use of 24-hour ventilation support. Daytime ventilation should be considered when waking PCO_2 exceeds 50 mm Hg or hemoglobin saturation is lower than 92% while awake.²¹⁴ Motorized wheelchairs can be adapted to handle ventilator systems so that the boys can remain active and mobile.

Once a patient with DMD requires daytime and nighttime ventilation and has severe bulbar muscle weakness, a decision must be made to elect ventilation by tracheostomy

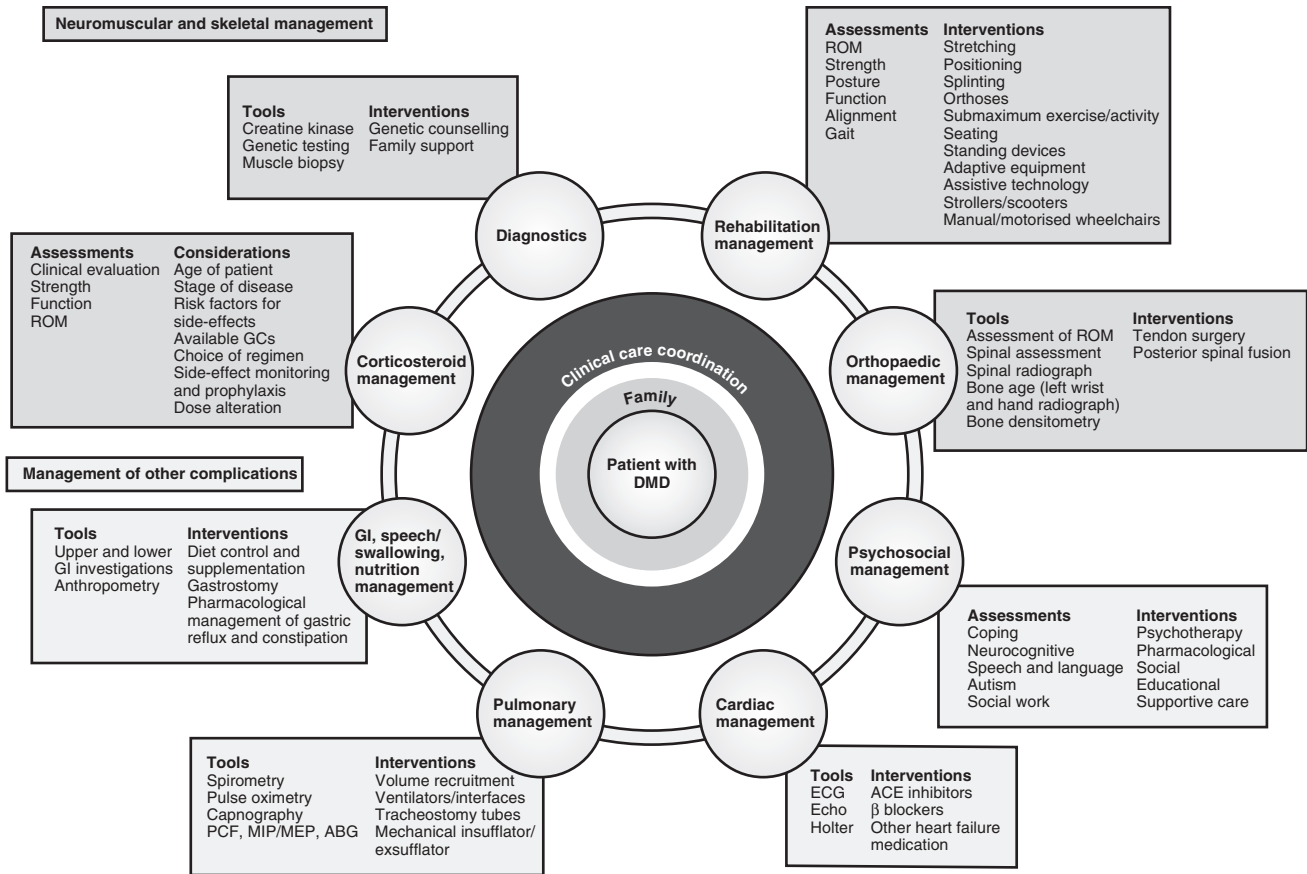

Figure 17-10 ■ Management of Duchenne muscular dystrophy (DMD). Coordination of clinical care is a crucial component of the management of DMD. This care is best provided in a multidisciplinary care setting in which an individual and family can access expertise for the required multisystem management of DMD in a collaborative effort. A coordinated clinical care role can be provided by a wide range of health care professionals depending on local services, including (but not limited to) neurologists or pediatric neurologists, rehabilitation specialists, neurogeneticists, pediatricians, and primary care physicians. It is crucial that the person responsible for the coordination of clinical care be aware of the available assessments, tools, and interventions to proactively manage all potential issues involving DMD. *ABG*, Arterial blood gas; *ACE*, angiotensin-converting enzyme; *DMD*, Duchenne muscular dystrophy; *ECG*, electrocardiogram; *Echo*, echocardiogram; *GC*, glucocorticoids; *GI*, gastrointestinal; *MEP*, maximum expiratory pressure; *MIP*, maximum inspiratory pressure; *PCF*, peak cough flow; *ROM*, range of motion. (From Bushby K, Finkel R, Birnkrant DJ, et al: Diagnosis and management of Duchenne muscular dystrophy, part 1: diagnosis, and pharmacological and psychosocial management. *Lancet Neurol* 9:77–93, 2010.)

or palliative care. Ventilation by tracheostomy allows higher ventilation pressures and a better patient-ventilator interface.²³² However, use of a tracheostomy requires careful stoma hygiene to prevent infections and mucus plugs and requires 24-hour caregiver vigilance.²³³ Although many patients and families adapt well to tracheostomy use, the ability to speak audibly may be affected. Consideration must be given to use of a speaking valve system.²¹⁴ Several cases of pneumothorax have been reported with long-term IPPV.²³⁴ Also, as increasing numbers of patients use long-term tracheostomy-based ventilation, the potential for tracheal erosion or tracheobronchomalacia, which must be monitored to prevent hemorrhaging, is increasing.²³⁵ As with patients with ALS, many significant treatment and ethical decisions must be made by the patient, family, and health care providers when submitting to prolonged HMV.²³⁶ Patient autonomy

and family input after adequate patient education about prolongation of life by tracheostomy ventilation must be respected.²¹⁴

Cardiomyopathy is present in 59% of children with DMD by 10 years of age, but the cardiac problems seldom become symptomatic until the end stages of DMD because the child's decreased activity level does not stress the weakened heart muscle. In later stages of the disease, however, cor pulmonale with right-sided heart failure may occur. Medical treatment of any cardiac symptoms generally follows the conventional interventions. Some boys with severe scoliosis that creates cardiac compression may require correction by spinal fixation.^{237,238} Retrospective data suggest that children treated before ventricular dysfunction with corticosteroids have a lower incidence of cardiac involvement.²¹⁴

Nutritional Concerns

Excessive weight gain that impairs functional ability is a frequent and difficult problem for children with DMD and their families. The typical active child needs approximately 2400 calories daily to maintain weight and grow; however, the child with DMD who is more sedentary or who is wheelchair dependent may need 1200 or fewer calories to maintain weight. Because of decreased esophageal and intestinal motility, exacerbated by weak or absent abdominal muscle strength, a healthy low-fat diet should be encouraged with adequate bulk foods, stool softeners, and fluids to facilitate bowel function and motility. Problems with obesity are often related to the family's typical pattern of eating and nurturing. The child and family members may "feed" their anxiety or depression about the disease.²²⁵ In many cases, family members and friends feel that the child's only pleasure may be eating. Although this may seem true, caring for a totally dependent obese teenager or young adult can become problematic for both the child and the caregivers. Before obesity becomes an issue, the child and his family should be referred for comprehensive nutritional advice from a specialist experienced in dealing with childhood obesity. Suggestions for adapting eating behavior and food choices will not be followed if they are too restrictive or unreasonable for the child's social situation.^{239,240}

Although obesity is a common problem for children with DMD (greater than 54%), malnutrition is also common. Malnutrition usually occurs in the late stages of the disease as a result of dysphagia.²¹⁴ Special care must be taken to provide adequate nutrition after spinal surgery. One review showed that postsurgical weight loss was related to the inability to self-feed; therefore the investigators suggest that before surgery a feeding evaluation should be done and an appropriate plan should be put in place to prevent postsurgical malnutrition.²⁴¹

As the disease progresses, some children develop problems swallowing, and then weight loss and malnutrition can become an issue. To decrease the possibility of aspiration, careful attention must be paid to food textures and chewing and swallowing functions (see page 537 for information on dealing with bulbar symptoms). Depending on the patient's and family's decisions about prolongation of life, some patients now elect to have a permanent PEG placed once self-feeding and swallowing become a problem rather than a pleasure. Even if the patient can still swallow and enjoys eating in the late stages of DMD, the patient may not be able to physically take in adequate calories; the PEG allows the delivery of needed calories and fluids beyond what the patient can take orally (see page 563 for information on dysphagia and eating issues).²⁴² Consensus is that body weight and body mass index should be reviewed regularly and family education on nutrition should be an ongoing process. Evaluation of swallowing should be assessed by taking a history of choking episodes and observing the child eat different foods and fluids. Videofluoroscopy should be used to determine if aspiration is a problem, and appropriate adjustments in feeding should be instituted under the supervision of the appropriate therapist.²¹⁴ (See also Bushby and colleagues.²²¹)

Treatment of Scoliosis

Scoliosis is a frequent complication of DMD, with a reported incidence of nearly 90%. Consequences of severe scoliosis are increased respiratory problems in boys with

respiratory compromise, chronic pain related to musculoskeletal problems, sitting tolerance difficulties, and caregiving issues. Figure 17-11 presents an example of a boy with moderate scoliosis that affects sitting posture. Note the pelvic asymmetry that would seriously affect sitting alignment.

Scoliosis tends to occur in two basic patterns: the early-onset form (seen in approximately 23%), which becomes evident before the child begins to use a wheelchair, and the late-onset form, which develops, on average, 4 years after wheelchair dependency. In the early-onset form the curve usually becomes severe and progressive, leading to pulmonary compromise and structural-based pain. In the late-onset form the course is usually mild. Unfortunately, attempts to control sitting posture through the use of a spinal orthosis and wheelchair seating inserts (inserts that place the child in lumbar lordosis to lock facets, thereby preventing rotation and lateral collapse, or, more commonly, lumbar and thoracic lateral supports) have been disappointing.²⁴³ Bach²⁴⁴ states that thoracolumbar bracing is never indicated to slow scoliosis development in DMD and it cannot substitute for surgical correction; however, spinal bracing may improve comfort and postural stability in some patients who are not eligible for surgical correction because of severe respiratory or cardiac involvement.²⁴²

Efforts have been made to delay the time of onset of scoliosis with steroid treatment protocols. Evidence supports the hypothesis that onset of scoliosis can be delayed; however, a longer follow-up period would be required to determine if scoliosis can be prevented.²⁴⁵

Cervellati and colleagues²⁴⁶ reported on a study of 20 boys treated from 1985 to 1995 and concluded that early surgery significantly reduces the risk factors associated with severe spinal deformities. The period after spinal surgery requires careful coordination of medical, respiratory, and physical therapy services. Depending on the hospital culture, PTs may be responsible for the pulmonary drainage and breathing exercise programs as well as typical passive and active exercise programs while the child is in ICU and postsurgical care environments. Preferably, therapists should introduce postural drainage and breathing techniques as well as exercise expectations to the child before surgery to gain better cooperation after surgery.

Figure 17-11 ■ Moderate scoliosis affecting sitting stability.

Treatment of Other Musculoskeletal Dysfunctions

The primary effect of progressive weakness in DMD generally results in secondary effects such as decreases in muscle extensibility, joint contractures, and bone demineralization. Strength loss diminishes the ability to move actively through full range, shift out of static positions, balance muscle forces around a joint, and avoid fibrotic changes in muscle tissue.²²¹ Loss of ROM from muscle shortening and joint stiffening will occur if not aggressively prevented. Once present, contractures can severely complicate function. Long bone fractures in children with DMD are a serious problem that can have a significant long-term impact on ambulation. In a study of 378 patients, 21% had incurred fractures, primarily from falling. Leg fractures predominate in independent ambulators and wheelchair users, whereas upper-extremity fractures more often occurred in boys using KAFOs. Twenty percent of those who had fractures lost the ability to ambulate.²⁴⁷

In standard treatment protocols for children with DMD who have impending loss of ability to walk independently, bilateral KAFOs are used in conjunction with surgical release of contractures.²⁴⁸ At the point of surgery, a pattern of contractures has magnified the effect of weakness from the loss of approximately 60% of muscle mass.²⁴⁹ Surgery is typically followed by an aggressive therapy program. Bach and McKeon²⁵⁰ studied 13 boys with DMD who had surgery to release lower-extremity contractures. Seven boys were ambulating independently before surgery (early surgery group), and six boys were preparing to use or had begun to use a wheelchair before surgery (late surgery group). Depending on the contracture patterns, the boys underwent surgical procedures that typically included subcutaneous release of the Achilles tendons and hamstring muscles and fasciotomy of the iliotibial bands. Four patients had rerouting of the posterior tibialis to the dorsal surface of the second or third cuneiform to balance the foot and prevent the often severe varus position of the foot. Boys in the late surgical group required more extensive inpatient rehabilitation, whereas boys in the early surgical group were treated as outpatients after a short hospitalization. Physical therapy was started on the second postoperative day. The program consisted of general conditioning exercises of the trunk and extremities (e.g., rolling, trunk stabilization, neck and head control), stretching exercises, and intensive weight bearing in standing while wearing bilateral long-leg casts or below-knee casts, depending on the surgery. One child participated in a pool therapy program. Bach and McKeon²⁵⁰ suggest that early surgery for contractures followed by intensive physical therapy can prolong brace-free ambulation. The number of falls experienced by the boys decreased markedly after the surgery and rehabilitation period. Boys in the early intervention groups benefited from the surgical interventions more than the boys in the later intervention groups. All patients and their families in the early surgery group thought that the procedures were helpful. Boys in the late surgery group, however, stated either that they would not have had the surgery if they had a chance to decide again or that they had no opinion. Roposch and colleagues²⁵¹ reviewed the records of 91 boys with the typical equinovarus deformity in DMD and strongly recommended surgical intervention, including a posterior tibialis transfer, over conservative, nonsurgical treatment to maintain foot position and lengthen time of ambulation.

Manzur and colleagues²⁵² carried out a randomized, controlled trial of 20 boys with DMD (ages 4 to 6 years) to study the effect of early release of contractures versus conservative (stretching) programs. The boys were followed for 12 months or more. Surgery corrected the contractions and improved the speed of gait and transfers over conservative treatment as measured at 12 months, but a 2-year follow-up of six of the boys who had surgery revealed a recurrence of ankle contractures. In addition, some of the boys in the operated group showed more rapid deterioration. The authors did not recommend routine early surgery to relieve contractures.

Therapeutic Management of Movement Dysfunction Associated with Duchenne Muscular Dystrophy

Like ALS, DMD has a relentless and incurable progression toward total dependence and eventual early death. The differences are the population (children rather than adults) and time course, with DMD taking 15 to 25 years rather than the 3 to 5 years typical of adults with ALS. As in ALS and GBS, strength and endurance remain the primary impairments of DMD, with secondary problems such as contractures and respiratory problems following from immobility. Unlike in the other neuromuscular disorders, the endurance problems in DMD are related to peripheral fatigue, fatigue stemming from the muscles themselves rather than from the lack of ability to recruit additional motor units.²⁵³ As in ALS and GBS, therapeutic management in DMD will involve evolution of the intensity and frequency of exercise to correspond to changes in the strength and endurance of the patient. In all three disorders, the general therapeutic goals are to maximize function, manage discomfort, and promote optimal quality of life. The differences among the disorders mean that the actual form of the exercises and interventions in DMD may require adaptation to suit a child or adolescent. Ideally, a team of specialists should be involved in the long-term care of a child with DMD and his family. The therapist's primary role is twofold: to perform serial examinations of the child's movement capabilities and to adjust the child's intervention program as the disease progresses. Even with relentlessly progressive diseases, rehabilitation programs can have potential psychological benefits, such as more positive coping strategies, while physical activity continues to decline.²⁵⁴

Examination

A typical therapy examination should include a history, systems review, and tests and measures to assess muscle strength, endurance, and ROM impairments along with levels of activity and participation. In some facilities the therapist also collects data on the child's pulmonary status.¹⁶⁷ History taking should include the course of the disease, any recent illnesses or losses of function, coexisting neuromotor or other medical conditions, current concerns, and the goals of the patient and family. Screening tests can help rule out sensory deficits, identify cardiac and respiratory issues, and determine skin integrity, especially in immobile patients. Checking vital signs at rest and immediately after activity, noting communication ability, and assessing ability to follow multistep commands are all important components. When screening tests indicate a deficit, follow-up should occur with additional testing or referral to

the appropriate professional. The tests and measures appropriate for assessing the movement dysfunction of patients with DMD include measures of strength, ROM, function, activity, and quality of life. Palmieri and colleagues²⁵⁵ review many of the measures reported in the literature for use in this population.

Manual Muscle Testing. MMT is used extensively for measuring muscle strength of children with DMD^{255,256} and is relatively reliable if consecutive examinations are made by the same rater. Intrarater reliability of scores in the gravity-eliminated position have been shown to be highest in this population.²⁵⁷ DMD shows a linear pattern of decreased muscle strength (loss of about 0.25 MMT unit per year from ages 6 to 13, and 0.06 MMT unit per year from age 13 on)²⁵⁸ without marked increases in the rate of deterioration in strength over time. Thus, marked, precipitous changes in muscle strength noted in a few months with initiation of bracing or wheelchair use,²²³ for example, or immobilization after fracture, generally reflect disuse atrophy rather than disease progression. Such transitory weakness may respond to increased activity and exercise. The history and medical records can help differentiate weakness stemming from various sources and thus determine the potential for strengthening. Cable and strain-gauge tensiometers, handheld myometers and dynamometers, and isokinetic dynamometers may also be useful for a more discriminating documentation of muscle strength.^{255,256}

Range of Motion. ROM is assessed with goniometry in most cases of DMD.²⁵⁶ As with MMT, serial ROM evaluations should be completed by the same therapist because intrarater reliability is higher than interrater reliability in this population.²⁵⁹ The two-joint muscles are most prone to developing shortness, so the positioning of limbs for testing of ROM must be considered. The lack of upright weight bearing and reliance on a wheelchair for mobility tend to accelerate contracture development in DMD; therapists should be particularly vigilant about monitoring lower-extremity ROM as the child becomes more sedentary.²⁶⁰ Some boys with significant shoulder girdle weakness begin to develop contractures even before they become wheelchair dependent. Early attention should be paid to possible subluxation of the shoulder.²⁶¹

Particular attention should be given to the accuracy of measuring hip ROM. Rideau and colleagues²⁶² recommend the “dangling leg” test, in which the child is placed supine with his lower legs hanging over the end of the table. An inability to bring the thighs to midline indicates shortening of the iliotibial band and hip abductors. One can quantify the shortening by measuring the distance of the thigh from the midline and from the surface of the table. In addition, the therapist should note pelvic obliquity, preferably with serial photographs taken with the child in the sitting and supine positions. Ideally, the patient can be photographed from the back in sitting position against a simple clear, framed plastic sheet with grid squares to allow easy, nonradiographic tracking of scoliosis.

Functional Status. The child’s functional status continues to be relatively stable for some time even when MMT indicates that the child is losing strength. Because the weakness is gradual, many children develop remarkably adaptive adjustments in movement patterns to remain functional even with marked strength loss. Lue and colleagues²⁶³ developed

the Muscular Dystrophy Functional Rating Scale (MDFRS) to standardize assessment of the functional impact of muscular dystrophy, including people with DMD—more than half of those tested. The MDFRS consists of 33 items covering mobility, basic ADLs, arm function, and impairment (including contractures, strength of the trunk and neck, scoliosis, and respiratory issues). The developers reported test-retest and interrater reliabilities of 0.98 to 0.99 and good evidence of validity. Brooke and colleagues²⁶⁴ and Vignos and colleagues²⁶⁵ have described previous functional scales for use in DMD; the MDFRS compares favorably with each of these, with some advantages for determining the child’s status and for predicting appropriate care, perhaps because it is longer.²⁶³ As part of any functional assessment in DMD, adaptive behaviors should be noted. For example, a child may not be able to lift his arm overhead, but he may use his fingers (strength often remains intact even after respiratory support is necessary) to “crawl” up his chest to reach his head or he may lean forward to approximate his chest to his hand or use his other arm or a lever system to assist with activities.²⁴⁴

For ambulatory patients, gait velocity can help predict how long the patient has before transitioning to a wheelchair. In a longitudinal study of 51 boys with DMD, 100% of those who took 9 seconds or more to walk 30 feet were wheelchair bound within 2 years.²⁵⁸ McDonald and colleagues²⁶⁶ also recommend the use of the 6-Minute Walk test as a standardized and functional measure of endurance for this population. Slight modifications may be necessary to keep younger children on-task for this test.²⁶⁶ Observational gait analysis can help to identify adaptive behaviors and use of compensatory strategies during locomotion.²⁵⁶

Respiratory Function. The PT’s role in evaluating respiratory status in children with DMD will vary depending on the facility and area of the country in which the therapist works. For more in-depth information regarding evaluating pulmonary status, refer to Chapter 30 or see Irwin and Tecklin.¹⁶⁷ At a minimum the therapist should evaluate bulbar function, cough effectiveness, and FVC (a simple spirometer available in most clinics is adequate). For more sophisticated testing, the child should be seen by a pulmonary function specialist. In addition, the therapist may monitor activity levels via armbands or pedometers or may assess metabolic equivalents or caloric consumption to design the optimal activity program for children with DMD and obesity.²⁵⁵ One method of testing a child’s energy cost during ambulation is the energy expenditure index,²⁶⁷ which divides walking heart rate (WHR) minus resting heart rate (RHR) by walking speed (distance [D] divided by time [T]): $(EEI = [WHR - RHR]/[D/T])$. Determinations of energy expenditure while walking may factor into the decision to transition to a wheelchair, at least for longer distances.

In late stages the therapist may need to assess the child’s bulbar function to prevent swallowing and aspiration problems caused by tongue and oral-facial muscle weakness.

Therapeutic Goals. The basic goals for a therapeutic program are straightforward: (1) to prevent contractures that can lead to further disability and pain, (2) to maintain maximal strength and endurance and prevent disuse atrophy, (3) to facilitate maximal functional abilities by using appropriate adaptive equipment, (4) to maintain maximal respiratory muscle strength and movement of secretions, and (5) to

foster realistic child and family expectations within the context of the environment. These are broad-based goals; the therapist will need to write more specific, time-oriented goals for a particular episode of care.

Therapeutic Interventions

Younger children with disabilities are usually eligible for school-based therapy services. However, therapists increasingly act primarily in the role of consultant rather than direct service provider, especially for older children. Much of the child's exercise program must be carried out at home by parents or caregivers. When both parents work outside the home or when the child lives in a single-parent home with a working parent, compliance with home programs can be problematic. As many exercise activities as possible should be encouraged within the child's school day so that parents can focus on parenting, nurturing, general caregiving, and simple positioning and bedtime exercises. Under the supervision of a consulting therapist, the child's therapy often can be provided in some form at the child's school if on-site therapists, personal attendants, or adaptive physical education teachers are available.

Respiratory and Dysphagia Care. In the school therapy environment, where most children with DMD are monitored, the therapist should be prepared to provide the child and family with methods to improve breathing efficiency. In the early stages of the disease, the child and family can be taught simple breathing exercises stressing diaphragmatic breathing, full chest expansion, air shifts, and rib cage stretching. Most children enjoy playing with handheld incentive spirometer units and playing blowing games (e.g., bubbles, pinwheels). Respiratory exercise in different studies has resulted in improvement in respiratory endurance,²⁶⁸ ventilatory muscle endurance but not respiratory muscle strength,^{269,270} and both respiratory muscle strength and endurance.²⁷¹ In the last study, two thirds of the 27 subjects had DMD, with percent predicted vital capacities of 27% to 96% that had decreased over the 6 months immediately preceding the exercise protocol. The exercise protocol, monitored via a visual feedback system, consisted of twice-daily sessions of 10 cycles of resisted inspiratory breaths at 70% to 80% of the patient's maximum inspiratory pressure, plus 10 maximal static inspiratory efforts that reached at least 90% of the maximally generated inspiratory pressure. The intervention lasted for 2 years, with increases noted in the first 10 months and a plateau maintained through the end of the training period. Winkler and colleagues²⁷² noted similar effects in a 9-month training protocol, somewhat dependent on the rapidity of respiratory function decline in the year preceding the training. In the 6-month training period of another study, subjects training with resisted inspiratory and expiratory breathing had significantly greater benefit than subjects randomly allocated to the group performing the same breathing exercises without resistance. The static inspiratory and expiratory pressures returned to baseline within 3 months after training ceased, but improvements in perceived exertion persisted for up to 1 year postintervention.²⁷³

Respiratory exercise cannot reverse the process of respiratory failure; however, attention to pulmonary hygiene can help the child cope more effectively with respiratory infections and the discomfort accompanying respiratory compromise.

Although inspiratory exercises tend to be the focus of interventions, expiratory inefficiency may play a major role in the inability to clear secretions.²⁷⁴ Once the child begins to have difficulty clearing secretions, the family should be taught manual or mechanically assisted postural drainage techniques as long as the patient has an adequate cough. Patients who need support with coughing can be taught "air stacking" techniques (taking a series of breaths without exhaling between breaths) to increase intrathoracic pressure needed to cough effectively. Some patients respond well to manual coughing assistance. Increasingly patients and caregivers are being taught to use a mechanical insufflator-exsufflator (positive pressure followed by negative pressure) to stimulate coughing.^{275,276} These techniques should be reviewed and used aggressively whenever the child is bed bound for more than 1 or 2 days and before and after all surgical procedures.²¹⁴ Physical therapy interventions, such as postural drainage and breathing exercises, are invaluable in preventing early death from respiratory failure. The Muscular Dystrophy Association continually updates its information on breathing and respiratory care.^{277,278}

In end stages of DMD when the child is dependent, dealing with oral-motor problems that may interfere with eating and swallowing is imperative. Techniques such as positioning, increased sensory input (texture, temperature), and volume changes in foods may improve the child's swallowing and allow the child to continue taking food orally.²⁷⁹ The interventions are similar to those described for ALS. The Muscular Dystrophy Association also publishes informational manuals dealing with dysphagia problems (see www.mdausa.org).

Prevention of Contractures. Diligent ROM exercises for the whole body will require cooperative efforts of the rehabilitation team and the patient and family. Stretching may progress as weakness dictates, from active to active-assisted to passive to prolonged elongation phases using positioning, splinting, orthoses, and standing devices.²²¹ During the ambulatory phase of the disease, focus should be on the hips, knees, and ankles. Later, focus will shift to the shoulders and the elbow, wrist, and finger flexors. At the first sign of loss of end ROM, the therapist should adjust the child's program to include specific stretches.^{261,280}

Evidence provides a protocol for stretching in people with normal muscles to increase ROM: stretches performed 2 to 5 days a week, once per day, held for 10 to 30 seconds for three or four repetitions over a 6-week time frame.^{281,282} Unfortunately, no such evidence exists for the best stretching protocols in DMD to maintain ROM. Palmieri and colleagues recommend that stretching be performed a minimum of 4 to 6 days per week for any joint or muscle group.²⁵⁵ The stretch should be slow to avoid muscle reflex contractions, and sustained at the end point for 10 to 30 seconds. To increase muscle extensibility, dry or wet heating, electromagnetic stimulation, or a warm bath may help; for best effect, follow a bath by drying with prewarmed towels to avoid shivering and muscle stiffening.²⁵⁵

In a 2010 Cochrane review²⁸³ of the best methods for increasing ankle ROM in patients with neuromuscular disease, only two studies of DMD were noted, with interventions of early surgery²⁵² or prednisone use.²⁸⁴ Surgery eliminated the contractures, but in most cases the contractures had recurred by the 2-year follow-up.²⁵² Prednisone

had no significant effect on ROM in comparison to a placebo or when comparing two different doses.²⁸⁴ Hyde and colleagues²⁸⁵ noted an annual delay of 23% in the development of contractures at the Achilles in boys with DMD randomly allocated to a group receiving both stretching and night splints compared with boys who had stretching alone. Brooke and colleagues²²⁰ reported similar findings, and Scott and colleagues²⁸⁶ noted that boys who had both AFOs and stretching were able to continue walking longer than boys who did not. This evidence indicates that multiple simultaneous strategies may be most beneficial in preventing shortening and maximizing function. Patient and family preferences must be considered for any plan to be effective, however. Some young patients do not tolerate night splinting well. In such cases, AFOs to control plantarflexion contractures may be preferred over long-leg orthotics that prevent knee flexion contractures or align hips (using an additional bar between legs to control rotations).

Early in the course of the disease process, both parents and the child must be educated about the expected changes in muscle balance and how they can play an active role in preventing or limiting the impact of contractures caused by muscle imbalance. Because contractures at the hip, knee, and ankle interfere with the mechanical alignment necessary to stand erect and walk, each day the child should be encouraged to move his own limbs to end ranges through normal play activities to slow development of contractures related to sedentary positioning. Some research supports the view that the combination of positioning, stretching, and splinting should begin before contractures exist. For example, the child can be encouraged to watch television or play video games while lying prone with legs aligned out of the common “frog leg” (hip abduction and external rotation) pattern. Once a child has significant hip flexor or iliotibial band contractures, stretching techniques must be specific because simple prone positioning can force the lumbar spine into excessive lordosis. Although difficult to accomplish in some mainstreamed school environments, positioning the child in a standing frame during several class periods helps provide prolonged stretch to hip, knee, and ankle musculature. Later in the course of the disease, resting hand splints are appropriate to control shortening of the long finger flexors.²²¹

Although development of contractures of the hip, knee, and ankle from muscle imbalances has been thought the cause of early loss of ambulation instead of weakness,²⁸⁷ others believe that weakness causes the loss of ambulation instead.²⁸⁰ Some authors note that loss of ambulation can occur from either case.²⁵⁵ Limiting contracture development facilitates mobility and handling throughout the course of the disease, however, and the best approach to contractures is to prevent them.²⁶⁰

Exercise and the Maintenance of Maximal Functional Level. Because DMD affects muscles throughout childhood and adolescence, when strength and endurance are generally developing, effectiveness of strengthening and aerobic exercise has been difficult to assess.²⁶⁷ Training programs may maximize muscle and cardiorespiratory function, but they have also led to reports of weakness after physical exertion.²⁸⁸ The debate over the value of exercise in DMD and the relative lack of controlled trials have limited the ability of clinicians to provide evidence-based therapy. No definitive

protocols can be provided at this time. In general, however, both strengthening and aerobic exercises should be considered, the frequency and intensity of which should be appropriately prescribed based on the disease course and the patient’s abilities and goals.

Strengthening exercises have had mixed support in the past.²⁸⁹ de Lateur and Giaconi²⁹⁰ noted small gains in strength of the exercised compared with the unexercised quadriceps muscle of four boys with DMD during and for 18 months after a 6-month exercise program of submaximal isokinetic contractions, 30 repetitions, 4 to 5 days per week. No postexercise weakness or increases in deterioration were noted in the exercised muscles. Vignos and Watkins²⁹¹ instituted a home program of maximal resistance exercises for 1 year; the 14 patients with DMD in the exercised group improved in strength for the first 4 months and then reached a plateau, compared with declines in strength of the control group. Scott and colleagues²⁹² noted diminished strength after a strengthening home-exercise program for 18 boys, although with no control group, possible reductions in disease progression could not be confirmed.

Evidence for the effectiveness of strengthening exercises in other muscle disorders is insufficient²⁹³ and cannot thus be generalized to DMD. Elder²⁹⁴ reviewed animal studies suggesting that dystrophic mice trained on a treadmill showed increased damage to muscle tissue, whereas forced swimming in dystrophic mice had no adverse effect. In a case review of three generations of patients with facioscapulohumeral muscular dystrophy (seven cases and one suspected case), Johnson and Braddom²⁹⁵ noted asymmetrical weakness of the upper extremities. They related the weakness to patterns of overuse (dominant side or side used most often in work activities). On the basis of their information and additional evidence that muscle-derived enzymes (CK and myoglobin concentrations in blood) were markedly elevated in patients with DMD after prolonged exercise,²⁹⁶ repetitive exercise may be contraindicated.²⁹⁷ In contrast, Cup and colleagues²⁹³ reported that in their review of 33 studies of exercise therapy for neuromuscular diseases, they found absent or negligible adverse effects; one study reported that “3 of 20 patients decreased their training for 1 or 2 sessions due to delayed-onset soreness.”

Given the evidence to date, Hasson²⁹⁸ concluded that exercise consisting of brief periods of low- or high-intensity activity can improve strength for patients with minimal to moderate weakness. The increased recruitment of motor units from training effects also may improve muscle coordination and reduce disuse atrophy. However, exercise programs have minimal effect on strength of muscles already severely weakened.

In addition to active and resistive exercise programs, Scott and colleagues²⁸⁶ completed a small study of the effect of intermittent, long-term, low-frequency electrical stimulation on dystrophic anterior tibialis muscles. They demonstrated a significant increase in mean voluntary contraction force and suggested that electrical stimulation can have a beneficial effect if used with children whose muscles are not already markedly weakened. Zupan²⁹⁹ supports this finding, but children under treatment were unable to maintain strength beyond 4 to 5 months.

Evidence for the effect of aerobic training in DMD is sparse.³⁰⁰ Hasson,²⁹⁸ in a review of exercise studies of patients with muscular dystrophy, reports that oxygen consumption improved with endurance training, although whether repetitive endurance training at moderate or high intensity (70% of $\dot{V}O_2\text{max}$) causes muscle damage is unknown. Muscle biopsies in DMD have revealed reduced or missing nitric oxide synthase, necessary for sufficient nitric oxide levels.⁵⁵ Nitric oxide normally limits vasoconstriction in muscles during and after exercise and also provides cytoprotection and antiinflammation in muscle tissue. Muscle fatigue in DMD may thus be exacerbated by ischemic exercise.⁵⁵ However, aerobic training in other muscular diseases has shown indications of positive effect on aerobic capacity as well as measures of activities and participation,²⁹³ so generalization to DMD has a possible rationale. In addition, strengthening exercises in combination with aerobic exercises in other muscle disorders have been shown to have a likely positive effect.²⁹³

Overall, the data from animal and human studies suggest that submaximal exercise is not harmful and it may be helpful in maintaining maximal function if the patient does not exercise into marked fatigue. Because muscle endurance and peak power are diminished in addition to muscle strength, a focus on program design related to functional exercises individualized to each child's functional requirements is recommended.²⁷⁴

Ideally, the child's exercise can be incorporated into pleasurable activities adapted for children with movement and weakness-related balance problems. Many ambulatory children enjoy ball activities, walking-based simple obstacle courses, parachute games, table tennis, cycling (preferably tandem), and especially swimming. Swimming is an excellent exercise for children with DMD because they often are quite buoyant because of their increased fat/muscle ratio. Many children can continue to float or swim independently on their backs even when nonambulatory (if supervised) and able to move only distal musculature. The Muscular Dystrophy Association has an excellent guide to water-based exercises: "No Sweat Exercise: Aquatics."³⁰¹

A safe indicator of extent and intensity of exercise is that the patient should recover from exercise fatigue after a night's rest. When designing an active play program, therapists should review the types of muscle contractions that the activity requires, considering that possible muscle damage occurs when muscles are active and functioning in an eccentric manner.³⁰² Concerns about damage from eccentric muscle contractions were supported in animal studies in which dystrophic muscles were found to be more susceptible to stretch-induced muscle damage.³⁰³ Figure 17-12 shows responses of normal and impaired muscle to exercise. (See Eagle's report on exercise in neuromuscular diseases.³⁰⁴) In a summary of findings on effects of physical exercise on conditioning in muscular dystrophy, Ansved³⁰⁵ found that the scientific basis for clear recommendations on exercise prescription is poor, but evidence does show the importance of maintaining an active lifestyle with limitations on high-resistance and eccentric training activities.³⁰⁵

Maintenance of Ambulation. As DMD progresses, the child's posture (a result of both weakness and contracture) and gait pattern abnormalities become extreme and he must work harder to maintain balance while walking. Most

Figure 17-12 ■ Idealized response of normal and impaired muscle to exercise. The therapeutic window of safe exercise narrows progressively. Activities (lower X axis) causing normal exercise effects in normal muscle (upper X axis) correlate with different effects in impaired muscle. (From Coble NO, Maloney FP: Effects of exercise on neuromuscular disease. In Maloney FP, Burks JS, Ringel SP, editors: *Interdisciplinary rehabilitation of multiple sclerosis and neuromuscular disorders*, New York, 1985, JB Lippincott.)

children gradually discontinue walking about a year after they lose their ability to deal with stairs or when daily ambulation time decreases to less than 30 minutes per day.²¹² Toward the end of the child's independent walking stage, he has a marked anterior pelvic tilt with lordosis and a protuberant abdomen. His shoulders are retracted and he may hold his hands behind his hips or elevated in a mid-guard position to stabilize his hips. He has a severe waddling gait with a shortened stride, and he must carefully lock his knees at each step. He falls frequently, which may result in fractures of the lower or upper extremities.

If the child and his family have followed an aggressive ROM, positioning, and activity program, the child's walking time may be extended by months. In most cases, however, the contractures from muscle imbalance continue relentlessly and the child begins to need support when walking.²⁶² When contractures at the hip, knee, and ankle show evidence of interfering with the child's ability to stabilize each joint during stance, most children are referred for surgery to restore functional joint motion. Figure 17-13 shows the typical walking pattern of a boy with DMD who is being considered for release of contractures and bracing.

Bracing either before or after surgery may be indicated to assist with positioning and stabilizing joints for function. Ideally, bilateral KAFOs should be measured and fitted in final form before surgery to release contractures so the child can begin upright weight bearing in the KAFO the day after surgery. KAFOs are commonly fabricated of molded plastic thigh units (ischial weight-bearing quadrilateral socket) with metal joints at the knee (drop locks) and ankle (or a flexible plastic ankle component) (Figure 17-14).³⁰⁶ If the orthoses are not immediately available, the child can begin the standing program in long-leg casts. Casting must be kept to a minimum because of the risk of disuse atrophy in immobilized muscles. (See Grossman and colleagues³⁰⁷ for a review

Figure 17-13 ■ Typical walking pattern of a boy with Duchenne muscular dystrophy who is being considered for release of contractures and bracing.

Figure 17-14 ■ Example of boy walking in knee-ankle-foot orthoses showing ischial weight-bearing quadrilateral socket, knee drop locks, and plastic ankle component.

of the effect of immobilization on normal muscle and appropriate therapy interventions.)

In the hospital, standing in bilateral KAFOs can be initiated on a tilt table. Most children are fearful after surgery and report significant pain when their legs are moved or if they are placed upright. For therapy to be successful during this early standing stage and during passive ROM exercises, the child must have adequate pain medication. If the child is not properly medicated in the first few days after surgery, the therapist may have to deal with difficult, resistant behaviors of the child that persist long after the pain should have subsided. Pain protocols must be discussed before the child's surgical procedures. The child should be medicated at least 30 minutes before the therapist's visit.

Gait training is usually begun within 48 hours after surgery. Initial work focuses on helping the child regain his sense of standing balance because his old patterns of equinus, lordosis, and shoulder retraction may no longer be adaptive. The child should be allowed to find his own best center of balance, and he should be allowed to use compensatory gait deviations necessary to allow the best mobility and stability. Depending on the child's upper-extremity strength and control, he may progress from parallel bars for balance assist, to pushing a wheelchair or weighted walker, to balance assist from a therapist with a safety strap to prevent falls. Some children who seem to need a walker for balance transition do best if they use a walker with forearm rests and vertical hand grips, which seem to help them stabilize their arms more effectively than a standard walker. Fortunately, most children do learn to walk independently without support again after surgery, although they are unable to negotiate steps or inclines or rise from the floor independently.³⁰⁸ Hyde and colleagues³⁰⁶ report that 24 of 30 boys treated with KAFOs were able to achieve functional ambulation again. Vignos and colleagues³⁰⁹ report in a review of long-term treatment of DMD that a combination of operative procedures, orthotics, stretching, and a program of standing and walking resulted in extended walking until a mean age of 13.6 years and standing for 2 years after that. With the early use of surgery and bracing procedures to maintain ambulation, the expected deterioration in muscle strength and function as a result of becoming sedentary in a wheelchair is deferred.³¹⁰

Because most children with DMD are discharged home within a few days of surgery, PTs must provide options for continuing standing within the home. Standing frames are often available through the child's school district or therapy unit. If they are not, the therapist can help the family build a simple standing frame for home. This frame often can be made from a piece of plywood, or a gluteal strap system can be attached to a table at home. If possible the child should be positioned just forward of the line of gravity to encourage back extension with facet stability and to allow the child better head control in the presence of weak anterior neck muscles. Use of swivel walkers has been recommended by some therapists and physicians because the child does not need upper-extremity control for support. Although the concept of hands-free walking seems logical, boys with DMD had more difficulty using the walkers compared with children with paraplegia because of the more delicate postural adjustments needed by children with dystrophy and their greater sensitivity to the motion restriction of the swivel

walker. In addition, older children with DMD are seldom willing to wear externally visible bracing outside the home or school system. Some therapists have reported success with the ORLAU variable center of gravity swivel walker (Mopac Ltd., Eau Claire, Wisconsin)³¹¹; however, support for its use is not widespread.

Bakker and colleagues³¹² reviewed the literature on the effectiveness of treatment with surgery and KAFOs. They found that the scientific strength of the studies was poor. Although the treatment approach seemed to prolong the walking time, whether it extended functional walking was not clear. The children who benefited most were highly motivated and had slower rates of deterioration.

Transition to Wheelchair. Although surgical and orthotic interventions may prolong ambulation within the home and classroom past the predicted time for cessation of independent walking (8 to 12 years), most children begin to use a wheelchair for community mobility and long distances before this time. When children begin to spend more time in their chair, the rate of development of contractures, disuse weakness, and obesity increases.^{249,306} Because of this more rapid deterioration in the child's functional skills, professionals and parents often discourage the child from using a chair for mobility. Children, however, tend to welcome use of the chair because they have more energy for their social interactions and learning tasks.³⁰⁶

Selection of the appropriate wheelchair is often difficult for the patient and family because of the multiple decisions that must be made. Few children with DMD can propel a manual wheelchair for more than a few years because of their increasing upper-extremity weakness. In addition, their propulsion speed in their manual chair is seldom adequate to keep up with their peers. Eventually, the child will need a motorized chair. Although this provides tremendous freedom for the child, a motorized chair presents problems to many families because transporting the chair requires a van and lift unit, which is seldom funded by insurance. Ideally, the child should have both a manual and a motorized chair; however, in today's health policy climate, parents or advocates often must engage in protracted efforts to obtain adaptive equipment for the patient.

An important consideration when purchasing a wheelchair is the trunk support system. Traditionally, boys with DMD are thought to develop a gravity collapse of the spine related to their functional sitting posture. To control the collapsing spine, spinal orthoses and seat inserts to lock the spine in extension (to prevent lateral bending and rotation) are frequently recommended. Unfortunately, the effectiveness of positioning devices to control the development of scoliosis has been disappointing.^{243,244} The therapist therefore should work with the child, the family, and the orthopedist to determine the best system to maintain optimal spinal alignment and trunk stability as the child weakens. In addition, as the child becomes more physically dependent, the chair may need to be fitted with a pressure-relief molded seat and trunk cushions, elevating leg rests, and a reclining back with a head rest.³¹³ The Tilt-in-Space chair (LABAC Systems, Denver) is a good example of a chair that can be motorized to allow mobility as well as maximal adjustment of seat position by using mouth control systems. It can also be adapted for a respirator attachment. The decision about the type of power chair necessary in the later stages of disease

progression takes considerable thought. Therapists, the patient, and the parents or caregivers must review environmental constraints, access issues, social goals, and work and recreational needs.

Because of the problems associated with increased wheelchair use, the therapist must work closely with the family and any school-based personnel to design a realistic plan to prevent rapid deterioration in strength and independent function. If possible, the child's standing program in KAFOs should be continued at school and at home as long as possible, with a goal of 3 to 5 hours of standing per day. With mainstreaming, however, continuing a standing program at school is sometimes difficult because attendants and equipment are not available, the child may need to move from room to room for different classes, and the child may not like being singled out for special treatment. It is helpful to caregivers if the child continues to wear his KAFOs when using the chair until he is totally dependent for transfers and can no longer be pivoted from the chair to another surface.

If the child uses a motorized wheelchair, directional control systems must be adapted to each child's needs. Most young people with advanced DMD do well for years with a standard joystick hand control system; however, because of extended survival times relative to the long-term use of mechanical ventilation, many patients must have their control systems adjusted frequently to minimize the need for muscle control, such as pinch strength. The need for ventilation support while using the wheelchair does not seem to interfere with the ability to drive.³¹⁴ (See Cooper³¹⁵ for a comprehensive manual on wheelchair selection. This information is equally valuable for patients with ALS and GBS.)

When the child can no longer tolerate the sitting position, some children have continued to attend school on a gurney. Once the person with DMD is no longer able to attend school or work, the home environment will need to be adapted for maximal self-direction despite significant physical dependence. Both low- and high-tech environmental control systems are more readily available today than they were 10 years ago. Television control units, voice-activated telephones, switch-activated bed controls, and page turners are among the low-tech systems. Sip-and-puff, blink-operated, and voice-activated control units can be adapted to operate most electronic devices. OTs and PTs can provide invaluable support to the person with DMD and the caregivers by making several home visits to suggest modifications and adaptive devices and systems. (See Cook and Hussey¹¹⁴ for detailed information on assistive technology systems. Also see an excellent website for home automation, environmental control, and electronic aids for daily living [EADLs]: www.makoa.org/ecu.htm.)

Psychosocial Issues

Psychosocial issues related to DMD are family issues. At the time of the child's diagnosis, the parents are often emotionally devastated and cycle back and forth through many phases of denial, anger, sadness, and active coping, especially if they feel guilt that they "caused" their child's disease. This process tends to recur when the child does not meet expected normal physical and social milestones or when he reaches predicted stages of deterioration, such as the transition to a wheelchair. Because children with DMD have concomitant developmental and cognitive

delays or issues, educational and social interactions can be compromised in addition to the physical changes. Because DMD is a multisystem multiprocess disease, early in the child's life the family should be guided to encourage the child's independence and to discourage overprotection.³¹⁶ Therapists can play an important role in helping the child and family identify realistic goals for independence. In addition, therapists can be instrumental in extending independence and a sense of self-direction by anticipating patient needs for adaptive equipment and identifying appropriate assistive devices and environmental control systems that empower the person with DMD and provide relief for caregivers from the constant attention required by a completely dependent person. Key to family support is access to a multidisciplinary clinic with specialists in neurology, pulmonology, orthopedics, rehabilitation services, psychology, social work, and dietetics. Only through comprehensive clinics do families of children and adults with DMD receive the level of education and support necessary to deal with the changing levels of function and demands on family systems.²¹⁴

Psychosocial support should be made available to the child and family during predictable times of crisis. Major times of crisis occur around the age of 5 years when the child begins to realize his differences, at age 8 to 12 years when the child loses the ability to walk independently, during the adolescent years when social interactions become restricted, and around the time of high school graduation when the child and family must face vocational limitations and almost certain death within the next decade.³¹⁷ Transition times are often accompanied by depression, withdrawal, and anxiety in the child and family members because parents had a marked preoccupation with their sons and a diminished expression of enjoyment.³¹³ Predictably, the integrity, strength, and intragenerational and intergenerational function and coping styles of the child's family contribute a great deal to the way the family responds to the child's progressive deterioration. Extended periods of anxiety and depression should be treated vigorously with cognitive interventions, support groups, respite care, and, when appropriate, short-term anxiolytics and antidepressants. Repeated opportunities to discuss end-of-life care must be given to both the child and parents. Professionals, however, tend to underestimate the quality of life for patients with end-stage DMD; therefore patients and family members must be educated about long-term options for ventilatory support or palliative care well ahead of any respiratory

emergency that might occur to ensure that the patient's desires are respected.^{214,318}

Because of the extended life opportunities for DMD patients who may now live into their 20s, home care requirements, the impact of in-home care on family members, and the financial impact must be fully reviewed and support systems put in place before caregiving stress becomes overwhelming. Positive family functioning while caring for a dependent child or adult with DMD is correlated with caregiver health and hardiness and requires multiple levels of family support from family, friends, and professionals.³¹⁹ Increasingly, young men with DMD are attending college even though they may require 24-hour assistance with ADLs and monitoring of ventilation equipment. To date, parents are providing most of the care to their children with DMD by attending colleges or living in dorms or apartments with their child. With life extended with ventilation, parents and the young person with DMD should begin early to plan for a future with maximal decision making by the young adult with DMD. This mindset of a "future" requires considerable problem solving by all people involved in the care of the young adult. Parents of children with DMD should involve their child early in life to make appropriate decisions about care, learn about medical needs and practices, and deal with finances necessary to run a home or hire an attendant. These issues related to independence (even though physically dependent) and caregivers are now being discussed by patients with DMD and their caregivers.³²⁰

Parents and the child should be given the opportunity to discuss the impending death in an accepting environment with persons who are experienced in dealing with degenerative diseases. Because the child and family have long anticipated the child's death and have made transitions through many levels of grieving, the process of separation and mourning may have occurred before the child's death. Each child and family member should therefore be helped to deal with the process according to his or her own pace and in response to individual needs. The child's death is sometimes considered a welcome relief.³²¹ This feeling of relief, however, is often accompanied by survivor guilt and a tremendous sense of loss of life focus for the family members whose lives have been so intertwined with that of the child's. Ideally, arrangements should be made for the family to meet with the professionals with whom they feel most comfortable several weeks after the child's death and again several months later so that the family (and caregivers) can deal with their thoughts and feelings (Case Study 17-3).^{322,323}

CASE STUDY 17-3 ■ JEREMY

Jeremy was 3 years old when he was diagnosed with DMD. He lived at home with his mother and a 5-year-old sister. There was no known family history of DMD, although family lore suggested that a cousin died quite young from pneumonia and a "wasting disease." Jeremy was referred for a medical evaluation when a playground supervisor at his preschool noted that he was clumsy when running and that he had difficulty on the playground climbing equipment and the slide. He also had

difficulty rising from the ground and needed to hold on to a railing when stepping up a stair.

During a medical history, Jeremy's mother said that she had noticed that he was "slow to develop" but was not worried because she thought he was just a "late bloomer." A muscle biopsy was positive for a diagnosis of DMD. A physical therapy evaluation 3 months after diagnosis showed ROM to be within normal limits for all joints. Muscle weakness was evident on

CASE STUDY 17-3 ■ JEREMY—cont'd

MMT with G- (4-) hip abduction and extension and quadriceps strength bilaterally. Hip flexion, knee flexion, dorsiflexion, and toe extension were in the G (4) range. Plantar flexion was G+ (4+) with evident hypertrophy. Shoulder abduction and flexion was in the G (4) range, although the patient had difficulty sustaining abduction for more than 5 seconds.

Jeremy had a moderate head lag when moving from supine to sitting, because of G- (4-) anterior neck muscles. The therapist made an on-site school visit to help the teachers identify obstacles to Jeremy's full integration with his classmates. The school custodian built some ramps to help Jeremy use the playground equipment.

Jeremy ambulated independently until age 8 years. His gait pattern was typical of late-stage ambulation (marked equinus, knee hyperextension during stance, bilateral Trendelenburg on stance, marked lordosis with a protuberant abdomen with arms held posterior to hips). He had 40-degree hip flexion contractures with iliotibial band tightness, no knee contractures, and 25-degree plantar flexion contractures. MMT showed the expected decrease in strength, with pelvic and shoulder girdle muscles being weaker than more distal musculature, except that the anterior tibialis and the peroneals were F+ (3+). He was unable to rise independently from the floor and needed assistance with stairs. Because his gait pattern was slow and he needed to rest frequently when walking more than 20 feet at school, Jeremy had been using a manual wheelchair for long-distance mobility since the age of 7 years.

On the recommendation of orthopedist consultants, Jeremy underwent bilateral percutaneous hip flexor lengthening, iliotibial band fasciotomy, and heel cord release. Bilateral KAFOs had been fitted before surgery, and Jeremy was placed in the braces after surgery. No casting was done. Despite his complaints, he was gradually brought to the full weight-bearing standing position by late afternoon on the day after surgery. Adjustments were made in his pain medication schedule to allow him to tolerate the process more comfortably. By the third hospital day, Jeremy participated in two therapy sessions per day and was standing in the parallel bars, where he was taught lateral and anteroposterior weight shifting in preparation for ambulation. Active assisted and passive ROM exercises were performed without the KAFOs twice a day. On the fourth hospital day, Jeremy began to take short steps using the parallel bars for balance. His mother was also taught his exercises so that Jeremy could have more than two therapy sessions a day.

On the fourth day, he practiced walking for 10 minutes six times a day with full physical therapy treatment twice a day.

Because Jeremy was from a rural area and daily physical therapy would not be available on discharge, he was kept in the hospital for 3 additional days for intensive rehabilitation. An OT worked with Jeremy to provide adaptive equipment for reaching, self-care, and eating (he was unable to raise his arms above 45 degrees and needed his left arm to assist the right when reaching). He was discharged home on the eighth day. An Elks traveling therapist arranged to visit the family once a week for the next month to continue ambulation training and to guide the mother in a home positioning and ROM program. The therapist also helped the mother adapt the home environment and his school to adjust expectations of Jeremy so he was less prone to falling and excessive fatigue.

The family was lost to follow-up, but by report Jeremy continued to ambulate in his KAFOs for approximately 9 months after surgery, when he chose to use his wheelchair full time. A motorized wheelchair was recommended; however, his mother believed that Jeremy was easier to handle in his manual chair. The Muscular Dystrophy Association loaned Jeremy a motorized wheelchair for school use. He had developed moderate scoliosis but did not report pain. He refused to wear a molded spinal corset, but the padded thoracic pads fitted to his chair increased his comfort. By age 15 years, Jeremy was dependent for all care except feeding. He was able to sit with support in a large living room chair and he enjoyed watching television and playing card games with a few friends who visited his home. He was disinterested in continuing school and missed more days than he attended. He was not cooperative with his home-based teacher.

During his fifteenth year, Jeremy had repeated episodes of chest congestion and difficulty handling stringy foods. The visiting therapist taught his mother some postural drainage and breathing exercises for Jeremy; however, the mother did not follow through with the recommendations. Because his mother had to work full time, a public agency provided in-home care during the days when Jeremy was not at school or after he returned from school. The mother refused in-home nursing care, preferring to continue with the attendant, who was not comfortable carrying out Jeremy's exercises or pulmonary care. The family refused counseling or support from parents of other children with disabilities. Jeremy died at home after a brief bout with pneumonia.

SUMMARY

In this chapter, discussion of three different diseases reveals the varied effects of neuromuscular pathology on a person's day-to-day function. ALS is an adult-onset degenerative disease of the upper and lower motor neurons; GBS is an inflammatory process affecting the PNS of children and adults; and DMD is an inherited degenerative disease manifesting in childhood that affects muscle tissue. In all three conditions the therapist must design a therapy program that will provide the patient with the impetus to become or remain as active as possible without causing possible muscle damage from excessive exercise demands or overwork.

Therapists must be aware of their own feelings and reactions to patients with severe neuromuscular diseases. Working with patients with GBS is usually a positive experience because most patients attain full recovery despite their often severe disability during the acute illness and long recovery period. Working with patients with degenerative terminal diseases, however, draws deeply on the therapist's emotional and spiritual strength. A typical response of health care professionals is to view these patients' conditions as hopeless and to assume that the patients must also perceive their existence as hopeless, depressing, and without value. Research does suggest an increased incidence of depression

and demoralization in patients with degenerative, terminal diseases compared with nonaffected populations. Other research, however, has indicated that many patients perceive their own life satisfaction much more positively than professionals would believe.^{318,324} Therapists must tap into patients' positive energy to design treatment programs that respect patients' goals and life plans within the context of their environment.

Limited evidence exists to document the effectiveness of rehabilitation for patients with progressive neurological diseases. Determining the most appropriate exercise and therapeutic intervention programs therefore requires diligent examination of the dysfunctions and needs of the individual patient and assessment of the effects of interventions appropriately adapted from use in other populations.

Because few medical-clinical facilities see a large enough sample of patients with any of these three diagnoses, therapists must align with their professional organizations to institute nationwide, multisite research studies to provide clear evidence of effectiveness of therapy in these populations.

OVERVIEW

The purpose of this chapter is twofold. The first purpose is to develop the concept that the entire nervous system forms a continuous tissue tract. This concept is central to the idea that movements of the trunk and/or limbs can have a profound biomechanical and physiological impact on the peripheral nervous system (PNS) and central nervous system (CNS). Mobility of the nervous system and some of the responses of the system to movement in normal and sensitized states are discussed.

The second purpose of this chapter is to develop in the reader an understanding of neurovascular entrapment syndrome. This is an underrecognized impairment present in some patients with a wide variety of diagnoses—for example, nonspecific arm pain, repetitive strain injury, carpal tunnel syndrome, and thoracic outlet syndrome. Standard medical care frequently fails with these patients. A theoretical model for the development and perpetuation of neurovascular entrapment syndrome is presented. Background information regarding the syndrome is provided, and the appropriate screening tools for assessment of the impairment are discussed. Treatment suggestions and a case study are presented at the end of the chapter.

PERIPHERAL NEUROANATOMY

The PNS is generally regarded as the portion of the nervous system that lies outside the CNS (i.e., the brain and spinal cord).^{1,2} The major components of the PNS include motor, sensory, and autonomic neurons found in spinal, peripheral, and cranial nerves. Although this partitioning is valid from an anatomical perspective, it often leads to a lack of appreciation as to the truly continuous nature and integrative function of the nervous system as a whole. The concept that the entire nervous system is a continuous tissue tract reinforces the idea that limb and trunk movements can have a mechanical effect on the PNS and the CNS that is local and global.

The nervous system is composed of two functional tissue types. One type of tissue is concerned with impulse conduction. This functional category includes nerve cells and Schwann cells. The second functional tissue type provides support and protection of the conduction tissues—that is, the connective tissues.

Three levels in the organization of a peripheral nerve have been described^{2,3} (Figure 18-1). At the innermost level the nerve fiber is the conducting component of a neuron (nerve cell). A connective tissue layer called the *endoneurium* surrounds each nerve fiber. The endoneurium surrounds the basement membrane of the neuron and plays an important role in maintaining fluid pressure within the endoneurial

space. There are no lymphatic channels within the endoneurial space. The pressure within the endoneurial space increases with compression of the neuron.⁴

The second level of organization consists of a collection of many nerve fibers (a fascicle) surrounded by a layer of connective tissue called the *perineurium*.^{2,3} The perineurium acts as a selective barrier to diffusion and as such exerts significant control over the local movement of fluid and ions. This connective tissue layer acts like a pressurized container—that is, extrusion of the contents occurs if the membrane is cut. The compartment enclosed by the perineurium does not contain lymphatic channels.⁴ This may be a problem during inflammatory states when edema is present deep to the perineurium. The perineurium is the last connective tissue layer to rupture in tensile testing of peripheral nerves.⁵ The outermost connective tissue layer of a peripheral nerve is called the *epineurium*. The epineurium surrounds, protects, and enhances gliding between the fascicles. Lymphatic channels are found within the epineurial compartment.

All three connective tissue layers are interconnected—they are not separate and distinct, but continuous tissue layers.^{2,3} Each of the connective tissue layers contains free nerve endings from the *nervi nervorum*. As a result, all three connective tissue layers are a potential source of pain. In addition, all three layers are continuous with the homologous connective tissue layers of the CNS—for example, the *dura mater* and the epineurium.

The vascular supply for peripheral nerves is designed to provide uninterrupted blood flow regardless of the position of the trunk and limbs. Extrinsic vessels provide blood flow to segmental vessels that in turn supply an extensive intrinsic (intra-neural) vasculature within the PNS. These segmental vessels branch off of the extrinsic vessels and enter peripheral nerves in areas of low nerve mobility relative to the surrounding tissue. The intrinsic vasculature supplies all three connective tissue layers within the PNS. Arterioles and venules are found in the epineurial and perineurial spaces, but only capillaries are found in the endoneurial compartment.

Peripheral nerves are regularly subjected to compression and elongation (stretching), which have been shown to increase intraneural pressure. An increase in intraneural pressure decreases the diameter of the intrinsic blood vessels and results in a reduction in blood flow within the nerve. Compressive forces of 20 to 30 mm Hg have been shown to adversely affect intraneural blood flow,⁶ and compressive forces of 50 to 70 mm Hg have been shown to result in complete arrest of blood flow⁷ and cause damage to myelin and axons.⁶ A strain (elongation) of 6% to 8% has been shown

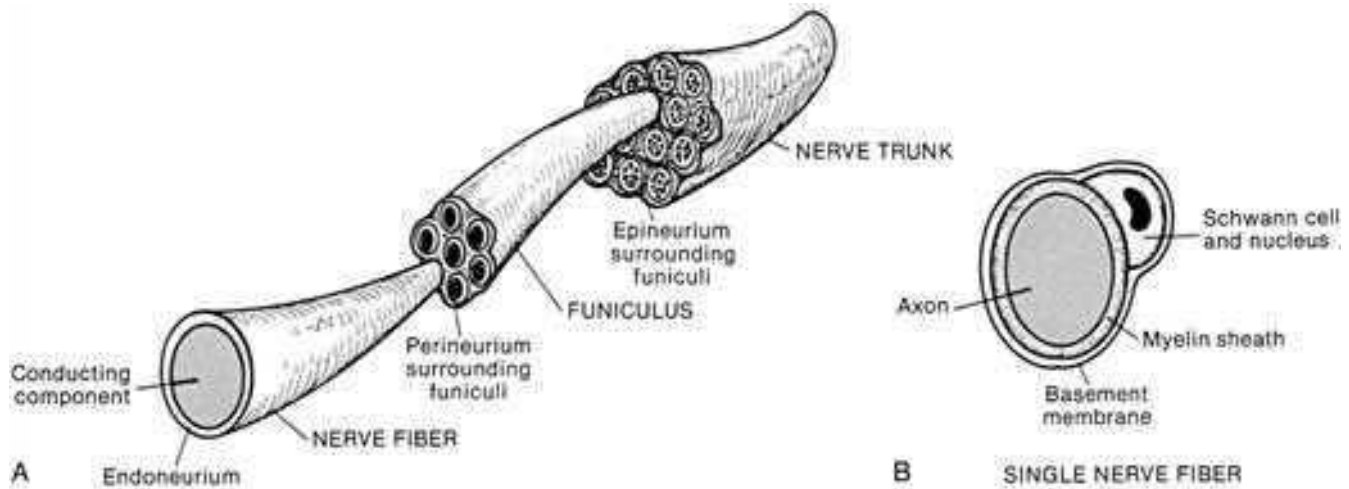

Figure 18-1 ■ Three levels of organization of a peripheral nerve or nerve trunk. **A**, Nerve trunk and components. **B**, Microscopic structure of nerve fiber.

to decrease intraneural blood flow by 50% to 70% in the sciatic nerve of rats.^{4,8,9} A strain of 15% in the sciatic nerve of a rabbit has been shown to result in complete arrest of blood flow,⁷ and the same strain produces an 80% reduction in blood flow in the rat sciatic nerve.⁹ Strains of 11% or greater are produced by some of the positions used in neurodynamic tests of the upper limb.⁶ Significant increases in intraneural pressure and concomitant decreases in intraneural blood flow have been shown to adversely affect neuronal conduction.^{7,10,11}

The cytoplasm in cells moves and has thixotropic properties—that is, the viscosity of cytoplasm is lower when it is continuously moving.⁴ In neurons the movement of the cytoplasm from the cell body through the axons (anterograde movement) occurs at two speeds. Fast axoplasmic flow occurs at a rate of about 100 to 400 mm/day and is used to carry ion channels and neurotransmitters (i.e., materials required for normal impulse conduction) to the nerve terminals. Slow axoplasmic flow occurs at a rate of about 6 mm/day and is used to transport cytoskeleton proteins, neurofilaments, and other materials used to maintain the physical health of the cell. A third flow occurs in the opposite direction (retrograde) at a rate of about 200 mm/day. Retrograde transport carries unused substances and exogenous materials taken up at the terminus—for example, neurotrophic factors. The material carried back to the cell body by retrograde transport has been shown to influence activity in the cell nucleus.⁴

Compression raises intraneural pressure, which has a negative impact on the flow of cytoplasm.⁴ Anterograde and retrograde flow of axoplasm is impaired with 30 mm Hg compression on the nerve, hypoxia, or a strain of 11% or greater.¹²⁻¹⁴ Prolonged or intense exposure to compression can result in conduction abnormalities, endoneurial edema, fibrin deposition, demyelination, and axonal sprouting. Each of these events increases the likelihood of developing adhesions and abnormal impulse-generating sites (AIGSs).⁴ (The negative impact of AIGSs is discussed in the section on adaptive responses to pain.)

MOBILITY OF THE PERIPHERAL NERVOUS SYSTEM

Several types of tissues (e.g., bone, fascia, and muscle) surround peripheral nerves as they “travel” to target tissues. Peripheral nerves can be thought of as passing through a series of tissue tunnels composed of various biological materials. The composition of the tissue tunnel changes with the passage of the nerve from the vertebral column (an osseous tunnel) to the target tissue—for example, from an osseous tunnel to a soft tissue and/or fibro-osseous tunnel. A “mechanical interface” exists at the junction between the nerve and the material adjacent to the nerve that forms the tissue tunnel. Movement of the trunk and/or limbs can cause three types of movement to occur in the peripheral nerves: unfolding, sliding, and elongation.¹⁵

When there is little or no tension in a peripheral nerve, the axon typically contains undulations (folds). As tension is applied the axon will “unfold” so that the undulations disappear. “Sliding” can be defined as movement between the nerve and the surrounding tissues at the mechanical interface (extraneural movement). Sliding by itself does not cause significant elongation or tension to develop within the nerve, so intraneural pressure remains relatively unchanged. Ultrasound studies have shown that the median, ulnar, sciatic, and tibial nerves undergo extraneural movement (sliding) with movement of the upper and lower limbs, respectively.¹⁶⁻¹⁹

“Elongation” of the nerve occurs when tension is applied to a nerve and there is little or no unfolding and sliding at the mechanical interface. Elongation causes movement to occur between the neural elements and connective tissue layers (intraneural movement). Elongation decreases the diameter of the nerve, resulting in an increase in the intraneural tension and pressure.¹⁵ An increase in intraneural pressure has been shown to decrease the flow of blood and axoplasm, resulting in altered neural function (see previous section). Elongation within the median and ulnar nerves has been shown to occur with movements of the upper limb.⁶

Both extraneural and intraneural movements may occur simultaneously within a nerve, but they may not be uniformly

distributed. When a body moves, some parts of the PNS will undergo primarily extraneural movement (sliding) with little or no development of tension while other areas undergo intraneural movement (elongation) that results in an increase in intraneural tension and pressure. As a consequence, some areas within a nerve slide, developing little or no tension, whereas other areas of the same nerve elongate significantly, increasing the amount of intraneural tension.⁶ In areas repeatedly exposed to high amounts of tension, for example, the median nerve at the wrist, the nerves are found to contain a higher-than-average amount of connective tissue.¹⁵

If one considers the entire nervous system as a continuous tissue tract, then the idea that movement and/or tension developed in one region of the nervous system can be distributed and dissipated throughout the entire nervous system becomes apparent.^{20,21} The inability of a component within the nervous system to dissipate and/or distribute movement and tension can lead to abnormal force development and lesions elsewhere in the continuous tissue tract.²²

PERIPHERAL NERVE ENTRAPMENT

Seddon's classification of nerve injury is based upon mechanical trauma.²³ Schaumbert² modified this paradigm into an anatomically based scheme containing three classes of injury (Table 18-1). Injuries in class II and III are caused by macrotrauma that results in some disruption to the integrity of the nerve fiber. The following discussion of entrapment is focused on microtrauma in which there is no breach in the anatomical integrity of the nerve fiber (class I). Mechanical microtrauma resulting in nerve entrapment can occur with excessive or abnormal friction, compression, and/or tension (elongation).²

Tissue tunnels, peripheral nerves, and the mechanical interfaces between them are all vulnerable to mechanical microtrauma—that is, abnormal friction, compression, and/or tension.^{2,15} Some peripheral nerves are exposed to bony hard interfaces, for example, the lower cords of the brachial plexus at the first rib, which are potential sources of abnormal friction. Inflammation and swelling within a tissue tunnel can produce compression of a nerve, for example, the median nerve within the carpal tunnel. The point at which a nerve branches limits the amount of gliding (extraneural movement) available at that location and increases the amount of local intraneural tension developed with movement, for example, the tibial nerve in the popliteal fossa.^{2,15}

Microtrauma can produce an intraneural lesion that causes a decrease in intraneural flow of blood and axoplasm, demyelination, and/or conduction defects.^{2,15} If the lesion occurs in the connective tissues of the nerve, there may be

pain, inflammation, proliferation of fibroblasts, and scar formation (fibrosis). Ultrasound studies have shown that the median nerve in patients with carpal tunnel syndrome is enlarged approximately 30%.²⁴ An intraneural scar decreases the compliance of the nerve and increases the amount of intraneural pressure and tension generated with elongation.²¹ Intraneural lesions can impair or completely block the ability of the nerve to conduct action potentials.^{2,15,25} Partial or complete conduction blocks can result in abnormal sensation, loss of motor function, autonomic dysfunction, and atrophy of target tissue, for example, muscle and/or skin.

Microtrauma can produce an extraneural lesion.^{2,15,21,25} The damage in an extraneural lesion occurs in the tissue surrounding the nerve or at the mechanical interface. Swelling within the tissue tunnel can produce compression of the nerve. Fibrosis can produce adhesions at the mechanical interface leading to a decrease in sliding of the nerve. A decrease in the ability of a nerve to slide within a tissue tunnel will result in an abnormal increase in intraneural tension and pressure as movement is imposed on the nerve. The increase in local intraneural tension can produce abnormal changes in the conduction of action potentials, and the tension will be distributed in an aberrant pattern throughout the continuous tract of the nervous system. The resultant abnormal distribution of tension predisposes the nervous system to the development of lesions at other sites.¹⁵

Friction, compression, and tension can produce microtrauma that results in intraneural and extraneural pathology.^{2,15} For example, fibrosis can produce a combined pathological state that results in a substantial reduction in the ability of a nerve to slide within the tissue tunnel and a substantial increase in intraneural tension during nerve elongation as the compliance of the nerve is decreased. Movement of the median nerve at the carpal tunnel has been shown to occur with movements of the upper limb.¹⁶⁻¹⁹ Longitudinal and transverse movements of the median nerve at the carpal tunnel have been shown to be reduced in the presence of microtrauma, that is, carpal tunnel syndrome,^{24,26} nonspecific arm pain,^{27,28} and whiplash injury.²⁸

Intraneural and extraneural lesions result in an abnormal distribution of sliding and tension throughout the nervous system with movement of the trunk and/or limbs. The abnormal distribution of tension within a nerve increases the probability of a second lesion or abnormality developing within the nerve. This situation led Upton and McComas²⁹ in 1973 to first use the term “double crush injury.” (This term should be considered a misnomer because a “crush” does not necessarily occur.) For example, entrapment of the

TABLE 18-1 ■ CLASSIFICATION OF ACUTE TRAUMATIC PERIPHERAL NERVE INJURY

ANATOMICAL CLASSIFICATION	CLASS I	CLASS II	CLASS III

median nerve at the carpal tunnel can cause the development of abnormal tension in cervical spinal nerves, resulting in a lesion at that site. Upton and McComas²⁹ have shown that a lesion at the carpal tunnel increases the risk of having a second neural lesion in the cervical region.

PATHOGENESIS OF NEUROVASCULAR ENTRAPMENT

Neurovascular entrapment can occur at any point along the continuous tract of the nervous system. The carpal tunnel, a common site of entrapment, has been studied and provides a framework of information regarding the pathogenesis of neurovascular entrapments. Sunderland³⁰ has reasoned that a change in the normal pressure gradients within the carpal tunnel can lead to compression of the median nerve. In order to maintain homeostasis in the carpal tunnel and the median nerve, blood must flow into the tunnel, then into the nerve and back out of the tunnel. For normal blood flow to occur in the median nerve the blood pressure must be highest within the epineurial arterioles and becomes progressively lower in the capillaries and epineurial venules and lowest within the extraneural space of the carpal tunnel. Any increase in the pressure of a single compartment has the potential to disrupt the normal pressure gradients and impair the flow of blood within the compartments of the carpal tunnel and median nerve. Impaired intraneural blood flow can lead to localized hypoxia, edema, inflammation, and fibrosis.³⁰

An increase in pressure within the carpal tunnel can occur for a variety of reasons, for example, synovial hyperplasia, thickening of tendons, venous congestion, inflammation, and/or edema. Venous blood flow within a nerve will be impaired and venous stasis will develop if pressure within the extraneural space of the carpal tunnel becomes greater than the pressure within the epineurial venules. Because blood pressure within venules is relatively low, partial occlusion of blood flow can begin to occur with pressures as low as 20 to 30 mm Hg.^{15,31}

The pressure within the carpal tunnel is normally about 3 mm Hg with the wrist in a neutral position.⁴ The pressure can rise to over 30 mm Hg when the wrist is placed in 90 degrees of extension³² or with the functional task of using a computer mouse to drag or point at an object.³³ Studies have shown that the pressure within the carpal tunnel in someone with carpal tunnel syndrome can be 30 mm Hg, or more, with the wrist in neutral and can increase to about 100 mm Hg when the wrist is in 90 degrees of flexion^{4,12,13} or extension.¹² Compressive forces of 20 to 30 mm Hg have been shown to adversely affect intraneural blood flow,⁶ whereas compressive forces of 50 to 70 mm Hg have been shown to result in complete arrest of blood flow⁷ and cause demonstrable damage to myelin and axons.⁶ Motor and sensory abnormalities begin to manifest at about 40 mm Hg, and complete blockade of the median nerve has been shown to occur at 50 mm Hg.³⁴ The pressure found in the carpal tunnel of people with carpal tunnel syndrome is clearly adequate to disrupt the normal flow of blood, axoplasm, and action potentials within the median nerve, causing severe impairment to normal nerve functions.

Sunderland³⁰ proposed that venous congestion or stasis within the carpal tunnel will lead to localized hypoxia, edema, and fibrosis. Hypoxia causes capillary endothelial cells to deteriorate and local C fibers to secrete substance

P and calcitonin gene-related peptide,⁴ which in turn cause mast cells to release histamine and serotonin.^{35,36} Together these chemical mediators augment the inflammatory state and cause the endothelial cells of capillaries to further deteriorate by becoming flatter, larger, and leakier, enhancing exudation and edema.

Deterioration of the capillary endothelium results in exudation and the formation of a protein-rich edema in the interstitial space. Protein-rich edema stimulates proliferation of fibroblasts, resulting in fibrosis, and intensifies the abnormal pressure gradients, resulting in more tissue hypoxia—that is, a positive feedback or self-perpetuating cycle of pathology is initiated. Intraneural fibrosis decreases compliance of the nerve, and extraneural fibrosis results in the formation of adhesions at the mechanical interface between the nerve and tissue tunnel. Fibrosis causes a nerve to become stiffer and less mobile, resulting in an abnormal increase in tension when movement is imposed on the nerve.

The set of circumstances described earlier may be referred to as a *neurovascular entrapment syndrome*, and it has the potential to cause the development of problems elsewhere in the system—that is, a double crush injury (see previous section). Upton and McComas²⁹ studied 115 subjects with carpal tunnel syndrome or ulnar impingement at the elbow. They found that 81 of the 115 subjects also had evidence of a neural lesion at the neck. Because all nerves essentially travel within tissue tunnels, the potential exists for this scenario to occur elsewhere in the continuous tissue tract of the nervous system, for example, the capsule of the dorsal root ganglion and the thoracic outlet.^{5,15,37}

ADAPTIVE RESPONSES TO PAIN

A thorough discussion of the pain associated with neurovascular entrapment is beyond the scope and intent of this chapter. The topic of pain management is discussed in Chapter 32 of this book. However, we would like to describe the development of hyperexcitable states and AIGSs in neurons as well as their role in the development of pain associated with neurovascular entrapment.

“Normal” or physiological pain occurs when peripheral nociceptors are subjected to a stimulus that is at or above the threshold for firing. “Abnormal” or pathological pain can occur when there is a change in the sensitivity (threshold) of the somatosensory system.³⁸ Devor³⁹ wrote that “the crucial pathophysiological process triggered by nerve injury is an increase in neuronal excitability.”

Neurons that become inflamed, hypoxic, and/or demyelinated can enter a hyperexcitable state.^{2,39-47} A neuron in a hyperexcitable state can begin to discharge spontaneously and/or develop a sustained rhythmic discharge after stimulation. In addition, hyperexcitable neurons can develop mechanosensitivity,⁴¹ chemosensitivity,⁴ and/or thermal sensitivity,⁴⁵ all of which can result in the production of allodynia, a form of pathological pain.* These changes in the behavior of a nerve can occur in the absence of detectable degeneration.⁴⁰⁻⁴² The changes in impulse generation and neuronal sensitivity are characteristics of an AIGS.⁴ A hyperexcitable state and an AIGS can develop with the mechanical microtrauma and inflammation often

*References 28, 39, 43, 45, 47, 48.

associated with peripheral nerve pathology, for example, compression, tension, and friction.^{2,39,48,49} A variety of chemical mediators have been implicated in the development of a hyperexcitable state in a neuron—for example, neurotrophins,^{50,51} histamine,⁵² and other inflammatory mediators,⁵³ which are thought to act through changes in gene expression,^{45,50,51} changes in voltage gated sodium channel expression,⁴⁵ and a reduction in anterograde axoplasmic transport.^{44,52}

The dorsal root ganglion appears to play a significant role in the pain associated with peripheral nerve pathology.^{38,41} Mechanical microtrauma to and inflammation of peripheral nerves can cause the dorsal root ganglion to become hyperexcitable (sensitized).⁴¹ The change in sensitivity allows what were weak, subthreshold stimuli to evoke pain and supra-threshold stimuli to evoke exaggerated pain (hyperalgesia). In addition, the dorsal root ganglion can develop mechanosensitivity, chemosensitivity, and thermal sensitivity, resulting in allodynia.⁴⁵ This change in sensitivity reflects a change in the physiology of the nerve and may be a component in the development of enhanced central sensitivity to pain and development of a chronic pain state.³⁸

As noted previously, the PNS and CNS represent a continuous tissue tract. The pain and symptoms associated with musculoskeletal injury and/or peripheral nerve pathology can include changes that are the result of an alteration in the autonomic nervous system, which is considered part of the continuous tissue tract of the nervous system.^{2,54} For example, catecholamines do not normally elicit pain. However, if a nerve is injured or if there is local inflammation, the catecholamines can induce pain (chemosensitivity) and they can maintain or enhance pain in inflamed tissues.⁴

Some patients who are treated for musculoskeletal injuries have signs that may be related to autonomic dysreflexia.³⁷ Wyke⁵⁵ demonstrated that stimulation of nociceptors in spinal joints resulted in reflex changes in the cardiovascular, respiratory, and endocrine systems. Dysregulated breathing has been documented in patients with chronic pain.⁵⁶ Patients with nonspecific arm pain have a reduced sympathetic vasoconstrictor response in the hand of the affected limb.⁵⁷ Thermal asymmetry has been documented in the hands of patients with neurogenic thoracic outlet syndrome.⁵⁸ Feinstein^{59,60} has shown that injecting saline solution into the thoracic paraspinal muscles caused pallor, diaphoresis, bradycardia, and a drop in the blood pressure. These cardiovascular and respiratory changes are often associated with an alteration in the output from the autonomic nervous system.^{37,54,61}

In patients with cumulative trauma disorder (CTD), signs of abnormal autonomic nervous system output can include (1) vasomotor reflexes leading to cool, pale skin,⁵⁷ (2) changes in the pattern of sweating (hypohidrosis and/or hyperhidrosis), (3) trophic changes in the skin, (4) hyperactive flexor withdrawal reflexes, and/or (5) paradoxical breathing patterns.³⁷ Edgelow has described paradoxical breathing as the predominant use of the scalene muscles for ventilation during quiet breathing versus normal ventilation, which is predominantly a function of the diaphragm.³⁷ Edgelow found that paradoxical breathing is present in most patients with CTD of the upper extremity.³⁷ A better appreciation of the contribution of the autonomic nervous system to the pathology and symptoms present in some

patients with neurovascular entrapment may enhance the effectiveness of their treatment.

CLINICAL EXAMINATION AND TREATMENT OF NEUROVASCULAR ENTRAPMENT

For an effective evaluation of a patient with a neurovascular entrapment problem, the whole person must be addressed and involved in the evaluation and treatment processes. This philosophy requires the therapist to become the evaluator, teacher, and guide for the patient. Wherever possible the testing procedures should be performed by the patient so that he or she can learn to self-assess his or her status before and after treatment procedures. This self-assessment gives the patient control, thus decreasing the fear of movement or reinjury. In some cases, if a therapist uses his or her hands it may be detrimental to the patient in a lifelong sense if it leads to dependence. The concept of the patient gaining control of the problem(s) is fundamental and must be integrated into the initial patient contact for development of an effective self-management approach. Without an effective self-management strategy, the patient is at risk for recurrent problems and development of a chronic condition.

The Edgelow protocol for examination and treatment of neurovascular entrapment challenges the traditional musculoskeletal paradigm by placing the primary emphasis on the response of the neurovascular and neuromotor systems to injury.⁶²⁻⁶⁴ The standard musculoskeletal evaluation centered on a biomechanical model of the musculoskeletal and nervous systems is adequate for patients with straightforward symptoms that appear to be of biomechanical origin. However, a biomechanical approach is inappropriate for patients with severe or irritable signs and symptoms that may be neurological or vascular in origin. Patients with neurovascular entrapment often have severe, irritable symptoms. First a subjective evaluation is conducted in a patient with a potential neurovascular entrapment problem to determine how the objective examination should proceed. The history of the condition is discussed with the patient. Key components that should be discussed include history of trauma, repetitive activities, sustained static or tension postures, such as computer keyboard work, or physical activities performed with a high level of cognitive demand, as seen in a pianist. The history should include a discussion of general health, including any potentially relevant medical conditions (e.g., asthma, diabetes, hypothyroidism). Phase I of differential diagnosis (medical screening) should be completed to ensure that the patient is appropriate for evaluation and intervention. (See Chapter 7 on medical screening.)

A discussion of the patient's symptoms and complaints should include questions that determine whether the neural or vascular system is a potential source of the problem. Symptoms relevant to the potential problem of neurovascular entrapment include complaints of fullness in the upper extremity; a feeling of swelling, tingling, pain, coldness, or numbness; or dropping things. In addition, the progression of the symptoms or complaints and the level of irritability should be determined. If pain is a major factor, then a functional pain questionnaire should be completed (see Chapter 32 on pain management). Motor changes of relevance to the potential problem of neurovascular entrapment include complaints of dropping things, weakness, or an inability to perform motor tasks that were done previously without

difficulty. The level of neural irritability and the presence of peripheral or central sensitization should be determined by asking the patient what activities aggravate and ease the symptoms. When an extended period of time is required for symptoms to ease after provocation, irritability may be a cause. Sensitization is indicated when minor mechanical or normally nonnoxious stimuli, such as clothing on the skin, provoke pain. Vascular complaints relevant to the potential problem of neurovascular entrapment include complaints of fullness, swelling, abnormal skin color, or cool skin temperatures. A change in the vascular symptoms with a change in limb position is particularly significant.

In a biomechanical evaluation model the therapist examines the quantity and quality of active movements and determines whether there is pain, spasm, or resistance at an

end feel. In patients with neurovascular entrapment, this procedure may evoke a significant flare and worsening of symptoms. In patients with neurovascular entrapment the “feel” of involuntary muscle tension can be the first sign of abnormality in assessing movement. This tension is often subtle and may occur earlier in the range of motion than where traditional biomechanical symptoms or the end feel normally occurs.⁶⁵ Moving into the range of motion to the initial onset of tension minimizes the risk of provoking adverse neurological or vascular consequences. In patients with suspected neurovascular entrapment who have symptoms suggestive of neural irritability and sensitization, the biomechanical examination and treatment techniques should be modified or deferred until the sensitivity and irritability of the nervous system are improved. See Table 18-2

for suggested modifications to a standard biomechanical evaluation.

One component of the examination involves evaluating the integrity of the vascular system in the extremities. The hands or feet should be inspected for discoloration, and the skin temperature should be determined in each of the peripheral nerve territories present in the affected limb. Cool, cyanotic skin can be an indication of arterial insufficiency or sympathetic dysreflexia in the area, whereas swelling can be an indication of inflammation and venous or lymphatic insufficiency. An Adson test and the elevated arm stress test (EAST) can be used to evaluate vascular integrity by determining whether the pulse pressure decreases with a change in the position of the limb.⁶⁶ The Adson test and EAST should be performed on both upper extremities, and the pulse pressure evaluated at 1, 2, and 3 minutes. These tests may be modified or deferred depending on the level of neural irritability found.

Sensory changes may be subtle and are not always accompanied by obvious motor dysfunction. The most

common complaint with neurovascular entrapment of the upper extremity is “I drop things,” yet standard tests of strength, light touch, and two-point discrimination may have normal results. Therapists often think of this problem as motor until our standard tests fail to demonstrate motor dysfunction. Subtle changes in the somatosensory cortex can occur as a consequence of repetitive motions, particularly when performed under conditions of intense concentration or in the presence of pain.⁶⁷⁻⁶⁹ Byl observed severe degradation in the representation of the hand in the somatosensory cortex of owl monkeys that were trained in a behavior of rapid, active opening and closing of the hand under conditions of high cognitive drive.⁶⁸ In addition, Byl⁶⁷ found a significant difference in response on some sensory integration and praxis tests in human subjects with diagnoses of tendinitis and focal dystonia. Byl has postulated that similar changes can be identified in humans with repetitive strain injuries with the use of Jean Ayers’s tests of sensory localization, stereognosis, and graphesthesia.⁶⁹

An assessment of the patient's breathing pattern at rest and palpation of the subclavius, pectoralis minor, and scalene muscles should be performed. The normal breathing pattern at rest is primarily diaphragmatic (Figure 18-2). However, patients with neurovascular entrapment often demonstrate a breathing pattern at rest that relies predominantly on the scalene muscles. The scalene breathing pattern mechanically narrows the thoracic outlet area, thus potentially perpetuating a neurovascular entrapment syndrome in the area. The scalene breathing pattern may be a sign of protective posturing. Palpation is used to determine whether tenderness or tightness is present. Palpation of the subclavius, pectoralis minor, and scalene muscles is significant because of the relationship these muscles have with the subclavian vein, brachial plexus components, and subclavian artery, respectively. The results of the palpation should be correlated to the neurological and vascular changes found elsewhere in the extremity.

Neurovascular Entrapment Examination

There are some common symptom patterns characteristic of neurovascular entrapment that alert the therapist to modify the physical examination. In addition to the symptoms mentioned previously, the following patterns help the therapist recognize a patient with a potentially sensitized nervous system.

Symptom Patterns Characteristic of Neurovascular Entrapment

1. Symptoms are severe and irritable.
2. Function is markedly reduced in the target task (injury-producing activity) and activities of daily living.
3. The patient reports feeling that his or her emotions are in a state of "being out of control."

In a modified examination scheme designed to evaluate for the presence of a neurovascular entrapment syndrome, patients typically have six signs. These signs, in addition to

the more traditional musculoskeletal signs, are used as guides in determining the effectiveness of treatment.

Six Common Signs of Neurovascular Entrapment

1. Abnormal hand temperature within the following parameters:
 - a. Cold hands defined as in the 70° F range at rest and during activity at the target task
 - b. Asymmetry between the temperatures of the second digit and the fifth digit, with the fifth digit being colder.⁷⁰
 - c. Asymmetry between hands in which there is an abnormal temperature cooling response to diaphragmatic breathing, aerobic walking, and repeated use of the upper extremities in an activity such as bouncing a gymnastic ball.
2. Abnormal breathing pattern: accessory, chest, or paradoxical rather than diaphragmatic.
3. Abnormal mobility and sensitivity of the nervous system: specifically the dura, the brachial plexus, or the sciatic nerve or sacral plexus.
4. Cardiovascular deconditioning: patient has a low level of endurance and is easily fatigued.
5. Sensory dysfunction of the hand at the cortical level: abnormal tactile localization, graphesthesia, and stereognosis.
6. A positive Kabat⁷¹ sign: weakness of the flexor pollicis brevis in the shortened range of adduction that is unilateral and reversed with a gentle 30-second isometric contraction of the longus colli obtained with the "thinker pose" (Figure 18-3).

This combination of symptoms and signs identifies neurovascular consequences of the injury. Improvements in these signs and symptoms serve as markers that identify treatment effectiveness—namely, decrease in pain, improvement in function, and a feeling of being more in control.

Figure 18-2 ■ Diaphragmatic breathing. As the client inhales, the stomach should rise and the lordosis in the low back should increase. During exhalation the stomach should fall and the back should flatten against the floor.

Figure 18-3 ■ The "thinker pose." Self-traction is applied by using gentle upward pressure from one upper extremity onto the chin.

Neurovascular Entrapment Examination

Procedures

Neurodynamics of the upper extremity is assessed with the use of upper limb neural dynamic tests as described by Butler.⁴ Passive neck flexion is examined to assess dural sensitivity, whereas the straight leg raise test is used to assess the sensitivity of the sciatic nerve and sacral plexus. In addition to these passive neural dynamic tests performed by the examining therapist, the patient is taught an “arm self-test” to use as a self-assessment technique.

The arm self-test is an adaptation of the brachial plexus tension test. This is an active test that the patient, the medical provider, and the physical therapist can use as an indicator of upper quarter neural sensitivity. The test provides immediate feedback regarding the patient’s response to an exercise or other form of intervention. The test results can be used as an indicator of a change in patient status. The test is nonspecific, meaning that it does not indicate which structure is the source of the protective tension response. The test is an important tool that helps the patient recognize and manage symptom flares. The arm self-test is one of the self-assessment tools that encourage the patient to take control of his or her treatment.

The arm self-test is performed by guiding the standing patient through a series of positions using the upper extremity (Figure 18-4). The sequence goes from position zero to five, with zero being the position of least general tension on the brachial plexus and five being a position of maximum elongation and general tension on the brachial plexus. Care must be taken to educate the patient to stop at the first sensation of tension and not linger with the arm in any self-test position that provokes symptoms. The test sequence begins in the *zero position* with the patient’s hand resting on the chest. In *position one* the patient’s arm is straight at the side; in *position two* the patient abducts the arm to shoulder height with the palm pronated. In *position three* the patient maintains abduction to shoulder height while supinating the forearm and hand; *position four* is performed by maintaining position three while extending the wrist. If the patient does not experience tension or pain in the previous positions, he or she can progress to *position five* by adding cervical lateral flexion away from the side being tested. Coppiters,⁷² in a cadaver study of nerve gliding, noted increased strain on the medial nerve in positions of wrist extension combined with elbow

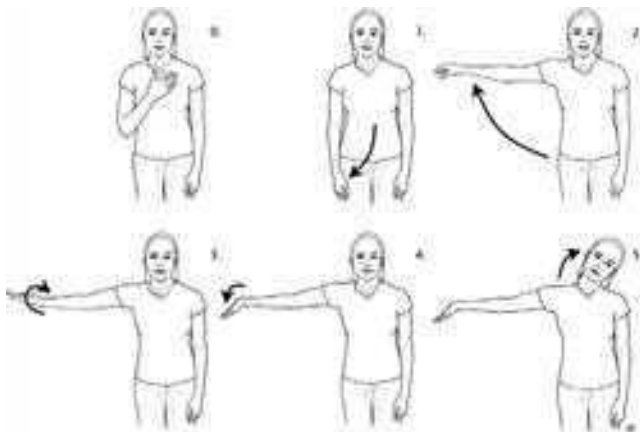

Figure 18-4 ■ Demonstration of arm self-test positions. The arm self-test is an active upper extremity neural dynamic test.

extension; thus position four of the arm self-test can be too provocative to use on the affected extremity in a patient with severe symptoms. (Please refer to the references at the end of this chapter for more information on neural dynamic tests.)

Hand temperature is assessed with an infrared hand-held thermometer. Measurements are made of the second digit (innervated by the upper roots of the brachial plexus) and fifth digit (innervated by the lower roots). Temperature is assessed during rest, diaphragmatic breathing, walking on a treadmill, and repeated movements of the upper extremities while a gymnastic ball is being bounced. A normal response is an increase in temperature in response to these activities. A cooling response is considered abnormal.

Breathing pattern is assessed by palpating the scalene muscles in the area between the inferior border of the sternocleidomastoid and superior to the clavicle. This procedure is best done while the patient performs relaxed inhalation. The scalene muscles are normally quiet during relaxed inhalation. Contraction of the scalene muscles and elevation of the sternum are considered to be abnormal during quiet inhalation. Patients are instructed to breathe with the “belly” only (diaphragmatic breathing). If they are unable to do this, breathing is considered to be paradoxical.

Cardiovascular fitness is assessed by treadmill walking. The patient is instructed to walk at a speed that does not cause an increase in symptoms for up to 20 minutes. Over time, patients are encouraged to increase their walking speed until they reach a level where they are aerobically fit on the basis of standard measures.

CNS sensory dysfunction of the hand (specifically tactile localization, graphesthesia, and stereognosis) is assessed by the methods of Byl.⁶⁹

Hand strength is assessed by examining for the presence of a Kabat sign.⁷¹ The patient is instructed to hold the arm at the side with the elbow flexed to 90 degrees and fully supinated. The wrist is positioned in neutral flexion-extension with the fingers fully extended and the thumb in the shortened range of adduction and flexion (thumb in the plane of the palm). The distal phalanx of the thumb is held in full extension. This starting position inhibits the median innervated muscles of the palm and finger flexors. A manual muscle test is done to test the strength of flexor pollicis brevis and adductor pollicis in the shortened range. If there is a “giving way” at the metacarpophalangeal joint, then this is quantified using a “thumbometer,” an inexpensive device consisting of an eye drop bottle attached to a blood pressure cuff sphygmomanometer. Clinical experience demonstrates that after longus colli isometric contraction there is a strengthening of the affected muscles in the thumb. There will be a weakening effect on thumb strength if the patient has cervical instability during the performance of activities or exercises. This indicates the activity is too much for the patient at that time. If there is no effect on thumb strength then the patient is stable enough for the activity.

Neurovascular Entrapment Interventions

Treatment must follow the same principles that guide the examination. The patient is taught self-assessment techniques and strategies so that the patient has control of the progression of treatment and activities of daily living. The patient may use any of the following self-assessment

techniques, as appropriate, to guide the course of treatment: a pain scale, a thermometer to test skin temperature, a neurodynamic test, or a Kabat strength test. Any treatment or activity that increases symptoms, protective posturing, or tension is modified or discontinued.

Treatment is begun using sensory motor integration with an emphasis on functional skills (e.g., breathing, balance, and hand function) in a manner that does not cause irritation of the patient's condition. The patient is guided through a series of breathing exercises designed to improve the circulation to the extremities, calm the nervous system, and retrain the scalene muscles, if appropriate. The breathing exercises are progressed through the use of foam rollers (Figure 18-5). These are used to increase the mobility of the spine and rib cage. The breathing exercises are combined with functional movements of the trunk and extremities in a manner that mobilizes the nervous system. Once the patient is able to manage the symptoms, the treatment can progress to stabilization exercises with a gym ball (Figure 18-6). If the patient has vestibular, balance, or sensory integration deficits, then specific techniques for vestibular, balance, or sensory retraining would be added.

Our intention is not to present every component of a total treatment program but rather highlight those core components that address the neurovascular consequences of the injury. Our experience is that modifying these neurovascular consequences is the first step and the foundation for recovery.

Core Components of Treatment

The reversible weakness of the thumb is addressed by strengthening the longus colli muscle. This is accomplished by a 30-second isometric contraction using the “thinker pose” (see Figure 18-3) and specific muscle reeducation for

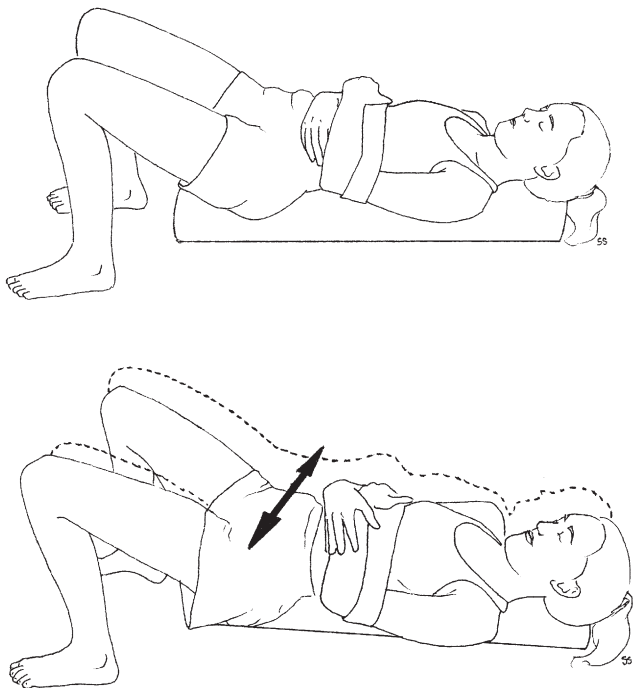

Figure 18-5 ■ Foam roller exercise for mobilization of the spine. The roller is placed underneath the spine with the client in the supine position. The client gently rolls from side to side to increase mobility of the spine.

Figure 18-6 ■ Patient in a quadrupedal position on a therapy ball with the chin tucked and the neck straight. The patient can lift an upper or lower extremity to provide a challenge to the muscles that stabilize the spine.

the longus colli with Jull's protocol.⁷³ The expected effect of the thinker pose is to reverse the identified weakness of the thumb. The patient is taught to minimize mechanical stress to the cervical and thoracic spine through instruction in body mechanics. An important concept is to train the patient to identify the coactivation position for stability of the neck and to visualize that position before moving the body away from the center of gravity or moving the arm. This method has the patient assume the thinker pose to stimulate the deep neck flexors to contract before the movement is performed.

The temperature, neurodynamic, and breathing dysfunctions are addressed by training the patient to perform relaxed diaphragmatic breathing with spinal motion (see Figure 18-2). The expected outcomes are to normalize hand temperature and increase the range of motion while decreasing sensitivity to the neurodynamic tests. Low cardiovascular endurance is addressed by having the patient begin a progressive aerobic conditioning program of walking. Because the examination identifies six signs of dysfunction, the goals of treatment are to normalize these six signs. Clinical experience teaches that as these signs improve there is a reduction in pain and an increase in function.

Role of the Patient

Maximizing the treatment response requires a unique partnership between the physical therapist and the patient that facilitates the patient's feeling of being in control. The feeling of being in control is thought to have a positive impact on the response to treatment. Patients are taught methods for self-assessment of the immediate effect of the treatment. They are taught to assess their responses to the core program on the basis of signs of hand strength and hand temperature and mobility and sensitivity of the nervous system. The patients are provided with self-assessment tools and treatment devices. The details of the exercise program are provided in a patient booklet, audiotapes, and a videotape, which can be found at www.edgelow.com.

This online service will, when available, provide a link for the reader to a Medline abstract for the article cited. There are 73 cited references and other general references for this chapter, with the majority of those articles being evidence-based citations.

CASE STUDY

The following case example describes brief components of this patient's physical therapy encounter. This presentation is not meant to describe a complete case but rather to illuminate key concepts in the clinical reasoning behind the physical therapy examination, assessment, and plan of care in a patient with signs and symptoms of neurovascular entrapment. Video clips of the patient using self-assessment techniques to evaluate his response to treatment are included.

PATIENT DESCRIPTION

The patient is a 27-year-old, right-handed caterer who 3 weeks ago, while lifting a box, felt a “pop” and strain in his right forearm. He was referred to physical therapy with a diagnosis of “forearm strain.” He has avoided using his right arm for 3 weeks, but his symptoms have not significantly improved.

The patient drew a body chart indicating symptoms not only in his right forearm but also in his upper arm, his wrist, and the right side of his neck (Figure 18-7). On further questioning he stated that another component of his work was developing menus. He develops menus using a laptop computer perched on some shelves in a cramped office space with his right arm sustained overhead in an awkward position.

Clinical Reasoning

Diagnostic hypothesis is based on the subjective examination findings:

1. Potential soft tissue strain of forearm flexors based on the mechanism of injury
2. Potential altered neural dynamics with sensitization on the basis of:
 - a. History of receptive use of the upper extremities in sustained awkward positions
 - b. Pattern of symptoms that do not fit localized forearm strain or cervical radiculopathy
 - c. Lack of response to 3 weeks of rest and self-care measures.

PHYSICAL EXAMINATION

Figure 18-8 is a photograph of the patient's sitting posture on initial examination. He demonstrated forward head posture and mildly protected posture of his right arm. Based on the patient's history, the nervous system was considered a potential source of dysfunction. (See Table 18-2 for suggested modifications to a biomechanically based musculoskeletal examination to use when the nervous system is considered a significant source of dysfunction.)

The patient was instructed to complete active movement testing just to the point of feeling tension or resistance to movement. This modification to the physical examination was meant to minimize the potential for a significant flare of symptoms from provocation testing of potentially irritable neurovascular structures while still providing a repeatable measure for reassessment.

The patient moved through full cervical range without complaints of tension or resistance. On palpation the scalene muscles were noted to be active during quiet breathing. The arm self-test indicated a restriction of mobility in his right brachial plexus as compared with his uninvolved left side. He indicated the onset of tension and the reproduction of his forearm symptom with the arm self-test.

Clinical Reasoning

Diagnostic hypothesis is based on physical examination findings:

1. Cervical postural dysfunction
2. Altered neural dynamics based on the presence of:
 - a. Early onset of protective muscle tension and reproduction of symptoms with arm self-test (indicator of possible neurovascular entrapment)
 - b. Scalene breathing pattern (indicator of possible adaptive response to pain)

INTERVENTION

The patient was taught a neural dynamic self-assessment technique to evaluate his response to activity. We called this his “arm self-test.” If he had a negative response to an exercise or activities of daily living, as evidenced by an increase in symptoms or a decrease in the range of his arm self-test, he was instructed to modify or discontinue the activity and perform a self-treatment that restored his tension-free range.

Videos 18-1 through 18-3 demonstrate the patient performing his arm self-test, engaging in an exercise on a foam roller, and repeating his arm self-test immediately after engaging in the foam roller exercise. The intention of the foam roller exercise was to help him mobilize his thoracic spine to improve his ability to correct his cervical posture on his own. After the roller exercise he demonstrated a dramatic increase in tension-free range of his right arm self-test. The difference was readily apparent to the patient and helped him grasp the concept of sensitivity of the nerves as well as the concept of the nerves as a continuous tract in which cervical posture correction was a key component of his treatment.

After the foam roller exercise his right-sided neck discomfort was unchanged. A trial of cervical traction with the use of a towel (Figure 18-9) was found to relieve his neck discomfort without producing forearm symptoms or worsening his arm self-test. During the first treatment, the techniques that he found successful for restoring his neural mobility were foam roller exercises, diaphragmatic breathing (see Figure 18-2), and supine cervical traction (see Figure 18-9). Therefore those interventions were the focus of his home program instruction.

The patient was issued a foam roller and instructed in spine mobilization exercises (see Figure 18-5). He was instructed in the towel cervical traction technique for symptom management (see Figure 18-9). A cervical posture correction exercise termed the “thinker position” (see Figure 18-3) was added to his home exercise program as a form of dynamic cervical posture correction. In addition, he was instructed to walk daily to maintain his aerobic capacity. Figure 18-8 shows the patient's posture before the initial examination. Figure 18-10 shows the patient's posture immediately after the initial treatment that included foam roller exercise, towel cervical traction, instruction in the self-assessment of upper extremity neural dynamic test, and dynamic cervical posture correction via the thinker position.

At 4 weeks (visit 4) treatment progressed to light resistive exercises. At this stage the patient no longer demonstrated signs of neural irritability. The patient was placed prone on a therapy ball to perform exercises that promote scapular

Continued

CASE STUDY—cont'd

stabilization, postural strengthening, and functional grip (see Figure 18-6). At visit 5 he reported a flare of his symptoms and what he did to resolve the problem. The patient experienced a flare of symptoms after an attempt to progress his strengthening exercises. He discontinued the strengthening exercise and used his symptom relief techniques of breathing exercises and towel cervical traction. He subsequently used the arm self-test to determine which strengthening exercise he could tolerate without producing a protective tension response of his arm. The sixth and final treatment session focused on problem solving related to symptom management, upper-quarter stabilization during simulated work tasks, and progression to recreational activities. Emphasis was placed on continued self-assessment of the response of the nervous system to the progression of activity.

OUTCOME

The early success with self-guided treatment set the stage for teaching the patient to evaluate the effect of any activity, manage symptoms with one or two easing techniques, and ultimately progress his own activity level. This approach gave the patient control of his problem so that he was capable of managing a flare of his symptoms.

The patient received a total of six treatments. At the time of discharge his grip strength was equal bilaterally and his upper extremity neural dynamic test results were equal bilaterally. At this point he was working full-time, regular duty with ergonomic improvements at his workstation.

DISCUSSION

This case illustrates the importance of evaluating the role of the nervous system in patients with symptoms associated with repetitive use of the upper extremity. In this case example the patient's problem did not seem to be chronic, because he reported a specific recent injury. However, on further investigation he also reported symptoms that were chronic in nature, which could have delayed his recovery if not appropriately assessed on initial examination. There can be a wide spectrum of presentations of neurovascular entrapments ranging from subtle signs and symptoms of nervous system involvement to dramatic, life-altering, complex problems in patients who have undergone multiple medical and surgical interventions without obtaining symptom relief. The key to success in treating patients with neurovascular entrapments is recognizing the signs and symptoms of subtle nervous system involvement early. Neural sensitization⁴ and possible processing changes in the CNS⁶⁷⁻⁶⁹ necessitate evaluation of the nervous system as a potential source of symptoms in patients with symptoms of CTD. If the issues of nervous system irritability and sensitization are not addressed during evaluation and throughout treatment, then the risk for increasing the patient's symptoms and continuing the cycle of nervous system hypersensitivity is high.

The indicators that this patient may have had a nervous system dysfunction were his history of repetitive work in an awkward position, the pattern of his symptoms, and his lack of response to standard medical care and rest. The indicators of nervous system dysfunction on physical examination were the restricted upper limb neural dynamic test (arm self-test), altered breathing pattern, and lack of objective signs of a

localized soft tissue strain. Other objective indicators not assessed initially that may have further guided the treatment would be Kabat testing,⁷¹ measuring the temperature of the hands,⁷⁰ and sensory testing of localization, graphesthesia, and stereognosis.⁶⁹

A key concept to keep in mind is the role of education in treating patients with a problem such as neurovascular entrapment. Patient-clinician communication is extremely important when dealing with all patients, but the clinician's communication skills are really challenged when dealing with a patient who has a neurovascular entrapment. Describing the dysfunction of a neurovascular entrapment to the patient in succinct, nonmedical terminology can be quite difficult, but it is a critical step in the patient encounter to help him or her develop an understanding of what is wrong so he or she can engage in self-treatment. Teaching the patient self-assessment tools restores the patient's control, allowing the patient to guide his or her own treatment and to be more responsible for his or her own well-being.

QUESTIONS

1. How would you describe a form of neural sensitization (mechanical allodynia) to a patient?

Answer: I say to the patient: Have you ever touched a hot plate? When you touched that hot plate what did your hand do? It quickly pulled away. Your body has reflexes that protect you, like tightening the muscles in your arm so you can pull your hand away from the hot plate. What if you touched this smooth, cool sink, but your finger did not recognize the smooth, cool sink. Instead your finger sent a signal to your brain that it was touching a hot plate. That's what your body does when it has experienced pain for a period of time—it becomes sensitized, meaning it starts to sense things that are normally not painful as now being painful. The body then tenses or tries to withdraw and get away from what it senses as pain.

2. How would you instruct a patient to do an active self-test of the arm?

Answer: I say to the patient: I am going to ask you to place your arm in a sequence of positions. The positions are numbered from 0-5. I want you to stop when you feel tightness anywhere in your arm or if you feel an increase or change in your pain. Remember the number where you stopped. We will redo the self-test after we have done some exercises. That way you can decide which exercise helps you the most.

After the patient has completed one self-test and one form of treatment followed by a reassessment self-test, then I help the patient interpret the body's response. If your self-test result was worse (lower number, less arm range), it means that your body responded as though it were touching the hot plate—it tightened and tried to withdraw. This means that the exercise we tried is not a helpful exercise for you at this time. If your self-test result was better (higher number, greater range), then this exercise was helpful; your body responded in a way that indicated calming of the protective response. The self-test is something you can always use to help you evaluate whether an exercise or activity is going to be helpful or hurtful for your arms.

OBJECTIVES

After reading this chapter the student or therapist will be able to:

1. Describe the pathological processes, prevalence, and clinical presentation of people with multiple sclerosis.
2. Compare and contrast the types of multiple sclerosis and the common disease progression in each.
3. Discuss the medical management of the disease and the disease symptoms.
4. Describe how the International Classification of Functioning, Disability and Health provides a common language for describing the impact of disease on people with multiple sclerosis and how it provides a framework for rehabilitation management.
5. Describe the outcome measures that can be used to examine people with multiple sclerosis that cover body system problems (impairments), functional skill and activity limitations, and participation restrictions.
6. Develop a rehabilitation plan of care using evidence-based interventions to maximize patient function and quality of life.

OVERVIEW OF MULTIPLE SCLEROSIS**Pathophysiology**

Multiple sclerosis (MS) is a chronic, inflammatory disease of the brain, optic nerve, and spinal cord mediated by the immune system.¹ It is characterized by lesions of disseminated focal demyelination accompanied by variable axon damage and destruction and reactive gliosis. Initially, MS was thought to be a disease of the white matter (WM); however, recent investigations have shown that the gray matter (GM) is significantly involved. Lesions found in the GM typically contain demyelination and loss of neurons without the immune system infiltrates and inflammation characteristic of lesions in the WM. Tissue damage has been found outside the focal lesions throughout the GM that is associated with brain and spinal cord atrophy. These areas of demyelination and axonal damage interfere with normal conduction of neural signals, leading to a disruption of function.

Early in the course of the disease, focal inflammatory WM lesions are composed of immune system components that produce demyelination, axonal injury, and loss of oligodendrocytes. Astrogliosis activated by the damaged neurons produces gliotic scarring (visualized as sclerosis in postmortem brain tissue) called *plaques*. Active disease is followed by periods of remission in which acute inflammation is reduced. Axonal remyelination occurs but is highly variable and is related to recovery of function during periods of remission. The degree of axonal loss is associated with the severity of the inflammation; however, axons are

spared in the majority of WM lesions. Treatment in the initial stages of the disease is aimed at reducing inflammation and immune system infiltration with disease-modifying agents (DMAs).

Later in the course of the disease, inflammation becomes uncommon while demyelination and axonal loss continue, suggesting replacement by a neurodegenerative disease process. Disease progression becomes more constant with a lack of exacerbation. The motor, sensory, and cognitive disability that accumulates in the advanced stages of the disease appears to be associated with the cortical GM pathology.² Owing to the lack of inflammation, DMAs have not been shown to be beneficial in the later stages of the disease.

Incidence and Prevalence

MS is the primary cause of nontraumatic disability in young and middle-aged adults and the most common inflammatory condition of the central nervous system (CNS). It is reported that approximately 350,000 to 400,000 people in the United States and over 2.5 million people worldwide have the disease.^{3,4} People are most commonly diagnosed at age 20 to 50 years, with an average age of 32. However, MS can be diagnosed in people of any age. Approximately 5% of all patients with MS are diagnosed before their sixteenth birthday.⁵

MS is found in people who reside above the northern or below the southern 40° latitude with greater frequency than those who live closer to the equator (Figure 19-1). Given the

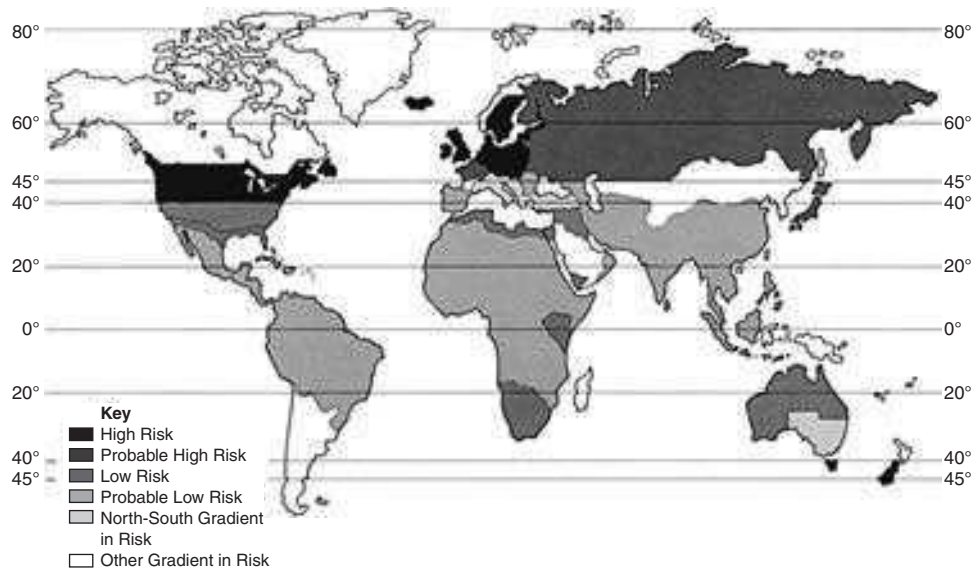

Figure 19-1 ■ World distribution of multiple sclerosis. (From Multiple Sclerosis Resource Center, www.msrg.co.uk.)

increased sun exposure of people living closer to the equator, lack of vitamin D is being investigated as a potential factor contributing to disease development.⁶ Many researchers believe that exposure to an infectious agent may trigger the disease process: Epstein-Barr virus is currently considered a likely candidate.

Women are affected two to four times more frequently than men. Even so, men are more likely to have a more aggressive disease progression and a worse prognosis.^{4,7} Caucasians with Northern European ancestry have the greatest incidence of MS, whereas people of Asian, African, or Hispanic ethnicity are at lower risk. African Americans have a lower incidence, but become disabled earlier than Caucasians, suggesting that tissue destruction occurs earlier and more rapidly.⁸ Inuits, Yakutes, Hutterites, Hungarian Romani, Norwegian Lapps, Australian Aborigines, and New Zealand Maoris do not appear to develop MS.⁹ Being diagnosed with MS may be related to age, gender, genetics, geography, or ethnic background. An identical twin with MS means that the other twin will have a 25% chance of diagnosis, suggesting something beyond genetics. Having a first-degree relative with MS will increase the risk of disease from 1/750 to 1/40.³

Types of Multiple Sclerosis and Clinical Characteristics

At least four types of MS have been identified (Figure 19-2). Although the course of the disease is highly variable even within a subtype of MS, there are characteristics common to each.

The initial neurological episode or attack is typically identified as *clinical isolated syndrome* (CIS). Symptoms must last for at least 24 hours and can be monofocal or multifocal. If there are lesions present on magnetic resonance imaging (MRI), there is a high risk of developing MS. In one group of people with CIS followed for 20 years, 63% were diagnosed with definite MS.¹⁰

Relapsing remitting MS (RRMS) represents about 85% of people with MS, characterized by exacerbations (attacks,

flairs, relapses) that can last days to months and are typically followed by periods of improved function. During remissions, function can return to prerelapse levels, but most frequently it does not recover fully. Attacks normally occur with a frequency of one or two per year. Approximately 90% of people with RRMS transition to SPMS after 20 years or around 40 years of age.

In *secondary progressive* MS (SPMS), relapses decrease in frequency over time and convert to a slow steady progression of increasing disability or disease severity. Relapses may occur early in SPMS but gradually lessen over time. People with RRMS eventually convert to SPMS 10 to 20 years after diagnosis.¹¹

It is thought that the clinical disability associated with SPMS results from the neurodegeneration that occurs as a result of tissue injury that accumulates from early in the disease process. In addition to less inflammation, there is a greater amount of brain atrophy in people with SPMS compared with RRMS. Figure 19-3 shows the natural history of RRMS and SPMS, comparing the change in brain volume with increasing clinical disability and disease burden.²

Primary progressive MS (PPMS) is less common, affecting only 10% to 15% of people with MS. From disease onset, progression results in a gradual worsening of symptoms without relapses. People tend to be older when diagnosed (late 30s or early 40s), have fewer abnormalities on brain MRI, and respond less favorably to standard MS therapies. Progressive myelopathy is commonly associated with PPMS.

Progressive relapsing MS (PRMS) is the least common form (5%). This form of MS typically begins with a progressive course with clear relapses or exacerbations.

Benign MS is identified when symptoms occur once and never recur. This happens in roughly 25% of cases.¹² Recently, Sayao and colleagues¹³ reported that 52% of people with benign MS had not developed MS 20 years later. However, the remainder of people went on to develop MS, with at least 21% requiring the use of a cane.

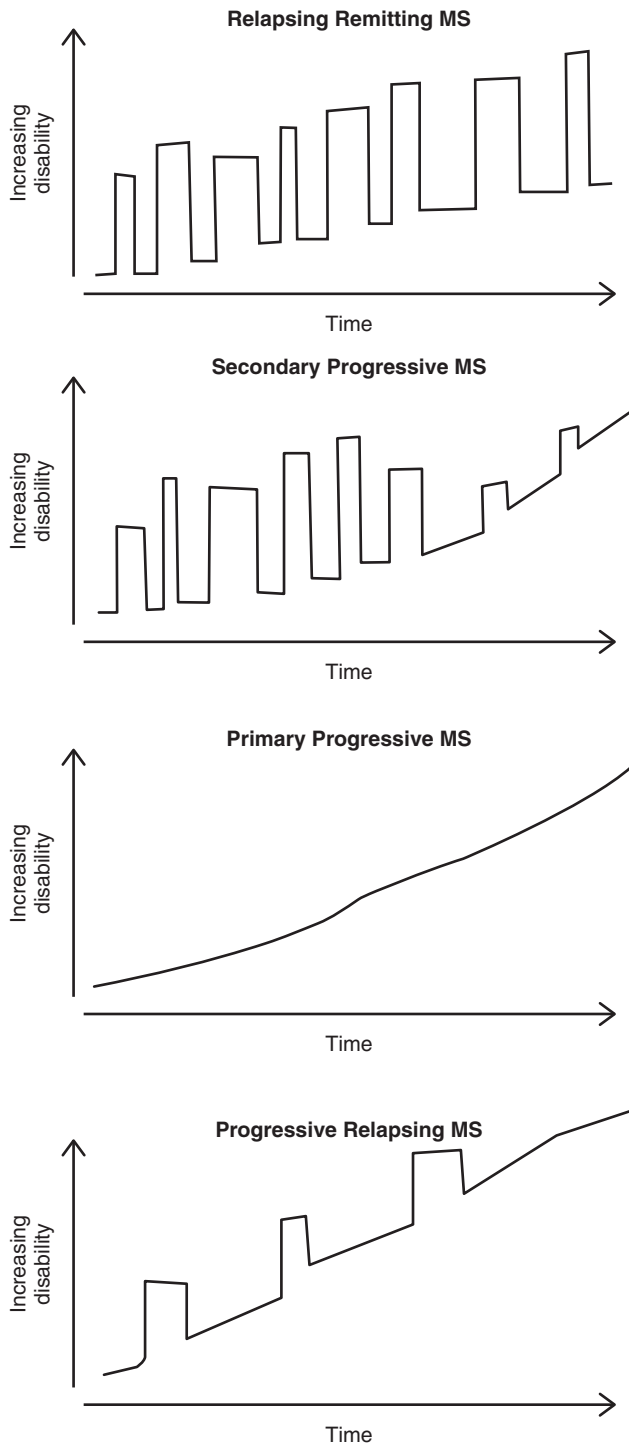

Figure 19-2 ■ Types of multiple sclerosis.

The authors could not identify any criteria associated with either developing MS or continuing to have the benign form.

The risk of a more rapid disease progression is correlated with older age at diagnosis; male sex; initial symptoms involving the motor, sphincter, or cerebellar systems; multifocal disease at onset; shorter time between first and second attacks; and frequent attacks in the first 5 years postdiagnosis.^{7,14}

Clinical Manifestations

MS can affect the optic nerve and any tissue within the brain or spinal cord, so almost any neurological symptom can result. Individual assessments are required to identify the problems present. Even so, the following list constitutes the most common problems encountered by people with MS.

Fatigue

Of people with MS, 65% to 97% report fatigue during the course of the disease; as many as 40% of people with MS state that fatigue is their most disabling symptom.¹⁵ There are two types of fatigue in people with MS: primary and secondary. Primary fatigue, often called *lassitude*, is caused by the effects of the demyelination and axonal destruction and its effect on nerve conduction. Restorative rehabilitation has little effect on primary fatigue from neurodegeneration. Secondary fatigue results from problems such as deconditioning, infections, sleep disturbances, poor nutrition, medication side effects, other medical conditions (such as thyroid disease), and heat intolerance. Clinicians should be extremely careful to separate the types of the fatigue in order to determine the most appropriate interventions.

Sensory Impairments

Sensory impairments are among the most common symptoms associated with MS and can affect the visual, somatosensory, and vestibular systems.¹⁶ The most common problem of the visual system is optic neuritis, which can produce blurry or double vision and/or painful eye movements and nystagmus. Somatosensory or proprioception disturbances can include dysesthesias (tingling, buzzing, or vibrations) or anesthetics (complete loss of sensation in part of the body). People may experience paresthesia or anesthesia in half of the body—upper or lower or side to side—or below a certain spinal cord level. Dysesthesias may be limited to small body areas such as a patch of skin on the head or a single upper or lower extremity. Vestibular system involvement occurs in 20% of people with MS at some time during their disease course¹⁷ and may manifest as dizziness and/or vertigo.

People with MS can have pain associated with the damage to neural tissue (neuropathic pain). This may manifest as neuralgias with burning, itching, or electric shocklike sensations. Lhermitte sign is an electric shock–like shooting sensation that can run into the upper extremities or down the back in response to flexion of the neck.

Motor Systems Impairments

Deficits in the motor system include weakness, spasticity, ataxia, and tremor. Paresis or muscular weakness is frequently seen in people with MS and is associated with several causes. Like fatigue, weakness can be caused by damage to the myelination and axons of motor and premotor neurons in the CNS that can manifest in many different patterns including monoparesis, paraparesis, hemiparesis, or quadriplegia. However, additional causes of muscle weakness can also be associated with disuse deconditioning and may also result in muscle atrophy. When muscle weakness or loss of motor control is seen in the muscles of speech, it results in dysarthria. Paralysis or total loss of muscle strength occurs with less frequency but can be devastating for patients. Several patterns of paralysis (or “-plegia”) occur in people with MS including paraplegia, hemiplegia, and quadriplegia.

Figure 19-3 ■ Natural history of relapsing remitting multiple sclerosis (RRMS)—conversion to secondary progressive multiple sclerosis (SPMS). Figure shows the typical clinical course of RRMS with conversion to SPMS. Magnetic resonance imaging (MRI) activity (*gray line and boxes*) indicates the inflammatory lesions; they occur more frequently early in the disease and occur with greater frequency than in clinical disability (*solid black line*). Brain volume indicated by the stippled line shows brain atrophy increasing as the inflammatory component of the disease slows and is replaced by neurodegeneration.

A broad clinical definition of spasticity is a velocity-sensitive resistance to muscle stretch or a muscle spasm during movement.¹⁸ Some people report heaviness in the limbs, difficulty moving a joint, jumping of the extremities, or involuntary painful movements. Muscle spasms or cramping are frequently experienced by people with MS. Eighty four percent of people with MS report spasticity, with 34% indicating that their spasticity is moderate to severe.¹⁹ Female sex or longer disease duration are both associated with higher prevalence of spasticity. Spasticity has been highly correlated with patient-reported disability and poorer quality of life (QOL).¹⁹ Spasticity may change according to position and may result from increased effort during activity or from the presence of a noxious stimulus such as an infection, skin lesions, fractures, renal stones, distention of bladder or colon, or other physiological stressors such as certain medications (DMAs or serotonin reuptake inhibitors) or psychological distress. Environmental factors such as tight clothing, hunger, or elevated body or air temperature may also lead to increased spasticity. Spasticity can cause muscle contractures, skin breakdown, pain, and sleep disturbances, which often lead to secondary activity limitations and participation restrictions that limit performance of activities of daily living (ADLs) and mobility.

Ataxia occurs in up to 80% of people with MS at some point in their disease progression.²⁰ This motor deficit can occur from disturbances in the vestibular system or cerebellum or a loss of proprioception. Ataxia or a lack of coordination can manifest as difficulty with walking to difficulty with movements of the extremities such as overshooting or undershooting targets (dysmetria) or an inability to produce rapid alternating movements (dysdiadochokinesia). Occasionally, patients experience sustained body positioning (dystonia) of the extremities or head and neck. In different research studies, tremor is reported by 25% to 58% of people with MS, with the majority of people experiencing mild to moderate dysfunction.^{21,22} Action tremor, both postural and intention, are found in people with MS, pointing to the

cerebellum as a likely source (see Chapter 21). Tremors affect the head, neck, vocal cords, limbs, and torso, with the upper extremities having the greatest occurrence.^{21,22}

MS affects many of the systems required for postural control and balance, including sensory input (visual, somatosensory, and vestibular), central processing, and motor output. Therefore it is not surprising that over 50% of people with MS report falling one or more times in the previous 6 months.²³⁻²⁶

Bowel and Bladder Dysfunction

The incidence of bowel problems (35% to 68%) and bladder problems (52% to 97%) make them common in people with MS, as reported by two research studies.^{27,28} Symptoms include urinary urgency, nocturia, or retention of urine or feces.²⁹ Incontinence of either system can also occur. Neurogenic detrusor muscle overactivity is the most common urological impairment in people with MS; 20% have detrusor muscle underactivity, and only 10% report no symptoms.²⁸

Sexual Dysfunction

Sexual dysfunction affects 40% to 85% of women with MS and 50% to 90% of men. It can manifest as erectile dysfunction, impotence, inability to achieve orgasm, and, in men, retrograde ejaculation.^{28,30,31}

Cognitive Impairments

Cognitive dysfunction occurs in roughly 40% to 70% of people with MS, with 70% demonstrating mild to moderate impairment.^{32,33} Although cognitive problems can occur at anytime, abilities affected early in the course of the disease are verbal fluency and verbal memory.³⁴ Other cognitive dysfunctions common in people with MS include impairments in memory, processing speed, executive functioning, attention, and visuospatial learning. There is a fair correlation between cognitive decline and ability to work and unemployment because of the impairments in short- and long-term

memory, problems with concentration, forgetfulness, and slowed word recall.^{35,36} This is a likely source of frustration for both patients and caregivers alike.

Depression

Depression is two to three times more common in people with chronic health conditions than in the general population and has a greater incidence than other neurological conditions.³⁷ From 26% to 50% of people with MS have been reported to experience depression during the course of the disease.^{32,38} Several factors contribute to the high incidence of depression in people with MS. The fact that MS is a chronic, progressive, and unpredictable disease that affects people in their early to middle adult years, is often invisible, and limits participation in many life roles often leads to a perceived reduction in QOL.³⁹ Suicide is of great concern for people with depression, and rates are significantly higher in people with MS than in the general population.⁴⁰ Depression is associated with a lower QOL and other symptoms of MS including fatigue, disability, pain, and cognitive impairment.⁴¹

Heat Intolerance

Uhthoff phenomenon is a temporary worsening of MS-related problems associated with an increase in core body temperature. Such increases can occur with physical exertion such as exercise or with a change in the environment such as hot baths or showers, hot weather, and hot air temperature.

MEDICAL MANAGEMENT

Diagnosis

Historically, people with MS would wait for a diagnosis for a year or more. Although there are no definitive tests that diagnose MS, the addition of MRI has accelerated diagnosis. In 2001 the International Panel on the Diagnosis of Multiple Sclerosis updated criteria to include MRI, visual evoked potentials, and cerebrospinal fluid (CSF) analysis. The 2005 Revised McDonald Criteria for MS diagnosis were designed to make the diagnostic process even more efficient and easier.⁴² The Poser criteria require the presence of two separate episodes over time, plus evidence of two or more lesions in separate brain or spinal cord regions identified by radiological imaging studies. Even with the improved technological measures used to facilitate diagnosis, an accurate clinical history is critical. Often patients will recall episodes of transient symptoms that did not last long enough to require attention by a primary care provider.

In addition to the clinical history, MRI studies have improved diagnosis of MS. Although T2-weighted MRI images show MS lesions as hyperintense and identify new or active lesions, MRI has been shown (Figure 19-4) to overestimate clinical relapses. Conventional MRI with T1 weighting identifies lesions as hypointense (black holes) and is able to identify brain atrophy. T1 imaging demonstrates a stronger correlation with clinical status and disease severity than the lesion load found with T2 weighting. Gadolinium-enhanced T1-weighted MRI images show active MS lesions as hyperintense (white).

Two additional medical tests can be used to aid in the diagnosis of MS and differentiate it from other diseases and

Figure 19-4 ■ T2-weighted magnetic resonance imaging (MRI) scan of plaques associated with multiple sclerosis. Plaques are indicated by arrows. (From Frey H, Lahtinen A, Heinonen T, Dastidar P: Clinical application of MRI image processing in neurology. *Int J Bioelectromagnet* 1(1), 1999.)

conditions. The first is the analysis of CSF. This requires a lumbar puncture in which CSF is gathered and analyzed to identify oligoclonal bands representing the presence of immune system proteins indicating that the body is attacking itself. The majority of people with MS have oligoclonal bands; however, because people with other diseases or conditions also have oligoclonal bands, the test is not specific for MS. The lack of oligoclonal bands at diagnosis has been related to a slower progression of the disease and increased time to reach markers of disability such as walking with an assistive device or confinement to a wheelchair.

Evoked potentials record the nervous system's response to stimulation of a specific sensory pathway (visual, auditory, vestibular, or general somatosensory). Demyelination and axonal degeneration cause a slowing of signal transmission along neurons and therefore will increase the response time to an externally applied sensory stimulus. Damage to the optic system is a common first symptom in MS, and therefore visual evoked potentials are often most helpful in diagnosis.

Disease severity and progression are monitored by ongoing medical checkups, MRI imaging, and the use of several outcome measures. The Kurtzke disease severity scale was developed to allow primary care providers a way to measure clinical disability and chart disease progression. It has been replaced by the Expanded Disability Status Scale (EDSS) (Table 19-1).⁴³ The EDSS is a 10-point ordinal scale completed by a physician or physician extender, with 0 indicating no disability and 10 indicating death caused by MS. Using a cane relates to an EDSS score of 6.0. The National MS Society (NMSS) Task Force on Clinical Outcomes Assessment also recommends the Multiple Sclerosis Functional Composite (MSFC)⁴⁴ as a measure of disease severity and progression. This set of outcome measures is used to

TABLE 19-1 ■ ABBREVIATED EXPANDED DISABILITY STATUS SCALE

SCORE	FUNCTION
1.0	Normal neurological examination findings
2.0	Minimal disability
3.0	Moderate disability
4.0	Ambulates 12 hours without aid
5.0	Disability impairs activity (walks 1500 feet without assistance)
6.0	Intermittent or unilateral constant assistance
6.5	Bilateral support required (walker, crutches, two canes)
7.0	Unable to walk 15 feet without assistance
8.0	Basically constrained to bed
9.0	Bedridden
10.0	Death from multiple sclerosis

chart change in physical and cognitive function and will be discussed later in this chapter. It includes three tests that measure upper-extremity function (Nine-Hole Peg Test [NHPT]), lower-extremity function and mobility (25-Foot Timed Walk [25FTW]), and cognitive function (Paced Auditory Serial Addition Test [PASAT]).

Medical management of MS has two major goals: long-term management of the disease and exacerbations and symptomatic management. Early after diagnosis with CIS, it is recommended that people take DMAs. Recent evidence suggests that as the disease progresses it becomes less inflammatory and more neurodegenerative. Therefore medications

aimed at reducing inflammation will be less effective as the disease progresses. Fox² suggests that early treatment is needed to compensate for the later stages of the disease when inflammation is less prevalent.

Medications

Disease-Modifying Agents

DMAs are aimed at reducing immune system dysfunction, thereby reducing damage to neural tissue and long-term disability for people with RRMS. There are several different medications that act on various components of the immune system with the intention of modifying the course of the disease (Table 19-2). In general, these drugs are approved for use with RRMS and are used off-label for other forms of MS and have been shown to reduce the number of attacks experienced. The majority of the drugs require injections; however, in 2010 the U.S. Food and Drug Administration (FDA) approved the first oral DMA, fingolimod. Measurement of therapeutic effectiveness includes relapse rate, progression of disability (EDSS), and quantitative evidence of lesions on MRI. All DMAs have side effects (see Table 19-2), but rarely are they serious. These medications are costly, and some people do not respond well or tolerate the side effects. It is common that people will try more than one type before finding the DMA they tolerate the best.

Antiinflammatory Medications

High-dose corticosteroids (such as prednisone or methylprednisolone) are used to reduce inflammatory response during exacerbations for people with RRMS. Although no medications have demonstrated effectiveness in people with

TABLE 19-2 ■ DISEASE-MODIFYING AGENTS: INDICATIONS AND SIDE EFFECTS

FDA-APPROVED DISEASE-MODIFYING AGENTS	INDICATION	COMMON SIDE EFFECTS
IFN beta-1a (Avonex)	CIS	Flulike symptoms
IFN beta-1a (Rebif)	RRMS	Injection-site reactions
IFN beta-1b (Betaseron)	SPMS	Depression
IFN beta-1b (Extavia)		Elevated liver enzymes
Glatiramer (Copaxone)	CIS	Injection-site reactions
	RRMS	Systemic reactions, immediately postinjection
		Elevated liver enzymes
Natalizumab (Tysabri)	RRMS	Progressive multifocal leukoencephalopathy
		Infusion reactions
		Hepatotoxicity
Mitoxantrone (Novantrone)	RRMS	Cardiotoxicity
Intravenous infusion	SPMS	Treatment-related leukemia
	PRMS	Infection risk
		Alopecia
		Amenorrhea
Fingolimod (Gilenya)	RRMS	Flulike symptoms
		Increased liver enzymes
		Headache
		Diarrhea
		Back pain
		Cough

CIS, Clinical isolated syndrome; FDA, U.S. Food and Drug Administration; IFN, interferon; RRMS, relapsing remitting multiple sclerosis; SPMS, secondary progressive multiple sclerosis.

PPMS, anecdotal evidence suggests that intermittent pulses of intravenous methylprednisolone can help slow progression of clinical disability in some patients.²

A host of additional medications are used to manage the symptoms associated with MS. Each will be discussed as part of symptom management. Also refer to Chapter 36 for additional information.

Symptom Management

Fatigue

The fatigue experienced by people with MS is generally divided into primary and secondary causes. Fatigue from primary causes results from the disease itself or to heat intolerance and is defined by the term *MS lassitude*. Heat intolerance may result in a temporary worsening of symptoms. It is sometimes referred to as *pseudoexacerbation* and occurs when core body temperature rises with exposure to raised ambient temperature or metabolic activity such as exercise. However, in addition to MS lassitude, other causes can include side effects of medications used in the treatment of MS, deconditioning from reduced activity levels, poor nutrition, infections or other medical conditions, depression, or sleep disturbances. Several medications combined with rehabilitation strategies have been recommended for management of fatigue. Amantadine (Symmetrel) and modafinil (Provigil) are frequently prescribed.

Spasticity

Spasticity can interfere with physical function and hygiene. However, spasticity can also add support to weakened limbs, allowing more effective mobility. The goal of medical management of spasticity is to maintain full range of motion (ROM) of muscle and soft tissue structures to allow maximal physical function and proper hygiene. Haselkorn and colleagues¹⁸ describe the clinical practice guidelines for managing spasticity in people with MS written by the Multiple Sclerosis Council. A complete assessment of the spasticity and how it affects the individual's life is required. Typically, successful management includes both pharmaceuticals and rehabilitation.

When spasticity is the result of CNS impairments, medical management often includes the use of oral pharmacotherapy including baclofen (Lioresal) or tizanidine (Zanaflex). Adjuvant therapies include diazepam (Valium) or clonazepam (Klonopin), dantrolene (Dantrium), gabapentin (Neurontin) or levetiracetam (Keppra), clonidine (Catapres), or muscle relaxants. Each of these drugs can have negative side effects that interfere with movement and therefore rehabilitation.

Management of focal spasticity may include local anesthetics such as lidocaine, bupivacaine, etidocaine, all of which are short acting with side effects of CNS and cardiovascular toxicity and hypersensitivity. Neurolysis treatment with phenol or alcohol is longer acting; however, these agents can have the side effects of pain, swelling, fibrosis, and dysesthesias. Focal spasticity affecting functional muscle groups can also be effectively treated with neuromuscular blocking agents including alcohol, phenol, or botulinum toxin. Botulinum toxin type A (Botox) has been shown to improve spasticity as measured by the Ashworth Scale and

the hygiene score, but no changes were noted in spasm frequency score.⁴⁵ Blocks last 1 to 3 months with relatively few side effects. Similarly, botulinum toxin type B was shown to reduce hip adductor spasticity.⁴⁶ Clinical practice guidelines¹⁸ recommend that neuromuscular blocks be performed by appropriate specialists in conjunction with a rehabilitation program.

Refractory spasticity is defined as unsuccessful treatment with oral medications and/or rehabilitation. In this situation two other options exist: surgery or placement of an intrathecal baclofen pump (ITB). Surgical procedures include tendon lengthening or tendon transfer and are performed to maintain adequate hygiene or prevent or correct contractures and therefore preserve function. Intrathecal pumps, inserted into the spinal cord, allow adjustable drug delivery. Baclofen, the drug of choice for the intrathecal pump, can be given in higher doses; use of the pump avoids the side effects often encountered when the drug is taken orally. Relapses are more commonly reported in people on oral medications than those using ITB. People using ITB also report higher levels of satisfaction, less spasticity, and fewer painful spasms compared with those on oral medications.¹⁹

Pain

Both nociceptive and neuropathic pain can be present in people with MS. Therefore it is important to discern the type of pain in order for the most appropriate treatment to be rendered. Nociceptive pain can often be treated with analgesics (acetaminophen, nonsteroidal antiinflammatory drugs [NSAIDs], or opioids) and is more amenable to physical therapy (discussed later under rehabilitation management). Neuropathic pain generally requires pharmacological intervention, although an interdisciplinary team approach may be valuable. First-line medications for neuropathic pain that occurs in the spinal cord are calcium channel blockers (gabapentinoids) or *N*-methyl-D-aspartate (NMDA) antagonists (ketamine). When pain is present in the head, the primary treatment is opioid drugs such as antidepressants (tricyclics) or anticonvulsants (gabapentin or pregabalin).⁴⁷ In the case of trigeminal neuralgia, the first choice is often carbamazepine. Refer to Chapter 32 on pain management for additional information.

Mobility

Physical rehabilitation is the primary intervention used to manage mobility dysfunctions. However, one medication has recently been FDA approved to improve gait. In clinical studies dalfampridine (Ampyra) demonstrated the ability to improve walking speed in people with MS.⁴⁸ However, changes in the quality of gait or movement were not measured.

Tremor

Tremor management using medications such as isoniazid, carbamazepine, ondansetron, or cannabis extract has been minimally effective.⁴⁹ Surgical interventions including stereotaxic thalamotomy and deep brain stimulation have been studied, but the evidence to support the effects on functional status and disability is lacking. The effectiveness of other options including physical therapy, tremor-reducing orthoses, and extremity cooling have yet to be proven beneficial in clinical trials.⁴⁹

Bowel and Bladder Management

Behavioral modification and rehabilitation are used to help alleviate the symptoms of bladder incontinence or detrusor muscle overactivity. A few medications have been shown to be helpful: anticholinergic agents are used to manage detrusor overactivity or dyssynergia, and underactivity is treated with cholinomimetic agents.²

People with constipation are encouraged to combine adequate fluid intake with dietary fiber or bulk-forming medications.²

Depression and Cognitive Impairments

Depression is very common in people with MS, yet it is infrequently identified or treated.⁵⁰ Therapy can include supportive psychotherapy and medication given individually or in combination. To date two pharmacological therapies have shown the most promise in reducing cognitive deficits (L-amphetamine sulfate and donepezil), and neither has serious adverse effects.^{51,52}

REHABILITATION MANAGEMENT

Overview

Chronic neurodegenerative conditions, such as MS, result in a loss of physical and cognitive function from the destruction of neurons and from a lack of activation of the affected systems. People with MS experience physical and cognitive impairments potentially leading to inactivity and resultant deconditioning (Figure 19-5). This often becomes a cycle that is difficult to break. One question that frames the rehabilitation strategy chosen is whether the focus should be compensation for or restoration of lost function. Compensation includes interventions such as wheelchairs or walkers to assist with mobility or braces for absent or inadequate muscle power. Restoration is aimed at increasing the capacity of the system—for example, maximizing cardiovascular endurance by increasing maximal oxygen uptake or restoring full ROM. Therefore, prescribing programs,

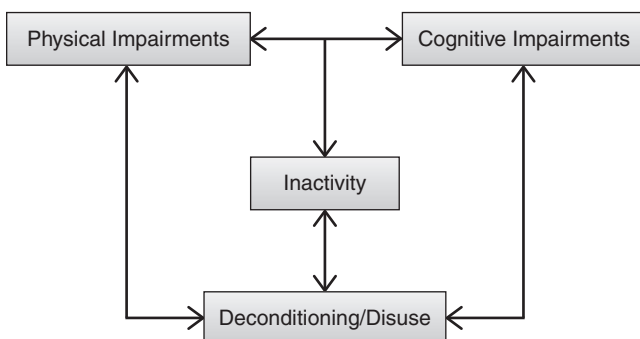

Figure 19-5 ■ Interaction among impairments, inactivity, and deconditioning. People with multiple sclerosis often experience physical and/or cognitive impairments that can lead to or be increased by inactivity. Deconditioning and disuse can reduce activity levels or be caused by inactivity. This can become a cycle that is self-perpetuating. (Modified from Multiple sclerosis treatment: impact on quality of life [Clinical monograph, p. 10]: Proceedings from Clinical Medical Education/Clinical Education Symposium at the Consortium of Multiple Sclerosis Centers Annual Meeting, Washington, DC, June 2007.)

activities, and exercises that provide an adequate stimulus to produce adaptation is critical to restore function or improve motor and cognitive performance. Although each patient case is unique, the most likely answer is that both strategies will be employed. The challenge for rehabilitation professionals is to sort out how much of a patient's dysfunction arises from neurodegeneration, which necessitates compensation, and how much occurs from inactivity and system deconditioning, in which case system capacity can be restored to some extent. Rehabilitation professionals must choose therapeutic interventions based on whether compensation or restoration is the goal.

Rehabilitation for people with MS occurs in every setting: inpatient hospitals, outpatient clinics, skilled nursing facilities, home care settings, and the community. With the current climate of decreasing access to and reducing coverage for rehabilitation, therapists must be able to make evidence-based arguments to primary care providers and insurers, as well as patients, to support effective therapeutic interventions that will achieve the goals of optimal physical and cognitive functioning, safety, and QOL.

For rehabilitation professionals managing people with MS, the International Classification of Functioning, Disability and Health (ICF) model (refer to Chapter 1) provides an excellent framework for assessment and management regardless of the setting in which the patient or client is encountered.⁵³ Although guided by the opening interview and chart review, the initial assessment must include how the individual with MS is functioning in home, at work, and in recreation environments and which impairments of bodily structure or function might be contributing to the identified activity limitations and participation restrictions. Rehabilitation professionals must consider how personal and environmental factors may impede or facilitate achievement of rehabilitation goals. Personal factors in people with MS may include whether the patient is heat intolerant, experiences MS-related fatigue, or has the confidence or motivation to perform certain tasks. Environmental factors that may be of particular importance for the patient with MS may be living in a hot climate or having access to cooling equipment such as air conditioning or cooling garments. It is critical to understand how the disease affects the lives of both individual patients and their caregivers. Outcome measures designed to test impairments, activity, and participation, along with assessments of environmental and personal factors, will help health care professionals understand the deficits of their patients and determine the best place to focus rehabilitation efforts and monitor the patient's response to intervention.⁵⁴

Because of the myriad CNS lesions and variable clinical presentations in people with MS, there is no one approach that is the gold standard for rehabilitation management. Whatever the approach, evidence is growing that rehabilitation is beneficial. Intensive inpatient therapy programs provide long-term improvement in a number of functional skills, participation, and QOL but may not change underlying impairments. Prospective studies have shown that intensive inpatient rehabilitation improves disability and QOL and that these benefits can be long lasting.⁵⁵⁻⁵⁸ High-intensity programs in the outpatient clinic or home environment offer evidence of short-term symptomatic changes that have translated into improved participation and QOL.^{56,59}

Assessment

The initial interview must include a quick screen or questioning about the body systems and areas that are commonly impaired in people with MS and the problems commonly encountered: motor strength, coordination, spasticity, sensory disruption (vestibular, visual, and somatosensory), bladder control, depression, and cognition. If impairments are present, there is a strong likelihood of negative impact on the patient's ability to perform ADLs or participate in activities related to work, home, and leisure. All patients with MS must be asked if they have fallen in the last 6 months because of the high rate of falling in people with MS.^{23-25,26} Results of the interview and chart review will help develop hypotheses about which potential impairments might be contributing to the patient's or client's physical or cognitive dysfunctions. Therefore the examination needs to be designed to observe the problematic tasks and test the hypotheses developed.

During the assessment, examiners must determine if the problems identified by the patient (or those found by the assessor) fit within their scope of practice or whether the patient requires a referral to an appropriate health care professional. A good example is identifying people with depression using a quick two-question screen. According to Mohr and colleagues,⁶⁰ these questions are 98.5% sensitive for identifying major depressive disorder. The two questions are (1) "During the past 2 weeks, have you often been bothered by feeling down, depressed, or hopeless?" and (2) "During the past two weeks, have you often been bothered by having little interest or pleasure in doing things?"⁶¹ An answer of yes to either question should trigger a referral to the patient's primary care provider for follow-up.

The physical examination might then start with testing the patient's ability to perform functional activities that the patient or his or her caregivers have identified as problematic. This might include performance of transfers, gait, ADLs, or cognitive tasks as well as the specific activities that the person states are compromised in his or her work, home, and recreational life. There are several measures of QOL that also cover participation issues relevant to people with MS.

Comprehensive lists of standardized tests and measures for impairment, activity limitations, and participation restrictions or QOL are provided in Chapter 8. The next section of this chapter will primarily focus on the tests and measures found to be valid and reliable in the examination of individuals with MS.

Assessing Body System Problems Contributing to Activity Limitations

In general, standardized methods of examining muscle strength and endurance, somatosensation, vision, coordination, cardiovascular status and endurance, posture, muscle tone, reflexes, ROM, pain, and cognition are useful in examining patients with MS. As with many neurological conditions, abnormal posturing or pain may necessitate using nonstandardized test positions or methods that must be noted in the patient documentation. If a patient is unable to attain the normal test position while performing a muscle strength test, the assessed strength is noted along with the position in which the muscle or muscle group was tested.

Spasticity. Spasticity can be measured using resistance to passive ROM and Ashworth⁶² and Modified Ashworth

Scales.⁶³ However, because these scales measure spasticity at rest, they may not reflect the degree to which spasticity may be interfering with function. Careful observation of the patient's movements may also inform the clinician about how spasticity is affecting the patient's ability to move.

Ataxia and Incoordination. Few standardized tests have been developed to specifically measure ataxia. One recent test is the Scale for the Assessment and Rating of Ataxia (SARA). Although this test has yet to be validated in people with MS, it has good reliability and validity in patients with cerebellar dysfunction, a common problem in people with MS.^{64,65}

Tests of nonequilibrium coordination are designed to measure the presence of dysmetria or dysdiadochokinesia, both of which occur in patients with MS. However, these tests (including finger to nose, heel to shin) are somewhat subjective and are therefore difficult to use to demonstrate improvement after an intervention. However, using a stopwatch during these tests can be an important tool to record objective data. Count the number of repetitions of a given activity performed in a set amount of time (e.g., how many alternating forearm supinations and pronations can be performed in 30 seconds), or record the time it takes to complete a set number of repetitions of a given activity (e.g., how long it takes to complete five alternating supination-pronation movements). Refer to Chapter 21 for additional assessment tools.

Vestibular Dysfunction. The vestibular system is affected by MS both centrally (lesions in the vestibular nuclei or cerebellum) and at the entry site of cranial nerve VIII.⁶⁶ However, benign paroxysmal positional vertigo (BPPV) can also occur.⁶⁷ The techniques used to assess and treat the effects of vestibular disorder in an individual with MS are the same as those discussed in Chapter 22. When vestibular symptoms are present, Williams and colleagues⁶⁸ suggest evaluation using computerized platform posturography (CPP) in people with MS with minimal to mild disability. It is important to keep in mind that the patient with MS will often have additional problems that might require modification of the vestibular intervention—for example, heat intolerance or additional visual or somatosensory deficits.

Fatigue. Identifying if and when fatigue occurs in individuals with MS is important to assessment and the structuring of intervention. Questions should address the type of fatigue, whether mental or physical; when during the day it occurs; whether it is related to physical or mental exertion; and what the person with MS does, if anything, to relieve it. In addition, fatigue-related self-report scales can help the rehabilitation professional gain an understanding of the perceived impact that fatigue may be having on a patient with MS. Two of the commonly used scales are the Modified Fatigue Impact Scale⁶⁹ and the Fatigue Severity Scale.⁷⁰ These measures may also aid the therapist in determining if the intervention had any impact on the patient's perceived level of fatigue.

Cognition. The PASAT,⁷¹ recommended by an expert panel of the National MS Society, is a test for cognitive impairments in people with MS. A more recent test, the Audio Recorded Cognitive Screen (ARCS),^{72,73} appears to be a more comprehensive cognitive assessment developed for people with dementia but the psychometric properties have not yet been determined in people with MS. However, Lechner-Scott and co-workers⁷⁴ found that compared with

the PASAT, the ARCS was similar in detecting impairments of cognition and more sensitive at identifying problems with memory or executive impairments.

Assessing Activity Performance and Participation

Outcome measures assess the ability of an individual to perform an activity or task as well as assess the perception of the person to use those tasks to fulfill life roles. Following are activity and participation measures commonly used in people with MS. An individual's perceived ability to participate may also be included in some QOL outcome measures that are included in the following sections.

Balance. Balance is foundational to upright movement and is produced by a complex interaction among sensory inputs, central processing, and motor responses. It can be discussed under both body structure and function or activity. In either case balance dysfunction has been identified in people with MS with minimal as well as more advanced disability.⁷⁵⁻⁷⁹ Cameron and Lord⁸⁰ report the three most common problems with balance to be delayed response to postural perturbations, increased body sway while standing quietly, and an inability to move outside the base of support.

Whereas some balance tests focus on stationary or static tasks that allow observation of body sway in standing, including single-leg stance test, Romberg test with eyes open or eyes closed, tandem stance, and CPP, others add movement and challenge dynamic balance (Functional Reach Test,⁸¹ Tinetti Performance-Oriented Mobility Assessment [POMA],⁸² and Berg Balance Scale [BBS]⁸³). Other tests challenge anticipatory balance (reactions to perturbations related to self-generated movement) or reactive balance (perturbation tests, CPP). Frzovic and co-workers⁸⁴ found that single-leg stance, tandem stance, response to external perturbations, and the Functional Reach Test were able to distinguish people with MS from healthy controls.

Several authors have studied measures of balance in people with MS. Cattaneo and colleagues⁸⁵ determined that four tests measuring balance during standing and gait and self-perception of balance had good intrarater and interrater reliability. The two tests measuring balance during standing and movement were the BBS and the Dynamic Gait Index (DGI).

CPP provides an objective assessment of sensory contributions to balance dysfunction in people with MS.⁸⁶ In particular, the Sensory Organization Test is useful in identifying the relative sensory contributions (visual, vestibular, and proprioceptive) to stationary balance and response to perturbation. Understanding the sensory conditions under which the patient loses balance and falls assists the therapist in providing exercises that will challenge those conditions in a safe and controlled manner. For example, the patient who relies heavily on visual input to maintain balance (conditions with eyes closed in the Sensory Organization Test) would be provided exercises and activities that challenge the vestibular and proprioceptive systems, such as standing on foam while the eyes are closed.

Developed by Horak and colleagues,⁸⁷ the Balance Evaluation Systems Test (BESTest) is an instrument examining complex balance disorders that includes the six domains that underlie orientation and postural stability: biomechanical constraints, stability limits and verticality, transitions and

anticipatory postural reactions, reactive postural responses, sensory orientation, and stability in gait. Both interrater reliability in people with parkinsonism and content validity are good, but testing in other populations has not yet been completed. There is an abbreviated version of the BESTest, the mini-BESTest,⁸⁸ that covers four of the six systems, focusing on dynamic balance. These promising tests may offer the clinician a better way of identifying which components of orientation and postural control are dysfunctional, which may allow more targeted interventions.

The Activities-specific Balance Scale (ABC)⁸⁹ is a questionnaire that rates people's self-perception of how confident they are to perform activities that challenge their balance. The Dizziness Handicap Inventory (DHI)⁹⁰ assesses three domains of disability related to dizziness: physical, emotional, and functional. The sum score or each subscale score can be reported. Higher scores mean greater levels of handicap and disability. Cattaneo and colleagues⁹¹ found that both the ABC and DHI tools discriminated between fallers and nonfallers and were therefore good predictors of fall status in people with MS. Refer to Chapter 22 for additional information on balance.

Gait. Gait can be measured in myriad ways depending on the goal of the assessment. Speed, distance, and quality may all be important to the patient and therapist. Observational gait analysis is the gold standard for clinical measurement of gait quality. Although motion-analysis laboratories are able to provide detailed kinetic and kinematic assessment of joint angles and gait cycle, it is costly and typically not available in most clinical settings. Instrumented mats such as the GaitRit can provide clinicians with temporal and spatial gait parameters such as step length, step width, cadence, and single-leg support and double-leg support times. Although this is less costly than motion analysis, it may still be out of reach for many clinics. Gait speed and velocity can also be measured by having the patient walk a given distance while being timed. These walks can occur at a self-selected pace or as fast as the person can walk safely. Several short-distance timed tests exist, the 25FTW and the timed 10-meter gait test,⁹² both of which have been shown to have good reliability and sensitivity to change.^{93,94} The 6-minute walk test (6MWT) measures walking endurance and is recommended by the NMSS Task Force on Clinical Outcome Measures as a measure of walking ability that is sensitive to change. Gijbels and co-workers⁹⁵ report that the 6MWT was better at predicting habitual walking in people with mild to moderate MS than the 25FTW. However, the 25FTW may be more sensitive to change when compared with the EDSS.⁹⁶ The 6MWT distance was reduced in people with MS compared with healthy controls and was inversely related to disability.⁹⁷

Two additional performance-based tests, the DGI and the Timed Up-and-Go Test (TUG), combine walking with other functional tasks. The DGI measures the ability of an individual to walk while adding various challenges such as slowing down or speeding up, head turning, stepping over or around obstacles, and stair climbing. It was developed to assess gait dysfunction associated with peripheral vestibular disease.⁹⁸ McConvey and Bennett⁹⁹ found the DGI to be a reliable and valid tool for use in people with MS. The TUG

test combines walking with transfers and turning. It is frequently used in both clinical and research settings and has been shown to be reliable in measuring function in people with MS.⁹³

The Multiple Sclerosis Walking Scale–12 (MSWS-12) is a 12-item patient-rated questionnaire that measures the perception of the impact of MS on walking ability. This scale has good reliability and validity and may be very useful to document patient perceived change in walking ability before and after intervention.^{100,101}

Upper-Extremity Tests of Function. Movement impairments of the upper extremities can result in decreased ability to perform ADLs and other functional activities. Standardized tests such as the Box and Block Test (BBT)¹⁰² or the NHPT¹⁰³ provide objective data about unilateral manual dexterity or the ability to manipulate objects. Both tests are inexpensive but do require some equipment and a stopwatch. The NHPT is part of the MSFC and therefore has been used extensively in evaluating people with MS.

Composite Tests. An expert panel of the NMSS recommended the use of the MSFC,^{44,104} including the 25FTW, the NHPT, and the PASAT. The MSFC has been tested against lesion load as measured via MRI, EDSS scores, and QOL measures, showing that it has good validity and reliability and is sensitive to change.¹⁰⁴⁻¹⁰⁶ Each component scale of the MSFC can also be used independently to monitor physical and cognitive function as written previously.

Assessing Quality of Life

QOL measures are patient-report tools that evaluate the value a person places on his or her abilities and limitations and how these affect the individual's social, emotional, and physical well-being. Many of these tools include questions that address an individual's perception of how well he or she is able to fulfill life roles and how the disease affects this participation. In a meta-analysis of exercise training on QOL in people with MS, Motl and Gosney¹⁰⁷ found that disease-specific measures of QOL detected larger changes than generic QOL measures. Several measures have been commonly used to evaluate people with MS: the Multiple Sclerosis Quality of Life–54 (MSQOL-54)¹¹³ and the Multiple Sclerosis Quality of Life Inventory (MSQLI).¹¹⁴ The multidimensional MSQOL-54 was based on the Health Status Questionnaire (SF-36), with 18 additional items specific to MS covering fatigue, and cognitive and sexual functioning. There are 12 subscales that cover physical function, role limitations—physical, role limitations—emotional, pain, emotional well-being, energy, health perceptions, social function, cognitive function, health distress, overall QOL and function, and change in health. The measure takes about 15 minutes to complete and requires 15 to 20 minutes to score. Reliability is good to excellent in people with MS.¹¹³

The MSQLI was developed by the Consortium of Multiple Sclerosis Centers Health Research Subcommittee in 1997. It is composed of 10 components covering issues important in MS. It includes the Health Status Questionnaire, Modified Fatigue Impact Scale, MOS Pain Effects Scale, Sexual Satisfaction Survey, Bladder Control Scale, Bowel Control Scale, Impact of Visual Impairment Scale, Perceived Deficits Questionnaire, Mental Health Inventory, and MOS Modified Social Support Survey. It takes about

45 minutes to administer the complete set of questionnaires and does not provide a sum score for all tests. There is good test-retest reliability for the MSQLI even in people with MS and cognitive dysfunction.¹⁰⁸ A shortened version of the tool exists, but the psychometric properties have not been thoroughly tested.

Disease Severity Measures

Disease severity is a measure of disablement. Interventions that change function (e.g., improve walking distances or decrease reliance on assistive devices to move) can reduce disability. There is also compelling evidence that exercise may actually modify disease progression in people with MS. Therefore disease progression may be used to assess the impact of an intervention on the patient's perceived level of disability. Although the EDSS⁴³ is the gold standard for assessing disease severity, it requires a trained primary care provider to administer. Disease Steps^{111,112} and Guy's Neurological Disability Scale (GNDS)¹⁰⁹ are two additional disability scales that have demonstrated good correlation with the EDSS. Whereas Disease Steps must be administered by a professional, GNDS can be given to patients to complete on their own.¹¹⁰

Interventions

The goals of rehabilitation for persons with MS are to maximize and maintain function and prevent complications so that they can participate fully in all aspects of their lives. The variable presentation that people with MS can manifest requires rehabilitation professionals to be flexible and creative. The plan of care developed to manage a patient must be linked to the impairments, activity limitations and participation restrictions identified during the assessment. Research provides evidence for the most effective interventions and must be coupled with the desires and needs of the individual with MS. The rehabilitation program must be negotiated with the patient/client in consultation with caregivers when available or appropriate.

The National Clinical Advisory Board of the National MS Society recommends that rehabilitation occur whenever there is a sudden or gradual decline in function or an increase in impairment that has a negative impact on an individual's safety, independence, mobility, or QOL. In addition, it is recommended that rehabilitation be a part of a comprehensive health care plan at all stages of the disease.¹¹⁵

Regardless of the type of intervention chosen, evidence is growing that increased activity, whether cognitive or physical, may have a neuroprotective effect on the brains of people with neurological insults. In fact, Golzari and colleagues¹¹⁶ demonstrated that an 8-week, 24-session, combined exercise program improved muscle strength and balance and reduced disability in people with MS. In this study, levels of proinflammatory immune system mediators were measured before and after the intervention. The authors demonstrated that this dosage of exercise reduced markers of inflammation in the blood. This is one of the first studies in people with MS showing that inflammation and therefore the disease process may be altered by the application of an exercise intervention, suggesting a role for rehabilitation in neuroprotection and not simply symptom management. This also implies that rehabilitation, specifically

exercise, should occur early in the course of the disease and not only after clinical disability has occurred. However, the exact dosage, intensity, or type of exercise required to produce activity-dependent neuroplasticity is not yet known. At least one study in an animal model of MS, experimental allergic encephalomyelitis, has shown the beneficial effects of exercise.¹¹⁷

In prescribing a rehabilitation program for persons with MS, each individual's level of fitness and physical and cognitive resources including memory, judgment, strength, endurance, spasticity, balance, and coordination must be taken into consideration. In addition, therapists must investigate the person's level of fatigue and heat sensitivity. If present, these factors will require modification of the rehabilitation program, including where the activity is performed, in what environment, and the time of day in relation to fatigue level and the other tasks the individual must perform. In other words, to be successful, the rehabilitation program must fit into the framework of the person's life.

Rehabilitation can occur in a variety of locations: inpatient, outpatient, home, and the community. Figure 19-6 shows a physical therapy–led community-based exercise program for people with MS in which group activities addressing strength, balance, and endurance are modified for

Figure 19-6 ■ Community exercise class for individuals with multiple sclerosis. A physical therapy–led community exercise class is shown. Participants perform group strengthening and balance activities that are modified for each individual.

each individual. In addition, a number of health providers can be members of the rehabilitation team, including nurses, occupational therapists, physical therapists, speech-language pathologists, psychologists, neuropsychologists, and physicians.

Exercise

Historically, exercise was thought to worsen disability and bring on exacerbations. Medical advice warned patients that overexertion could hasten relapse and progression. There now exists clear evidence that this is not the case. Regular, appropriate exercise has been shown to increase strength, aerobic capacity, overall function, and QOL. In 1996 Petajan and colleagues published a seminal study in which a 60% $\dot{V}O_{2\max}$ aerobic ergometer exercise program was well tolerated in people with MS and did not provoke remission.¹¹⁸ After 10 weeks, participants had improvements in $\dot{V}O_{2\max}$, work capacity, isometric strength, and blood lipids and reduced depression, anger, and fatigue. In a 2009 systematic review of the literature,¹¹⁹ exercise was shown to be an effective intervention for people with MS to improve muscle strength, endurance, mobility-related actions, and to a lesser extent mood compared with control conditions. This evidence did not suggest the superiority of one particular type of exercise program over others. It is very important to note that adverse effects were rarely seen in any of the exercise studies, and when they did occur they did not last for longer than 24 hours, indicating that exercise is safe for people with MS.

In a review of the exercise literature, White and Dressendorfer¹²⁰ recommend that endurance exercise programs for people with MS with mild to moderate disability use the following guideline: perform regularly, two or three sessions per week, at an intensity of 65% to 75% heart rate maximum, and last 20 to 30 minutes per session. Resistance exercise should include 15 to 18 repetitions for one to three sets initially with a goal of increasing to three to four sets. Training should last at least 12 weeks.¹²¹ Owing to heat intolerance, exercise should incorporate intermittent rest periods that allow heat to dissipate.¹²⁰ Heesen and colleagues¹²² developed a guideline for exercise prescription for people with MS for all levels of disability (Table 19-3).

Prescribed early in the course of the disease when mild to moderate disability is present, exercise can be used to restore function by reducing physical or cognitive decline from disuse or deconditioning. As clinical disability accrues in the later stages of the disease, exercise may then be used to compensate for missing function or prevent secondary complications—for example, stretching hip adductor muscles with decreased range of motion to allow adequate personal hygiene to occur.

Evidence-Based Interventions for Specific Problems

Fatigue

Fatigue is one of the most frequent and disabling symptoms associated with MS and is best managed with a multidisciplinary team composed of physicians, physical therapists, occupational therapists, and nurses. As described earlier, the causes of fatigue can be divided into two basic categories:

TABLE 19-3 ■ GENERAL EXERCISE GUIDELINES FOR LEVELS OF DISABILITY

LEVEL OF DISABILITY	EDSS LEVEL	TRAINING PROGRAM
None: no fatigue or thermosensitivity	0	Full exertion, aerobic and resistance exercise, no extreme sports
Minimal: limited fatigue and heat sensitivity; minor balance or gait problems	1-2	Monitored exercise program including strengthening and endurance using a variety of exercise types, precooling if heat-sensitive, avoid overtraining
Moderate: limited gait; may have spasticity, weakness, ataxia, balance problems	3-5	Deficit-driven exercise protocols including strengthening and endurance training using methods tolerated, walking, cycle ergometry, precooling if needed
Severe: cannot participate in all daily activities; short-distance, aided walking only	6-7	Movement preservation, stretching, targeted strengthening needed for task-specific training
Bedridden	8-9	Primarily passive movements to maintain motion, breathing exercises

Modified from Heesen C, Romberg A, Gold S, Schulz KH: Physical exercise in multiple sclerosis: supportive care of a putative disease-modifying treatment. *Expert Rev Neurother* 6:347–355, 2006.

EDSS, Expanded Disease Severity Scale.

primary and secondary. Primary fatigue related to demyelination and neurodegeneration may have fewer options for treatment. Secondary fatigue caused by deconditioning, comorbidities, depression, poor nutrition, heat intolerance, sleep disturbance, and medications may be more easily managed. Several strategies for fatigue management have been reported and show promise; however, few research studies have demonstrated effectiveness in randomized controlled trials or in comparisons among approaches. Interventions for fatigue management include cooling devices, energy conservation education training, exercise, and a multifaceted class aimed at teaching people with MS how to manage their fatigue.

One study found that the cooling suit was shown to improve all dimensions of fatigue on the Fatigue Impairment Scale (physical, cognitive, and psychosocial) in a small multiple-case study.¹²³ Although recommended in the clinical practice guidelines on fatigue and MS by expert opinion and anecdotal reports of people with MS, little additional evidence exists to support cooling as a therapeutic intervention. Two additional studies have shown that cooling garments can reduce symptoms of fatigue and improve ambulatory ability.^{124,125}

Exercise shows promise as an intervention that can improve fatigue for people with MS that may improve muscle weakness caused by disuse and deconditioning. However, no one type of exercise, resistance or aerobic, or program has been proven most effective. One program included a 5-day-per-week, 30-minute bicycle aerobic training program for 4 weeks that improved fitness and showed a tendency for reduced fatigue. This study had an age, sex, and activity level control group.¹²⁶ Di Fabio⁵⁸ showed that a prolonged outpatient rehabilitation program in patients with progressive MS led to a decrease in MS-related symptoms, including fatigue. However, there was no control group. A randomized study comparing bicycle training with yoga found that fatigue improved in both groups, with neither group shown to be better than the other.¹²⁷

Energy conservation is defined by the fatigue and MS guidelines of the Multiple Sclerosis Council for Clinical

Practice Guidelines¹²⁸ as energy effectiveness and includes an analysis of individuals' home, work, and leisure activities and the environments in which they occur in order to develop activity modifications designed to reduce fatigue. This can include a variety of strategies such as reducing energy expenditure through activity and modification, workspace organization and improving efficiency of movements; balancing work and rest periods; delegating tasks; evaluating standards and prioritizing activities; and using assistive technologies that conserve energy usage.^{129,130} In a randomized controlled trial, a 6-week community-based energy conservation class using the strategies listed previously was compared with a wait-list control group. Immediate post-course improvements in fatigue were noted¹²⁹ and were present after a 1-year follow-up period.¹³¹

The multidimensional fatigue management class "Fatigue: Take Control" was developed based on the recommendations of the Fatigue Management Guidelines of the NMSS from 1998.¹³² The content of the 6-week class includes many of the aspects of fatigue management education and training that were described previously. The pilot study found that participants had less fatigue compared with a wait-list control group.¹³² These classes are often offered by local chapters of the NMSS.

Patients may need to be prescribed assistive devices for ADLs. People with MS who have spasticity have a greater cost of walking.¹³³ Using wheeled mobility for longer-distance outings (to the shopping mall, an extended event, on vacation) can conserve energy and extend the time a person can participate in activities of importance to him or her. However, therapists should be aware that using assistive devices such as walkers or crutches actually increases energy expenditure for elderly people,¹³⁴ and therefore the need for improved support must be balanced with the increased energy burden an assistive device might add.

Spasticity

Several rehabilitation strategies to manage spasticity are available, including ROM, stretching, light pressure or stroking,¹³⁵ cold therapy, electrical stimulation, and education. Although none of these interventions is supported by

strong research evidence, many are used routinely in clinical practice (ROM, stretching). Other approaches (cold therapy, light pressure or stroking) are recommended for use in conjunction with stretching or ROM programs. Regardless of the technique employed, educating individuals and caregivers about the importance of adhering to a spasticity management program is essential. The Multiple Sclerosis Council for Clinical Practice Guidelines¹⁸ recommends, based on expert opinion, stretching a muscle with spasticity for 60 seconds or longer or using a prolonged stretch, lasting hours, with braces or splints.

Cold can be applied in a number of ways: baths, towels, or cooling garments. There are multiple quasi-experimental research studies that suggest an improvement in spasticity for a brief period after cooling¹⁸; however, the number of subjects and study methods make these results equivocal. Nilsagård and co-workers¹³⁶ found subjective reports of improved spasticity after a single session of cooling, although no statistically significant differences in spasticity measures were found.

Balance and Postural Control

Balance is foundational to the ability to stay upright and perform dynamic movements. It is a frequent problem in people with MS and results in a person limiting his or her participation in home, work, and leisure activities. Abnormalities of balance along with cane use and poor performance on tests of balance and ambulation can increase the risk of falling.²⁶ Other fall risk factors that have been identified include fear of falling, male sex, poor concentration or forgetfulness, and urinary incontinence.²⁵ Rehabilitation programs must be based on a thorough understanding of the impairments and personal and environmental factors that may be contributing to the balance dysfunction. Cattaneo and co-workers¹³⁷ compared the effects of three balance interventions on falling and other measures of balance. Three rehabilitation groups were included: one in which motor and sensory strategies were targeted, the second focusing on motor strategies alone, and the third group not receiving balance-specific training. The greatest reduction in falls and improvement on the BBS were associated with group one, and the least with group three. Hayes¹³⁸ compared 12 weeks of standard physical therapy with high-intensity resistance exercise (60% to 80% maximal contraction) added to standard therapy and found that standard therapy produced better balance outcomes. In addition, strength and the ability to ascend and descend stairs were all better in the standard therapy group. Importantly, people with MS tolerated the high intensity resistance exercise without problems. One pilot study found that a 12-week, biweekly aerobic exercise program did not improve balance as measured by the Functional Reach Test but did result in an improvement in walking distance.¹³⁹ For additional intervention strategies on balance, refer to Chapter 22.

Mobility

People with MS rate gait as one of the most important bodily functions¹²²; gait is often adversely affected in people with MS. Gait disturbances have been observed in people with MS even before disability is measured on the EDSS scores.¹⁴⁰ Lesions in the brain and spinal cord

produce a wide variety of potential impairments that can adversely affect gait. In a review article by Kelleher and colleagues,¹⁴¹ imbalance, fatigue, spasticity, incoordination, muscle weakness, and sensory system impairments were all reported to negatively affect ambulation ability. Therefore addressing each of these impairments has the potential to improve gait. A recent literature review of therapeutic interventions for mobility problems suggests that a variety of different methods can be used to improve ambulation.¹⁴² Snook and Motl¹⁴³ performed a meta-analysis of exercise studies aimed at improving walking mobility in people with MS and found that greater effects were associated with supervised exercise training, programs of less than 3 months' duration, in mixed samples of people with RRMS and progressive MS.

Task-specific gait training has been evaluated in people with MS. A randomized controlled trial compared two different treatment groups—facilitation and task-specific training—that each received 15 to 19 1-hour treatment sessions over 5 to 7 weeks and found that both improved 10-m gait speed, stride length, and balance; however, there was no control group.¹⁴⁴ Treadmill training has been investigated in several small, pilot or case studies with promising results of improved QOL, energy expenditure, and gait parameters.¹⁴⁵⁻¹⁴⁷

Several exercise studies have an association with improved gait. A combined resistance and aerobic home program lasting 23 weeks improved gait speed for short and longer distances in exercise compared with a control group.¹⁴⁸ Rampello and co-workers¹⁴⁹ compared a neurorehabilitation program with an aerobic training program of similar duration (three times per week for 8 weeks). The authors found that aerobic training improved walking distances and speeds and measures of aerobic capacity over the neurorehabilitation group. Both groups had QOL improvements in emotional well-being and health distress; the neurorehabilitation group demonstrated improved mental health.

An additional technique that shows promise for improving mobility in people with MS is an evaluation and intervention approach that uses small amounts of weight placed on the torso in response to identified balance dysfunction. Balance-Based Torso-Weighting (BBTW) is an intervention that uses directional loss of balance in both static and dynamic assessment to determine where small amounts of weight (generally less than 1% to 1.5% of body weight) are placed in a treatment orthotic called BalanceWear. The BalanceWear orthotic can be worn during the performance of activities in therapy or daily for home, work, or leisure activities. A recent randomized controlled trial in people with MS who reported gait abnormalities showed that when wearing the weighted BalanceWear orthotic participants increased their gait speed compared with no weight controls, and improved TUG scores compared with a standard weighted control.¹⁵⁰

When people with MS do not respond to therapeutic interventions to restore function, mobility assistive devices such as canes, crutches, walkers, wheelchairs, and scooters are used to enhance mobility through compensation. Mobility-assisted technology (MAT) can improve function in people with moderate to severe impairments of ambulation and may reduce activity limitations and participation restrictions by reducing fatigue and enhancing energy conservation to allow greater involvement in work, family, social,

vocational, and leisure activities. Other MAT technologies include functional electrical stimulation (FES), neuroprostheses, and orthotics. FES is applied to specific muscles or muscle groups to activate weak muscles. Some of these stimulators can be built into a neuroprosthesis that can be set up for use during exercising or walking.¹⁵¹ Orthotics such as the ankle-foot orthosis (AFO) or hip flexion assist orthosis (HFAO)¹⁵² can compensate for muscle weakness in the lower extremity, improve foot and knee positioning, and reduce energy expenditure. Therapists often work cooperatively with orthotists to ensure proper fit. Use of wheeled mobility devices such as a manual wheelchair, power wheelchair, or scooter requires a formal evaluation by an occupational or physical therapist with justification that it is required for mobility at home at least on a part-time basis. Therapists must take a long-term view of the projected needs of the patient when prescribing wheeled mobility, as most insurance companies will replace this equipment only every 5 years.

Pain and Dysesthesias

The occurrence of pain in people with MS is often underestimated. Pain can be acute, as in optic neuritis or Lhermitte syndrome, or chronic, as in dysesthesias in the limbs or joints or mechanical pain related to abnormal positions or repeated movements that cause abnormal wear and tear on the musculoskeletal system. Occupational and physical therapists can address poor body mechanics and weakness and poor movement patterns with retraining, and soft collars may help reduce Lhermitte syndrome. However, little evidence supports these interventions.¹⁵³ Transcutaneous electrical nerve stimulation has been suggested anecdotally by Kassirer¹⁵⁴ as beneficial for reducing pain. Cognitive-behavioral therapy has been researched for managing chronic pain¹⁵⁵; however, little evidence exists for using it in people with MS.

Bladder Dysfunction

Urinary incontinence and retention are common and often embarrassing problems for people with MS. Patients may be advised to avoid bladder irritants including caffeine, alcohol, concentrated urine, and infection. Physical therapists may work with patients to assess the factors contributing to bladder dysfunction by retraining hyperactive or weak pelvic floor muscles using biofeedback techniques and exercise. Nurses may need to teach patients with urinary retention intermittent catheterization. Refer to Chapter 29 for additional information on pelvic floor dysfunction and its treatment.

Cognition

Strategies for managing cognitive impairments include compensation techniques such as memory notebooks, diaries, calendars, and computer-assisted programs for memory, attention, or other executive functions. Neuropsychologists, speech-language pathologists, and occupational therapists can all direct cognitive rehabilitation programs. Strategies for coping with cognitive impairments are often shared with the other members of the health care team for reinforcement with patients.

There is growing evidence to support psychological interventions for people with mild to severe MS-related cognitive deficits, aimed at alleviating depressive symptoms and helping

people cope with and adjust to their impairments.^{156,157} However, the evidence is not yet convincing for specific programs addressing attention and executive functioning. O'Brien¹⁵⁶ was able to recommend the use of a modified story technique to address learning and memory deficits in people with MS. In a systematic review Maitra¹⁵⁸ found that cognitive behavioral therapy programs performed by occupational therapists were positively correlated with improvement in Functional Independence Measure (FIM) scores. Refer to Chapter 27 for additional information regarding interventions with individuals with cognitive problems.

Dysphagia and Dysarthria

Dysphagia or difficulty with chewing and swallowing becomes more prevalent in people with MS as the disease progresses.¹⁵⁹ Therapists facilitate proper swallowing with exercises that will improve posture to prevent aspiration and strengthen muscles of mastication. Other interventions may include diet modifications and education for the patient and his or her family or caregivers. Dietitians may be consulted to facilitate proper food choices.

Dysarthria from the disruption of muscular control in the central and peripheral speech mechanisms leads to abnormalities of speed, range, timing, strength, sound, and accuracy of speech movements. Speech-language pathologists determine therapy programs that take into consideration the stage of the disease and speech quality. Typical programs may include exaggerating articulation, increasing voice volume, and increasing strength of oral musculature. Exercise programs designed to increase respiratory muscle strength have not been successful in improving voice quality or production.¹⁶⁰

SUMMARY

This chapter has focused on the pathophysiology, clinical presentation, medical management, and rehabilitation of people with MS. Understanding the type of MS, clinical disability, and stage of the disease will help therapists determine the best assessment and intervention strategies for management of the rehabilitation program. Using the ICF framework will facilitate the assessment of the impairments, activity limitations and participation restrictions affecting patients and clients. In addition, including the environmental and personal factors present will help tailor the program to the patient's needs. Using QOL measures developed for people with MS should help the therapist understand the entire range of problems that patients may have.

Many websites are available to assist therapists and their patients with MS to understand the disease and find resources to help them manage the disease. The National MS Society (www.nationalmssociety.org) and the Multiple Sclerosis Foundation (www.msfocus.org) are both excellent resources.

CASE STUDY 19-1

INITIAL INTERVIEW

Mrs. P. is a 54-year-old woman with a 28-year history of RRMS. She was first diagnosed after her third daughter was born and remembers having a lot of trouble walking. Mrs. P. is concerned about her trunk weakness, back pain, and difficulty with walking; she often stumbles, especially when she does not use her single-point cane. She reports having fallen twice in the past year when she lost her balance and was unable to catch herself. One fall was at home, and one in the backyard. Therefore she has been using the cane more, especially on days when she feels off balance. Mrs. P. is limited to 10 minutes of walking and standing secondary to trunk fatigue and difficulty balancing. She is overweight and reports some bladder incontinence and heat sensitivity. Mrs. P. is a homemaker with 4 children; the youngest is 11. Leisure activities include playing the piano, singing, doing the Wii balance exercise for 20 min/day, and doing 10 minutes of treadmill walking at 3.0 mph after using a cooling vest. After her treadmill walking, she feels fatigue for 3 to 4 hours. Recently she has noted having more difficulty with singing and at times feels out of breath. Mrs. P.'s goals are improved posture, better breath control, no back pain, the ability to walk without stumbling or using a cane, and the ability to keep up with her children and her busy life.

ASSESSMENT

Mrs. P.'s Disease Steps classification is 3 (she uses a cane intermittently and is able to walk for 100 feet without it), and her EDSS score is 6.0. Vital signs are within normal limits (WNL) at rest and for exercise. This patient is cognitively intact and reliable in her response to questions. Her active and passive ROM is WNL throughout her extremities, trunk, and neck. She has selective motor control with normal tone. Manual muscle tests of bilateral upper extremity (UE) were normal, with the lower extremity (LE) 4/5 except for right hip flexion 3+/5, hip extension-abduction and plantarflexion 3/5. Abdominals 2/5, back extensors 3/5 (able to lift trunk against gravity through full range with difficulty and unable to take resistance). Sensation to light touch (LT), pain, and proprioception are intact throughout except for bilateral (B) feet, noted to have diminished sensation to LT. In sitting her posture is extremely slumped (from 30 to 45 degrees when fatigued) with notable thoracic kyphosis. She requires standby assist from supine to prone secondary to trunk weakness and instability. She requires use of B UEs in weight bearing to move from sitting to standing. During observational gait analysis, she demonstrates an asymmetrical step length with the left longer than the right and a right heel strike that is notably loud or audible. Her TUG score is 8 seconds using B UEs to stand up. Tinetti balance (POMA) = 14/16 and gait = 6/12 for a total score of 20/24 (19 to 24 risk for falls). Single-limb stance on the right = 4 seconds and left = 6 seconds, tandem stance = 4 seconds. Perturbation tests reveal loss of stability with an anterior nudge (posterior loss of balance [LOB]), posterior nudge (anterior LOB), and lateral and upper and lower trunk (LOB to opposite side). Rotational resistance tests to the right upper and lower trunk result in a stepping response, and the patient is unable to maintain stability, resulting in a stepping response. Results of rotational resistance tests to left upper and lower trunk are normal.

PLAN OF CARE AND GOALS

Mrs. P. had weakness in B LEs, balance problems, and an unsteady gait with an increased risk of falling, interfering with her functional mobility and QOL. The physical therapy plan included balance and gait training, improved posture and time standing, and increased endurance and cardiovascular fitness. Goals included a decreased fall risk with an improved Tinetti score of 25/28, improved B LE and trunk strength (4/5 in all muscle groups), improved endurance to stand and walk to 30 to 45 minutes, decreased back pain to 0 to 1/10 on most days, and improved endurance and cardiovascular fitness to 45 minutes to 1 hour in 12 to 24 weeks.

INTERVENTION

BBTW placement of 1.5 pounds of weight to the torso to address the perturbation and rotational asymmetries (posterior right upper and lower trunk and anterior near navel) was effective in reducing her kyphotic posture and impaired reactive balance control. The rigid component of the BBTW resolved back pain immediately; she felt better breath control and trunk support, and her Tinetti balance 15/16 and gait 12/12 = 27/28 significantly improved. TUG score remained the same, but she no longer needed her UE to stand up. Her posture also improved to 50% less kyphosis. During gait while weighted, a softer (inaudible) right heel strike was noted, and her step length was even. Mrs. P. expressed that she felt much steadier and more balanced with the BBTW BalanceWear vest and was thrilled to have no back pain.

Mrs. P. was seen in a managed care setting and was able to make significant progress with her physical therapy program. She was seen in physical therapy (1×/week × 1 month, 2×/week × 2 months, 1×/month × 3 months) to improve her posture, strength, balance, and fitness. Breath-control exercises using her diaphragm were implemented to improve singing, monitoring progress with an inspiratory spirometer. Because this patient understood the principles of exercise, she was advised to perform the specific exercise until she experienced a decrease in the quality of movement or the muscles fatigued. A general stretching program was initiated, including specific stretches to improve her posture in sitting and standing. For strengthening exercise she started with one set of 8 to 15 reps; resistance was increased by 2% to -5% when 15 reps were efficient for major muscle groups including hip flexion-extension-abduction, heel raises for plantarflexion, rowing (shoulder retraction) with yellow Thera-Band in standing, curl-ups in hook-lying, and quadruped weight shifts, which were performed 2× to 3×/week. To address her deconditioning, an interval treadmill-training program was implemented on alternating days. Recommendation was to maintain the intensity of 3.0 mph at 65% to 75% of HRmax and do intervals of four blocks of 3 minutes with 1- to 2-minute rest breaks in between and to continue to use the cooling vest before exercise. She continued with the Wii balance program, increasing to 30 minutes on the days she was not doing the treadmill. On those days she also performed specific balance exercises in the corner, beginning with her eyes open (single-leg stance; tandem stance). Mrs. P. was advised to use the BBTW rigid vest for 2 hours during functional activities and walking and to perform her exercises with it every other day. If she became less steady, she was advised to wear the vest an additional 1 to 2 hours per day.
