a large scale. A study of 118 hospitals participating in NSQIP between 2005 to 2007 showed that 82% of hospitals decreased their complication rates, and there was a decrease in morbidity of 11% and mortality of 17% annually per hospital.[32] Currently, over 400 private-sector U.S. hospitals participate in the program.

NSQIP uses a risk-adjusted ratio of the observed to expected outcome (focusing primarily on 30-day morbidity and mortality) to compare the performance of participating hospitals with their peers. The data the program has compiled also can be used to conduct observational studies using prospectively collected information on more than 1.5 million patients and operations. The expansion of NSQIP to the private sector has helped shift the focus from merely preventing the provider errors and sentinel events highlighted by the IOM publication "To Err Is Human" to the larger goal of preventing all adverse postoperative outcomes.

Several insights about patient safety have arisen as a result of NSQIP. First, safety is indistinguishable from overall quality of surgical care and should not be addressed separately. Defining quality in terms of keeping a patient safe from adverse outcomes allows the NSQIP data to be used to assess and improve quality of care by making improvements in patient safety. In other words, prevention of errors is synonymous with the reduction of adverse outcomes and can be used as a reliable quality measure. Second, during an episode of surgical care, adverse outcomes, and hence, patient safety, are primarily determined by the quality of the systems of care. Errors in hospitals with higher than expected observed to expected outcomes ratios are more likely to be from system errors than from provider incompetence. This underscores the importance of adequate communication, coordination, and teamwork in achieving quality surgical care. Finally, reliable comparative outcomes data are imperative for the identification of system problems. Risk-adjusted rates of adverse outcomes must be compared with those at peer institutions to appreciate more subtle system errors that lead to adverse outcomes to prompt changes in the quality of an institution's processes and structures.

The Leapfrog Group

One of the largest efforts to standardize evidence-based medicine in the United States is led by The Leapfrog Group, an alliance of large public and private healthcare purchasers representing more than 37 million individuals across the United States. This healthcare consortium was founded in 2000 with the aim to exert their combined leverage toward improving nationwide standards of healthcare quality, optimizing patient outcomes, and ultimately lowering healthcare costs. The Leapfrog Group's strategy to achieve these goals is through providing patient referral, financial incentives, and public recognition for hospitals that practice or implement evidence-based healthcare standards.

The healthcare quality and safety practices (leaps) that Leapfrog initially identified to measure healthcare standards were hospital use of computerized physician order entry systems, 24-hour ICU physician staffing, and evidence-based hospital referral (EBHR) standards for five high-risk operations.[33] In 2010, after the National Quality Forum (NQF) released its updated Safe Practices for Better Healthcare, Leapfrog added a safe practices leap, which includes eight practices from the NQF report.[34]

Leapfrog collects data on these practices through administration of an ongoing, voluntary, web-based hospital quality and safety survey. This survey is conducted in 41 regions that cover over half of the U.S. population and 62% of all hospital beds in the country. In 2011, more than 1200 urban, suburban, and rural hospitals participated in the survey. Leapfrog asks for information on eight high-risk conditions or procedures, including coronary artery bypass graft, percutaneous coronary intervention, abdominal aortic aneurysm (AAA) repair, pancreatic resection, and esophagectomy. These procedures were chosen because evidence exists that adherence to certain process measures can dramatically improve the outcomes of these procedures. In addition, more than 100 studies also have demonstrated that better results are obtained at high-volume hospitals when undergoing cardiovascular surgery, major cancer resections, and other high-risk procedures. Hospitals fulfilling the EBHR Safety Standard are expected to meet the hospital and surgeon volume criteria shown in Table 12-6. Hospitals that do not meet these criteria but adhere to the Leapfrog-endorsed process measures for coronary artery bypass graft surgery, percutaneous coronary intervention, AAA repair, and care for high-risk neonates, receive partial credit toward fulfilling the EBHR Safety Standard. Leapfrog purchasers work to recognize and reward hospitals that provide care for their enrollees who meet EBHR standards.[32]

Table 12-6

Recommended annual volumes: hospitals and surgeons

1. Coronary artery bypass graft	≥450/100
2. Percutaneous coronary intervention	≥400/75
3. Abdominal aortic aneurysm repair	≥50/22
4. Aortic valve replacement	≥120/22
5. Pancreatic resection	≥11/2
6. Esophagectomy	≥13/2
7. Bariatric surgery	>100/20

In a recent study, Brooke and associates analyzed whether achieving Leapfrog's established evidence-based standards for AAA repair, including meeting targets for case volume and perioperative β-blocker usage, correlated with improved patient outcomes over time.[33] After controlling for differences in hospital and patient characteristics, hospitals that implemented a policy for perioperative β-blocker usage had an estimated 51% reduction in mortality following open AAA repair cases. Among 111 California hospitals in which endovascular AAA repair was performed, in-hospital mortality was reduced by an estimated 61% over time among hospitals meeting Leapfrog case volume standards, although this result was not statistically significant. These results suggest that hospital compliance with Leapfrog standards for elective AAA repair is an effective means to help improve in-hospital mortality outcomes over time and support further efforts aimed at standardizing patient referral to hospitals that comply with evidence-based medicine standards for other surgical procedures.

The newest effort of the Leapfrog group is to promote transparency of hospital outcomes using a safety scorecard. This information can be viewed at hospitalsafetyscore.org.

World Health Organization "Safe Surgery Saves Lives" Initiative

In October 2004, the WHO launched a global initiative to strengthen healthcare safety and monitoring systems by creating the World Alliance for Patient Safety. As part of the group's efforts to improve patient safety, the alliance implemented a

series of safety campaigns that brought together experts in specific problem areas through individual Global Patient Safety Challenges. The second Global Patient Safety Challenge focuses on improving the safety of surgical care. The main goal of the campaign, called *Safe Surgery Saves Lives*, is to reduce surgical deaths and complications through the universal adaptation of a comprehensive perioperative surgical safety checklist in ORs worldwide. In addition to the checklist, the WHO defined a set of uniform measures for national and international surveillance of surgical care to better assess the quantity and quality of surgical care being delivered worldwide.[21] At the population level, metrics include the number of surgeon, anesthesia, and nurse providers per capita, the number of ORs per capita, and overall surgical case volumes and mortality rates. At the hospital level, metrics include safety improvement structures and a surgical "Apgar score," a validated method of prognosticating patient outcomes based on intraoperative events (i.e., hypotension, tachycardia, blood loss).[35]

National Quality Forum

The National Quality Forum (NQF) is a coalition of healthcare organizations that has worked to develop and implement a national strategy for healthcare quality measurement and reporting. Their mission is to improve the quality of American healthcare by setting national priorities and goals for performance improvement, endorsing national consensus standards for measuring and publicly reporting on performance, and promoting the attainment of national goals through education and outreach programs.

One of the major contributions of the NQF is the development of a list of Serious Reportable Events, which are frequently referred to as "*never events*."[36] According to the NQF, "never events" are errors in medical care that are clearly identifiable, preventable, and serious in their consequences for patients and that indicate a real problem in the safety and credibility of a healthcare facility. Examples of "never events" include surgery performed on the wrong body part; a foreign body left in a patient after surgery; a mismatched blood transfusion; a major medication error; a severe "pressure ulcer" acquired in the hospital; and preventable postoperative deaths (Table 12-7). Criteria for inclusion as a "never event" are listed below. The event must be:

6▶

- Unambiguous (i.e., the event must be clearly identifiable and measurable, and thus feasible to include in a reporting system);
- Usually preventable, with the recognition that some events are not always avoidable, given the complexity of healthcare;
- Serious, resulting in death or loss of a body part, disability, or more than transient loss of a body function; and
- Any one of the following:
- Adverse, and/or
- Indicative of a problem in a healthcare facility's safety systems, and/or
- Important for public credibility or public accountability.

These events are not a reasonable medical risk of undergoing surgery that the patient must accept but medical errors that should never happen (Case 12-4). The occurrence of any of these events signals that an organization's patient safety culture or processes have defects that need to be evaluated and corrected (Table 12-8).

Table 12-7

Surgical "never events"

- Surgery performed on the wrong body part
- Surgery performed on the wrong patient
- Wrong surgical procedure performed on a patient
- Unintended retention of a foreign object in a patient after surgery or other procedure
- Intraoperative or immediately postoperative death in an ASA Class 1 patient

ASA = American Society of Anesthesiologists.

Case 12-4 Surgical "never event"

In 2002, Mike Hurewitz, a reporter for *The Times Union* of Albany, suddenly began vomiting blood 3 days after donating part of his liver to his brother while recovering on a hospital floor in which 34 patients were being cared for by one first-year resident. He aspirated and died immediately with no other physician available to assist the overworked first-year resident.

Recognized for its advances in the field of liver transplantation, at the time, Mount Sinai Hospital was performing more adult-to-adult live-donor operations than any other hospital in the country. But the program was shut down by this event. Mount Sinai was held accountable for inadequate care and was banned from performing any live-donor adult liver transplants for more than 1 year. Of the 92 complaints investigated by the state, 75 were filed against the liver transplant unit, with 62 involving patient deaths. The state concluded that most of the 33 serious violations exhibited by the hospital occurred within the liver transplant unit.

As a result of the investigation, Mount Sinai revamped many of the procedures within its transplant unit. Among the changes, first-year residents no longer staffed the transplant service, two healthcare practitioners physically present in the hospital oversaw the transplant unit at all times, and any page coming from the transplant unit had to be answered within 5 minutes of the initial call. In addition, nurses monitored patients' vital signs more closely after surgery, transplant surgeons were required to make postoperative visits to both organ donor and recipient, and each registered nurse was assigned to four patients, rather than six or seven. The death also led New York to become the first state to develop guidelines for treating live organ donors. Finally, Mike Hurewitz's widow became a patient safety advocate, urging stricter controls on live donor programs.

"NEVER EVENTS" IN SURGERY

Never events are errors in medical care that are clearly identifiable, preventable, and serious in their consequences for patients and that indicate a real problem in the safety and credibility of a healthcare facility.[36] Despite widespread agreement that surgical never events are preventable and despite several national and local programs being launched to decrease them, never events are still a significant problem. A study from Mehtsun

Table 12-8

Four patient events that advanced the modern field of patient safety

PATIENT	INSTITUTION	YEAR	EVENT	ROOT CAUSE	OUTCOME
Libby Zion	New York Hospital, New York, NY	1984	Missed allergy to Demerol	Physician fatigue	Bell Commission shortened resident work hours
Betsy Lehman	Dana-Farber Cancer Institute, Boston, MA	1994	Chemotherapy overdose	Lack of medication checks and triggers	Fired doctor, three pharmacists, 15 nurses; overhauled safety program
Josie King	Johns Hopkins Hospital, Baltimore, MD	2001	Severe dehydration	Poor communication	Increased safety research funding
Mike Hurewitz	Mt. Sinai Hospital, New York, NY	2002	Inadequate postoperative care	Inadequate supervision	Transplant program shut down until better patient safety safeguards implemented

and colleagues showed that from October 1990 to October 2010, nationwide there were 9744 paid malpractice claims for never events. Of these, mortality was reported in 6.6%, permanent injury in 33%, and temporary injury in 59%. The cost of the never events totaled $1.3 billion. Also, of physicians who were named in a surgical never event claim, 12.4% were named in a future never events claim.[37] Another study in 2010 by The Joint Commission found that wrong-site surgery occurs 40 times per week nationwide.[38] Future directions for decreasing these problems include public reporting of never events by hospitals to increase hospital accountability, more formal training in teamwork, and CUSP programs in hospitals that have higher rates of never events to help elucidate the root cause.

Retained Surgical Items

A retained surgical item refers to any surgical item found to be inside a patient after he or she has left the OR, thus requiring a second operation to remove the item.[39] Estimates of retained foreign bodies in surgical procedures range from one case per 8000 to 18,000 operations, corresponding to one case or more each year for a typical large hospital or approximately 1500 cases per year in the United States.[40] This estimate is based on an analysis of malpractice claims and is likely to underestimate the true incidence. The risk of having a retained surgical item increases during emergency surgery, when there are unplanned changes in procedure (due to new diagnoses encountered in the OR), and in patients with higher body mass index (Table 12-9).[40]

The most common retained surgical item is a surgical sponge, but other items, such as surgical instruments and needles, can also be inadvertently left inside a patient after an operation. Retained surgical sponges are commonly discovered as an incidental finding on a routine postoperative radiograph, but also have been discovered in patients presenting with a mass or abdominal pain. Patients with sponges that were originally left in an intracavitary position (such as inside the chest or abdomen) also can present with complications such as abscess, erosion through the skin, fistula formation, bowel obstruction, hematuria, or the development of a new, tumor-like lesion.

Table 12-9

Risk factors for retained surgical sponges

- Emergency surgery
- Unplanned changes in procedure
- Patient with higher body mass index
- Multiple surgeons involved in same operation
- Multiple procedures performed on same patient
- Involvement of multiple operating room nurses/staff members
- Case duration covers multiple nursing "shifts"

Retained surgical needles usually are discovered incidentally, and reports of retained needles are uncommon. Retained surgical needles have not been reported to cause injury in the same way that nonsurgical needles (e.g., sewing needles, hypodermic needles) have been reported to perforate bowel or lodge in vessels and migrate. However, there have been reports of chronic pelvic pain and ocular irritation caused by retained surgical needles. A study of plain abdominal radiographs in pigs has demonstrated that medium- to large-size needles can easily be detected. The decision to remove these retained needles depends on symptoms and patient preference. Needles smaller than 13 mm have been found to be undetectable on plain radiograph in several studies, have not been shown to cause injury to vessels or visceral organs, and can probably be left alone.

Although the actual incidence of retained surgical instruments is unknown, they are retained with far less frequency than surgical sponges. The initial presentation of a retained surgical instrument is most commonly pain in the surgical site or the sensation of a mass of fullness after a surgical procedure that leads to the discovery of a metallic object on a radiographic study. Commonly retained instruments include the malleable and "FISH" instrument that are used to protect the viscera when closing abdominal surgery.

A retained surgical foreign body should be included in the differential diagnosis of any postoperative patient who presents with pain, infection, a palpable mass, or a radiopaque structure on imaging. The diagnosis can usually be made using a computed tomographic (CT) scan, and this is often the only test needed. If a retained surgical item is identified in the setting of an acute clinical presentation, the treatment usually is removal of the item. However, if the attempt to remove the retained surgical item can potentially cause more harm than the item itself, as in the case of a needle or a small part of a surgical item, then removal is occasionally not recommended. Retained surgical sponges should always be removed.

The American College of Surgeons and the Association of Perioperative Registered Nurses, in addition to The Joint Commission, have issued guidelines to try to prevent the occurrence of retained surgical items. Current recommendations include the use of standard counting procedures, performing a thorough wound exploration before closing a surgical site, and using only x-ray–detectable items in the surgical wound. These organizations also strongly endorse the completion of a postoperative debriefing after every operation. An x-ray at the completion of an operation is encouraged if there is any concern for a foreign body based on confusion regarding the counts by even a single member of the OR team or in the presence of a risk factor.

Surgical Counts

The benefit of performing surgical counts to prevent the occurrence of retained surgical items is controversial. The increased risk of a retained surgical item during emergency surgery in the study by Gawande and colleagues appeared to be related to bypassing the surgical count in many of these cases.[40] However, in another study, the "falsely correct count," in which a count is performed and declared correct when it is actually incorrect, occurred in 21% to 100% of cases in which a retained surgical item was found.[39] This type of count was the most common circumstance encountered in all retained surgical item cases, which suggests that performing a surgical count in and of itself does not prevent this error from taking place. The counting protocol also imposes significant demands on the nursing staff and distracts them from focusing on other primarily patient-centered tasks, often during critical portions of the case.[16]

A retained surgical item can occur even in the presence of a known incorrect count. This event is usually a result of poor communication in which a surgeon will dismiss the incorrect count and/or fail to obtain a radiograph before the patient leaves the OR. Having stronger institutional policies in place in case of an incorrect count (such as requiring a mandatory radiograph while the patient is still in the OR) can avoid conflict among caregivers and mitigate the likelihood of a retained surgical item occurring as a result of a known incorrect count.

Although there is no single tool to prevent all errors, the development of multiple lines of defense to prevent retained surgical items and universally standardizing and adhering to OR safety protocols by all members of the surgical team will help reduce the incidence of this never event.[41] Surgeons should take the lead in the prevention of retained surgical items by avoiding the use of small or nonradiologically detectable sponges in large cavities, performing a thorough wound inspection before closing any surgical incision, and having a vested interest in the counting procedure performed by nursing staff. The value of routine radiography to prevent a retained surgical item in emergency cases or when major procedures involving multiple surgical teams are being performed is becoming more apparent.

The widely accepted legal doctrine when a foreign body is erroneously left in a patient is that the mere presence of the item in the plaintiff's body indicates that the patient did not receive proper surgical care. The characteristics of the surgeon and their style, bedside manner, honesty, and confidence demonstrated in the management of the case can go a long way in averting a lawsuit or mitigating damages.

Wrong-Site Surgery

Wrong-site surgery is any surgical procedure performed on the wrong patient, wrong body part, wrong side of the body, or wrong level of a correctly identified anatomic site. It is difficult to determine the true incidence of wrong-site surgery for several reasons. First, there is no standard definition for what constitutes wrong-site surgery among various healthcare organizations. Another factor is that wrong-site surgery is underreported by healthcare providers. Finally, the total number of potential opportunities for each type of wrong-site error is unknown. However, various studies show incidences ranging from one in 112,994 cases to one in 15,500 cases.[42] The Washington University School of Medicine suggests a rate of one in 17,000 operations, which adds up to approximately 4000 wrong-site surgeries in the United States each year. If these numbers are correct, wrong-site surgery is the third most frequent life-threatening medical error in the United States.[43]

Several states now require mandatory reporting of all wrong-site surgery events, including near misses. These data provide some insight into the number of actual errors compared to the number of potential opportunities to perform wrong-site surgery. Of the 427 reports of wrong-site surgery submitted from June 2004 through December 2006 to the Pennsylvania Patient Safety Reporting System, more than 40% of the errors actually reached the patient, and nearly 20% involved completion of a wrong-site procedure.[42]

The risk of performing wrong-site surgery increases when there are multiple surgeons involved in the same operation or multiple procedures are performed on the same patient, especially if the procedures are scheduled or performed on different areas of the body.[43] Time pressure, emergency surgery, abnormal patient anatomy, and morbid obesity are also thought to be risk factors.[43] Communication errors are the root cause in more than 70% of the wrong-site surgeries reported to The Joint Commission.[42] Other risk factors include receiving an incomplete preoperative assessment; having inadequate procedures in place to verify the correct surgical site; or having an organizational culture that lacks teamwork or reveres the surgeon as someone whose judgment should never be questioned.[42]

There is a one in four chance that surgeons who work on symmetric anatomic structures will be involved in a wrong-site error sometime during their careers.[43] The specialties most commonly involved in reporting wrong-site surgeries according to The Joint Commission are orthopedic/podiatric surgery (41%), general surgery (20%), neurosurgery (14%), urology (11%), and maxillofacial, cardiovascular, otolaryngology, and ophthalmology (14%).[42] Most errors involved symmetric anatomic structures: lower extremities (30%), head/neck (24%), and genital/urinary/pelvic/groin (21%).[38] Although orthopedic surgery is the most frequently involved, this may be due to the higher volume of cases performed as well as the increased opportunity for lateralization errors inherent in the specialty. In addition, because the American Academy of Orthopaedic Surgeons has historically tried as a professional organization to reduce wrong-site operations, orthopedic surgeons may be more likely to report these events when they do occur.[43]

The Joint Commission Universal Protocol to Ensure Correct Surgery

The movement to eliminate wrong-site surgery began among professional orthopedic societies in the mid-1990s, when both the Canadian Orthopaedic Association and the American Academy of Orthopaedic Surgeons issued position statements and embarked on educational campaigns to prevent the occurrence of wrong-site surgery within their specialty.[43] Other organizations that issued position statements advocating for the

elimination of wrong-site surgery include the North American Spine Society, the American Academy of Ophthalmology, the Association of Perioperative Registered Nurses, and the American College of Surgeons. After issuing a review of wrong-site surgery in their Sentinel Event Alert in 1998, The Joint Commission made the elimination of wrong-site surgery one of their first National Patient Safety Goals in 2003 and adopted a universal protocol for preventing wrong-site, wrong-procedure, and wrong-person surgery in 2004. The protocol has been endorsed by more than 50 professional associations and organizations.

A preoperative "time-out" or "pause for the cause" to confirm the patient, procedure, and site to be operated on before incision was recommended by The Joint Commission and is now mandatory for all ORs in the United States. Elements of the protocol include the following:

- Verifying the patient's identity
- Marking the surgical site
- Using a preoperative site verification process such as a checklist
- Confirming the availability of appropriate documents and studies before the start of a procedure
- Taking a brief time-out immediately before skin incision, in which all members of the surgical team actively communicate and provide oral verification of the patient's identity, surgical site, surgical procedure, administration of preoperative medications, and presence of appropriate medical records, imaging studies, and equipment
- Monitoring compliance with protocol recommendations

Focusing on individual process components of the universal protocol, such as surgical site marking or the time-out, is not enough to prevent wrong-site surgery. Over a 30-month period in Pennsylvania, 21 wrong-side errors occurred despite the proper use of time-out procedures, with 12 of these errors resulting in complete wrong-side procedures. During the same period, correct site markings failed to prevent another 16 wrong-site surgeries, of which six were not recognized until after the procedure had been completed.[43]

Site verification begins with the initial patient encounter by the surgeon, continues throughout the preoperative verification process and during multiple critical points in the OR, and requires the active participation of the entire operating team, especially the surgeon and anesthesia provider. Based on a recent review of malpractice claims, two thirds of wrong-site operations could have been prevented by a site-verification protocol.[44]

Despite the proliferation of wrong-site protocols in the last decade, their effectiveness is difficult to measure as the incidence of wrong-site surgery is too rare to measure as a rate. Interestingly, the number of sentinel events reported to The Joint Commission has not changed significantly since the widespread implementation of the Universal Protocol in 2004.[43] This could be due to an increase in reporting rather than an actual increase in the incidence of wrong-site surgery.

The legal treatment of wrong-site surgery is similar to that of surgical items erroneously left in a patient: the mere fact that it occurred indicates that the patient did not receive proper surgical care. A malpractice claim may lead to a settlement or award on verdict in the six- or seven-figure range in 2011 U.S. dollars.[37]

Ultimately, the occurrence of retained surgical items or wrong-site surgery is a reflection of the quality of professional communication between caregivers and the degree of teamwork among the members of the operating team. In addition to standardizing procedures like the surgical count, instituting mandatory postoperative radiographs in the presence of a known miscount, and reforming the processes of patient identification and site verification, organizations should also strive to create a culture of safety, create independent and redundant checks for key processes, and create a system in which caregivers can learn from their mistakes (Table 12-10).[45]

Table 12-10

Best practices for operating room safety

- Conduct The Joint Commission Universal Protocol ("time-out") to prevent wrong-site surgery.
- Perform an operating room briefing (checklist) to identify and mitigate hazards early.
- Promote a culture of speaking up about safety concerns.
- Use a screening x-ray to detect foreign bodies in high-risk cases.
- Begin patient sign-outs with the most likely immediate safety hazard.

TRANSPARENCY IN HEALTHCARE

Despite a large increase in data being collected about patient safety and harm, much of it is not available to the public or other hospitals. This lack of transparency allows some hospitals to continue to practice outdated medicine and, in some cases, puts patients at a higher risk of serious complications. In a study by Mark Chassin, the health commissioner of New York State, having hospitals publicly disclose their mortality rates for coronary artery bypass graft (CABG) procedures resulted in a 41% decline in mortality from CABGs statewide.[46] In this study, when CABG mortality data were initially made public, there was a wide range in cardiac surgery-related mortality from 1% to 18%, depending on the hospital; the standard of care is 2%. The reasons for higher mortality in the poorly performing hospitals ranged from poor communication between care teams to one rogue surgeon operating when the surgeon should not have been. The consequence of making this data transparent was that the hospitals held multidisciplinary, CUSP-like meetings, where as a team they decided on the measures to implement for improvement. Through this, over the next year, most hospitals decreased their mortality rate to below 2%. Even the hospital that had an 18% mortality rate decreased it to 7% within 3 years and 1.7% over the next several years.

Transparency in healthcare is becoming central to the healthcare quality discussion. A new SCIP core measure is publishing practitioner performance, and all Leapfrog survey results are published online where other hospitals and the public can see them. Additionally, different large medical societies, including the Society for Thoracic Surgery (STS), are encouraging and rewarding practitioners and hospitals that are transparent with their outcomes. Making hospital outcomes transparent makes hospitals accountable to the public for their outcomes and, in the case of New York, caused a radical improvement in the quality of care provided to patients. It also empowers patients by making them better informed about which hospital they choose for their care, which will further incentivize hospitals to improve.

RISK MANAGEMENT

Between one half and two thirds of hospital-wide adverse events are attributable to surgical care. Most surgical errors occur in the OR and are technical in nature. Surgical complications and adverse outcomes have previously been linked to lack of surgeon specialization, low hospital volume, communication breakdowns, fatigue, surgical residents and trainees, and numerous other factors.[47]

However, poor surgical outcomes are not necessarily correlated with a surgeon's level of experience in performing a certain procedure. In one study, three fourths of the technical errors that occurred in a review of malpractice claims data involved fully trained and experienced surgeons operating within their area of expertise, and 84% occurred in routine operations that do not require advanced training. Rather than surgeon expertise, these errors likely occurred due to situations complicated by patient comorbidity, complex anatomy, repeat surgery, or equipment problems (Table 12-11). Because these errors occurred during routine operations, previous suggestions to limit the performance of high-complexity operations using selective referral, regionalization, or limitation of privileging may not actually be effective in reducing the incidence of technical error among surgical patients.[47]

In any event, although there has been much emphasis on reducing the prevalence of surgical technical errors as a way of improving surgical care, a technical error in the OR may not be the most important indicator of whether a surgeon will be sued by a patient. Recent studies point to the importance of a surgeon's communication skills in averting malpractice litigation. In the American College of Surgeons' Closed Claims Study, although intraoperative organ injuries occurred in 40% of patients, a surgical technical misadventure was the most deficient component of care in only 12% of patients. In fact, communication and practice pattern violations were the most common deficiency in care for one third of patients in the Closed Claims Study who received the expected standard of surgical care.[48]

The Importance of Communication in Managing Risk

The manner and tone in which a physician communicates is potentially more important to avoiding a malpractice claim than the actual content of the dialogue. For example, a physician relating to a patient in a "negative" manner may trigger litigious feelings when there is a bad result, whereas a physician relating in a "positive" manner may not. Expressions of dominance, in which the voice tone is deep, loud, moderately fast, unaccented, and clearly articulated, may communicate a lack of empathy and understanding for the patient, whereas concern or anxiety in the surgeon's voice is often positively related to expressing concern and empathy. General and orthopedic surgeons whose tone of voice was judged to be more dominant were more likely to have been sued than those who sounded less dominant.[49]

When significant medical errors do occur, physicians have an ethical and professional responsibility to immediately disclose them to patients. Failure to disclose errors to patients undermines public confidence in medicine and can create legal liability related to fraud. Physicians' fear of litigation represents a major barrier to error disclosure. However, when handled appropriately, immediate disclosure of errors frequently leads to improved patient rapport, improved satisfaction, and fewer malpractice claims.[50] In fact, rapport is the most important factor in determining whether a lawsuit is filed against a physician.

7▶

In 1987, the Department of Veterans Affairs Hospital in Lexington, Kentucky, implemented the nation's first formal apology and medical error full disclosure program, which called for the hospital and its doctors to work with patients and their families to settle a case. As a result, the hospital improved from having one of the highest malpractice claims totals in the VA system to being ranked among the lowest quartile of a comparative group of similar hospitals for settlement and litigation costs over a 7-year period. Its average payout in 2005 was $16,000 per settlement, vs. the national VA average of $98,000 per settlement, and only two lawsuits went to trial during a 10-year period. As a result of the success of this program, the Department of Veteran Affairs expanded the program to all VA hospitals nationwide in October 2005. This model also was replicated at the University of Michigan Health System with similar results. Its full-disclosure program cut the number of pending lawsuits by one half and reduced litigation costs per case from $65,000 to $35,000, saving the hospital approximately $2 million in defense litigation bills each year. In addition, University of Michigan doctors, patients, and lawyers are happier with this system. The cultural shift toward honesty and openness also has led to the improvement of systems and processes to reduce medical errors, especially repeat medical errors.[51]

With regard to risk management, the importance of good communication by surgeons and other care providers cannot be overemphasized. Whether alerting other members of the care team about a patient's needs, openly discussing concerns the patient and/or family might have, or disclosing the cause of a medical error, open communication with all parties involved can reduce anger and mistrust of the medical system; the frequency, morbidity, and mortality of preventable adverse events; and the likelihood of litigation.

Table 12-11

Common causes of lawsuits in surgery

- Positional nerve injury
- Common bile duct injury
- Failure to diagnose or delayed diagnosis
- Failure to treat, delayed treatment, or wrong treatment
- Inadequate documentation
- Inappropriate surgical indication
- Failure to call a specialist
- Cases resulting in amputation/limb loss

COMPLICATIONS

Despite the increased focus on improving patient safety and minimizing medical errors, it is impossible to eliminate human error entirely. Individual errors can cause minor or major complications during or after a surgical procedure. Although these types of errors may not be publicized as much as wrong-site surgery or a retained surgical item, they can still lead to surgical complications that prolong the course of illness, lengthen hospital stay, and increase morbidity and mortality rates.

Complications in Minor Procedures

Central Venous Access Catheters. Complications of central venous access catheters are common. Improvements in ultrasound technology and mass education surrounding the use and

techniques in ultrasonography have led to increased employment and enthusiasm for its use in central venous catheter placement. Numerous institutions have recently begun to mandate use of ultrasound for placement of all central venous lines. Anecdotally, many subclavian catheters have been alternatively placed at the internal jugular position due to a perceived benefit of decreasing complications. Literature exists that there is some merit to this; however, one should proceed with caution as the decrease in pneumothoraces may not be balanced by the increase in line infections as the neck is difficult to keep the site clean and the dressing intact. Steps to decrease complications include the following:

- Ensure that central venous access is indicated.
- Experienced personnel should insert the catheter or should supervise the insertion.
- Use proper positioning and sterile technique.
- Ultrasound is recommended for internal jugular vein insertion.
- All central venous catheters should be assessed on a daily basis and should be exchanged only for specific indications (not as a matter of routine).
- All central catheters should be removed as soon as possible.

Common complications of central venous access include the following.

Pneumothorax Occurrence rates from both subclavian and internal jugular vein approaches are 1% to 6%. Prevention requires proper positioning of the patient and correct insertion technique. A postprocedure chest x-ray is mandatory to confirm the presence or absence of a pneumothorax, regardless of whether a pneumothorax is suspected. Pneumothorax rates are higher among the inexperienced but occur with experienced operators as well. If the patient is stable, and the pneumothorax is small (<15%), close expectant observation may be adequate. If the patient is symptomatic, a thoracostomy tube should be placed. Occasionally, pneumothorax will occur as late as 48 to 72 hours after central venous access attempts. This usually creates sufficient compromise that a tube thoracostomy is required.

Arrhythmias Arrhythmias result from myocardial irritability secondary to guidewire placement and usually resolve when the catheter or guidewire is withdrawn from the right heart. Prevention requires electrocardiogram (ECG) monitoring whenever possible during catheter insertion and rapid recognition when a new arrhythmia begins.

Arterial Puncture Inadvertent puncture or laceration of an adjacent artery with bleeding can occur, but the majority will resolve with direct pressure on or near the arterial injury site. Rarely will angiography, stent placement, or surgery be required to repair the puncture site, but close observation and a chest x-ray are indicated. Ultrasound guided insertion has not mitigated this complication, but may decrease the incidence of arterial puncture. Ultrasound has also been shown to decrease the number of attempts and the time it takes to complete insertion.

Lost Guidewire A guidewire or catheter that inadvertently migrates further into the vascular space away from the insertion site can be readily retrieved with interventional angiography techniques. A prompt chest x-ray and close monitoring of the patient until retrieval are indicated.

Air Embolus Although estimated to occur in only 0.2% to 1% of patients, an air embolism can be dramatic and fatal. If an embolus is suspected, the patient should immediately be placed into a left lateral decubitus Trendelenburg position, so the entrapped air can be stabilized within the right ventricle. Auscultation over the precordium may reveal a "crunching" noise, but a portable chest x-ray will help confirm the diagnosis. Aspiration via a central venous line accessing the heart may decrease the volume of gas in the right side of the heart and minimize the amount traversing into the pulmonary circulation. Subsequent recovery of intracardiac and intrapulmonary air may require open surgical or angiographic techniques. Treatment may prove futile if the air bolus is larger than 50 mL, however.

Pulmonary Artery Rupture Flow-directed, pulmonary artery ("Swan-Ganz") catheters can cause pulmonary artery rupture due to excessive advancement of the catheter into the pulmonary circulation. There usually is a sentinel bleed with coughing noted when a pulmonary artery catheter balloon is inflated, followed by uncontrolled hemoptysis. Reinflation of the catheter balloon is the initial step in management, followed by immediate airway intubation with mechanical ventilation, an urgent portable chest x-ray, and notification of the OR that an emergent thoracotomy may be required. If there is no further bleeding after the balloon is reinflated, the x-ray shows no significant consolidation of lung fields from ongoing bleeding, and the patient is easily ventilated, then a conservative nonoperative approach may be considered. However, more typically a pulmonary angiogram with angioembolization or vascular stenting is required. Hemodynamically unstable patients rarely survive because of the time needed to initiate and perform interventional procedures or a thoracotomy and to identify the ruptured branch of the pulmonary artery.

Central Venous Line Infection The CDC reports mortality rates of 12% to 25% when a central venous line infection becomes systemic, with a cost of approximately $25,000 per episode.[52-54] The CDC does not recommend routine central line changes, but when the clinical suspicion is high, the site of venous access must be changed. Nearly 15% of hospitalized patients will acquire central venous line sepsis. In many instances, once an infection is recognized as central line sepsis, removing the line is adequate. *Staphylococcus aureus* infections, however, present a unique problem because of the potential for metastatic seeding of bacterial emboli. The required treatment is 4 to 6 weeks of tailored antibiotic therapy. Using a checklist when inserting central venous catheters has been shown to significantly decrease rates of line infections.[55] Following a checklist strategy and close monitoring of catheters has resulted in significant reductions in infection rates for numerous institutions and many are now reporting zero annual infection rates.

Arterial Lines. Arterial lines are placed to facilitate arterial blood gas sampling and hemodynamic monitoring. The use of ultrasound to assist in placement of these catheters has become commonplace and markedly reduces the number of attempts and time for insertion completion.

Arterial access requires a sterile Seldinger technique, and a variety of arteries are used, including the radial, femoral, brachial, axillary, dorsalis pedis, or superficial temporal arteries. Although complications occur less than 1% of the time, they can be catastrophic. Complications include thrombosis, bleeding, hematoma, arterial spasm (nonthrombotic pulselessness), and infection. Thrombosis or embolization of an extremity arterial catheter can result in the loss of a digit, hand, or foot, and the risk is nearly the same for both femoral and radial cannulation.

Thrombosis with distal tissue ischemia is treated with anticoagulation, but occasionally surgical intervention is required. Pseudoaneurysms and arteriovenous fistulae can also occur.

Endoscopy and Bronchoscopy. The principal risk of gastrointestinal (GI) endoscopy is perforation. Perforations occur in 1:10,000 patients with endoscopy alone, but have a higher incidence rate when biopsies are performed (up to 10%). This increased risk is due to complications of intubating a GI diverticulum (either esophageal or colonic), or from the presence of weakened or inflamed tissue in the intestinal wall (e.g., diverticulitis, glucocorticoid use, or inflammatory bowel disease).

Patients will usually complain of diffuse abdominal pain shortly after the procedure, and then progress with worsening abdominal discomfort and peritonitis on examination. In obtunded or elderly patients, a change in clinical status may take 24 to 48 hours. Radiologic studies to look for free intraperitoneal air, retroperitoneal air, or a pneumothorax are diagnostic. Open or laparoscopic exploration locates the perforation and allows repair and local decontamination of the surrounding tissues.

The occasional patient who may be a candidate for nonoperative management is one in whom perforation arises during an elective, bowel-prepped endoscopy and who does not have significant pain or clinical signs of infection. These patients must be closely observed in a monitored setting, on strict dietary restriction and broad-spectrum antibiotics.

Complications of bronchoscopy include bronchial plugging, hypoxemia, pneumothorax, lobar collapse, and bleeding. When diagnosed in a timely fashion, they are rarely life threatening. Bleeding usually resolves spontaneously and rarely requires surgery, but may require repeat endoscopy for thermocoagulation or fibrin glue application. The presence of a pneumothorax necessitates placement of a thoracostomy tube when significant deoxygenation occurs or the pulmonary mechanics are compromised. Lobar collapse or mucous plugging usually responds to aggressive pulmonary toilet, but occasionally requires repeat bronchoscopy. If biopsies have been performed, the risk for these complications increases.

Tracheostomy. Tracheostomy facilitates weaning from a ventilator, may decrease length of ICU or hospital stay, and improves pulmonary toilet. Tracheostomies are performed open, percutaneously, with or without bronchoscopy, and with or without Doppler guidance. Arguments for percutaneous tracheostomy largely side with efficiency and cost containment over open tracheostomy. A recent literature review examining early (<3–7 days) vs. late (>14 days) tracheostomy demonstrates little difference in outcomes but does demonstrate greater patient comfort in those patients with tracheostomy than those with an endotracheal tube. Complications and outcomes between the two different methods remain largely equivalent.

Recent studies do not support obtaining a routine chest x-ray after percutaneous or open tracheostomy.[56,57] However, significant lobar collapse can occur from copious tracheal secretions or mechanical obstruction. The most dramatic complication of tracheostomy is tracheoinnominate artery fistula (TIAF) (Fig. 12-7).[58,59] This occurs rarely (~0.3%) but carries a 50% to 80% mortality rate. TIAFs can occur as early as 2 days or as late as 2 months after tracheostomy. A sentinel bleed occurs in 50% of TIAF cases, followed by a large-volume bleed. Should a TIAF be suspected, the patient should be transported immediately to the OR for fiberoptic evaluation. If needed, remove the tracheostomy and place a finger through the tracheostomy site to apply direct pressure anteriorly for compression of the innominate artery while preparation for a more definitive approach is organized.

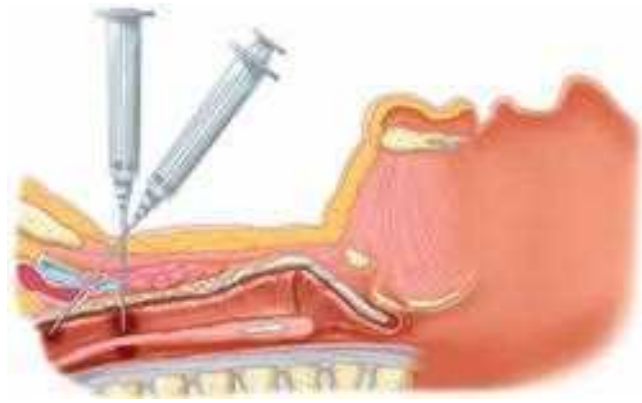

Figure 12-7. This illustration depicts improper positioning of the percutaneous needle. It is possible to access the innominate artery via the trachea, thus placing the patient at risk for early tracheoinnominate artery fistula.

Percutaneous Endogastrostomy. A misplaced percutaneous endogastrostomy (PEG) tube may lead to intra-abdominal sepsis with peritonitis and/or an abdominal wall abscess with necrotizing fasciitis. As in other minor procedures, the initial placement technique must be fastidious to avoid complications. Transillumination of the abdomen may decrease the risk for error, but this is unsubstantiated in the literature. Inadvertent colotomies, intraperitoneal placement of the tube and subsequent leakage of tube feeds with peritonitis, and abdominal wall abscesses require surgery to correct the complications and to replace the PEG with an alternate feeding tube, usually a jejunostomy.

A dislodged or prematurely removed PEG tube should be replaced as early as possible after dislodgment because the gastrostomy site closes rapidly. A contrast x-ray (sinogram) should be performed to confirm the tube's intragastric position before feeding. If there is uncertainty of the tube location, conversion to an open tube placement procedure is required.

Tube Thoracostomy. Chest tube insertion is performed for pneumothorax, hemothorax, pleural effusions, or empyema. In most patients, a chest tube can be easily placed with a combination of local analgesia and light conscious sedation. Common complications include inadequate analgesia or sedation, incomplete penetration of the pleura with formation of a subcutaneous track for the tube, lacerations to the lung or diaphragm, intraperitoneal placement of the tube through the diaphragm, and bleeding related to these various lacerations or injury to pleural adhesions. Additional problems include slippage of the tube out of position or mechanical problems related to the drainage system. In patients with bullous disease, there can be significant intrapleural scarring and it can be easy to mistakenly place the chest tube into a bullae. All of these complications can be avoided with proper initial insertion techniques, plus a daily review of the drainage system and follow-up radiographs. Tube removal can create a residual pneumothorax if the patient does not maintain positive intrapleural pressure by Valsalva's maneuver during tube removal and dressing application.

Complications of Angiography. Intramural dissection of a cannulated artery can lead to complications such as ischemic stroke from a carotid artery dissection or occlusion, mesenteric ischemia from dissection of the superior mesenteric artery,

or a more innocuous finding of "blue toe syndrome" from a dissected artery in a peripheral limb. Invasive or noninvasive imaging studies confirm the suspected problem. The severity of ischemia and extent of dissection determine if anticoagulation therapy or urgent surgical exploration is indicated.

Bleeding from a vascular access site usually is obvious, but may not be visible when the blood loss is tracking into the retroperitoneal tissue planes after femoral artery cannulation. These patients can present with hemorrhagic shock; an abdominopelvic CT scan delineates the extent of bleeding along the retroperitoneum. Initial management is direct compression at the access site and resuscitation as indicated. Urgent surgical exploration may be required to control the bleeding site and evacuate larger hematomas.

Renal complications of angiography occur in 1% to 2% of patients. Contrast nephropathy is a temporary and preventable complication of radiologic studies such as CT, angiography, and/or venography. Intravenous (IV) hydration before and after the procedure is the most efficient method for preventing contrast nephropathy. Nonionic contrast also may be of benefit in higher-risk patients. Close communication between providers is often required to resolve the priorities in care as well as to balance the risks versus benefits of renal protection when managing patients in need of angiographic procedures.

Complications of Biopsies. Lymph node biopsies have direct and indirect complications that include bleeding, infection, lymph leakage, and seromas. Measures to prevent direct complications include proper surgical hemostasis, proper skin preparation, and a single preoperative dose of antibiotic to cover skin flora 30 to 60 minutes before incision. Bleeding at a biopsy site usually can be controlled with direct pressure. Infection at a biopsy site will appear 5 to 10 days postoperatively and may require opening of the wound to drain the infection. Seromas or lymphatic leaks resolve with aspiration of seromas and the application of pressure dressings, but may require repeated treatments or even placement of a vacuum drain.

Organ System Complications

Neurologic System. Neurologic complications that occur after surgery include motor or sensory deficits and mental status changes. Peripheral motor and sensory deficits are often due to neurapraxia secondary to improper positioning and/or padding during operations. Treatment is largely clinical observation, and the majority of deficits resolve spontaneously within 1 to 3 months.

Direct injury to nerves during a surgical intervention is a well-known complication of several specific operations, including superficial parotidectomy (facial nerve), carotid endarterectomy (hypoglossal nerve), thyroidectomy (recurrent laryngeal nerve), prostatectomy (nervi erigentes), inguinal herniorrhaphy (ilioinguinal nerve), and mastectomy (long thoracic and thoracodorsal nerves). The nerve injury may be a stretch injury or an unintentionally severed nerve. In addition to loss of function, severed nerves can result in a painful neuroma that may require subsequent surgery.

Mental status changes in the postoperative patient can have numerous causes (Table 12-12). Mental status changes must be continually assessed. A noncontrast CT scan should be used early to detect new or evolving intracranial causes.

Atherosclerotic disease increases the risk for intraoperative and postoperative stroke (cerebrovascular accident). Postoperatively, hypotension and hypoxemia are the most likely causes of a cerebrovascular accident. Neurologic consultation should be obtained immediately to confirm the diagnosis. Management is largely supportive and includes adequate intravascular volume replacement plus optimal oxygen delivery. Advents in interventional radiology by radiologists and vascular and neurologic surgeons have proven successful alternatives in patients requiring diagnostic and therapeutic care in the immediate and acute postoperative period. Catheter-directed therapy with anticoagulants such as the kinases and tissue plasminogen activator (tPA) has potential benefit in postoperative thrombosis where reoperation carries significant risk. In addition, endoluminal stents with drug-eluting stents (DESs) or non-DESs have been used with some degree of success. DESs do require systemic antiplatelet therapy due to the alternative coagulation pathway. Duration of antiplatelet therapy of 1 year is routine.

Eyes, Ears, and Nose. Corneal abrasions are unusual, but are due to inadequate protection of the eyes during anesthesia. Overlooked contact lenses in patients occasionally may cause conjunctivitis.

Table 12-12

Common causes of mental status changes

ELECTROLYTE IMBALANCE	TOXINS	TRAUMA	METABOLIC	MEDICATIONS
Sodium	Ethanol	Closed head injury	Thyrotoxicosis	Aspirin
Magnesium	Methanol	Pain	Adrenal insufficiency	β-Blockers
Calcium	Venoms and poisons	Shock	Hypoxemia	Narcotics
Inflammation	Ethylene glycol	Psychiatric	Acidosis	Antiemetics
Sepsis	Carbon monoxide	Dementia	Severe anemia	MAOIs
AIDS		Depression	Hyperammonemia	TCAs
Cerebral abscess		ICU psychosis	Poor glycemic control	Amphetamines
Meningitis		Schizophrenia	Hypothermia	Antiarrhythmics
Fever/hyperpyrexia			Hyperthermia	Corticosteroids, anabolic steroids

AIDS = acquired immunodeficiency syndrome; ICU = intensive care unit; MAOI = monoamine oxidase inhibitor; TCA = tricyclic antidepressant.

Persistent epistaxis can occur after nasogastric tube placement or removal, and nasal packing is the best treatment option if prolonged persistent direct pressure on the external nares fails. Anterior and posterior nasal gauze packing with balloon tamponade, angioembolization, and fibrin glue placement may be required in refractory cases. The use of antibiotics for posterior packing is controversial.

External otitis and otitis media occasionally occur postoperatively. Patients complain of ear pain or decreased hearing, and treatment includes topical antibiotics and nasal decongestion for symptomatic improvement.

Ototoxicity due to aminoglycoside administration occurs in up to 10% of patients, and is often irreversible. Vancomycin-related ototoxicity occurs about 3% of the time when used alone, and as often as 6% when used with other ototoxic agents.[60,61]

Vascular Problems of the Neck. Complications of carotid endarterectomy include central or regional neurologic deficits or bleeding with an expanding neck hematoma. An acute change in mental status or the presence of localized neurologic deficit requires an immediate return to the OR. An expanding hematoma may warrant emergent airway intubation and subsequent transfer to the OR for control of hemorrhage. Intraoperative anticoagulation with heparin during carotid surgery makes bleeding a postoperative risk. Other complications include arteriovenous fistulae, pseudoaneurysms, and infection, all of which are treated surgically.

Intraoperative hypotension during manipulation of the carotid bifurcation can occur and is related to increased tone from baroreceptors that reflexly cause bradycardia. Should hypotension occur when manipulating the carotid bifurcation, an injection of 1% lidocaine solution around this structure should attenuate this reflexive response.

The most common delayed complication following carotid endarterectomy remains myocardial infarction. The possibility of a postoperative myocardial infarction should be considered as a cause of labile blood pressure and arrhythmias in high-risk patients.

Thyroid and Parathyroid Glands. Surgery of the thyroid and parathyroid glands can result in hypocalcemia in the immediate postoperative period. Manifestations include ECG changes (shortened P-R interval), muscle spasm (tetany, Chvostek's sign, and Trousseau's sign), paresthesias, and laryngospasm. Treatment includes calcium gluconate infusion and, if tetany ensues, chemical paralysis with intubation. Maintenance treatment is thyroid hormone replacement (after thyroidectomy) in addition to calcium carbonate and vitamin D.

Recurrent laryngeal nerve (RLN) injury occurs in less than 5% of patients. Of those with injury, approximately 10% are permanent. Dissection near the inferior thyroid artery is a common area for RLN injury. At the conclusion of the operation, if there is suspicion of an RLN injury, direct laryngoscopy is diagnostic. The cord on the affected side will be in the paramedian position. With bilateral RLN injury, the chance of a successful extubation is poor. If paralysis of the cords is not permanent, function may return 1 to 2 months after injury. Permanent RLN injury can be treated by various techniques to stent the cords in a position of function.

Superior laryngeal nerve injury is less debilitating, as the common symptom is loss of projection of the voice. The glottic aperture is asymmetrical on direct laryngoscopy, and management is limited to clinical observation.

Respiratory System. Surgical complications that put the respiratory system in jeopardy are not confined to technical errors. Malnutrition, inadequate pain control, inadequate mechanical ventilation, inadequate pulmonary toilet, and aspiration can cause serious pulmonary problems.

Pneumothorax can occur from central line insertion during anesthesia or from a diaphragmatic injury during an abdominal procedure. Hypotension, hypoxemia, and tracheal deviation away from the affected side may be present. A tension pneumothorax can cause complete cardiovascular collapse. Treatment is by needle thoracostomy, followed by tube thoracostomy. The chest tube is inserted at the fifth intercostal space in the anterior axillary line. The anterior chest wall is up to 1 cm thicker than the lateral chest wall, so needle decompression is more effective in the lateral position. Attempted prehospital needle decompression in the traditional anterior position results in only 50% needle entry into the thoracic cavity.

Hemothoraces should be evacuated completely. Delay in evacuation of a hemothorax leaves the patient at risk for empyema and entrapped lung. If evacuation is incomplete with tube thoracostomy, video-assisted thoracoscopy or open evacuation and pleurodesis may be required.

Pulmonary atelectasis results in a loss of functional residual capacity (FRC) of the lung and can predispose to pneumonia. Poor pain control in the postoperative period contributes to poor inspiratory effort and collapse of the lower lobes in particular. The prevention of atelectasis is facilitated by sitting the patient up as much as possible, early ambulation, and adequate pain control. An increase in FRC by 700 mL or more can be accomplished by sitting patients up to greater than 45°. For mechanically ventilated patients, simply placing the head of the bed at 30 to 45° elevation and delivering adequate tidal volumes (8–10 mL/kg) improves pulmonary outcomes.

Patients with inadequate pulmonary toilet are at increased risk for bronchial plugging and lobar collapse. Patients with copious and tenacious secretions develop these plugs most often, but foreign bodies in the bronchus can be the cause of lobar collapse as well. The diagnosis of bronchial plugging is based on chest x-ray and clinical suspicion with acute pulmonary decompensation with increased work of breathing and hypoxemia. Fiberoptic bronchoscopy can be useful to clear mucous plugs and secretions.

Aspiration complications include pneumonitis and pneumonia. The treatment of pneumonitis is similar to that for acute respiratory distress syndrome (see later in this section) and includes oxygenation with general supportive care. Antibiotics are not indicated. Hospitalized patients who develop aspiration pneumonitis have a mortality rate as high as 70% to 80%. Early, aggressive, and repeated bronchoscopy for suctioning of aspirated material from the tracheobronchial tree will help minimize the inflammatory reaction of pneumonitis and facilitate improved pulmonary toilet. Forced diuresis to overcome anasarca and over-resuscitation remains controversial and unsubstantiated. Complications of forced diuresis include electrolyte disturbances, replacement of those electrolytes, metabolic alkalosis, hypotension, and acute kidney injury.

Pneumonia is the second most common nosocomial infection and is the most common infection in ventilated patients. Ventilator-associated pneumonia (VAP) occurs in 15% to 40% of ventilated ICU patients, with a probability rate of 5% per day, up to 70% at 30 days. The 30-day mortality rate of nosocomial pneumonia can be as high as 40% and depends on the

microorganisms involved and the timeliness of initiating appropriate antimicrobials Protocol-driven approaches for prevention and treatment of VAP are recognized as beneficial in managing these difficult infectious complications.

Once the diagnosis of pneumonia is suspected (an abnormal chest x-ray, fever, productive cough with purulent sputum, and no other obvious fever sources), it is invariably necessary to initially begin treatment with broad-spectrum antibiotics until proper identification, colony count (≥100,000 colony-forming units [CFU]), and sensitivity of the microorganisms are determined.[62] The spectrum of antibiotic coverage should be narrowed as soon as the culture sensitivities are determined. Double-coverage antibiotic strategy for the two pathogens, *Pseudomonas* and *Acinetobacter* spp., may be appropriate if the local prevalence of these particularly virulent organisms is high. One of the most helpful tools in treating pneumonia and other infections is the tracking of a medical center's antibiogram every 6 to 12 months.[63]

Epidural analgesia decreases the risk of perioperative pneumonia. This method of pain control improves pulmonary toilet and the early return of bowel function; both have a significant impact on the potential for aspiration and for acquiring pneumonia. The routine use of epidural analgesia results in a lower incidence of pneumonia than patient-controlled analgesia.[64]

Acute lung injury (ALI) was a diagnosis applied to patients with similar findings to those with acute respiratory distress syndrome (ARDS). The Berlin definition of ARDS developed by the American-European Consensus Conference of 2012 effectively not only simplifies the definition of ARDS, but eliminates the term ALI from critical care vernacular. ARDS is now classified by partial pressure of oxygen in arterial blood (Pao_2)/fraction of inspired oxygen (Fio_2) ratios as mild (300–201 mmHg), moderate (200–101 mmHg), and severe (<100 mmHg). Elements of modification of the definition include the following: less than 7 days of onset; removal of pulmonary artery occlusion pressure; and clinical judgment for characterizing hydrostatic pulmonary edema is acceptable, unless risk factors for ARDS have been eliminated, in which case objective analysis is necessary.[65-68]

The definition of ARDS traditionally included five criteria (Table 12-13). The multicenter ARDS Research Network (ARDSnet) research trial demonstrated improved clinical outcomes for ARDS patients ventilated at tidal volumes of only 5 to 7 mL/kg.[69] This strategy is no longer prescribed solely for patients with ARDS, but is also recommended for patients with normal pulmonary physiology as well who are intubated for reasons other than acute respiratory failure. The beneficial effects of positive end-expiratory pressure (PEEP) for ARDS were confirmed in this study as well. The maintenance of PEEP during ventilatory support is determined based on blood gas analysis, pulmonary mechanics, and requirements for supplemental oxygen. As gas exchange improves with resolving ARDS, the initial step in decreasing ventilatory support should be to decrease the levels of supplemental oxygen first, and then to slowly bring the PEEP levels back down to minimal levels.[70] This is done to minimize the potential for recurrent alveolar collapse and a worsening gas exchange.

Not all patients can be weaned easily from mechanical ventilation. When the respiratory muscle energy demands are not balanced or there is an ongoing active disease state external to the lungs, patients may require prolonged ventilatory support.

Table 12-13

Inclusion criteria for the acute respiratory distress syndrome

Acute onset
Predisposing condition
Pao_2:Fio_2 <200 (regardless of positive end-expiratory pressure)
Bilateral infiltrates
Pulmonary artery occlusion pressure <18 mmHg
No clinical evidence of right heart failure

Fio_2 = fraction of inspired oxygen; Pao_2 = partial pressure of arterial oxygen

Protocol-driven ventilator weaning strategies are successful and have become part of the standard of care. The use of a weaning protocol for patients on mechanical ventilation greater than 48 hours reduces the incidence of VAP and the overall length of time on mechanical ventilation. Unfortunately, there is still no reliable way of predicting which patient will be successfully extubated after a weaning program, and the decision for extubation is based on a combination of clinical parameters and measured pulmonary mechanics.[71] The Tobin Index (frequency [breaths per minute]/tidal volume [L]), also known as the *rapid shallow breathing index*, is perhaps the best negative predictive instrument.[72] If the result equals less than 105, then there is nearly a 70% chance the patient will pass extubation. If the score is greater than 105, the patient has an approximately 80% chance of failing extubation. Other parameters such as the negative inspiratory force, minute ventilation, and respiratory rate are used, but individually have no better predictive value than the rapid shallow breathing index.[73]

Malnutrition and poor nutritional support may adversely affect the respiratory system. The respiratory quotient (RQ), or respiratory exchange ratio, is the ratio of the rate of carbon dioxide (CO_2) produced to the rate of oxygen uptake ($RQ = V\dot{C}O_2/V\dot{O}_2$). Lipids, carbohydrates, and protein have differing effects on CO_2 production. Patients consuming a diet of mostly carbohydrates have an RQ of 1 or greater. The RQ for a diet of mostly lipids is closer to 0.7, and that for a diet of mostly protein is closer to 0.8. Ideally, an RQ of 0.75 to 0.85 suggests adequate balance and composition of nutrient intake. An excess of carbohydrate may negatively affect ventilator weaning because of the abnormal RQ due to higher CO_2 production and altered pulmonary gas exchange.

Although not without risk, tracheostomy decreases the pulmonary dead space and provides for improved pulmonary toilet. When performed before the tenth day of ventilatory support, tracheostomy may decrease the incidence of VAP, the overall length of ventilator time, and the number of ICU patient days.

The occurrence of PE is probably underdiagnosed. Its etiology is thought to stem from DVT. This concept, however, has recently been questioned from Spaniolas et al.[74] The diagnosis of PE is made when a high degree of clinical suspicion for PE leads to imaging techniques such as ventilation:perfusion nuclear scans or CT pulmonary angiogram. Clinical findings include elevated central venous pressure, hypoxemia, shortness of breath, hypocarbia secondary to tachypnea, and right heart strain on ECG. Ventilation:perfusion nuclear scans are often

indeterminate in patients who have an abnormal chest x-ray and are less sensitive than a CT angiogram or pulmonary angiogram for diagnosing PE. The pulmonary angiogram remains the gold standard for diagnosing PE, but spiral CT angiogram has become an alternative method because of its relative ease of use and reasonable rates of diagnostic accuracy. For cases without clinical contraindications to therapeutic anticoagulation, patients should be empirically started on heparin infusion until the imaging studies are completed if the suspicion of a PE is high.

Sequential compression devices on the lower extremities and low-dose subcutaneous heparin or low molecular weight heparinoid administration are routinely used to prevent DVT and, by inference, the risk of PE. Neurosurgical and orthopedic patients have higher rates of PE, as do obese patients and those at prolonged bed rest.

When anticoagulation is contraindicated, or when a known clot exists in the inferior vena cava (IVC), decreasing risk for PE includes insertion of an IVC filter. The Greenfield filter has been most widely studied, and it has a failure rate of less than 4%. Newer devices include those with nitinol wire that expands with body temperature and retrievable filters. Retrievable filters, however, must be considered as permanent. In most studies, the actual retrievable rate only reached about 20%. Some studies recognize the benefit of automated reminders and diligence of outlying patient follow-up, where higher retrieval rates have been achieved.[75] Patients with spinal cord injury and multiple long-bone or pelvic fractures frequently receive IVC filters, and there appears to be a low, but not insignificant, long-term complication rate with their use. However, IVC filters do not prevent PEs that originate from DVTs of the upper extremities.

Cardiac System. Arrhythmias are often seen preoperatively in elderly patients but may occur postoperatively in any age group. Atrial fibrillation is the most common arrhythmia[76] and occurs between postoperative days 3 to 5 in high-risk patients. This is typically when patients begin to mobilize their interstitial fluid into the vascular fluid space. Contemporary evidence suggests that rate control is more important than rhythm control for atrial fibrillation.[77,78] The first-line treatment includes β-blockade and/or calcium channel blockade. β-Blockade must be used judiciously, because hypotension, as well as withdrawal from β-blockade with rebound hypertension, is possible. Calcium channel blockers are an option if β-blockers are not tolerated by the patient, but caution must be exercised in those with a history of congestive heart failure. Although digoxin is still a standby medication, it has limitations due to the need for optimal dosing levels. Cardioversion may be required if patients become hemodynamically unstable and the rhythm cannot be controlled.

Ventricular arrhythmias and other tachyarrhythmias may occur in surgical patients as well. Similar to atrial rhythm problems, these are best controlled with β-blockade, but the use of other antiarrhythmics or cardioversion may be required if patients become hemodynamically unstable.

Cardiac ischemia is a cause of postoperative mortality. Acute myocardial infarction (AMI) can present insidiously, or it can be more dramatic with the classic presentation of shortness of breath, severe angina, and sudden cardiogenic shock. The workup to rule out an AMI includes an ECG and cardiac enzyme measurements. The patient should be transferred to a monitored (telemetry) floor. *M*orphine, supplemental *o*xygen, *n*itroglycerine, and *a*spirin (MONA) are the initial therapeutic maneuvers for those being investigated for AMI.

Gastrointestinal System. Surgery of the esophagus is potentially complicated because of its anatomic location and blood supply. Nutritional support strategies should be considered for esophageal resection patients to maximize the potential for survival. The two primary types of esophageal resection performed are the transhiatal resection and the transthoracic (Ivor-Lewis) resection.[79] The transhiatal resection has the advantage that a formal thoracotomy incision is avoided. However, dissection of the esophagus is blind, and anastomotic leaks occur more than with other resections. However, when a leak does occur, simple opening of the cervical incision and draining the leak is all that is usually required.

The transthoracic Ivor-Lewis resection includes an esophageal anastomosis performed in the chest near the level of the azygos vein. These have lower leak rates, but leaks result in mediastinitis and can be difficult to control. The reported mortality is about 50% with an anastomotic leak, and the overall mortality is about 5%, which is similar to transhiatal resection.

Postoperative ileus is related to dysfunction of the neural reflex axis of the intestine. Excessive narcotic use may delay return of bowel function. Epidural anesthesia results in better pain control, and there is an earlier return of bowel function and a shorter length of hospital stay. The limited use of nasogastric tubes and the initiation of early postoperative feeding are associated with an earlier return of bowel function.[80] The use of chewing gum and other oral stimulants to minimize ileus remains controversial.

Pharmacologic agents commonly used to stimulate bowel function include metoclopramide and erythromycin. Metoclopramide's action is limited to the stomach and duodenum, and it may help primarily with gastroparesis. Erythromycin is a motilin agonist that works throughout the stomach and bowel. Several studies demonstrate significant benefit from the administration of erythromycin in those suffering from an ileus.[81] Alvimopan, a newer agent and a mu-opioid receptor antagonist, has shown some promise in many studies for earlier return of gut function and subsequent reduction in length of stay.[82,83] Neostigmine has been used in refractory pan-ileus patients (Ogilvie's syndrome) with some degree of success. It is recommended for patients receiving this type of therapy to be in a monitored unit.[84 0]

Small bowel obstruction occurs in less than 1% of early postoperative patients. When it does occur, adhesions are usually the cause. Internal and external hernias, technical errors, and infections or abscesses are also causative. Hyaluronidase is a mucolytic enzyme that degrades connective tissue, and the use of a methylcellulose form of hyaluronidase, Seprafilm, has been shown to result in a 50% decrease in adhesion formation in some patients.[85,86] This should translate into a lower occurrence of postoperative bowel obstruction, but this has yet to be proven.

Fistulae are the abnormal communication of one structure to an adjacent structure or compartment and are associated with extensive morbidity and mortality. Common causes for fistula formation are summarized in the mnemonic FRIENDS (*F*oreign body, *R*adiation, *I*schemia/Inflammation/Infection, *E*pithelialization of a tract, *N*eoplasia, *D*istal obstruction, and *S*teroid use). Postoperatively, they are most often caused by infection or obstruction leading to an anastomotic leak. The cause of the fistula must be recognized early, and treatment may include nonoperative management with observation and nutritional support, or a delayed operative management strategy that also includes nutritional support and wound care.

GI bleeding can occur perioperatively (Table 12-14). Technical errors such as a poorly tied suture, a nonhemostatic

Table 12-14

Common causes of upper and lower gastrointestinal (GI) hemorrhage

UPPER GI BLEED	LOWER GI BLEED
Erosive esophagitis	Angiodysplasia
Gastric varices	Radiation proctitis
Esophageal varices	Hemangioma
Dieulafoy's lesion	Diverticulosis
Aortoduodenal fistula	Neoplastic diseases
Mallory-Weiss tear	Trauma
Peptic ulcer disease	Vasculitis
Trauma	Hemorrhoids
Neoplastic disease	Aortoenteric fistula Intussusception Ischemic colitis Inflammatory bowel disease Postprocedure bleeding

staple line, or a missed injury can all lead to postoperative intestinal bleeding.[87,88] The source of bleeding is in the upper GI tract about 85% of the time and is usually detected and treated endoscopically. Surgical control of intestinal bleeding is required in up to 40% of patients.[89]

When patients in the ICU have a major bleed from stress gastritis, the mortality risk is as high as 50%. It is important to keep the gastric pH greater than 4 to decrease the overall risk for stress gastritis in patients mechanically ventilated for 48 hours or greater and patients who are coagulopathic.[90] Proton pump inhibitors, H_2-receptor antagonists, and intragastric antacid installation are all effective measures. However, patients who are not mechanically ventilated or who do not have a history of gastritis or peptic ulcer disease should not be placed on gastritis prophylaxis postoperatively because it carries a higher risk of causing pneumonia.

Hepatobiliary-Pancreatic System. Complications involving the hepatobiliary system are usually due to technical errors. Laparoscopic cholecystectomy has become the standard of care for cholecystectomy, but common bile duct injury remains a nemesis of this approach. Intraoperative cholangiography has not been shown to decrease the incidence of common bile duct injuries because the injury to the bile duct usually occurs before the cholangiogram.[91,92] Early recognition and immediate repair of an injury are important, because delayed bile duct leaks often require a more complex repair.

Ischemic injury due to devascularization of the common bile duct has a delayed presentation days to weeks after an operation. Endoscopic retrograde cholangiopancreatography (ERCP) demonstrates a stenotic, smooth common bile duct, and liver function studies are elevated. The recommended treatment is a Roux-en-Y hepaticojejunostomy.

A bile leak due to an unrecognized injury to the ducts may present after cholecystectomy as a biloma. These patients may present with abdominal pain and hyperbilirubinemia. The diagnosis of a biliary leak can be confirmed by CT scan, ERCP, or radionuclide scan. Once a leak is confirmed, a retrograde biliary stent and external drainage are the treatment of choice.

Hyperbilirubinemia in the surgical patient can be a complex problem. Cholestasis makes up the majority of causes for hyperbilirubinemia, but other mechanisms of hyperbilirubinemia include reabsorption of blood (e.g., hematoma from trauma), decreased bile excretion (e.g., sepsis), increased unconjugated bilirubin due to hemolysis, hyperthyroidism, and impaired excretion due to congenital abnormalities or acquired disease. Errors in surgery that cause hyperbilirubinemia largely involve missed or iatrogenic injuries.

The presence of cirrhosis predisposes to postoperative complications. Abdominal or hepatobiliary surgery is problematic in the cirrhotic patient. Ascites leak in the postoperative period can be an issue when any abdominal operation has been performed. Maintaining proper intravascular oncotic pressure in the immediate postoperative period can be difficult, and resuscitation should be maintained with crystalloid solutions. Prevention of renal failure and the management of the hepatorenal syndrome can be difficult, as the demands of fluid resuscitation and altered glomerular filtration become competitive. Spironolactone with other diuretic agents may be helpful in the postoperative care. These patients often have a labile course, and bleeding complications due to coagulopathy are common. The operative mortality in cirrhotic patients is 10% for Child class A, 30% for Child class B, and 82% for Child class C patients.[93]

Pyogenic liver abscess occurs in less than 0.5% of adult admissions, due to retained necrotic liver tissue, occult intestinal perforations, benign or malignant hepatobiliary obstruction, sepsis, and hepatic arterial occlusion. The treatment is long-term antibiotics with percutaneous drainage of large abscesses.

Pancreatitis can occur following injection of contrast during cholangiography and ERCP. These episodes range from a mild elevation in amylase and lipase with abdominal pain, to a fulminant course of pancreatitis with necrosis requiring surgical débridement. Traumatic injuries to the pancreas can occur during surgical procedures on the kidneys, GI tract, and spleen most commonly. Treatment involves serial CT scans and percutaneous drainage to manage infected fluid and abscess collections; sterile collections should not be drained because drain placement can introduce infection. A pancreatic fistula may respond to antisecretory therapy with a somatostatin analogue. Management of these fistulae initially includes ERCP with or without pancreatic stenting, percutaneous drainage of any fistula fluid collections, total parenteral nutrition (TPN) with bowel rest, and repeated CT scans. The majority of pancreatic fistulae will eventually heal spontaneously.

Renal System. Renal failure can be classified as prerenal failure, intrinsic renal failure, and postrenal failure. Postrenal failure, or obstructive renal failure, should always be considered when low urine output (oliguria) or anuria occurs. The most common cause is a misplaced or clogged urinary catheter. Other, less common causes to consider are unintentional ligation or transection of ureters during a difficult surgical dissection (e.g., colon resection for diverticular disease) or a large retroperitoneal hematoma (e.g., ruptured aortic aneurysm).

Oliguria is initially evaluated by flushing the urinary catheter using sterile technique. Urine electrolytes should also be measured (Table 12-15). A hemoglobin and hematocrit level should be checked immediately. Patients in compensated shock from acute blood loss may manifest anemia and end-organ malperfusion as oliguria.

Acute tubular necrosis (ATN) carries a mortality risk of 25% to 50% due to the many complications that can cause, or result from, this insult. When ATN is due to poor inflow

Table 12-15

Urinary electrolytes associated with acute renal failure and their possible etiologies

	FE_{Na}	OSMOLARITY	UR_{Na}	ETIOLOGY
Prerenal	<1	>500	<20	CHF, cirrhosis
Intrinsic failure	>1	<350	>40	Sepsis, shock

CHF = congestive heart failure; FE_{Na} = fractional excretion of sodium; UR_{Na} = urinary excretion of sodium.

(prerenal failure), the remedy begins with IV administration of crystalloid or colloid fluids as needed. If cardiac insufficiency is the problem, the optimization of vascular volume is achieved first, followed by inotropic agents, as needed. Intrinsic renal failure and subsequent ATN are often the result of direct renal toxins. Aminoglycosides, vancomycin, and furosemide, among other commonly used agents, contribute directly to nephrotoxicity. Contrast-induced nephropathy usually leads to a subtle or transient rise in creatinine. In patients who are volume depleted or have poor cardiac function, contrast nephropathy may permanently impair renal function.[94-97]

The treatment of renal failure due to myoglobinuria has shifted away from the use of sodium bicarbonate for alkalinizing the urine, to merely maintaining brisk urine output of 100 mL/h with crystalloid fluid infusion. Mannitol and furosemide are not recommended. Patients who do not respond to resuscitation are at risk for needing renal replacement therapy. Fortunately, most of these patients eventually recover from their renal dysfunction.

Musculoskeletal System. A compartment syndrome can develop in any compartment of the body. Compartment syndrome of the extremities generally occurs after a closed fracture. The injury alone may predispose the patient to compartment syndrome, but aggressive fluid resuscitation can exacerbate the problem. Pain with passive motion is the hallmark of compartment syndrome, and the anterior compartment of the leg is usually the first compartment to be involved. Confirmation of the diagnosis is obtained by direct pressure measurement of the individual compartments. If the pressures are greater than 20 to 25 mmHg in any of the compartments, then a four-compartment fasciotomy is considered. Compartment syndrome can be due to ischemia-reperfusion injury, after an ischemic time of 4 to 6 hours. Renal failure (due to myoglobinuria), tissue loss, and a permanent loss of function are possible results of untreated compartment syndrome.

Decubitus ulcers are preventable complications of prolonged bed rest due to traumatic paralysis, dementia, chemical paralysis, or coma. Unfortunately, they are still occurring despite extensive research and clinical initiatives that demonstrate successful prevention strategies. Ischemic changes in the microcirculation of the skin can be significant after 2 hours of sustained pressure. Routine skin care and turning of the patient help ensure a reduction in skin ulceration. This can be labor intensive, and special mattresses and beds are available to help. The treatment of a decubitus ulcer in the noncoagulopathic patient is surgical débridement. Once the wound bed has a viable granulation base without an excess of fibrinous debris, a vacuum-assisted closure dressing can be applied. Wet to moist dressings with frequent dressing changes is the alternative and is labor intensive. Expensive topical enzyme preparations are also available. If the wounds fail to respond to these measures, soft tissue coverage by flap is considered.

Contractures are the result of muscle disuse. Whether from trauma, amputation, or vascular insufficiency, contractures can be prevented by physical therapy and splinting. If not attended to early, contractures will prolong rehabilitation and may lead to further wounds and wound healing issues. Depending on the functional status of the patient, contracture releases may be required for long-term care.

Hematologic System. The transfusion guideline of maintaining the hematocrit level in all patients at greater than 30% is no longer valid. Only patients with symptomatic anemia, who have significant cardiac disease, or who are critically ill and require increased oxygen-carrying capacity to adequately perfuse end organs require higher levels of hemoglobin. Other than these select patients, the decision to transfuse should generally not occur until the hemoglobin level reaches 7 mg/dL or the hematocrit reaches 21%.

Transfusion reactions are common complications of blood transfusion. These can be attenuated with a leukocyte filter, but not completely prevented. The manifestations of a transfusion reaction include simple fever, pruritus, chills, muscle rigidity, and renal failure due to myoglobinuria secondary to hemolysis. Discontinuing the transfusion and returning the blood products to the blood bank is an important first step, but administration of antihistamine and possibly steroids may be required to control the reaction symptoms. Severe transfusion reactions are rare but can be fatal.

Infectious complications in blood transfusion range from cytomegalovirus transmission, which is benign in the nontransplant patient, to human immunodeficiency virus (HIV) infection, to passage of the hepatitis viruses (Table 12-16).

Patients on warfarin (Coumadin) who require surgery can have anticoagulation reversal by administration of fresh-frozen plasma. Each unit of fresh frozen plasma contains 200 to 250 mL of plasma and includes one unit of coagulation factor per milliliter of plasma.

Thrombocytopenia may require platelet transfusion for a platelet count less than 20,000/mL when invasive procedures are performed, or when platelet counts are low and ongoing bleeding from raw surface areas persists. One unit of platelets will increase the platelet count by 5000 to 7500 per mL in adults. It is important to delineate the cause of the low platelet count.

Table 12-16

Rate of viral transmission in blood product transfusions[a]

HIV	1:1.9 million
HBV[b]	1:137,000
HCV	1:1 million

[a]Post-nucleic acid amplification technology (1999). Earlier rates were erroneously reported higher due to lack of contemporary technology.
[b]HBV is reported with pre-nucleic acid amplification technology. Statistical information is unavailable with post-nucleic acid amplification technology at this writing.
Note that bacterial transmission is 50 to 250 times higher than viral transmission per transfusion.
HBV = hepatitis B virus; HCV = hepatitis C virus.

Usually there is a self-limiting or reversible condition such as sepsis. Rarely, it is due to heparin-induced thrombocytopenia I and II. Complications of heparin-induced thrombocytopenia II can be serious because of the diffuse thrombogenic nature of the disorder. Simple precautions to limit this hypercoagulable state include saline solution flushes instead of heparin solutions and limiting the use of heparin-coated catheters. The treatment is anticoagulation with synthetic agents such as argatroban.

For patients with uncontrollable bleeding due to disseminated intravascular coagulopathy (DIC), a potentially useful drug is factor VIIa, but its use should be judicious.[98-100] Originally used in hepatic trauma and obstetric emergencies, this agent was lifesaving in some circumstances. The CONTROL Trial,[101] however, has largely decreased overuse of this agent because investigators demonstrated no benefit over simple factor replacement in severely coagulopathic patients. Factor VIIa use may also be limited due to its potential thrombotic complications. For some situations, the combination of ongoing, nonsurgical bleeding and renal failure can occasionally be successfully treated with desmopressin.

In addition to classic hemophilia, other inherited coagulation factor deficiencies can be difficult to manage in surgery. When required, transfusion of appropriate replacement products is coordinated with the regional blood bank center before surgery. Other blood dyscrasias seen by surgeons include hypercoagulopathic patients. Those who carry congenital anomalies such as the most common factor V Leiden deficiency, as well as protein C and S deficiencies, are likely to form thromboses if inadequately anticoagulated, and these patients should be managed in conjunction with a hematologist.

Abdominal Compartment Syndrome. Multisystem trauma, thermal burns, retroperitoneal injuries, and surgery related to the retroperitoneum are the major initial causative factors that may lead to abdominal compartment syndrome (ACS). Ruptured AAA, major pancreatic injury and resection, or multiple intestinal injuries are also examples of clinical situations in which a large volume of IV fluid resuscitation puts these patients at risk for intra-abdominal hypertension. Manifestations of ACS typically include progressive abdominal distention followed by increased peak airway ventilator pressures, oliguria followed by anuria, and an insidious development of intracranial hypertension.[102] These findings are related to elevation of the diaphragm and inadequate venous return from the vena cava or renal veins secondary to the transmitted pressure on the venous system.

Measurement of abdominal pressures is easily accomplished by transducing bladder pressures from the urinary catheter after instilling 100 mL of sterile saline into the urinary bladder.[103] A pressure greater than 20 mmHg constitutes intra-abdominal hypertension, but the diagnosis of ACS requires intra-abdominal pressure greater than 25 to 30 mmHg, with at least one of the following: compromised respiratory mechanics and ventilation, oliguria or anuria, or increasing intracranial pressures.[104-106]

The treatment of ACS is to open any recent abdominal incision to release the abdominal fascia or to open the fascia directly if no abdominal incision is present. Immediate improvement in mechanical ventilation pressures, intracranial pressures, and urine output is usually noted. When expectant management for ACS is considered in the OR, the abdominal fascia should be left open and covered under sterile conditions (e.g., a vacuum-assisted open abdominal wound closure system) with plans made for a second-look operation and delayed fascial closure. Patients with intra-abdominal hypertension should be monitored closely with repeated examinations and measurements of bladder pressure, so that any further deterioration is detected and operative management can be initiated. Left untreated, ACS may lead to multiple system end-organ dysfunction or failure and has a high mortality.

Abdominal wall closure should be attempted every 48 to 72 hours until the fascia can be reapproximated. If the abdomen cannot be closed within 5 to 7 days following release of the abdominal fascia, a large incisional hernia is the net result. A variety of surgical options have evolved for prevention and closure of the resultant hernias, but no standard approach has yet evolved.

Wounds, Drains, and Infection

Wound (Surgical Site) Infection. No prospective, randomized, double-blind, controlled studies exist that demonstrate antibiotics used beyond 24 hours in the perioperative period prevent infections. Prophylactic use of antibiotics should simply not be continued beyond this time. Irrigation of the operative field and the surgical wound with saline solution has shown benefit in controlling wound inoculum.[107] Irrigation with an antibiotic-based solution has not demonstrated significant benefit in controlling postoperative infection.

Antibacterial-impregnated polyvinyl placed over the operative wound area for the duration of the surgical procedure has not been shown to decrease the rate of wound infection.[108-112] Although skin preparation with 70% isopropyl alcohol has the best bactericidal effect, it is flammable and could be hazardous when electrocautery is used. The contemporary formulas of chlorhexidine gluconate with isopropyl alcohol remain more advantageous.[113-115]

There is a difference between wound colonization and infection. Overtreating colonization is just as injurious as undertreating infection. The strict definition of wound (soft tissue) infection is more than 10^5 CFU per gram of tissue. This warrants expeditious and proper antibiotic/antifungal treatment.[63,116] Often, however, clinical signs raise enough suspicion that the patient is treated before a confirmatory culture is undertaken. The clinical signs of wound infection include *rubor*, *tumor*, *calor*, and *dolor* (redness, swelling, heat, and pain). Once the diagnosis of wound infection has been established, the most definitive treatment remains open drainage of the wound. The use of antibiotics for wound infection treatment should be limited.[117-120]

One type of wound dressing/drainage system that is gaining popularity is the vacuum-assisted closure dressing. The principle of the system is to decrease local wound edema and to promote healing through the application of a sterile dressing that is then covered and placed under controlled suction for a period of 2 to 4 days at a time. Although costly, the benefits are frequently dramatic and may offset the costs of nursing care, frequent dressing changes, and operative wound débridement.

Drain Management. The four indications for applying a surgical drain are:

- To collapse surgical dead space in areas of redundant tissue (e.g., neck and axilla)
- To provide focused drainage of an abscess or grossly infected surgical site
- To provide early warning notice of a surgical leak (either bowel contents, secretions, urine, air, or blood)—the so-called *sentinel drain*
- To control an established fistula leak

Open drains are often used for large contaminated wounds such as perirectal or perianal fistulas and subcutaneous abscess cavities. They prevent premature closure of an abscess cavity in a contaminated wound. More commonly, surgical sites are drained by closed suction drainage systems, but data do not support closed suction drainage to "protect an anastomosis" or to "control a leak" when placed at the time of surgery. Closed suction devices can exert a negative pressure of 70 to 170 mmHg at the level of the drain; therefore, the presence of this excess suction may call into question whether an anastomosis breaks down on its own or whether the drain creates a suction injury that promotes leakage (Fig. 12-8).[121]

On the other hand, CT- or ultrasound-guided placement of percutaneous drains is now the standard of care for abscesses, loculated infections, and other isolated fluid collections such as pancreatic leaks. The risk of surgery is far greater than the placement of an image-guided drain.

The use of antibiotics when drains are in place is often unnecessary as the drain provides direct source control. Twenty-four to 48 hours of antibiotic use after drain placement is prophylactic, and after this period, only specific treatment of positive cultures should be performed, to avoid increased drug resistance and superinfection.

Urinary Catheters. Several complications of urinary catheters can occur that lead to an increased length of hospital stay and morbidity. In general, use of urinary catheters should be minimized and every opportunity to expeditiously remove them should be encouraged. If needed, it is recommended that the catheter be inserted its full length up to the hub and that urine flow is established before the balloon is inflated, because misplacement of the catheter in the urethra with premature inflation of the balloon can lead to tears and disruption of the urethra.

Enlarged prostatic tissue can make catheter insertion difficult, and a catheter coudé may be required. If this attempt is also unsuccessful, then a urologic consultation for endoscopic placement of the catheter may be required to prevent harm to the urethra. For patients with urethral strictures, filiform-tipped catheters and followers may be used, but these can potentially cause bladder injury. If endoscopic attempts fail, the patient may require a percutaneously placed suprapubic catheter to obtain decompression of the bladder. Follow-up investigations of these patients are recommended so definitive care of the urethral abnormalities can be pursued.

The most frequent nosocomial infection is urinary tract infection (UTI). These infections are classified into complicated and uncomplicated forms. The uncomplicated type is a UTI that can be treated with outpatient antibiotic therapy. The complicated UTI usually involves a hospitalized patient with an indwelling catheter whose UTI is diagnosed as part of a fever workup. The interpretation of urine culture results of less than 100,000 CFU/mL is controversial. Before treating such a patient, one should change the catheter and then repeat the culture to see if the catheter was simply colonized with organisms. Cultures with more than 100,000 CFU/mL should be treated with the appropriate antibiotics and the catheter changed or removed as soon as possible. Undertreatment or misdiagnosis of a UTI can lead to urosepsis and septic shock.

Recommendations are mixed on the proper way to treat *Candida albicans* fungal bladder infections. Continuous bladder washings with fungicidal solution for 72 hours have been recommended, but this is not always effective. Replacement of the urinary catheter and a course of fluconazole are appropriate

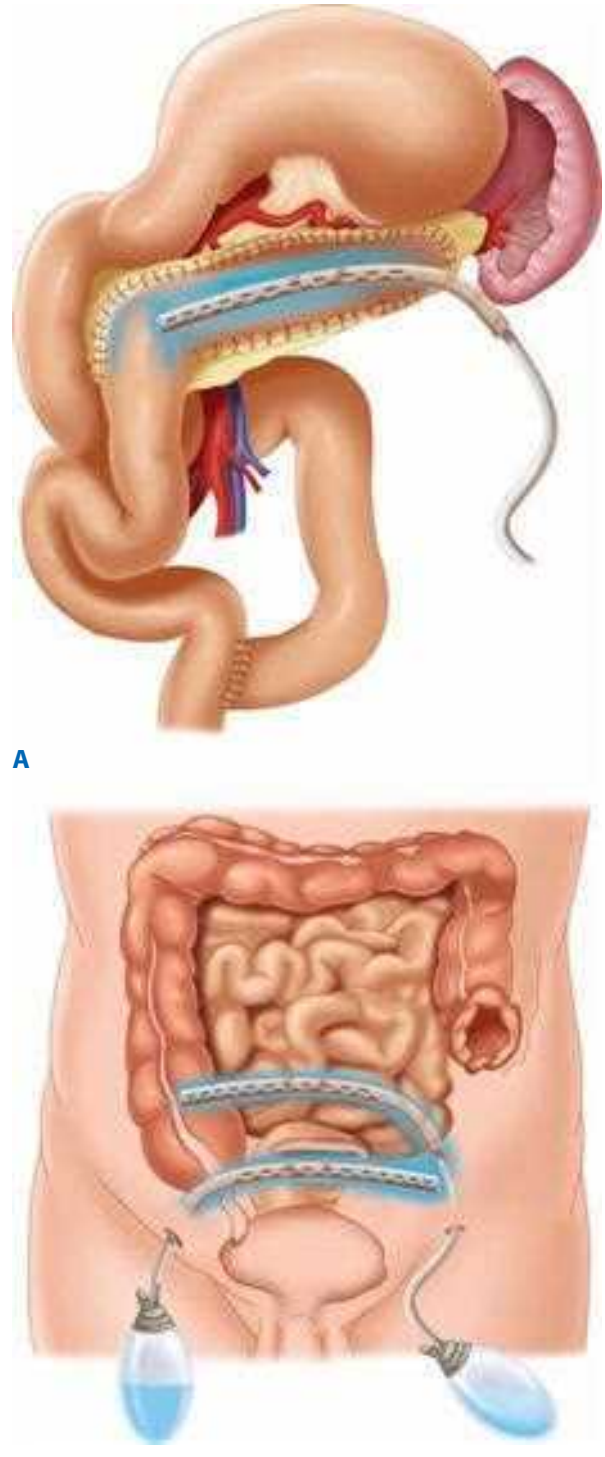

Figure 12-8. This illustration demonstrates typical intraoperative placement of closed suction devices in pancreatic or small bowel surgery, where there may be an anastomosis. At negative pressures of 70 to 170 mmHg, these devices may actually encourage anastomotic leaks and not prevent them or become clogged by them.

treatments, but some infectious disease specialists claim that *C. albicans* in the urine may serve as an indication of fungal infection elsewhere in the body. If this is the case, then screening cultures for other sources of fungal infection should be performed whenever a fungal UTI is found.

Empyema. One of the most debilitating infections is an empyema, or infection of the pleural space. Frequently, an

overwhelming pneumonia is the source of an empyema, but a retained hemothorax, systemic sepsis, esophageal perforation from any cause, and infections with a predilection for the lung (e.g., tuberculosis) are potential etiologies as well. The diagnosis is confirmed by chest x-ray or CT scan, followed by aspiration of pleural fluid for bacteriologic analysis. Gram's stain, lactate dehydrogenase, protein, pH, and cell count are obtained, and broad-spectrum antibiotics are initiated while the laboratory studies are performed. Once the specific organisms are confirmed, anti-infective agents are tailored appropriately. Placement of a thoracostomy tube is needed to evacuate and drain the infected pleural fluid, but depending on the specific nidus of infection, video-assisted thoracoscopy may also be helpful for irrigation and drainage of the infection. Refractory empyemas require specialized surgical approaches.

Abdominal Abscesses. Postsurgical intra-abdominal abscesses can present with vague complaints of intermittent abdominal pain, fever, leukocytosis, and a change in bowel habits. Depending on the type and timing of the original procedure, the clinical assessment of these complaints is sometimes difficult, and a CT scan is usually required. When a fluid collection within the peritoneal cavity is found on CT scan, antibiotics and percutaneous drainage of the collection is the treatment of choice. Initial antibiotic treatment is usually with broad-spectrum antibiotics such as piperacillin-tazobactam or imipenem. Should the patient exhibit signs of peritonitis and/or have free air on x-ray or CT scan, then re-exploration should be considered.

For patients who present primarily (i.e., not postoperatively) with the clinical and radiologic findings of an abscess but are clinically stable, the etiology of the abscess must be determined. A plan for drainage of the abscess and decisions about further diagnostic studies with consideration of the timing of any definitive surgery all need to be balanced. This can be a complex set of decisions, depending on the etiology (e.g., appendicitis or diverticulitis), but if the patient exhibits signs of peritonitis, urgent surgical exploration should be performed.

Necrotizing Fasciitis. Postoperative infections that progress to the fulminant soft tissue infection known as *necrotizing fasciitis* are uncommon. Group A streptococcal (M types 1, 3, 12, and 28) soft tissue infections, as well as infections with *Clostridium perfringens* and *C. septicum*, carry a mortality of 30% to 70%. Septic shock can be present, and patients can become hypotensive less than 6 hours following inoculation. Manifestations of a group A *Streptococcus pyogenes* infection in its most severe form include hypotension, renal insufficiency, coagulopathy, hepatic insufficiency, ARDS, tissue necrosis, and erythematous rash.

These findings constitute a surgical emergency, and the mainstay of treatment remains wide débridement of the necrotic tissue to the level of bleeding, viable tissue. A gray serous fluid at the level of the necrotic tissue is usually noted, and as the infection spreads, thrombosed blood vessels are noted along the tissue planes involved with the infection. Typically, the patient requires serial trips to the OR for wide débridement until the infection is under control. Antibiotics are an important adjunct to surgical débridement, and broad-spectrum coverage should be used because these infections may be polymicrobial (i.e., so-called *mixed-synergistic infections*). *S. pyogenes* is eradicated with penicillin, and it should still be used as the initial drug of choice.

Table 12-17

Mortality associated with patients exhibiting two or more criteria for systemic inflammatory response syndrome (SIRS)

PROGNOSIS	MORTALITY (%)
2 SIRS criteria	5
3 SIRS criteria	10
4 SIRS criteria	15–20

Systemic Inflammatory Response Syndrome, Sepsis, and Multiple-Organ Dysfunction Syndrome. The systemic inflammatory response syndrome (SIRS) and the multiple-organ dysfunction syndrome (MODS) carry significant mortality risks (Table 12-17). Specific criteria have been established for the diagnosis of SIRS (Table 12-18), but two criteria are not required for the diagnosis of SIRS: lowered blood pressure and blood cultures positive for infection. SIRS is the result of proinflammatory cytokines related to tissue malperfusion or injury. The dominant cytokines implicated in this process include interleukin (IL)-1, IL-6, and tissue necrosis factor (TNF). Other mediators include nitric oxide, inducible macrophage-type nitric oxide synthase, and prostaglandin I_2.

Sepsis is categorized as sepsis, severe sepsis, and septic shock. Sepsis is SIRS plus infection. Severe sepsis is sepsis plus signs of cellular hypoperfusion or end-organ dysfunction. Septic shock is sepsis plus hypotension after adequate fluid resuscitation.

MODS is the culmination of septic shock and multiple end-organ failure.[122] Usually there is an inciting event (e.g., perforated sigmoid diverticulitis), and as the patient undergoes resuscitation, he or she develops cardiac hypokinesis and oliguric or anuric renal failure, followed by the development of ARDS and eventually septic shock with death.

The international Surviving Sepsis Campaign (http://www.sccm.org/Documents/SSC-Guidelines.pdf) continues to demonstrate the importance of early recognition and initiation of specific treatment guidelines for optimal management of sepsis. Management of SIRS/MODS includes aggressive global resuscitation and support of end-organ perfusion, correction of the inciting etiology, control of infectious complications, and management of iatrogenic complications.[123-125] Drotrecogin-α, or recombinant activated protein C, appears to specifically counteract the cytokine cascade of SIRS/MODS, but its use is still limited.[126,127] Other adjuncts for supportive therapy include

Table 12-18

Inclusion criteria for the systemic inflammatory response syndrome

Temperature >38°C or <36°C (>100.4°F or <96.8°F)
Heart rate >90 beats/min
Respiratory rate >20 breaths/min or $Paco_2$ <32 mmHg
White blood cell count <4000 or >12,000 cells/mm^3 or >10% immature forms

$Paco_2$ = partial pressure of arterial carbon dioxide.

tight glucose control, low tidal volumes in ARDS, vasopressin in septic shock, and steroid replacement therapy.

Nutritional and Metabolic Support Complications

Nutrition-Related Complications. A basic principle is to use enteral feeding whenever possible, but complications can intervene such as aspiration, ileus, and to a lesser extent, sinusitis. There is no difference in aspiration rates when a small-caliber feeding tube is placed post-pyloric or if it remains in the stomach. Patients who are fed via nasogastric tubes are at risk for aspiration pneumonia, because these relatively large-bore tubes stent open the gastroesophageal junction, creating the possibility of gastric reflux. The use of enteric and gastric feeding tubes obviates complications of TPN, such as pneumothorax, line sepsis, upper extremity DVT, and the related expense. There is growing evidence to support the initiation of enteral feeding in the early postoperative period, before the return of bowel function, where it is usually well tolerated.

In patients who have had any type of nasal intubation who are having high, unexplained fevers, sinusitis must be entertained as a diagnosis. CT scan of the sinuses is warranted, followed by aspiration of sinus contents so the organism(s) are appropriately treated.

Patients who have not been enterally fed for prolonged periods secondary to multiple operations, those who have had enteral feeds interrupted for any other reason, or those with poor enteral access are at risk for the refeeding syndrome, which is characterized by severe hypophosphatemia and respiratory failure. Slow progression of the enteral feeding administration rate can avoid this complication.

Common TPN problems are mostly related to electrolyte abnormalities that may develop. These electrolyte errors include deficits or excesses in sodium, potassium, calcium, magnesium, and phosphate. Acid-base abnormalities can also occur with the improper administration of acetate or bicarbonate solutions.

The most common cause for hypernatremia in hospitalized patients is underresuscitation, and conversely, hyponatremia is most often caused by fluid overload. Treatment for hyponatremia is fluid restriction in mild or moderate cases and the administration of hypertonic saline for severe cases. An overly rapid correction of the sodium abnormality may result in central pontine myelinolysis, which results in a severe neurologic deficit. Treatment for hyponatremic patients includes fluid restriction to correct the free water deficit by 50% in the first 24 hours. An overcorrection of hyponatremia can result in severe cerebral edema, a neurologic deficit, or seizures.

Glycemic Control. In 2001, Van den Berghe and colleagues demonstrated that tight glycemic control by insulin infusion is associated with a 50% reduction in mortality in the critical care setting.[128] This prospective, randomized, controlled trial of 1500 patients had two study arms: the intensive-control arm, where the serum glucose was maintained between 80 and 110 mg/dL with insulin infusion; and the control arm, where patients received an insulin infusion only if blood glucose was greater than 215 mg/dL, but serum glucose was then maintained at 180 to 200 mg/dL.

The tight glycemic control group had an average serum glucose level of 103 mg/dL, and the average glucose level in the control group was 153 mg/dL. Hypoglycemic episodes (glucose <40 mg/dL) occurred in 39 patients in the tightly controlled group, while the control group had episodes in six patients. The overall mortality was reduced from 8% to 4.6%, but the mortality of those patients whose ICU stay lasted longer than 5 days was reduced from 20% to 10%. Secondary findings included an improvement in overall morbidity, a decreased percentage of ventilator days, less renal impairment, and a lower incidence of bloodstream infections. These finding have been corroborated by subsequent similar studies, and the principal benefit appears to be a greatly reduced incidence of nosocomial infections and sepsis. It is not known whether the benefits are due to strict euglycemia, to the anabolic properties of insulin, or both, but the maintenance of strict euglycemia between 140 and 180 mg/dL appears to be a powerful therapeutic strategy.[128-130] A number of studies followed this sentinel publication of tight glycemic control. NICE-SUGAR[131] and COIITSS[132] revisited the Van den Berghe study and found that the glycemic goals found initially to improve outcomes in critically ill patients were now found to be associated with a higher mortality when glucose was kept below 180 mg/dL, due to an increase in incidents of hypoglycemia. When targeted goals of 180 mg/dL are achieved, less occurrences of hypoglycemia have been documented and improved survivorship has been achieved. In addition, some studies find no relationship between glycemic control and improved outcomes. Thus, glycemic control in the critically ill still remains unclear and elusive at best.[133,134] Part of the difficulty in achieving "tight glycemic control" is the necessity for frequent (every 1–2 hours) blood glucose determinations. When this is performed, glycemic control is enhanced and hypoglycemia is avoided.

Metabolism-Related Complications. "Stress dose steroids" have been advocated for the perioperative treatment of patients on corticosteroid therapy, but recent studies strongly discourage the use of supraphysiologic doses of steroids when patients are on low or maintenance doses (e.g., 5–15 mg) of prednisone daily. Parenteral glucocorticoid treatment need only replicate physiologic replacement steroids in the perioperative period. When patients are on steroid replacement doses equal to or greater than 20 mg per day of prednisone, it may be appropriate to administer additional glucocorticoid doses for no more than 2 perioperative days.[135-137]

Adrenal insufficiency may be present in patients with a baseline serum cortisol less than 20 µg/dL. A rapid provocative test with synthetic adrenocorticotropic hormone may confirm the diagnosis. After a baseline serum cortisol level is drawn, 250 µg of cosyntropin is administered. At exactly 30 and 60 minutes following the dose of cosyntropin, serum cortisol levels are obtained. There should be an incremental increase in the cortisol level of between 7 and 10 µg/dL for each half hour. If the patient is below these levels, a diagnosis of adrenal insufficiency is made, and glucocorticoid and mineralocorticoid administration is then warranted. Mixed results are common, but the complication of performing major surgery on an adrenally insufficient patient is sudden or profound hypotension that is not responsive to fluid resuscitation.[123]

Thyroid hormone abnormalities usually consist of previously undiagnosed thyroid abnormalities. Hypothyroidism and the so-called *sick-euthyroid syndrome* are more commonly recognized in the critical care setting. When surgical patients are not progressing satisfactorily in the perioperative period, screening for thyroid abnormalities should be performed. If the results show mild to moderate hypothyroidism, then thyroid replacement should begin immediately and thyroid function studies should be monitored closely. All patients should

be reassessed after the acute illness has subsided regarding the need for chronic thyroid replacement therapy.

Problems with Thermoregulation

Hypothermia. Hypothermia is defined as a core temperature less than 35°C (95°F) and is divided into subsets of mild (35–32°C [95–89.6°F]), moderate (32–28°C [89.6–82.4°F]), and severe (<28°C [<82.4°F]) hypothermia. Shivering, the body's attempt to reverse the effects of hypothermia, occurs between 37 and 31°C (98.6 and 87.8°F), but ceases at temperatures below 31°C (87.8°F). Patients who are moderately hypothermic are at higher risk for complications than are those who are more profoundly hypothermic.

Hypothermia creates a coagulopathy that is related to platelet and clotting cascade enzyme dysfunction. This triad of metabolic acidosis, coagulopathy, and hypothermia is commonly found in long operative cases and in patients with blood dyscrasias. The enzymes that contribute to the clotting cascade and platelet activity are most efficient at normal body temperatures; therefore all measures must be used to reduce heat loss intraoperatively.[138]

The most common cardiac abnormality is the development of arrhythmias when body temperature drops below 35°C (95°F). Bradycardia occurs with temperatures below 30°C (86°F). It is well known that hypothermia may induce CO_2 retention, resulting in respiratory acidosis. Renal dysfunction of hypothermia manifests itself as a paradoxic polyuria and is related to an increased glomerular filtration rate, as peripheral vascular constriction creates central shunting of blood. This is potentially perplexing in patients who are undergoing resuscitation for hemodynamic instability, because the brisk urine output provides a false sense of an adequate intravascular fluid volume.

Induced peripheral hypothermia for hyperpyrexia due to infection (not to include neurologic or cardiac disease) is likely deleterious and does not appear to be beneficial. Placing cooling blankets on or under the patient or ice packs in the axillae or groin may be effective in cooling the skin, and when this occurs, a subsequent feedback loop triggers the hypothalamus to raise the internally regulated set point, thus raising core temperature even higher. This paradoxical reaction may be why outcomes for those who feel the need to treat a fever in the ICU by cooling the skin and arguably the core have worse outcomes. Cooling core temperatures can be achieved reliably with catheter-directed therapy with commercially available devices. Whether this is a worthwhile practice or not may be controversial. Poor data exist in support of treating fevers lower than 42°C in any fashion.[133,134,139-142]

Adult trauma patients who underwent induced hypothermia had poor outcomes in a recent investigation, and thus, this remains a procedure to be avoided. In a similar vein, pediatric patients who were induced did not show any improvement, and therefore, induced hypothermia is not recommended. Complications with induced hypothermia include, but are not limited to, hypokalemia, diuresis, DVT (due to catheter-related vein injury), arrhythmias, shivering, undiagnosed catheter-related bloodstream infection, and bacteremia.[143-146]

Neurologic dysfunction is inconsistent in hypothermia, but a deterioration in reasoning and decision-making skills progresses as body temperature falls, and profound coma (and a flat electroencephalogram) occurs as the temperature drops below 30°C (86°F). The diagnosis of hypothermia is important, so accurate measurement techniques are required to get a true core temperature.

Methods used to warm patients include warm air circulation over the patient and heated IV fluids, and more aggressive measures such as bilateral chest tubes with warm solution lavage, intraperitoneal rewarming lavage, and extracorporeal membrane oxygenation. A rate of temperature rise of 2 to 4°C/h (3.6–7.2°F/h) is considered adequate, but the most common complication for nonbypass rewarming is arrhythmia with ventricular arrest.

Table 12-19

Common causes of elevated temperature in surgical patients

HYPERTHERMIA	HYPERPYREXIA
Environmental	Sepsis
Malignant hyperthermia	Infection
Neuroleptic malignant syndrome	Drug reaction
Thyrotoxicosis	Transfusion reaction
Pheochromocytoma	Collagen disorders
Carcinoid syndrome	Factitious syndrome
Iatrogenic	Neoplastic disorders
Central/hypothalamic responses	
Pulmonary embolism	
Adrenal insufficiency	

Hyperthermia. Hyperthermia is a core temperature greater than 38.6°C (101.5°F) and has a host of etiologies (Table 12-19).[147] Hyperthermia can be environmentally induced (e.g., summer heat with inability to dissipate heat or control exposure), iatrogenically induced (e.g., heat lamps and medications), endocrine in origin (e.g., thyrotoxicosis), or neurologically induced (i.e., hypothalamic).

Malignant hyperthermia occurs after exposure to agents such as succinylcholine and some halothane-based inhalational anesthetics. The presentation is dramatic, with rapid onset of increased temperature, rigors, and myoglobinuria related to myonecrosis. Medications must be discontinued immediately and dantrolene administered (2.5 mg/kg every 5 minutes) until symptoms subside. Aggressive cooling methods are also implemented, such as an alcohol bath, or packing in ice. In cases of severe malignant hyperthermia, the mortality rate is nearly 30%.

Thyrotoxicosis can occur after surgery due to undiagnosed Graves' disease. Hyperthermia (>40°C [104°F]), anxiety, copious diaphoresis, congestive heart failure (present in about one fourth of episodes), tachycardia (most commonly atrial fibrillation), and hypokalemia (up to 50% of patients) are hallmarks of the disease. The treatment of thyrotoxicosis includes glucocorticoids, propylthiouracil, β-blockade, and iodide (Lugol's solution) delivered in an emergent fashion. As the name suggests, these patients are usually toxic and require supportive measures as well. Acetaminophen, the cooling modalities noted in the previous paragraph, and vasoactive agents often are indicated.

chapter 13

Physiologic Monitoring of the Surgical Patient

Louis H. Alarcon and Mitchell P. Fink

INTRODUCTION

The Latin verb *monere*, which means "to warn, or advise" is the origin for the English word *monitor*. In modern medical practice, patients undergo monitoring to detect pathologic variations in physiologic parameters, providing advanced warning of impending deterioration in the status of one or more organ systems. The intended goal of this endeavor is to allow the clinician to take appropriate actions in a timely fashion to prevent or ameliorate the physiologic derangement. Furthermore, physiologic monitoring is used not only to warn, but also to titrate therapeutic interventions, such as fluid resuscitation or the infusion of vasoactive or inotropic drugs. The intensive care unit (ICU) and operating room are the two locations where the most advanced monitoring capabilities routinely are employed in the care of critically ill patients.

In the broadest sense, physiologic monitoring encompasses a spectrum of endeavors, ranging in complexity from the routine and intermittent measurement of the classic vital signs (i.e., temperature, heart rate, arterial blood pressure, and respiratory rate) to the continuous recording of the oxidation state of cytochrome oxidase, the terminal element in the mitochondrial electron transport chain. The ability to assess clinically relevant parameters of tissue and organ status and employ this knowledge to improve patient outcomes represents the "holy grail" of critical care medicine. Unfortunately, consensus often is lacking regarding the most appropriate parameters to monitor in order to achieve this goal. Furthermore, making an inappropriate therapeutic decision due to inaccurate physiologic data or misinterpretation of good data can lead to a worse outcome than having no data at all. 1▶ Of the highest importance is the integration of physiologic data obtained from monitoring into a coherent and evidenced-based treatment plan. Current technologies available to assist the clinician in this endeavor are summarized in this chapter. Also presented is a brief look at emerging techniques that may soon enter into clinical practice.

In essence, the goal of hemodynamic monitoring is to ensure that the flow of oxygenated blood through the microcirculation is sufficient to support aerobic metabolism at the cellular level. In general, mammalian cells cannot store oxygen for subsequent use in oxidative metabolism, although a relatively tiny amount is stored in muscle tissue as oxidized myoglobin. Thus, aerobic synthesis of adenosine triphosphate (ATP), the energy "currency" of cells, requires the continuous delivery of oxygen by diffusion from hemoglobin in red blood cells to the oxidative machinery within mitochondria. Delivery of oxygen to mitochondria may be insufficient for several reasons. For example, cardiac output, hemoglobin concentration of blood, or the oxygen content of arterial blood each can be inadequate for independent reasons. Alternatively, despite adequate cardiac output, perfusion of capillary networks can be impaired as a consequence of dysregulation of arteriolar tone, microvascular thrombosis, or obstruction of nutritive vessels by sequestered leukocytes or platelets. Hemodynamic monitoring that does not take into account all of these factors will portray an incomplete and perhaps misleading picture of cellular physiology.

Key Points

1. The delivery of modern critical care is predicated on the ability to monitor a large number of physiologic variables and formulate evidenced-based therapeutic strategies to manage these variables. Technological advances in monitoring have at least a theoretical risk of exceeding our ability to understand the clinical implications of the derived information. This could result in the use of monitoring data to make inappropriate clinical decisions. Therefore, the implementation of any new monitoring technology must take into account the relevance and accuracy of the data obtained, the risks to the patient, as well as the evidence supporting any intervention directed at correcting the detected abnormality.
2. The routine use of invasive monitoring devices, specifically the pulmonary artery catheter, must be questioned in light of the available evidence which does not demonstrate a clear benefit to its widespread use in various populations of critically ill patients. The future of physiologic monitoring will be dominated by the application of noninvasive and highly accurate devices which guide evidenced-based therapy.

Under normal conditions when the supply of oxygen is plentiful, aerobic metabolism is determined by factors other than the availability of oxygen. These factors include the hormonal milieu and mechanical workload of contractile tissues. However, in pathologic circumstances when oxygen availability is inadequate, oxygen utilization (VO_2) becomes dependent upon oxygen delivery (DO_2). The relationship of VO_2 to DO_2 over a broad range of DO_2 values is commonly represented as two intersecting straight lines. In the region of higher DO_2 values, the slope of the line is approximately zero, indicating that VO_2 is largely independent of DO_2. In contrast, in the region of low DO_2 values, the slope of the line is nonzero and positive, indicating that VO_2 is supplydependent. The region where the two lines intersect is called *the point of critical oxygen delivery* (DO_{2crit}), and represents the transition from supply-independent to supply-dependent oxygen uptake. Below a critical threshold of oxygen delivery, increased oxygen extraction cannot compensate for the delivery deficit; hence, oxygen consumption begins to decrease. The slope of the supply-dependent region of the plot reflects the maximal oxygen extraction capability of the vascular bed being evaluated.

The subsequent sections will describe the techniques and utility of monitoring various physiologic parameters.

ARTERIAL BLOOD PRESSURE

The pressure exerted by blood in the systemic arterial system, commonly referred to as *"blood pressure,"* is a cardinal parameter measured as part of the hemodynamic monitoring of patients. Extremes in blood pressure are either intrinsically deleterious or are indicative of a serious perturbation in normal physiology. Arterial blood pressure is a complex function of both cardiac output and vascular input impedance. Thus, inexperienced clinicians may assume that the presence of a normal blood pressure is evidence that cardiac output and tissue perfusion are adequate. This assumption frequently is incorrect and is the reason why some critically ill patients may benefit from forms of hemodynamic monitoring in addition to measurement of arterial pressure.

Blood pressure can be determined directly by measuring the pressure within the arterial lumen or indirectly using a cuff around an extremity. When the equipment is properly set up and calibrated, direct intra-arterial monitoring of blood pressure provides accurate and continuous data. Additionally, intra-arterial catheters provide a convenient way to obtain samples of blood for measurements of arterial blood gases and other laboratory studies. Despite these advantages, intra-arterial catheters are invasive devices and occasionally are associated with serious complications.

Noninvasive Measurement of Arterial Blood Pressure

Both manual and automated means for the noninvasive determination of blood pressure use an inflatable sphygmomanometer cuff to increase pressure around an extremity, and a means for detecting the presence or absence of arterial pulsations. Several methods exist for this purpose. The time-honored approach is the auscultation of the Korotkoff sounds, which are heard over an artery distal to the cuff as the cuff is deflated from a pressure higher than systolic pressure to one less than diastolic pressure. *Systolic pressure* is defined as the pressure in the cuff when tapping sounds are first audible. *Diastolic pressure* is the pressure in the cuff when audible pulsations first disappear.

Another means for pulse detection when measuring blood pressure noninvasively depends upon the detection of oscillations in the pressure within the bladder of the cuff. This approach is simple, and unlike auscultation, can be performed even in a noisy environment (e.g., a busy emergency room). Unfortunately, this approach is neither accurate nor reliable. Other methods, however, can be used to reliably detect the reappearance of a pulse distal to the cuff and thereby estimate systolic blood pressure. Two excellent and widely available approaches for pulse detection are use of a Doppler stethoscope (reappearance of the pulse produces an audible amplified signal) or a pulse oximeter (reappearance of the pulse is indicated by flashing of a light-emitting diode).

A number of automated devices are capable of repetitively measuring blood pressure noninvasively. Some of these devices measure pressure oscillations in the inflatable bladder encircling the extremity to detect arterial pulsations as pressure in the cuff is gradually lowered from greater than systolic to less than diastolic pressure. Other automated noninvasive devices use a piezoelectric crystal positioned over the brachial artery as a pulse detector. The accuracy of these devices is variable, and often dependent on the size mismatch between the arm circumference and the cuff size.[1] If the cuff is too narrow (relative to the extremity), the measured pressure will be artifactually elevated. Therefore, the width of the cuff should be approximately 40% of its circumference.

Another noninvasive approach for measuring blood pressure relies on a technique called *photoplethysmography*. This

method is capable of providing continuous information, since systolic and diastolic blood pressures are recorded on a beat-to-beat basis. Photoplethysmography uses the transmission of infrared light to estimate the amount of hemoglobin (directly related to the volume of blood) in a finger placed under a servo-controlled inflatable cuff. A feedback loop controlled by a microprocessor continually adjusts the pressure in the cuff to maintain the blood volume of the finger constant. Under these conditions, the pressure in the cuff reflects the pressure in the digital artery. The measurements obtained using photoplethysmography generally agree closely with those obtained by invasive monitoring of blood pressure.[2] However, these readings may be less accurate in patients with hypotension or hypothermia.

Invasive Monitoring of Arterial Blood Pressure

Direct and continuous monitoring of arterial pressure in critically ill patients may be performed by using fluid-filled tubing to connect an intra-arterial catheter to an external strain-gauge transducer. The signal generated by the transducer is electronically amplified and displayed as a continuous waveform by an oscilloscope. Digital values for systolic and diastolic pressure also are displayed. Mean pressure, calculated by electronically averaging the amplitude of the pressure waveform, also can be displayed. The fidelity of the catheter-tubing-transducer system is determined by numerous factors, including the compliance of the tubing, the surface area of the transducer diaphragm, and the compliance of the diaphragm. If the system is underdamped, then the inertia of the system, which is a function of the mass of the fluid in the tubing and the mass of the diaphragm, causes overshoot of the points of maximum positive and negative displacement of the diaphragm during systole and diastole, respectively. Thus, in an underdamped system, systolic pressure will be overestimated and diastolic pressure will be underestimated. In an overdamped system, displacement of the diaphragm fails to track the rapidly changing pressure waveform, and systolic pressure will be underestimated and diastolic pressure will be overestimated. It is important to note that even in an underdamped or over-damped system, mean pressure will be accurately recorded, provided the system has been properly calibrated. For these reasons, when using direct measurement of intra-arterial pressure to monitor patients, clinicians should make clinical decisions based primarily on the measured mean arterial blood pressure.

The radial artery at the wrist is the site most commonly used for intra-arterial pressure monitoring. Other sites include the femoral and axillary artery. It is important to recognize, however, that measured arterial pressure is determined in part by the site where the pressure is monitored. Central (i.e., aortic) and peripheral (e.g., radial artery) pressures typically are different as a result of the impedance and inductance of the arterial tree. Systolic pressures typically are higher and diastolic pressures are lower in the periphery, whereas mean pressure is approximately the same in the aorta and more distal sites.

Distal ischemia is an uncommon complication of intra-arterial catheterization. The incidence of thrombosis is increased when larger-caliber catheters are employed and when catheters are left in place for an extended period of time. The incidence of thrombosis can be minimized by using a 20-gauge (or smaller) catheter in the radial artery and removing the catheter as soon as feasible. The risk of distal ischemic injury can be reduced by ensuring that adequate collateral flow is present prior to catheter insertion. At the wrist, adequate collateral flow can be documented by performing a modified version of the Allen test, wherein the artery to be cannulated is digitally compressed while using a Doppler stethoscope to listen for perfusion in the palmar arch vessels.

Another potential complication of intra-arterial monitoring is retrograde embolization of air bubbles or thrombi into the intracranial circulation. In order to minimize this risk, care should be taken to avoid flushing arterial lines when air is present in the system, and only small volumes of fluid (less than 5 mL) should be employed for this purpose. Catheter-related infections can occur with any intravascular monitoring device. However, catheter-related bloodstream infection is a relatively uncommon complication of intra-arterial lines used for monitoring, occurring in 0.4% to 0.7% of catheterizations.[3] The incidence increases with longer duration of arterial catheterization.

ELECTROCARDIOGRAPHIC MONITORING

The electrocardiogram (ECG) records the electrical activity associated with cardiac contraction by detecting voltages on the body surface. A standard 3-lead ECG is obtained by placing electrodes that correspond to the left arm (LA), right arm (RA), and left leg (LL). The limb leads are defined as lead I (LA-RA), lead II (LL-RA), and lead III (LL-LA). The ECG waveforms can be continuously displayed on a monitor, and the devices can be set to sound an alarm if an abnormality of rate or rhythm is detected. Continuous ECG monitoring is widely available and applied to critically ill and perioperative patients. Monitoring of the ECG waveform is essential in patients with acute coronary syndromes or blunt myocardial injury, because dysrhythmias are the most common lethal complication. In patients with shock or sepsis, dysrhythmias can occur as a consequence of inadequate myocardial oxygen delivery or as a complication of vasoactive or inotropic drugs used to support blood pressure and cardiac output. Dysrhythmias can be detected by continuously monitoring the ECG tracing, and timely intervention may prevent serious complications. With appropriate computing hardware and software, continuous ST-segment analysis also can be performed to detect ischemia or infarction.

Additional information can be obtained from a 12-lead ECG, which is essential for patients with potential myocardial ischemia or to rule out cardiac complications in other acutely ill patients. Continuous monitoring of the 12-lead ECG is now available and is proving to be beneficial in certain patient populations. In a study of 185 vascular surgical patients, continuous 12-lead ECG monitoring was able to detect transient myocardial ischemic episodes in 20.5% of the patients.[4] This study demonstrated that the precordial lead V_4, which is not routinely monitored on a standard 3-lead ECG, is the most sensitive for detecting perioperative ischemia and infarction. To detect 95% of the ischemic episodes, two or more precordial leads were necessary. Thus, continuous 12-lead ECG monitoring may provide greater sensitivity than 3-lead ECG for the detection of perioperative myocardial ischemia, and may become standard for monitoring high-risk surgical patients.

Currently, there is considerable interest in using computerized approaches to analyze ECG waveforms and patterns to uncover hidden information that can be used to predict sudden cardiac death or the development of serious dysrhythmias. ECG patterns of interest include repetitive changes in the morphology of the T-wave [T-wave alternans (TWA)][5]and heart rate variability.[6]

Integrated monitoring systems employ software that integrates vital signs to produce a single-parameter index which allows early detection of physiologic perturbations. The input variables include noninvasive measurements of heart rate, respiratory rate, blood pressure, blood oxygen saturation via pulse oximetry (SpO_2), and temperature. The software uses sophisticated algorithms refined in an iterative fashion to develop a probabilistic model of normality, previously developed from a representative sample patient training set. Variance from these data set are used to evaluate the probability that the patient-derived vital signs are within the normal range. An abnormal index can occur while no single vital sign parameter is outside the range of normal if their combined patterns are consistent with known instability patterns. Employing such an integrated monitoring system in step-down unit patients has been shown to be a sensitive method to detect early physiologic abnormalities that may precede hemodynamic instability.[7]

CARDIAC OUTPUT AND RELATED PARAMETERS

Bedside catheterization of the pulmonary artery was introduced into clinical practice in the 1970s. Although the pulmonary artery catheter (PAC) initially was used primarily to manage patients with cardiogenic shock and other acute cardiac diseases, indications for this form of invasive hemodynamic monitoring gradually expanded to encompass a wide variety of clinical conditions. Clearly, many clinicians believe that information valuable for the management of critically ill patients is afforded by having a PAC in place. However, unambiguous data in support of this view are scarce, and several studies suggest that bedside PAC may not benefit most critically ill patients, and in fact lead to some serious complications (see next).

Determinants of Cardiac Performance

Preload. Starling's law of the heart states that the force of muscle contraction depends on the initial length of the cardiac fibers. Using terminology that derives from early experiments using isolated cardiac muscle preparations, preload is the stretch of ventricular myocardial tissue just prior to the next contraction. Thus, cardiac preload is determined by end-diastolic volume (EDV). For the right ventricle, central venous pressure (CVP) approximates right ventricular end-diastolic pressure (EDP). For the left ventricle, pulmonary artery occlusion pressure (PAOP), which is measured by transiently inflating a balloon at the end of a pressure monitoring catheter positioned in a small branch of the pulmonary artery, approximates left ventricular end-diastolic pressure. The presence of atrioventricular valvular stenosis may alter this relationship.

Clinicians frequently use EDP as a surrogate for EDV, but EDP is determined not only by volume but also by the diastolic compliance of the ventricular chamber. Ventricular compliance is altered by various pathologic conditions and pharmacologic agents. Furthermore, the relationship between EDP and true preload is not linear, but rather is exponential.

Afterload. Afterload is another term derived from in vitro experiments using isolated strips of cardiac muscle, and is defined as the force resisting fiber shortening once systole begins. Several factors comprise the in vivo correlate of ventricular afterload, including ventricular intracavitary pressure, wall thickness, chamber radius, and chamber geometry. Since these factors are difficult to assess clinically, afterload is commonly approximated by calculating systemic vascular resistance, defined as mean arterial pressure (MAP) divided by cardiac output.

Contractility. Contractility is defined as the inotropic state of the myocardium. Contractility is said to increase when the force of ventricular contraction increases at constant preload and afterload. Clinically, contractility is difficult to quantify, because virtually all of the available measures are dependent to a certain degree on preload and afterload. If pressure-volume loops are constructed for each cardiac cycle, small changes in preload and/or afterload will result in shifts of the point defining the end of systole. These end-systolic points on the pressure vs. volume diagram describe a straight line, known as the *end-systolic pressure-volume line*. A steeper slope of this line indicates greater contractility.

Placement of the Pulmonary Artery Catheter

In its simplest form, the pulmonary artery catheter (PAC) has four channels. One channel terminates in a balloon at the tip of the catheter. The proximal end of this channel is connected to a syringe to permit inflation of the balloon with air (saline should never be used). Prior to insertion of the PAC, the integrity of the balloon should be verified by inflating it. In order to minimize the risk of vascular or ventricular perforation by the relatively inflexible catheter, it also is important to verify that the inflated balloon extends just beyond the tip of the device. A second channel in the catheter contains wires that are connected to a thermistor located near the tip of the catheter. At the proximal end of the PAC, the wires terminate in a fitting that permits connection to appropriate hardware for the calculation of cardiac output using the thermodilution technique (see next). The final two channels are used for pressure monitoring and the injection of the thermal indicator for determinations of cardiac output. One of these channels terminates at the tip of the catheter. The other terminates 20 cm proximal to the tip.

Placement of a PAC requires access to the central venous circulation. Such access can be obtained at a variety of sites, including the antecubital, femoral, jugular, and subclavian veins. Percutaneous placement through either the jugular or subclavian vein generally is preferred. Right internal jugular vein cannulation carries the lowest risk of complications, and the path of the catheter from this site into the right atrium is straight. In the event of inadvertent arterial puncture, local pressure is significantly more effective in controlling bleeding from the carotid artery compared to the subclavian artery. Nevertheless, it is more difficult to keep occlusive dressings in place on the neck than in the subclavian fossa. Furthermore, the anatomic landmarks in the subclavian position are quite constant, even in patients with anasarca or massive obesity; the subclavian vein always is attached to the deep (concave) surface of the clavicle. In contrast, the appropriate landmarks to guide jugular venous cannulation are sometimes difficult to discern in obese or very edematous patients. However, ultrasonic guidance, which should be used routinely, has been shown to facilitate bedside jugular venipuncture.[8]

Cannulation of the vein normally is performed percutaneously, using the Seldinger technique. A small-bore needle is inserted through the skin and subcutaneous tissue into the vein. After documenting return of venous blood, a guidewire with a flexible tip is inserted through the needle into the vein and the needle is withdrawn. A dilator/introducer sheath is passed over the wire, and the wire and the dilator are removed. The proximal terminus of the distal port of the PAC is connected through low-compliance tubing to a strain-gauge transducer, and the tubing-catheter system is flushed with fluid. While constantly

observing the pressure tracing on an oscilloscope, the PAC is advanced with the balloon deflated until respiratory excursions are observed. The balloon is then inflated, and the catheter advanced further ("floated"), while monitoring pressures sequentially in the right atrium and right ventricle en route to the pulmonary artery. The pressure waveforms for the right atrium, right ventricle, and pulmonary artery are each characteristic. The catheter is advanced out into the pulmonary artery until a damped tracing indicative of the "wedged" position is obtained. The balloon is then deflated, taking care to ensure that a normal pulmonary arterial tracing is again observed on the monitor; leaving the balloon inflated can increase the risk of pulmonary infarction or perforation of the pulmonary artery. Unnecessary measurements of the pulmonary artery occlusion pressure are discouraged as rupture of the pulmonary artery may occur.

Hemodynamic Measurements

Even in its simplest embodiment, the PAC is capable of providing clinicians with a remarkable amount of information about the hemodynamic status of patients. Additional information may be obtained if various modifications of the standard PAC are employed. By combining data obtained through use of the PAC with results obtained by other means (i.e., blood hemoglobin concentration and oxyhemoglobin saturation), derived estimates of systemic oxygen transport and utilization can be calculated. Direct and derived parameters obtainable by bedside pulmonary arterial catheterization are summarized in Table 13-1. The equations used to calculate the derived parameters are summarized in Table 13-2. The approximate normal ranges for a number of these hemodynamic parameters (in adults) are shown in Table 13-3.

Table 13-1

Directly Measured and Derived Hemodynamic Data Obtainable by Bedside Pulmonary Artery Catheterization

STANDARD PAC	PAC WITH ADDITIONAL FEATURE(S)	DERIVED PARAMETERS
CVP	$S\bar{v}O_2$ (continuous)	SV (or SVI)
PAP	Q_T or Q_T* (continuous)	SVR (or SVRI)
PAOP	RVEF	PVR (or PVRI)
$S\bar{v}O_2$ (intermittent)		RVEDV
Q_T or Q_T* (intermittent)		$\dot{D}O_2$ $\bar{v}O_2$ ER Q_S/Q_T

CVP = mean central venous pressure; $\dot{D}O_2$ = systemic oxygen delivery; ER = systemic oxygen extraction ratio; PAOP = pulmonary artery occlusion (wedge) pressure; PAP = pulmonary artery pressure; PVR = pulmonary vascular resistance; PVRI = pulmonary vascular resistance index; Q_S/Q_T = fractional pulmonary venous admixture (shunt fraction); Q_T = cardiac output; Q_T* = cardiac output indexed to body surface area (cardiac index); RVEDV = right ventricular end-diastolic volume; RVEF = right ventricular ejection fraction; SV = stroke volume; SVI = stroke volume index; $S\bar{v}O_2$ = fractional mixed venous (pulmonary artery) hemoglobin saturation; SVR = systemic vascular resistance; SVRI = systemic vascular resistance index; = $\bar{v}O_2$ systemic oxygen utilization.

Table 13-2

Formulas for calculation of hemodynamic parameters that can be derived by using data obtained by pulmonary artery catheterization

Q_T* (L·min^{-1}·m^{-2}) = Q_T/BSA, where BSA is body surface area (m^2)

SV (mL) = Q_T/HR, where HR is heart rate (min^{-1})

SVR (dyne·sec·cm^{-5}) = [(MAP – CVP) × 80] /Q_T, where MAP is mean arterial pressure (mm Hg)

SVRI (dyne·sec·cm^{-5}m^{-2}) = [(MAP – CVP) × 80] /Q_T*

PVR (dyne·sec·cm^{-5}) = [(PAP – PAOP) × 80] /QT, where PAP is mean pulmonary artery pressure

PVRI (dyne·sec·cm^{-5}m^{-2}) = [(PAP – PAOP) × 80] /Q_T*

RVEDV (mL) = SV/RVEF

$\dot{D}O_2$(mL·min^{-1}·m^{-2}) = Q_T* × CaO_2 × 10, where CaO_2 is arterial oxygen content (mL/dL)

$\bar{v}O_2$(mL·min^{-1}·m^{-2}) = Q_T* × (CaO_2 – $C\bar{v}O_2$) × 10, where $C\bar{v}O_2$ is mixed venous oxygen content (mL/dL)

CaO_2 = (1.36 × Hgb × SaO_2) + (0.003 + PaO_2), where Hgb is hemoglobin concentration (g/dL), SaO_2 is fractional arterial hemoglobin saturation, and PaO_2 is the partial pressure of oxygen in arterial blood

$C\bar{v}O_2$ = (1.36 × Hgb × $S\bar{v}O_2$) + (0.003 + $P\bar{v}O_2$), where $P\bar{v}O_2$ is the partial pressure of oxygen in pulmonary arterial (mixed venous) blood

Q_S/Q_T = (CcO_2 – Ca O_2)/ (CcO_2 – Cv O_2), where Cc O_2 (mL/dL) is the content of oxygen in pulmonary end capillary blood

CcO_2 = (1.36 × Hgb) + (0.003 + PAO_2), where PAO_2 is the alveolar partial pressure of oxygen

PAO_2 = [FIO_2 × (P_B – PH_2O)] – $PaCO_2$/RQ, where FIO_2 is the fractional concentration of inspired oxygen, P_B is the barometric pressure (mm Hg), P_{H_2O} is the water vapor pressure (usually 47 mm Hg), $PaCO_2$ is the partial pressure of carbon dioxide in arterial blood (mm Hg), and RQ is respiratory quotient (usually assumed to be 0.8)

$C\bar{v}O_2$ = central venous oxygen pressure; CVP = mean central venous pressure; $\dot{D}O_2$ = systemic oxygen delivery; PAOP = pulmonary artery occlusion (wedge) pressure; PVR = pulmonary vascular resistance; PVRI = pulmonary vascular resistance index; Q_S/Q_T = fractional pulmonary venous admixture (shunt fraction); Q_T = cardiac output; Q_T* = cardiac output indexed to body surface area (cardiac index); RVEDV = right ventricular end-diastolic volume; RVEF = right ventricular ejection fraction; SV = stroke volume; SVI = stroke volume index; $S\bar{v}O_2$ = fractional mixed venous (pulmonary artery) hemoglobin saturation; SVR = systemic vascular resistance; SVRI = systemic vascular resistance index; $\bar{v}O_2$ = systemic oxygen utilization.

Measurement of Cardiac Output by Thermodilution

Before the development of the PAC, determining cardiac output (Q_T) at the bedside required careful measurements of oxygen consumption (Fick method) or spectrophotometric determination of indocyanine green dye dilution curves. Measurements of Q_T using the thermodilution technique are simple and reasonably accurate. The measurements can be performed repetitively and the principle is straightforward. If a bolus of an indicator is rapidly and thoroughly mixed with a moving fluid upstream from a detector, then the concentration of the indicator at the detector will increase sharply and then exponentially diminish back

Table 13-3

Approximate normal ranges for selected hemodynamic parameters in adults

PARAMETER	NORMAL RANGE
CVP	0–6 mm Hg
Right ventricular systolic pressure	20–30 mm Hg
Right ventricular diastolic pressure	0–6 mm Hg
PAOP	6–12 mm Hg
Systolic arterial pressure	100–130 mm Hg
Diastolic arterial pressure	60–90 mm Hg
MAP	75–100 mm Hg
Q_T	4–6 L/min
Q_T*	2.5–3.5 $L \cdot min^{-1} \cdot m^{-2}$
SV	40–80 mL
SVR	800–1400 $dyne \cdot sec \cdot cm^{-5}$
SVRI	1500–2400 $dyne \cdot sec \cdot cm^{-5} \cdot m^{-2}$
PVR	100–150 $dyne \cdot sec \cdot cm^{-5}$
PVRI	200–400 $dyne \cdot sec \cdot cm^{-5} \cdot m^{-2}$
CaO_2	16–22 mL/dL
CvO_2	~15 mL 02 dL blood
$\dot{D}O_2$	400–660 $mL \cdot min^{-1} \cdot m^{-2}$
$\bar{V}O_2$	115–165 $mL \cdot min^{-1} \cdot m^{-2}$

CaO_2 = arterial oxygen content; CvO_2 = central venous oxygen pressure; CVP = mean central venous pressure; = $\dot{D}O_2$ systemic oxygen delivery; MAP = mean arterial pressure; PAOP = pulmonary artery occlusion (wedge) pressure; PVR = pulmonary vascular resistance; PVRI = pulmonary vascular resistance index; Q_T = cardiac output; Q_T* = cardiac output indexed to body surface area (cardiac index); SV = stroke volume; SVI = stroke volume index; SVR = systemic vascular resistance; SVRI = systemic vascular resistance index; = $\bar{V}O_2$ systemic oxygen utilization.

to zero. The area under the resulting time-concentration curve is a function of the volume of indicator injected and the flow rate of the moving stream of fluid. Larger volumes of indicator result in greater areas under the curve, and faster flow rates of the mixing fluid result in smaller areas under the curve. When Q_T is measured by thermodilution, the indicator is heat and the detector is a temperature-sensing thermistor at the distal end of the PAC. The relationship used for calculating Q_T is called the Stewart-Hamilton equation:

$$Q_T = [V \times (T_B - T_I) \times K_1 \times K_2] / \int T_B(t)dt$$

where V is the volume of the indicator injected, T_B is the temperature of blood (i.e., core body temperature), T_I is the temperature of the indicator, K_1 is a constant that is the function of the specific heats of blood and the indicator, K_2 is an empirically derived constant that accounts for several factors (the dead space volume of the catheter, heat lost from the indicator as it traverses the catheter, and the injection rate of the indicator), and $\int T_B(t)dt$ is the area under the time-temperature curve. In clinical practice, the Stewart-Hamilton equation is solved by a microprocessor.

Determination of cardiac output by the thermodilution method is generally quite accurate, although it tends to systematically overestimate Q_T at low values. Changes in blood temperature and Q_T during the respiratory cycle can influence the measurement. Therefore, results generally should be recorded as the mean of two or three determinations obtained at random points in the respiratory cycle. Using cold injectate widens the difference between T_B and T_I and thereby increases signal-to-noise ratio. Nevertheless, most authorities recommend using room temperature injectate (normal saline or 5% dextrose in water) to minimize errors resulting from warming of the fluid as it transferred from its reservoir to a syringe for injection.

Technologic innovations have been introduced that permit continuous measurement of Q_T by thermodilution. In this approach, thermal transients are not generated by injecting a bolus of a cold indicator, but rather by heating the blood with a tiny filament located on the PAC upstream from the thermistor. By correlating the amount of current supplied to the heating element with the downstream temperature of the blood, it is possible to estimate the average blood flow across the filament and thereby calculate Q_T. Based upon the results of several studies, continuous determinations of Q_T using this approach agree well with data generated by conventional measurements using bolus injections of a cold indicator.[9] Information is lacking regarding the clinical value of being able to monitor Q_T continuously.

Mixed Venous Oximetry

The Fick equation can be written as $Q_T = VO_2/(CaO_2 - CVO_2)$, where CaO_2 is the content of oxygen in arterial blood and CVO_2 is the content of oxygen in mixed venous blood. The Fick equation can be rearranged as follows: $CVO_2 = CaO_2 - VO_2/Q_T$. If the small contribution of dissolved oxygen to CVO_2 and CaO_2 is ignored, the rearranged equation can be rewritten as $SVO_2 = Sao_2 - VO_2/(Q_T \times Hgb \times 1.36)$, where SVO_2 is the fractional saturation of hemoglobin in mixed venous blood, Sao_2 is the fractional saturation of hemoglobin in arterial blood, and Hgb is the concentration of hemoglobin in blood. Thus it can be seen that SVO_2 is a function of VO_2 (i.e., metabolic rate), Q_T, Sao_2, and Hgb. Accordingly, subnormal values of SVO_2 can be caused by a decrease in Q_T (due, for example, to heart failure or hypovolemia), a decrease in Sao_2 (due, for example, to intrinsic pulmonary disease), a decrease in Hgb (i.e., anemia), or an increase in metabolic rate (due, for example, to seizures or fever). With a conventional PAC, measurements of SVO_2 require aspirating a sample of blood from the distal (i.e., pulmonary arterial) port of the catheter and injecting the sample into a blood gas analyzer. Therefore for practical purposes, measurements of SVO_2 can be performed only intermittently.

By adding a fifth channel to the PAC, it has become possible to monitor SVO_2 continuously. The fifth channel contains two fiber-optic bundles, which are used to transmit and receive light of the appropriate wavelengths to permit measurements of hemoglobin saturation by reflectance spectrophotometry. Continuous SVO_2 devices provide measurements of SVO_2 that agree quite closely with those obtained by conventional analyses of blood aspirated from the pulmonary artery. Despite the theoretical value of being able to monitor SVO_2 continuously, data are lacking to show that this capability favorably improves outcomes. In a prospective, observational study of 3265 patients undergoing cardiac surgery with either a standard PAC or a PAC with continuous SVO_2 monitoring, the oximetric catheter was associated with fewer arterial blood gas and thermodilution cardiac output determinations, but no difference in patient

outcome.[10] Since pulmonary artery catheters that permit continuous monitoring of SVO_2 are more expensive than conventional PACs, the routine use of these devices cannot be recommended.

The saturation of oxygen in the right atrium or superior vena cava ($ScVO_2$) correlates closely with SVO_2 over a wide range of conditions,[11] although the correlation between $ScVO_2$ and SVO_2 has been questioned under certain conditions (e.g., septic shock).[12] Since measurement of $ScVO_2$ requires placement of a central venous catheter rather than a PAC, it is somewhat less invasive and easier to carry out. By using a central venous catheter equipped to permit fiber-optic monitoring of $ScVO_2$, it may be possible to titrate the resuscitation of patients with shock using a less invasive device than the PAC.[11,13] The Surviving Sepsis Campaign international guidelines for the management of severe sepsis and septic shock recommends that during the first 6 hours of resuscitation, the goals of initial resuscitation of sepsis-induced hypoperfusion should include all of the following: CVP 8–12 mm Hg, MAP ≥ 65 mm Hg, urine output ≥ 0.5 mL/kg/h. $ScVO_2$ of 70% or $SVO_2$of 65%.[14]

Effect of Pulmonary Artery Catheterization on Outcome

Despite initial enthusiasm for using the PAC in the management of critically-ill patients, several studies have failed to show improved outcomes with their use. Connors and colleagues reported results of a major observational study evaluating the value of PAC in critically ill patients.[15] These researchers compared two groups of patients: those who did and those who did not undergo placement of a PAC during their first 24 hours of ICU care. The investigators recognized that the value of their intended analysis was completely dependent on the robustness of their methodology for case-matching, because sicker patients (i.e., those at greater risk of mortality based upon the severity of their illness) were presumably more likely to undergo pulmonary artery catheterization. Accordingly, the authors used sophisticated statistical methods for generating a cohort of study (i.e., PAC) patients, each one having a paired control matched carefully for severity of illness. Connors et al concluded that placement of a pulmonary artery catheter during the first 24 hours of stay in an ICU is associated with a significant increase in the risk of mortality, even when statistical methods are used to account for severity of illness.[15]

A number of prospective, randomized controlled trials of PAC are summarized in Table 13-4. The study by Pearson et al was underpowered with only 226 patients enrolled.[16] In addition, the attending anesthesiologists were permitted to exclude patients from the CVP group at their discretion; thus, randomization was compromised. The study by Tuman et al was large (1094 patients were enrolled), but different anesthesiologists were assigned to the different groups.[17] Furthermore, 39 patients in the CVP group underwent placement of a PAC because of hemodynamic complications. All of the individual

Table 13-4

Summary of randomized, prospective clinical trials comparing pulmonary artery catheter with central venous pressure monitoring

AUTHOR	STUDY POPULATION	GROUPS	OUTCOMES
Pearson et al[16]	"Low risk" patients undergoing cardiac or vascular surgery	CVP catheter (group 1); PAC (group 2); PAC with continuous $S\bar{v}O_2$ readout (group 3)	No differences among groups for mortality or length of ICU stay; significant differences in costs (group 1 < group 2 < group 3)
Tuman et al[17]	Cardiac surgical patients	PAC; CVP	No differences between groups for mortality, length of ICU stay, or significant noncardiac complications
Bender et al[18]	Vascular surgery patients	PAC; CVP	No differences between groups for mortality, length of ICU stay, or length of hospital stay
Valentine et al[19]	Aortic surgery patients	PAC + hemodynamic optimization in ICU night before surgery; CVP	No differences between groups for mortality or length of ICU stay; significantly higher incidence of postoperative complications in PAC group
Sandham et al[20]	"High risk" major surgery	PAC; CVP	No differences between groups for mortality, length of ICU stay; increased incidence of pulmonary embolism in PAC group
Harvey S, et al[21]	Medical and surgical ICU patients	PAC vs. no PAC, with option for alternative CO measuring device in non-PAC group	No differences in hospital mortality between the 2 groups, increased incidence of complications in the PAC group
Binanay, et al[23]	Patients with CHF	PAC vs. no PAC	No difference in hospital mortality between the 2 groups, increased incidence of adverse events in the PAC group
Wheeler, et al[24]	Patients with ALI	PAC vs. CVC with a fluid and inotropic management protocol	No difference in ICU or hospital mortality, or incidence of organ failure between the 2 groups; increased incidence of adverse events in the PAC group

ALI = acute lung injury, CHF = congestive heart failure, CO = cardiac output, CVC = central venous catheter, ICU = intensive care unit, PAC = pulmonary artery catheter, = $S\bar{v}O_2$ fractional mixed venous (pulmonary artery) hemoglobin saturation.

single-institution studies of vascular surgery patients were relatively underpowered, and all excluded at least certain categories of patients (e.g., those with a history of recent myocardial infarction).[18,19]

In the largest randomized controlled trial of the PAC, Sandham et al randomized nearly 2000 American Society of Anesthesiologists (ASAs) class III and IV patients undergoing major thoracic, abdominal, or orthopedic surgery to placement of a PAC or CVP catheter.[20] In the patients assigned to receive a PAC, physiologic goal-directed therapy was implemented by protocol. There were no differences in mortality at 30 days, 6 months, or 12 months between the two groups, and ICU length of stay was similar. There was a significantly higher rate of pulmonary emboli in the PAC group (0.9% vs. 0%). This study has been criticized because most of the patients enrolled were not in the highest risk category.

In the "PAC-Man" trial, a multicenter, randomized trial in 65 United Kingdom hospitals, over 1000 ICU patients were managed with or without a PAC.[21] The specifics of the clinical management were then left up to the treating clinicians. There was no difference in hospital mortality between the 2 groups (with PAC 68% vs. without PAC 66%, p = 0.39). However, a 9.5% complication rate was associated with the insertion or use of the PAC, although none of these complications were fatal. Clearly, these were critically ill patients, as noted by the high hospital mortality rates. Supporters of the PAC use cite methodology problems with this study, such as loose inclusion criteria and the lack of a defined treatment protocol.

A meta-analysis of 13 randomized studies of the PAC included over 5000 patients was published in 2005.[22] A broad spectrum of critically ill patients was included in these heterogeneous trials, and the hemodynamic goals and treatment strategies varied. While the use of the PAC was associated with an increased use of inotropes and vasodilators, there were no differences in mortality or hospital length of stay between the patients managed with a PAC and those managed without a PAC.

The ESCAPE trial (which was one of the studies included in the previous meta-analysis)[23] evaluated 433 patients with severe or recurrent congestive heart failure (CHF) admitted to the ICU. Patients were randomized to management by clinical assessment and a PAC or clinical assessment without a PAC. The goal in both groups was resolution of CHF, with additional PAC targets of a pulmonary capillary occlusion pressure of 15 mm Hg and a right atrial pressure of 8 mm Hg. There was no formal treatment protocol, but inotropic support was discouraged. Substantial reduction in symptoms, jugular venous pressure, and edema was noted in both groups. There was no significant difference in the primary end point of days alive and out of the hospital during the first 6 months, or hospital mortality (PAC 10%; vs. without PAC 9%). Adverse events were more common among patients in the PAC group (21.9% vs.11.5%; $P = 0.04$).

Finally, the Fluids and Catheters Treatment Trial (FACTT) conducted by the Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network was published in 2006.[24] The risks and benefits of PAC compared with central venous catheters (CVC) were evaluated in 1000 patients with acute lung injury. Patients were randomly assigned to receive either a PAC or a CVC to guide management for 7 days via an explicit protocol. Patients also were randomly assigned to a conservative or liberal fluid strategy in a 2 × 2 factorial design (outcomes based on the fluid management strategy were published separately). Mortality during the first 60 days was similar in the PAC and CVC groups (27% and 26%, respectively; $P = 0.69$). The duration of mechanical ventilation and ICU length of stay also were not influenced by the type of catheter used. The type of catheter employed did not affect the incidence of shock, respiratory or renal failure, ventilator settings, or requirement for hemodialysis or vasopressors. There was a 1% rate of crossover from CVC-guided therapy to PAC-guided therapy. The type of catheter used did not affect the administration of fluids or diuretics, and the net fluid balance was similar in the two groups. The PAC group had approximately twice as many catheter-related adverse events (mainly arrhythmias).

Few subjects in critical care medicine have historically generated more emotional responses among experts in the field than the use of the PAC. As these studies demonstrate, it is not possible to show that therapy directed by use of the PAC saves lives when it is evaluated in a large population of patients. Certainly, given the available evidence, routine use of the PAC cannot be justified. Whether selective use of the device in a few relatively uncommon clinical situations is warranted or valuable remains a controversial issue. Consequently, a marked decline in the use of the PAC from 5.66 per 1000 medical admissions in 1993 to 1.99 per 1000 medical admissions in 2004 has been seen.[25] Based upon the results and exclusion criteria in these prospective randomized trials, reasonable criteria for perioperative monitoring without use of a PAC are presented in Table 13-5.

2▶

One of the reasons for using a PAC to monitor critically ill patients is to optimize cardiac output and systemic oxygen delivery. Defining what constitutes the optimum cardiac output, however, has proven to be difficult. A number of randomized trials evaluating the effect on outcome of goal-directed compared to conventional hemodynamic resuscitation have been published. Some studies provide support for the notion that interventions designed to achieve supraphysiologic goals for DO_2, VO_2, and Q_T improve outcome.[26,27] However, other published studies do not support this view, and a meta-analysis concluded that interventions designed to achieve supraphysiological goals for oxygen transport do not significantly reduce mortality rates in critically ill patients.[28,29] At this time, supraphysiological resuscitation of patients in shock cannot be endorsed.

There is no simple explanation for the apparent lack of effectiveness of pulmonary artery catheterization, although several concurrent possibilities exist. First, even though bedside pulmonary artery catheterization is quite safe, the procedure

Table 13-5

Suggested criteria for perioperative monitoring without use of a pulmonary artery catheter in patients undergoing cardiac or major vascular surgical procedures

No anticipated need for suprarenal or supraceliac aortic cross-clamping
No history of myocardial infarction during 3 months prior to operation
No history of poorly compensated congestive heart failure
No history of coronary artery bypass graft surgery during 6 weeks prior to operation
No history of ongoing symptomatic mitral or aortic valvular heart disease
No history of ongoing unstable angina pectoris

is associated with a finite incidence of serious complications, including ventricular arrhythmias, catheter-related sepsis, central venous thrombosis, pulmonary arterial perforation, and pulmonary embolism.[20] The adverse effects of these complications on outcome may equal or even outweigh any benefits associated with using a PAC to guide therapy. Second, the data generated by the PAC may be inaccurate, leading to inappropriate therapeutic interventions. Third, the measurements, even if accurate, may often be misinterpreted.[29] Furthermore, the current state of understanding is primitive when it comes to deciding what is the best management for certain hemodynamic disturbances, particularly those associated with sepsis or septic shock. Taking all of this into consideration, it may be that interventions prompted by measurements obtained with a PAC are actually harmful to patients. As a result, the marginal benefit now available by placing a PAC may be quite small. Less invasive modalities are available that may provide clinically useful hemodynamic information.

It may be true that aggressive hemodynamic resuscitation of patients, guided by various forms of monitoring, is valuable only during certain critical periods, such as the first few hours after presentation with septic shock or during surgery. For example, Rivers and colleagues reported that survival of patients with septic shock is significantly improved when resuscitation in the emergency department is guided by a protocol that seeks to keep $ScVO_2$ greater than 70%.[13] Similarly, a study using an ultrasound-based device (see Doppler Ultrasonography below) to assess cardiac filling and SV showed that maximizing SV intraoperatively results in fewer postoperative complications and shorter hospital length of stay.[30]

Minimally Invasive Alternatives to the Pulmonary Artery Catheter

Because of the cost, risks and questionable benefit associated with bedside pulmonary artery catheterization, there has been interest in the development of practical means for less invasive monitoring of hemodynamic parameters. Several approaches have been developed, which have achieved variable degrees of success. None of these methods render the standard thermodilution technique of the pulmonary artery catheter obsolete. However, these strategies may contribute to improvements in the hemodynamic monitoring of critically ill patients.

Doppler Ultrasonography. When ultrasonic sound waves are reflected by moving erythrocytes in the bloodstream, the frequency of the reflected signal is increased or decreased, depending on whether the cells are moving toward or away from the ultrasonic source. This change in frequency is called the *Doppler shift*, and its magnitude is determined by the velocity of the moving red blood cells. Therefore, measurements of the Doppler shift can be used to calculate red blood cell velocity. With knowledge of both the cross-sectional area of a vessel and the mean red blood cell velocity of the blood flowing through it, one can calculate blood flow rate. If the vessel in question is the aorta, then Q_T can be calculated as:

$$Q_T = HR \times A \times \int V(t)dt$$

where A is the cross-sectional area of the aorta and $\int V(t)dt$ is the red blood cell velocity integrated over the cardiac cycle.

Two approaches have been developed for using Doppler ultrasonography to estimate Q_T. The first approach uses an ultrasonic transducer, which is positioned manually in the suprasternal notch and focused on the root of the aorta. Aortic cross-sectional area can be estimated using a nomogram, which factors in age, height, and weight, back-calculated if an independent measure of Q_T is available, or by using two-dimensional transthoracic or transesophageal ultrasonography. While this approach is completely noninvasive, it requires a highly-skilled operator in order to obtain meaningful results, and is laborintensive. Moreover, unless Q_T measured using thermodilution is used to back-calculate aortic diameter, accuracy using the suprasternal notch approach is not acceptable. Accordingly, this method is useful only for obtaining very intermittent estimates of Q_T, and has not been widely adopted by clinicians.

A second more promising, albeit more invasive, approach has been introduced. In this method blood flow velocity is continuously monitored in the descending thoracic aorta using a continuous-wave Doppler transducer introduced into the esophagus. The probe is connected to a monitor, which continuously displays the blood flow velocity profile in the descending aorta as well as the calculated Q_T. In order to maximize the accuracy of the device, the probe position must be adjusted to obtain the peak velocity in the aorta. In order to transform blood flow in the descending aorta into Q_T, a correction factor is applied that is based on the assumption that only 70% of the flow at the root of the aorta is still present in the descending thoracic aorta. A meta-analysis of the available data show a good correlation between cardiac output estimates obtained by trans-esophageal Doppler and PAC in critically-ill patients.[31] The ultrasonic device also calculates a derived parameter termed *flow time corrected* (FTc), which is the systolic flow time in the descending aorta corrected for heart rate. FTc is a function of preload, contractility, and vascular input impedance. Although it is not a pure measure of preload, Doppler-based estimates of SV and FTc have been used successfully to guide volume resuscitation in high-risk surgical patients undergoing major operations.[30]

Impedance Cardiography. The impedance to flow of alternating electrical current in regions of the body is commonly called *bioimpedance*. In the thorax, changes in the volume and velocity of blood in the thoracic aorta lead to detectable changes in bioimpedance. The first derivative of the oscillating component of thoracic bioimpedance (dZ/dt) is linearly related to aortic blood flow. On the basis of this relationship, empirically derived formulas have been developed to estimate SV, and subsequently Q_T, noninvasively. This methodology is called *impedance cardiography*. The approach is attractive because it is noninvasive, provides a continuous readout of Q_T, and does not require extensive training. Despite these advantages, measurements of Q_T obtained by impedance cardiography are not sufficiently reliable to be used for clinical decision making and have poor correlation with thermodilution.[32]

Because of the limitations of bioimpedance devices, a newer approach for processing the impedance signal was developed and commercialized. This approach is based on the recognition that the impedance signal has two components: amplitude and phase. Whereas the amplitude of the thoracic impedance signal is determined by all of the components of the thoracic cavity (bone, blood, muscle and other soft tissues), phase shifts are determined entirely by pulsatile flow. The vast majority of pulsatile flow is related to blood moving within the aorta. Therefore, the "bioreactance" signal correlates closely with aortic flow, and cardiac output determined using this approach agrees closely with cardiac output measured using conventional indicator dilution techniques.[33]

Pulse Contour Analysis. Another method for determining cardiac output is an approach called *pulse contour analysis* for estimating SV on a beat-to-beat basis. The mechanical properties of the arterial tree and SV determine the shape of the arterial pulse waveform. The pulse contour method of estimating Q_T uses the arterial pressure waveform as an input for a model of the systemic circulation in order to determine beat-to-beat flow through the circulatory system. The parameters of resistance, compliance, and impedance are initially estimated based on the patient's age and sex, and subsequently can be refined by using a reference standard measurement of Q_T. The reference standard estimation of Q_T is obtained periodically using the indicator dilution approach by injecting the indicator into a central venous catheter and detecting the transient increase in indicator concentration in the blood using an arterial catheter. In one commercially available embodiment of this approach, the lithium ion (Li+) is the indicator used for the periodic calibrations of the device. The lithium carbonate indicator can be injected into a peripheral vein, and the doses do not exert pharmacologically relevant effects in adult patients. The Li+ indicator dilution method has shown to be at least as reliable as other thermodilution methods over a broad range of CO in a variety of patients.[33] In another commercially available system, a conventional bolus of cold fluid is used as the indicator for calibration. The thermodilution-based calibration requires central venous catheterization, although the temperature change is detected in a transpulmonary fashion (i.e., in a peripheral artery).

Measurements of Q_T based on pulse contour monitoring using these two approaches are comparable in accuracy to standard PAC thermodilution methods, but are less invasive since transcardiac catheterization is not needed.[34] Using on-line pressure waveform analysis, the computerized algorithms can calculate SV, Q_T, systemic vascular resistance, and an estimate of myocardial contractility, (i.e., the rate of rise of the arterial systolic pressure [dP/dT]). The use of pulse contour analysis has been applied using noninvasive photoplethysmographic measurements of arterial pressure. However, the accuracy of this technique has been questioned and its clinical utility remains to be determined.[35]

One commercially available device, which can be used for estimating cardiac output, does not require external calibration. Instead, the relationship between pulse pressure and stroke volume is determined using a proprietary algorithm that uses biometric data, such as age, gender, and height, as inputs. Although this methodology is gaining fairly wide acceptance in critical care medicine, reported accuracy (in comparison to "gold standard" approaches) is not very good.[33]

Partial Carbon Dioxide Rebreathing. Partial carbon dioxide (CO_2) rebreathing uses the Fick principle to estimate Q_T noninvasively. By intermittently altering the dead space within the ventilator circuit via a rebreathing valve, changes in CO_2 production ($V\dot{C}O_2$) and end-tidal CO_2 ($ETCO_2$) are used to determine cardiac output using a modified Fick equation ($Q_T = \Delta V\dot{C}O_2/\Delta ETCO_2$). Commercially available devices use this Fick principle to calculate Q_T using intermittent partial CO_2 rebreathing through a disposable rebreathing loop. These devices consist of a CO_2 sensor based on infrared light absorption, an airflow sensor, and a pulse oximeter. Changes in intrapulmonary shunt and hemodynamic instability impair the accuracy of Q_T estimated by partial CO_2 rebreathing. Continuous in-line pulse oximetry and inspired fraction of inspired O_2 (FIO_2) are used to estimate shunt fraction to correct Q_T.

Some studies of the partial CO_2 rebreathing approach suggest that this technique is not as accurate as thermodilution, the gold standard for measuring Q_T.[34,36] However, other studies suggest that the partial CO_2 rebreathing method for determination of Q_T compares favorably to measurements made using a PAC in critically ill patients.[37]

Transesophageal Echocardiography. Transesophageal echocardiography (TEE) has made the transition from operating room to intensive care unit. TEE requires that the patient be sedated and usually intubated for airway protection. Using this powerful technology, global assessments of LV and RV function can be made, including determinations of ventricular volume, EF, and Q_T. Segmental wall motion abnormalities, pericardial effusions, and tamponade can be readily identified with TEE. Doppler techniques allow estimation of atrial filling pressures. The technique is somewhat cumbersome and requires considerable training and skill in order to obtain reliable results. Recently, a TEE probe has been introduced into practice that is small enough in diameter that it can be left in place for as long as 72 hours. While only limited data are currently available with this probe, it seems like it will be a useful cardiac monitoring tool for use in selected, patients with complex problems.

Assessing Preload Responsiveness. Although pulse contour analysis or partial CO_2 rebreathing may be able to provide estimates of SV and Q_T, these approaches alone can offer little or no information about the adequacy of preload. Thus, if Q_T is low, some other means must be employed to estimate preload. Many clinicians assess the adequacy of cardiac preload by determining CVP or PAOP. However, neither CVP nor PAOP correlate well with the true parameter of interest, left ventricular end-diastolic volume (LVEDV).[38] Extremely high or low CVP or PAOP results are informative, but readings in a large middle zone (i.e., 5–20 mm Hg) are less useful. Furthermore, changes in CVP or PAOP fail to correlate well with changes in stroke volume.[37,39] Echocardiography can be used to estimate LVEDV, but this approach is dependent on the skill and training of the individual using it, and isolated measurements of LVEDV fail to predict the hemodynamic response to alterations in preload.[40]

When intrathoracic pressure increases during the application of positive airway pressure in mechanically ventilated patients, venous return decreases, and as a consequence, left ventricular stroke volume (LVSV) also decreases. Therefore, pulse pressure variation (PPV) during a positive pressure episode can be used to predict the responsiveness of cardiac output to changes in preload.[39,41] PPV is defined as the difference between the maximal pulse pressure and the minimum pulse pressure divided by the average of these two pressures. This approach has been validated by comparing PPV, CVP, PAOP, and systolic pressure variation as predictors of preload responsiveness in a cohort of critically ill patients. Patients were classified as being "preload responsive" if their cardiac index [Q_T/Body Surface Area (BSA)] increased by at least 15% after rapid infusion of a standard volume of intravenous fluid.[42] Receiver-operating characteristic (ROC) curves demonstrated that PPV was the best predictor of preload responsiveness. Although atrial arrhythmias can interfere with the usefulness of this technique, PPV remains a useful approach for assessing preload responsiveness in most patients because of its simplicity and reliability.[40]

Near-infrared Spectroscopic Measurement of Tissue Hemoglobin Oxygen Saturation. Near-infrared spectroscopy (NIRS) allows continuous, noninvasive measurement of tissue

hemoglobin oxygen saturation (StO_2) using near-infrared wavelengths of light (700–1000 nm). This technology is based on Beer's law, which states that the transmission of light through a solution with a dissolved solute decreases exponentially as the concentration of the solute increases. In mammalian tissue, three compounds change their absorption pattern when oxygenated: cytochrome aa3, myoglobin, and hemoglobin. Because of the distinct absorption spectra of oxyhemoglobin and deoxyhemoglobin, Beer's law can be used to detect their relative concentrations within tissue. Thus, the relative concentrations of the types of hemoglobin can be determined by measuring the change in light intensity as it passes through the tissue. Since about 20% of blood volume is intra-arterial and the StO_2 measurements are taken without regard to systole or diastole, spectroscopic measurements are primarily indicative of the venous oxyhemoglobin concentration.

NIRS has been evaluated to assess the severity of traumatic shock in animal models and in trauma patients. Studies have shown that peripheral muscle StO2, as determined by NIRS, is as accurate as other end points of resuscitation (i.e., base deficit, mixed venous oxygen saturation) in a porcine model of hemorrhagic shock.[43] Continuously-measured StO_2 has been evaluated in blunt trauma patients as a predictor of the development of multiple organ dysfunction syndrome (MODS) and mortality.[44] Exactly 383 patients were studied at seven level 1 trauma centers. $StO_2$was monitored for 24 hours after admission along with vital signs and other endpoints of resuscitation, such as base deficit (BD). Minimum StO_2(using a minimum $StO_2 \leq 75\%$ as a cutoff) had a similar sensitivity and specificity in predicting the development of MODS as BD ≥ 6 mEq/L. StO_2 and BD were also comparable in predicting mortality. Thus, NIRS-derived muscle StO_2 measurements perform similarly to BD in identifying poor perfusion and predicting the development of MODS or death after severe torso trauma, yet have the additional advantages of being continuous and noninvasive. Ongoing prospective studies will help determine the clinical utility of continuous monitoring of StO_2 in clinical scenarios such as trauma, hemorrhagic shock, and sepsis.

RESPIRATORY MONITORING

The ability to monitor various parameters of respiratory function is of utmost importance in critically ill patients. Many of these patients require mechanical ventilation. Monitoring of their respiratory physiology is necessary to assess the adequacy of oxygenation and ventilation, guide weaning and liberation from mechanical ventilation, and detect adverse events associated with respiratory failure and mechanical ventilation. These parameters include gas exchange, neuromuscular activity, respiratory mechanics, and patient effort.

Arterial Blood Gases

Blood gas analysis may provide useful information when caring for patients with respiratory failure. However, even in the absence of respiratory failure or the need for mechanical ventilation, blood gas determinations also can be valuable to detect alterations in acid-base balance due to low Q_T, sepsis, renal failure, severe trauma, medication or drug overdose, or altered mental status. Arterial blood can be analyzed for pH, Po_2, Pco_2, HCO_3^- concentration and calculated base deficit. When indicated, carboxyhemoglobin and methemoglobin levels also can be measured. In recent years, efforts have been made to decrease the unnecessary use of arterial blood gas analysis. Serial arterial blood gas determinations are not necessary for routine weaning from mechanical ventilation in the majority of postoperative patients.

Most bedside blood gas analyses still involve removal of an aliquot of blood from the patient, although continuous bedside arterial blood gas determinations are now possible without sampling via an indwelling arterial catheter that contains a biosensor. In studies comparing the accuracy of continuous arterial blood gas and pH monitoring with a conventional laboratory blood gas analyzer, excellent agreement between the two methods has been demonstrated.[45] Continuous monitoring can reduce the volume of blood loss due to phlebotomy and dramatically decrease the time necessary to obtain blood gas results. Continuous monitoring, however, is expensive and is not widely employed.

Determinants of Oxygen Delivery

The primary goal of the cardiovascular and respiratory systems is to deliver oxygenated blood to the tissues. DO_2 is dependent to a greater degree on the oxygen saturation of hemoglobin (Hgb) in arterial blood (Sao_2) than on the partial pressure of oxygen in arterial blood (Pao_2). DO_2 also is dependent on Q_T and Hgb. Dissolved oxygen in blood, which is proportional to the PaO_2, makes only a negligible contribution to DO_2, as is apparent from the equation:

$$DO_2 = Q_T \times [(Hgb \times Sao_2 \times 1.36) + (Pao_2 \times 0.0031)]$$

Sao_2 in mechanically ventilated patients depends on the mean airway pressure, the fraction of inspired oxygen (FIo_2),and SVO_2. Thus, when Sao_2 is low, the clinician has only a limited number of ways to improve this parameter. The clinician can increase mean airway pressure by increasing positive-end expiratory pressure (PEEP) or inspiratory time. FIo_2 can be increased to a maximum of 1.0 by decreasing the amount of room air mixed with the oxygen supplied to the ventilator. SVO_2 can be increased by increasing Hgb or Q_T or decreasing oxygen utilization (e.g., by administering a muscle relaxant and sedation).

Peak and Plateau Airway Pressure

Airway pressures routinely are monitored in mechanically ventilated patients. The peak airway pressure measured at the end of inspiration (P_{peak}) is a function of the tidal volume, the resistance of the airways, lung/chest wall compliance, and peak inspiratory flow. The airway pressure measured at the end of inspiration when the inhaled volume is held in the lungs by briefly closing the expiratory valve is termed *the plateau airway pressure* ($P_{plateau}$). As a static parameter, plateau airway pressure is independent of the airway resistance and peak airway flow, and is related to the lung/chest wall compliance and delivered tidal volume. Mechanical ventilators monitor P_{peak} with each breath and can be set to trigger an alarm if the P_{peak} exceeds a predetermined threshold. $P_{plateau}$ is not measured routinely with each delivered tidal volume, but rather is measured intermittently by setting the ventilator to close the exhalation circuit briefly at the end of inspiration and record the airway pressure when airflow is zero.

If both P_{peak} and $P_{plateau}$ are increased (and tidal volume is not excessive), then the underlying problem is a decrease in the compliance in the lung/chest wall unit. Common causes of this problem include pneumothorax, hemothorax, lobar atelectasis, pulmonary edema, pneumonia, acute respiratory distress

syndrome (ARDS), active contraction of the chest wall or diaphragmatic muscles, abdominal distention, and intrinsic PEEP, such as occurs in patients with bronchospasm and insufficient expiratory times. When P_{peak} is increased but $P_{plateau}$ is relatively normal, the primary problem is an increase in airway resistance, such as occurs with bronchospasm, use of a small-caliber endotracheal tube, or kinking or obstruction of the endotracheal tube. A low P_{peak} also should trigger an alarm, as it suggests a discontinuity in the airway circuit involving the patient and the ventilator.

Ventilator-induced lung injury (VILI) is now an established clinical entity of great relevance to the care of critically ill patients. Excessive airway pressure and tidal volume adversely affect pulmonary and possibly systemic responses to critical illness. Subjecting the lung parenchyma to excessive pressure, known as *barotrauma*, can result in parenchymal lung injury, diffuse alveolar damage similar to ARDS, and pneumothorax, and can impair venous return and therefore limit cardiac output. Lung-protective ventilation strategies have been developed to prevent the development of VILI and improve patient outcomes. In a large, multicenter randomized trial of patients with ARDS from a variety of etiologies, limiting plateau airway pressure to less than 30 cm H_2O and tidal volume to less than 6 mL/kg of ideal body weight reduced 28-day mortality by 22% relative to a ventilator strategy that used a tidal volume of 12 mL/kg.[46] For this reason, monitoring of plateau pressure and using a low tidal volume strategy in patients with ARDS is now the standard of care. Recent data also suggest that a lung-protective ventilation strategy is associated with improved clinical outcomes in ventilated patients without ARDS.[47]

Pulse Oximetry

The pulse oximeter is a microprocessor-based device that integrates oximetry and plethysmography to provide continuous noninvasive monitoring of the oxygen saturation of arterial blood (Sao_2). It is considered one of the most important and useful technologic advances in patient monitoring. Continuous, noninvasive monitoring of arterial oxygen saturation is possible using light-emitting diodes and sensors placed on the skin. Pulse oximetry employs two wavelengths of light (i.e., 660 nm and 940 nm) to analyze the pulsatile component of blood flow between the light source and sensor. Because oxyhemoglobin and deoxyhemoglobin have different absorption spectra, differential absorption of light at these two wavelengths can be used to calculate the fraction of oxygen saturation of hemoglobin. Under normal circumstances, the contributions of carboxyhemoglobin and methemoglobin are minimal. However, if carboxyhemoglobin levels are elevated, the pulse oximeter will incorrectly interpret carboxyhemoglobin as oxyhemoglobin and the arterial saturation displayed will be falsely elevated. When the concentration of methemoglobin is markedly increased, the Sao_2 will be displayed as 85%, regardless of the true arterial saturation.[48] The accuracy of pulse oximetry begins to decline at Sao_2 values less than 92%, and tends to be unreliable for values less than 85%.[49]

Several studies have assessed the frequency of arterial oxygen desaturation in hospitalized patients and its effect on outcome. Monitoring pulse oximetry in surgical patients is associated with a reduction in unrecognized deterioration, rescue events and transfers to the ICU.[50] Because of its clinical relevance, ease of use, noninvasive nature, and cost-effectiveness, pulse oximetry has become a routine monitoring strategy in patients with respiratory disease, intubated patients, and those undergoing surgical intervention under sedation or general anesthesia. Pulse oximetry is especially useful in the titration of FIO_2 and PEEP for patients receiving mechanical ventilation, and during weaning from mechanical ventilation. The widespread use of pulse oximetry has decreased the need for arterial blood gas determinations in critically ill patients.

Capnometry

Capnometry is the measurement of carbon dioxide in the airway throughout the respiratory cycle. Capnometry is most commonly measured by infrared light absorption. CO_2 absorbs infrared light at a peak wavelength of approximately 4.27 μm. Capnometry works by passing infrared light through a sample chamber to a detector on the opposite side. More infrared light passing through the sample chamber (i.e., less CO_2) causes a larger signal in the detector relative to the infrared light passing through a reference cell. Capnometric determination of the partial pressure of CO_2 in end-tidal exhaled gas ($PETCO_2$) is used as a surrogate for the partial pressure of CO_2 in arterial blood ($PaCO_2$) during mechanical ventilation. In healthy subjects, $PETCO_2$ is about 1 to 5 mm Hg less than $PaCO_2$.[51] Thus, $PETCO_2$ can be used to estimate $PaCO_2$ without the need for blood gas determination. However, changes in $PETCO_2$ may not correlate with changes in $PaCO_2$ during a number of pathologic conditions (see next).

Capnography allows the confirmation of endotracheal intubation and continuous assessment of ventilation, integrity of the airway, operation of the ventilator, and cardiopulmonary function. Capnometers are configured with either an in-line sensor or a sidestream sensor. The sidestream systems are lighter and easy to use, but the thin tubing that samples the gas from the ventilator circuit can become clogged with secretions or condensed water, preventing accurate measurements. The in-line devices are bulky and heavier, but are less likely to become clogged. Continuous monitoring with capnography has become routine during surgery under general anesthesia and for some intensive care patients. A number of situations can be promptly detected with continuous capnography. A sudden reduction in $PETCO_2$ suggests either obstruction of the sampling tubing with water or secretions, or a catastrophic event such as loss of the airway, airway disconnection or obstruction, ventilator malfunction, or a marked decrease in Q_T. If the airway is connected and patent and the ventilator is functioning properly, then a sudden decrease in $PETCO_2$ should prompt efforts to rule out cardiac arrest, massive pulmonary embolism, or cardiogenic shock. $PETCO_2$ can be persistently low during hyperventilation or with an increase in dead space such as occurs with pulmonary embolization (even in the absence of a change in Q_T). Causes of an increase in $PETCO_2$ include reduced minute ventilation or increased metabolic rate.

RENAL MONITORING

Urine Output

Bladder catheterization with an indwelling catheter allows the monitoring of urine output, usually recorded hourly by the nursing staff. With a patent Foley catheter, urine output is a gross indicator of renal perfusion. The generally accepted normal urine output is 0.5 mL/kg per hour for adults and 1 to 2 mL/kg per hour for neonates and infants. Oliguria may reflect inadequate renal artery perfusion due to hypotension, hypovolemia, or low Q_T. Low urine flow also can be a sign of intrinsic renal

dysfunction. It is important to recognize that normal urine output does not exclude the possibility of impending renal failure.

Bladder Pressure

The triad of oliguria, elevated peak airway pressures, and elevated intra-abdominal pressure is known as the abdominal compartment syndrome (ACS). This syndrome, first described in patients after repair of ruptured abdominal aortic aneurysm, is associated with interstitial edema of the abdominal organs, resulting in elevated intra-abdominal pressure (IAP). When IAP exceeds venous or capillary pressures, perfusion of the kidneys and other intra-abdominal viscera is impaired. Oliguria is a cardinal sign. While the diagnosis of ACS is a clinical one, measuring IAP is useful to confirm the diagnosis. Ideally, a catheter inserted into the peritoneal cavity could measure IAP to substantiate the diagnosis. In practice, transurethral bladder pressure measurement reflects IAP and is most often used to confirm the presence of ACS. After instilling 50 to 100 mL of sterile saline into the bladder via a Foley catheter, the tubing is connected to a transducing system to measure bladder pressure. Intra-abdominal hypertension is defined as an IAP ≥ 12 mm Hg recorded on three standard measurements conducted 4 to 6 hours apart, while the diagnosis of ACS is the presence of an IAP ≥ 20 mm Hg recorded by three measurements 1 to 6 hours apart.[52,60] Less commonly, gastric or inferior vena cava pressures can be monitored with appropriate catheters to detect elevated intra-abdominal pressures.

NEUROLOGIC MONITORING

Intracranial Pressure

Because the brain is rigidly confined within the bony skull, cerebral edema or mass lesions increase intracranial pressure (ICP). Monitoring of ICP currently is recommended in patients with severe traumatic brain injury (TBI), defined as a Glasgow Coma Scale (GCS) score less than or equal to 8 with an abnormal CT scan, and in patients with severe TBI and a normal CT scan if two or more of the following are present: age greater than 40 years, unilateral or bilateral motor posturing, or systolic blood pressure less than 90 mm Hg.[53] ICP monitoring also is indicated in patients with acute subarachnoid hemorrhage with coma or neurologic deterioration, intracranial hemorrhage with intraventricular blood, ischemic middle cerebral artery stroke, fulminant hepatic failure with coma and cerebral edema on CT scan, and global cerebral ischemia or anoxia with cerebral edema on CT scan. The goal of ICP monitoring is to ensure that cerebral perfusion pressure (CPP) is adequate to support perfusion of the brain. CPP is equal to the difference between MAP and ICP: CPP = MAP – ICP.

One type of ICP measuring device, the ventriculostomy catheter, consists of a fluid-filled catheter inserted into a cerebral ventricle and connected to an external pressure transducer. This device permits measurement of ICP, but also allows drainage of cerebrospinal fluid (CSF) as a means to lower ICP and sample CSF for laboratory studies. Other devices locate the pressure transducer within the central nervous system and are used only to monitor ICP. These devices can be placed in the intraventricular, parenchymal, subdural, or epidural spaces. Ventriculostomy catheters are the accepted standard for monitoring ICP in patients with TBI due to their accuracy, ability to drain CSF, and low complication rate. The associated complications include infection (5%), hemorrhage (1.1%), catheter malfunction or obstruction (6.3%–10.5%), and malposition with injury to cerebral tissue.[54]

The purpose of ICP monitoring is to detect and treat abnormal elevations of ICP that may be detrimental to cerebral perfusion and function. In TBI patients, ICP >20 mm Hg is associated with unfavorable outcomes.[55] However, few studies have shown that treatment of elevated ICP improves clinical outcomes in human trauma patients. In a randomized, controlled, double-blind trial, Eisenberg and colleagues demonstrated that maintaining ICP less than 25 mm Hg in patients without craniectomy and less than 15 mm Hg in patients with craniectomy is associated with improved outcome.[56] In patients with low CPP, therapeutic strategies to correct CPP can be directed at increasing MAP, decreasing ICP, or both. While it has been recommended that CPP be maintained between 50 and 70 mm Hg, the evidence to support this recommendation is not overly compelling.[57] Furthermore, a retrospective cohort study of patients with severe TBI found that ICP/CPP-targeted neuro-intensive care was associated with prolonged mechanical ventilation and increased therapeutic interventions, without evidence for improved outcome in patients who survive beyond 24 hours.[58]

Electroencephalogram and Evoked Potentials

Electroencephalogram offers the capacity to monitor global neurologic electrical activity, while evoked potential monitoring can assess pathways not detected by the conventional EEG. Continuous EEG (CEEG) monitoring in the intensive care unit (ICU) permits ongoing evaluation of cerebral cortical activity. It is especially useful in obtunded and comatose patients. CEEG also is useful for monitoring of therapy for status epilepticus and detecting early changes associated with cerebral ischemia. CEEG can be used to adjust the level of sedation, especially if high-dose barbiturate therapy is being used to manage elevated ICP. Somatosensory and brain stem evoked potentials are less affected by the administration of sedatives than is the EEG. Evoked potentials are useful for localizing brain stem lesions or proving the absence of such structural lesions in cases of metabolic or toxic coma. They also can provide prognostic data in posttraumatic coma.

An advance in EEG monitoring is the use of the bispectral index (BIS) to titrate the level of sedative medications. While sedative drugs are usually titrated to the clinical neurologic examination, the BIS device has been used in the operating room to continuously monitor the depth of anesthesia. The BIS is an empirical measurement statistically derived from a database of over 5000 EEGs.[59] The BIS is derived from bifrontal EEG recordings and analyzed for burst suppression ratio, relative alpha:beta ratio, and bicoherence. Using a multivariate regression model, a linear numeric index (BIS) is calculated, ranging from 0 (isoelectric EEG) to 100 (fully awake). Its use has been associated with lower consumption of anesthetics during surgery and earlier awakening and faster recovery from anesthesia.[60] The BIS also has been validated as a useful approach for monitoring the level of sedation for ICU patients, using the revised Sedation-Agitation Scale as a gold standard.[61]

Transcranial Doppler Ultrasonography

This modality provides a noninvasive method for evaluating cerebral hemodynamics. Transcranial Doppler (TCD) measurements of middle and anterior cerebral artery blood flow velocity are useful for the diagnosis of cerebral vasospasm after subarachnoid hemorrhage. Qureshi et al demonstrated that an increase in the middle cerebral artery mean flow velocity as

assessed by TCD is an independent predictor of symptomatic vasospasm in a prospective study of patients with aneurysmal subarachnoid hemorrhage.[62] In addition, while some have proposed using TCD to estimate ICP, studies have shown that TCD is not a reliable method for estimating ICP and CPP, and currently cannot be endorsed for this purpose.[63] TCD also is useful to confirm the clinical examination for determining brain death in patients with confounding factors such as the presence of CNS depressants or metabolic encephalopathy.

Jugular Venous Oximetry

When the arterial oxygen content, hemoglobin concentration, and the oxyhemoglobin dissociation curve are constant, changes in jugular venous oxygen saturation (Sjo_2) reflect changes in the difference between cerebral oxygen delivery and demand. Generally, a decrease in Sjo_2 reflects cerebral hypoperfusion, whereas an increase in Sjo_2 indicates the presence of hyperemia. Sjo_2 monitoring cannot detect decreases in regional cerebral blood flow if overall perfusion is normal or above normal. This technique requires the placement of a catheter in the jugular bulb, usually via the internal jugular vein. Catheters that permit intermittent aspiration of jugular venous blood for analysis or continuous oximetry catheters are available.

Low Sjo_2 is associated with poor outcomes after TBI.[64] Nevertheless, the value of monitoring Sjo_2 remains unproven. If it is employed, it should not be the sole monitoring technique, but rather should be used in conjunction with ICP and CPP monitoring. By monitoring ICP, CPP, and Sjo_2, early intervention with volume, vasopressors, and hyperventilation has been shown to prevent ischemic events in patients with TBI.[65]

Transcranial Near-Infrared Spectroscopy

Transcranial near-infrared spectroscopy (NIRS) is a noninvasive continuous monitoring method to determine cerebral oxygenation. It employs technology similar to that of pulse oximetry to determine the concentrations of oxy- and deoxyhemoglobin with near-infrared light and sensors, and takes advantage of the relative transparency of the skull to light in the near-infrared region of the spectrum. Continuous monitoring of cerebral perfusion via transcranial NIRS may provide a method to detect early cerebral ischemia in patients with traumatic brain injury.[66] Nevertheless, this form of monitoring remains largely a research tool at the present time.

Brain Tissue Oxygen Tension

While the standard of care for patients with severe TBI includes ICP and CPP monitoring, this strategy does not always prevent secondary brain injury. Growing evidence suggests that monitoring local brain tissue oxygen tension ($PbtO_2$) may be a useful adjunct to ICP monitoring in these patients. Normal values for $PbtO_2$ are 20 to 40 mm Hg, and critical levels are 8 to 10 mm Hg. A recent clinical study sought to determine whether the addition of a $PbtO_2$ monitor to guide therapy in severe traumatic brain injury was associated with improved patient outcomes.[67] Twenty-eight patients with severe traumatic brain injury (GCS score ≤8) were enrolled in an observational study at a level I trauma center. These patients received invasive ICP and $PbtO_2$monitoring and were compared with 25 historical controls matched for age, injuries, and admission GCS score that had undergone ICP monitoring alone. Goals of therapy in both groups included maintaining an ICP <20 mm Hg and a CPP >60 mm Hg. Among patients with $PbtO_2$ monitoring, therapy also was directed at maintaining $PbtO_2$>25 mm Hg. The groups had similar mean daily ICP and CPP levels. The mortality rate in the historical controls treated with standard ICP and CPP management was 44%. Mortality was significantly lower in the patients who had therapy guided by $PbtO_2$ monitoring in addition to ICP and CPP (25%; $P<0.05$). The benefits of $PbtO_2$ monitoring may include the early detection of brain tissue ischemia despite normal ICP and CPP. In addition, $PbtO_2$-guided management may reduce potential adverse effects associated with therapies to maintain ICP and CPP.

CONCLUSIONS

Modern intensive care is predicated by the need and ability to continuously monitor a wide range of physiologic parameters. This capability has dramatically improved the care of critically ill patients and advanced the development of the specialty of critical care medicine. In some cases, the technological ability to measure such variables has surpassed our understanding of the significance or the knowledge of the appropriate intervention to ameliorate such pathophysiologic changes. In addition, the development of less invasive monitoring methods has been promoted by the recognition of complications associated with invasive monitoring devices. The future portends the continued development of noninvasive monitoring devices along with their application in an evidenced-based strategy to guide rational therapy.

chapter 14

Minimally Invasive Surgery, Robotics, Natural Orifice Transluminal Endoscopic Surgery, and Single-Incision Laparoscopic Surgery

Donn H. Spight, John G. Hunter, and Blair A. Jobe

INTRODUCTION

Minimally invasive surgery describes an area of surgery that crosses all traditional disciplines, from general surgery to neurosurgery. It is not a discipline unto itself, but more a philosophy of surgery, a way of thinking. Minimally invasive surgery is a means of performing major operations through small incisions, often using miniaturized, high-tech imaging systems, to minimize the trauma of surgical exposure. Some believe that the term *minimal access surgery* more accurately describes the small incisions generally necessary to gain access to surgical sites in high-tech surgery, but John Wickham's term *minimally invasive surgery* (MIS) is widely used because it describes the paradox of postmodern high-tech surgery—small holes, big operations.

Robotic surgery today is practiced using a single platform (Intuitive, Inc., Sunnyvale, CA) and should better be termed *computer-enhanced surgery* because the term *robotics* assumes autonomous action that is not a feature of the da Vinci robotic system. Instead, the da Vinci robot couples an ergonomic workstation that features stereoptic video imaging and intuitive micromanipulators (surgeon side) with a set of arms delivering specialized laparoscopic instruments enhanced with more degrees of freedom than are allowed by laparoscopic surgery alone (patient side). A computer between the surgeon side and patient side removes surgical tremor and scales motion to allow precise microsurgery, which is helpful for microdissection and difficult anastomoses.

Single-incision laparoscopic surgery (SILS), also called laparoendoscopic single-site surgery (LESS), is a recent addition to the armamentarium of the minimally invasive surgeon. As public awareness has grown, so too has its spread outside of larger institutions. SILS challenges the well-established paradigm of standard laparoscopic surgery by placing multiple trocars within the fascia at the umbilicus or through a single multichannel trocar at the umbilicus. The manipulation of tightly spaced instruments across the fulcrum of the abdominal wall requires that the surgeon either operate in a crossed hands fashion or use specialized curved instruments to avoid clashing outside the body while working intra-abdominally. The primary advantage of SILS is the reduction to one surgical scar. Greater efficacy, safety, and cost savings have yet to be fully elucidated in the increasing number of procedures that are being attempted in this manner. The advent of a robotic SILS platform now enables the computer reassignment of the surgeon's hands, thus eliminating the difficult ergonomic challenges making the technique far more accessible.

Natural orifice transluminal endoscopic surgery (NOTES) is an extension of interventional endoscopy. Using the mouth, anus, vagina, and urethra (natural orifices), flexible endoscopes are passed through the wall of the esophagus, stomach, colon, bladder, or vagina entering the mediastinum, the pleural space, or the peritoneal cavity. The advantage of this method of minimal access is principally the elimination of the scar associated with laparoscopy or thoracoscopy. Other advantages have yet to be elucidated, including pain reduction, need for hospitalization, and cost savings.

HISTORICAL BACKGROUND

Although the term *minimally invasive surgery* is relatively recent, the history of its component parts is nearly 100 years old. What is considered the newest and most popular variety

Key Points

1. Minimally invasive surgery describes a philosophical approach to surgery in which access trauma is minimized without compromising the quality of the surgical procedure.
2. The carbon dioxide pneumoperitoneum used for laparoscopy induces some unique pathophysiologic consequences.
3. Robotic surgery has been most valuable in the pelvis for performance of minimally invasive prostatectomy and gynecologic and fertility procedures.
4. Natural orifice transluminal endoscopic surgery represents a new opportunity to develop truly scar-free surgery.
5. Single-incision laparoscopic surgery reduces the amount of abdominal wall trauma but presents unique challenges to the traditional tenets of laparoscopic ergonomics.
6. Laparoscopy during pregnancy is best performed in the second trimester and is safe if appropriate monitoring is performed.
7. Laparoscopic surgery for cancer is also appropriate if good tissue handling techniques are maintained.
8. Training for laparoscopy requires practice outside of the operating room in a simulation laboratory.

of MIS, laparoscopy, is, in fact, the oldest. Primitive laparoscopy, placing a cystoscope within an inflated abdomen, was first performed by Kelling in 1901.[1] Illumination of the abdomen required hot elements at the tip of the scope and was dangerous. In the late 1950s, Hopkins described the rod lens, a method of transmitting light through a solid quartz rod with no heat and little light loss.[1] Around the same time, thin quartz fibers were discovered to be capable of trapping light internally and conducting it around corners, opening the field of fiber optics and allowing the rapid development of flexible endoscopes.[2,3] In the 1970s, the application of flexible endoscopy grew faster than that of rigid endoscopy except in a few fields such as gynecology and orthopedics.[4] By the mid-1970s, rigid and flexible endoscopes made a rapid transition from diagnostic instruments to therapeutic ones. The explosion of video-assisted surgery in the past 20 years was a result of the development of compact, high-resolution, charge-coupled devices (CCDs) that could be mounted on the internal end of flexible endoscopes or on the external end of a Hopkins telescope. Coupled with bright light sources, fiber-optic cables, and high-definition video monitors, the videoendoscope has changed our understanding of surgical anatomy and reshaped surgical practice.

Flexible endoscopic imaging started in the 1960s with the first bundling of many quartz fibers into bundles, one for illumination and one for imaging. The earliest upper endoscopes revolutionized the diagnosis and treatment of gastroesophageal reflux and peptic ulcer disease and made possible early detection of upper and lower gastrointestinal (GI) cancer at a stage that could be cured. The first endoscopic surgical procedure was the colonoscopic polypectomy, developed by Shinya and Wolfe, two surgeons from New York City. The percutaneous endoscopic gastrostomy (PEG) invented by Gauderer and Ponsky may have been the first NOTES procedure, reported in 1981.[5] Endoscopic pancreatic pseudocyst drainage is thought to be the next NOTES procedure developed; however, there was little energy and money put into the development of NOTES until a number of gastroenterologists claimed the ability to remove the gallbladder with a flexible endoscope, using a transgastric technique. With this pronouncement, the surgical community took notice and seized the momentum for NOTES research and development. Today most intra-abdominal NOTES procedures remain within the realm of research or incorporate a hybrid laparoscopic technique outside of highly specialized centers. Clinically the transvaginal approach has been studied the most extensively. Evaluation of 551 female patients from the German NOTES registry has shown conversion and complication rates similar to conventional laparoscopic surgery for cholecystectomy and appendectomy procedures.[6] Endoscopic mucosal resection (EMR) of early-stage esophageal and gastric lesions has revolutionized the management of these malignancies. The peroral endoscopic myotomy (POEM) procedure for achalasia is showing clinical efficacy and gaining popularity.

As the race to minimize the size and increase the functionality of laparoscopic instruments progressed, the notion of using fewer access points to accomplish the same operations resulted in the development of *single-incision laparoscopic surgery* (SILS), synonymously termed *laparoendoscopic single-site surgery* (LESS). Viewed as a progression of laparoscopic surgery, SILS has recently garnered greater enthusiasm over its transvisceral NOTES counterpart.[7] Currently the single-incision technique is used regularly across a wide variety of surgical areas including general, urologic, gynecologic, colorectal, and bariatric surgery.[8] Although optical imaging produced the majority of MIS procedures, other (traditionally radiologic) imaging technologies allowed the development of innovative procedures in the 1970s. Fluoroscopic imaging allowed the adoption of percutaneous vascular procedures, the most revolutionary of which was balloon angioplasty. Balloon-based procedures spread into all fields of medicine used to open up clogged lumens with minimal access. Stents were then developed that were used in many disciplines to keep the newly ballooned segment open. The culmination of fluoroscopic balloon and stent proficiency is exemplified by the transvenous intrahepatic portosystemic shunt and by the aortic stent graft, which has nearly replaced open elective abdominal aortic aneurysm repair.

MIS procedures using ultrasound imaging have been limited to fairly crude exercises, such as fragmenting kidney stones and freezing liver tumors, because of the relatively low resolution of ultrasound devices. Newer, high-resolution ultrasound methods with high-frequency crystals may act as a guide while performing minimally invasive resections of individual layers of the intestinal wall.

Axial imaging, such as computed tomography (CT), has allowed the development of an area of MIS that often is not recognized because it requires only a CT scanner and a long needle. CT-guided drainage of abdominal fluid collections and percutaneous biopsy of abnormal tissues are minimally invasive

means of performing procedures that previously required a celiotomy. CT-guided percutaneous radiofrequency (RF) ablation has emerged as a useful treatment for primary and metastatic liver tumors. This procedure also is performed laparoscopically under ultrasound guidance.[9]

A powerful, noninvasive method of imaging that will allow the development of the least invasive—and potentially noninvasive—surgery is magnetic resonance imaging (MRI). MRI is an extremely valuable diagnostic tool, but it is only slowly coming to be of therapeutic value. One obstacle to the use of MRI for MIS is that image production and refreshment of the image as a procedure progresses are slow. Another is that all instrumentation must be nonmetallic when working with the powerful magnets of an MRI scanner. Moreover, MRI magnets are bulky and limit the surgeon's access to the patient. Open magnets have been developed that allow the surgeon to stand between two large MRI coils, obtaining access to the portion of the patient being scanned. The advantage of MRI, in addition to the superb images produced, is that there is no radiation exposure to patient or surgeon. Some neurosurgeons are accumulating experience using MRI to perform frameless stereotactic surgery.

Robotic surgery has been dreamed about for some time, and many science fiction–like devices have been developed over the years to provide mechanical assistance for the surgeon. The first computer-assisted robot was designed to accurately drill femoral shaft bone for wobble-free placement of hip prostheses. Although the concept was appealing, the robot proved no better than a skilled orthopedic surgeon and was a good deal slower. Following this, the first and only two commercially successful robots for laparoscopic surgery were developed in California. Computer Motion, founded by Yulun Wang in Santa Barbara, used National Science Foundation funds to create a mechanical arm, the Aesop robot, which held and moved the laparoscope with voice, foot, or hand control. In Northern California, a master-slave system first developed for surgery on the multinational space station by Philip Green was purchased by Fred Moll and Lonnie Smith, and then reengineered with the surgeon in mind to create a remarkably intuitive computer-enhanced surgical platform. The company, Intuitive Surgical, was aptly named, and their primary product, the da Vinci robot, is currently the only major robotic platform on the market. Although eschewed by many experienced laparoscopists, the da Vinci achieved a toehold among many skilled surgeons who found that the robot could facilitate MIS procedures that were difficult with standard laparoscopic procedures. The latest iteration of the da Vinci platform released in 2009 features high-definition, three-dimensional vision and a dual-console capability allowing greater visualization, assistance, and instruction capabilities.

PHYSIOLOGY AND PATHOPHYSIOLOGY OF MINIMALLY INVASIVE SURGERY

Even with the least invasive of the MIS procedures, physiologic changes occur. Many minimally invasive procedures require minimal or no sedation, and there are few adverse consequences to the cardiovascular, endocrinologic, or immunologic systems. The least invasive of such procedures include stereotactic biopsy of breast lesions and flexible GI endoscopy. Minimally invasive procedures that require general anesthesia have a greater physiologic impact because of the anesthetic agent, the incision (even if small), and the induced pneumoperitoneum.

Laparoscopy

The unique feature of laparoscopic surgery is the need to lift the abdominal wall from the abdominal organs. Two methods have been devised for achieving this.[10] The first, used by most surgeons, is a pneumoperitoneum. Throughout the early twentieth century, intraperitoneal visualization was achieved by inflating the abdominal cavity with air, using a sphygmomanometer bulb.[11] The problem with using air insufflation is that nitrogen is poorly soluble in blood and is slowly absorbed across the peritoneal surfaces. Air pneumoperitoneum was believed to be more painful than nitrous oxide (N_2O) pneumoperitoneum, but less painful than carbon dioxide (CO_2) pneumoperitoneum. 2▶ Subsequently, CO_2 and N_2O were used for inflating the abdomen. N_2O had the advantage of being physiologically inert and rapidly absorbed. It also provided better analgesia for laparoscopy performed under local anesthesia when compared with CO_2 or air.[12] Despite initial concerns that N_2O would not suppress combustion, controlled clinical trials have established its safety within the peritoneal cavity.[13] In addition, N_2O has been shown to reduce the intraoperative end-tidal CO_2 and minute ventilation required to maintain homeostasis when compared to CO_2 pneumoperitoneum.[13] The effect of N_2O on tumor biology and the development of port site metastasis are unknown. As such, caution should be exercised when performing laparoscopic cancer surgery with this agent. Finally, the safety of N_2O pneumoperitoneum in pregnancy has yet to be elucidated.

The physiologic effects of CO_2 pneumoperitoneum can be divided into two areas: (a) gas-specific effects and (b) pressure-specific effects (Fig. 14-1). CO_2 is rapidly absorbed across the peritoneal membrane into the circulation. In the circulation, CO_2 creates a respiratory acidosis by the generation of carbonic acid.[14] Body buffers, the largest reserve of which lies in bone, absorb CO_2 (up to 120 L) and minimize the development of hypercarbia or respiratory acidosis during brief endoscopic procedures.[14] Once the body buffers are saturated, respiratory acidosis develops rapidly, and the respiratory system assumes the burden of keeping up with the absorption of CO_2 and its release from these buffers.

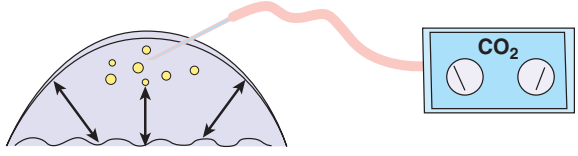

Figure 14-1. Carbon dioxide gas insufflated into the peritoneal cavity has both local and systemic effects that cause a complex set of hemodynamic and metabolic alterations. *(Reproduced with permission from Hunter JG, ed.* Bailliere's Clinical Gastroenterology Laparoscopic Surgery. *London/Philadelphia: Bailliere Tindall; 1993:758. Copyright Elsevier.)*

In patients with normal respiratory function, this is not difficult; the anesthesiologist increases the ventilatory rate or vital capacity on the ventilator. If the respiratory rate required exceeds 20 breaths per minute, there may be less efficient gas exchange and increasing hypercarbia.[15] Conversely, if vital capacity is increased substantially, there is a greater opportunity for barotrauma and greater respiratory motion–induced disruption of the upper abdominal operative field. In some situations, it is advisable to evacuate the pneumoperitoneum or reduce the intra-abdominal pressure to allow time for the anesthesiologist to adjust for hypercarbia.[16] Although mild respiratory acidosis probably is an insignificant problem, more severe respiratory acidosis leading to cardiac arrhythmias has been reported.[17] Hypercarbia also causes tachycardia and increased systemic vascular resistance, which elevates blood pressure and increases myocardial oxygen demand.[14,17]

The pressure effects of the pneumoperitoneum on cardiovascular physiology also have been studied. In the hypovolemic individual, excessive pressure on the inferior vena cava and a reverse Trendelenburg position with loss of lower extremity muscle tone may cause decreased venous return and decreased cardiac output.[14,18] This is not seen in the normovolemic patient. The most common arrhythmia created by laparoscopy is bradycardia. A rapid stretch of the peritoneal membrane often causes a vagovagal response with bradycardia and, occasionally, hypotension.[19] The appropriate management of this event is desufflation of the abdomen, administration of vagolytic agents (e.g., atropine), and adequate volume replacement.[20]

With the increased intra-abdominal pressure compressing the inferior vena cava, there is diminished venous return from the lower extremities. This has been well documented in the patient placed in the reverse Trendelenburg position for upper abdominal operations. Venous engorgement and decreased venous return promote venous thrombosis.[21,22] Many series of advanced laparoscopic procedures in which deep venous thrombosis (DVT) prophylaxis was not used demonstrate the frequency of pulmonary embolus. This usually is an avoidable complication with the use of sequential compression stockings, subcutaneous heparin, or low molecular weight heparin.[20,23] In short-duration laparoscopic procedures, such as appendectomy, hernia repair, or cholecystectomy, the risk of DVT may not be sufficient to warrant extensive DVT prophylaxis.

The increased pressure of the pneumoperitoneum is transmitted directly across the paralyzed diaphragm to the thoracic cavity, creating increased central venous pressure and increased filling pressures of the right and left sides of the heart. If the intra-abdominal pressures are kept under 20 mmHg, the cardiac output usually is well maintained.[22–24] The direct effect of the pneumoperitoneum on increasing intrathoracic pressure increases peak inspiratory pressure, pressure across the chest wall, and also, the likelihood of barotrauma. Despite these concerns, disruption of blebs and consequent pneumothoraces are rare after uncomplicated laparoscopic surgery.[24] Pneumothoraces occurring with laparoscopic esophageal surgery may be very significant. The pathophysiology and management are discussed at the end of this section. Increased intra-abdominal pressure decreases renal blood flow, glomerular filtration rate, and urine output. These effects may be mediated by direct pressure on the kidney and the renal vein.[25,26] The secondary effect of decreased renal blood flow is to increase plasma renin release, thereby increasing sodium retention. Increased circulating antidiuretic hormone levels also are found during the pneumoperitoneum, increasing free water reabsorption in the distal tubules.[27] Although the effects of the pneumoperitoneum on renal blood flow are immediately reversible, the hormonally mediated changes such as elevated antidiuretic hormone levels decrease urine output for up to 1 hour after the procedure has ended. Intraoperative oliguria is common during laparoscopy, but the urine output is not a reflection of intravascular volume status; intravenous (IV) fluid administration during an uncomplicated laparoscopic procedure should not be linked to urine output. Because insensible fluid losses through the open abdomen are eliminated with laparoscopy, the need for supplemental fluid during a laparoscopic surgical procedure should only keep up with venous pooling in the lower limbs, third-space losses into the bowel, and blood loss, which is generally less than occurs with an equivalent open operation.

The hemodynamic and metabolic consequences of pneumoperitoneum are well tolerated by healthy individuals for a prolonged period and by most individuals for at least a short period. Difficulties can occur when a patient with compromised cardiovascular function is subjected to a long laparoscopic procedure. It is during these procedures that alternative approaches should be considered or insufflation pressure reduced. Alternative gases that have been suggested for laparoscopy include the inert gases helium, neon, and argon. These gases are appealing because they cause no metabolic effects, but are poorly soluble in blood (unlike CO_2 and N_2O) and are prone to create gas emboli if the gas has direct access to the venous system.[22] Gas emboli are rare but serious complications of laparoscopic surgery.[23,28] They should be suspected if hypotension develops during insufflation. Diagnosis may be made by listening (with an esophageal stethoscope) for the characteristic "mill wheel" murmur. The treatment of gas embolism is to place the patient in a left lateral decubitus position with the head down to trap the gas in the apex of the right ventricle.[23] A rapidly placed central venous catheter then can be used to aspirate the gas out of the right ventricle.

In some situations, minimally invasive abdominal surgery should be performed without insufflation. This has led to the development of an abdominal lift device that can be placed through a 10- to 12-mm trocar at the umbilicus.[29] These devices have the advantage of creating little physiologic derangement, but they are bulky and intrusive. The exposure and working room offered by lift devices also are inferior to those accomplished by pneumoperitoneum. Lifting the anterior abdominal wall reduces space available laterally and thereby displaces the bowel medially and anteriorly into the operative field. A pneumoperitoneum, with its well-distributed intra-abdominal pressure, provides better exposure. Abdominal lift devices also cause more postoperative pain, but they do allow the performance of MIS with standard (nonlaparoscopic) surgical instruments.

Endocrine responses to laparoscopic surgery are not always intuitive. Serum cortisol levels after laparoscopic operations are often higher than after the equivalent operation performed through an open incision.[30] The greatest difference between the endocrine response of open and laparoscopic surgery is the more rapid equilibration of most stress-mediated hormone levels after laparoscopic surgery. Immune suppression also is less after laparoscopy than after open surgery. There is a trend toward more rapid normalization of cytokine levels after a laparoscopic procedure than after the equivalent procedure performed by celiotomy.[31]

Transhiatal mobilization of the distal esophagus is commonly performed as a component of many laparoscopic upper

abdominal procedures. If there is compromise of the mediastinal pleura with resultant CO_2 pneumothorax, the defect should be enlarged so as to prevent a tension pneumothorax. Even with such a strategy, tension pneumothorax may develop, as mediastinal structures may seal the hole during inspiration, allowing the chest to fill during expiration. In addition to enlargement of the hole, a thoracostomy tube (chest tube) should be placed across the breach into the abdomen with intra-abdominal pressures reduced below 8 mmHg, or a standard chest tube may be placed. When a pneumothorax occurs with laparoscopic Nissen fundoplication or Heller myotomy, it is preferable to place an 18-French red rubber catheter with multiple side holes cut out of the distal end across the defect. At the end of the procedure, the distal end of the tube is pulled out a 10-mm port site (as the port is removed), and the pneumothorax is evacuated to a primitive water seal using a bowl of sterile water or saline. During laparoscopic esophagectomy, it is preferable to leave a standard chest tube, as residual intra-abdominal fluid will tend to be siphoned through the defect postoperatively, if the tube is removed at the end of the case.

Thoracoscopy

The physiology of thoracic MIS (thoracoscopy) is different from that of laparoscopy. Because of the bony confines of the thorax, it is unnecessary to use positive pressure when working in the thorax.[32] The disadvantages of positive pressure in the chest include decreased venous return, mediastinal shift, and the need to keep a firm seal at all trocar sites. Without positive pressure, it is necessary to place a double-lumen endotracheal tube so that the ipsilateral lung can be deflated when the operation starts. By collapsing the ipsilateral lung, working space within the thorax is obtained. Because insufflation is unnecessary in thoracoscopic surgery, it can be beneficial to use standard instruments via extended port sites in conjunction with thoracoscopic instruments. This approach is particularly useful when performing advanced procedures such as thoracoscopic anatomic pulmonary resection.

Extracavitary Minimally Invasive Surgery

Many MIS procedures create working spaces in extrathoracic and extraperitoneal locations. Laparoscopic inguinal hernia repair usually is performed in the anterior extraperitoneal Retzius space.[33,34] Laparoscopic nephrectomy often is performed with retroperitoneal laparoscopy. Endoscopic retroperitoneal approaches to pancreatic necrosectomy have seen some limited use.[35] Lower extremity vascular procedures and plastic surgical endoscopic procedures require the development of working space in unconventional planes, often at the level of the fascia, sometimes below the fascia, and occasionally in nonanatomic regions.[36] Some of these techniques use insufflation of gas, but many use balloon inflation to develop the space, followed by low-pressure gas insufflation or lift devices to maintain the space (Fig. 14-2). These techniques produce fewer and less severe adverse physiologic consequences than does the pneumoperitoneum, but the insufflation of carbon dioxide into extraperitoneal locations can spread widely, causing subcutaneous emphysema and metabolic acidosis.

Anesthesia

Proper anesthesia management during laparoscopic surgery requires a thorough knowledge of the pathophysiology of the CO_2 pneumoperitoneum.[20] The laparoscopic surgeon can influence cardiovascular performance by reducing or removing the CO_2 pneumoperitoneum. Insensible fluid losses are negligible, and therefore, IV fluid administration should not exceed that necessary to maintain circulating volume. MIS procedures are often outpatient procedures, so short-acting anesthetic agents are preferable. Because the factors that require hospitalization after laparoscopic procedures include the management of nausea, pain, and urinary retention, the anesthesiologist should minimize the use of agents that provoke these conditions and maximize the use of medications that prevent such problems. Critical to the anesthesia management of these patients is the use of nonnarcotic analgesics (e.g., ketorolac) when hemostasis allows it and the liberal use of antiemetic agents, including ondansetron and steroids.

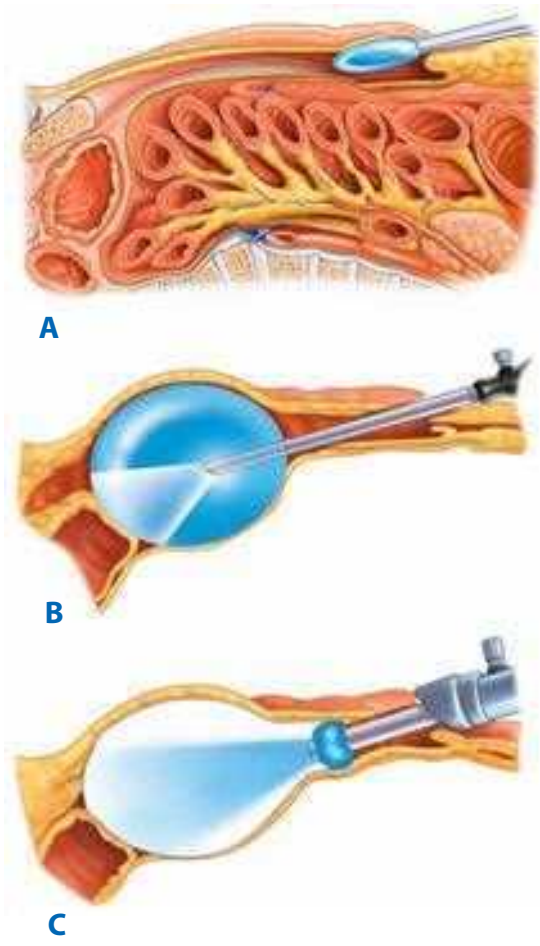

Figure 14-2. Balloons are used to create extra-anatomic working spaces. In this example (**A** through **C**), a balloon is introduced into the space between the posterior rectus sheath and the rectus abdominal muscle. The balloon is inflated in the preperitoneal space to create working room for extraperitoneal endoscopic hernia repair.

The Minimally Invasive Team

From the beginning, the tremendous success of MIS was founded on the understanding that a team approach was necessary. The many laparoscopic procedures performed daily range from basic to advanced complexity, and require that the surgical team have an intimate understanding of the operative conduct (Table 14-1). Minimally invasive procedures require complicated and fragile equipment that demands constant maintenance. In addition, multiple intraoperative adjustments to the equipment, camera, insufflator, monitors, and patient/surgeon

Table 14-1

Laparoscopic surgical procedures

BASIC	ADVANCED	
Appendectomy	Nissen fundoplication	Lymph node dissection
Cholecystectomy	Heller myotomy	Robotics
Hernia repair	Gastrectomy	Stereo imaging
	Esophagectomy	Telemedicine
	Enteral access	Laparoscopy-assisted procedures
	Bile duct exploration	Hepatectomy
	Colectomy	Pancreatectomy
	Splenectomy	Prostatectomy
	Adrenalectomy	Hysterectomy
	Nephrectomy	

position are made during these procedures. As such, a coordinated team approach is mandated to ensure patient safety and excellent outcomes. More and more, flexible endoscopes are used to guide or provide quality control for laparoscopic procedures. As NOTES, SILS, and robotic surgery penetrate the operative theatre, hybrid procedures (laparoscopy and endoscopy) and complicated robotics cases will require a nursing staff capable of maintaining flexible endoscopes and understanding the operation of sophisticated technology.

A typical MIS team may consist of a laparoscopic surgeon and an operating room (OR) nurse with an interest in laparoscopic and endoscopic surgery. Adding dedicated assistants and circulating staff with an intimate knowledge of the equipment will add to and enhance the team nucleus. Studies have demonstrated that having a designated laparoscopic team increases the efficiency and safety of laparoscopic surgery, which is translated into a benefit for patient and hospital.[37]

Room Setup and the Minimally Invasive Suite

Nearly all MIS, whether using fluoroscopic, ultrasound, or optical imaging, incorporates a video monitor as a guide. Occasionally, two images are necessary to adequately guide the operation, as in procedures such as endoscopic retrograde cholangiopancreatography, laparoscopic common bile duct exploration, and laparoscopic ultrasonography. When two images are necessary, the images should be displayed on two adjacent video monitors or projected on a single screen with a picture-in-picture effect. The video monitor(s) should be set across the operating table from the surgeon. The patient should be interposed between the surgeon and the video monitor; ideally, the operative field also lies between the surgeon and the monitor. In pelviscopic surgery, it is best to place the video monitor at the patient's feet, and in laparoscopic cholecystectomy, the monitor is placed at the 10 o'clock position (relative to the patient) while the surgeon stands on the patient's left at the 4 o'clock position. The insufflating and patient-monitoring equipment ideally also is placed across the table from the surgeon, so that the insufflating pressure and the patient's vital signs and end-tidal CO_2 tension can be monitored.

The development of the minimally invasive surgical suite has been a tremendous contribution to the field of laparoscopy

Figure 14-3. An example of a typical minimally invasive surgery suite. All core equipment is located on easily movable consoles.

in that it has facilitated the performance of advanced procedures and techniques (Fig. 14-3). By having the core equipment (monitors, insufflators, and imaging equipment) located within mobile, ceiling-mounted consoles, the surgery team is able to accommodate and make small adjustments rapidly and continuously throughout the procedure. The specifically designed minimally invasive surgical suite serves to decrease equipment and cable disorganization, ease the movements of operative personnel around the room, improve ergonomics, and facilitate the use of advanced imaging equipment such as laparoscopic ultrasound.[38] Although having a minimally invasive surgical suite available is very useful, it is not essential to successfully carry out advanced laparoscopic procedures.

Patient Positioning

Patients usually are placed in the supine position for laparoscopic surgery. When the operative field is the gastroesophageal junction or the left lobe of the liver, it is easiest to operate from between the legs. The legs may be elevated in Allen stirrups or abducted on leg boards to achieve this position. When pelvic procedures are performed, it usually is necessary to place the legs in Allen stirrups to gain access to the perineum. A lateral decubitus position with the table flexed provides the best access to the retroperitoneum when performing nephrectomy or adrenalectomy. For laparoscopic splenectomy, a 45° tilt of the patient provides excellent access to the lesser sac and the lateral peritoneal attachments to the spleen. For thoracoscopic surgery, the patient is placed in the lateral position with table flexion to open the intercostal spaces and the distance between the iliac crest and costal margin (Fig. 14-4). Additional consideration must be made in robotic operations to position the patient appropriately before starting. Clashing of the robotic arms with surrounding equipment or each other can occur if not positioned correctly. Once the robot is docked to the patient, the bed cannot be moved without undocking.

When the patient's knees are to be bent for extended periods or the patient is going to be placed in a reverse Trendelenburg position for more than a few minutes, DVT prophylaxis should be used. Sequential compression of the lower extremities during prolonged (>90 minutes) laparoscopic procedures increases venous return and provides inhibition of thromboplastin activation.

Figure 14-4. Proper padding and protection of pressure points is an essential consideration in laparoscopic and thoracoscopic approaches. In preparation for thoracoscopy, this patient is placed in left lateral decubitus position with the table flexed, which serves to open the intercostal spaces and increase the distance between the iliac crest and the inferior costal margin.

General Principles of Access

The most natural ports of access for MIS and NOTES are the anatomic portals of entry and exit. The nares, mouth, urethra, and anus are used to access the respiratory, GI, and urinary systems. The advantage of using these points of access is that no incision is required. The disadvantages lie in the long distances between the orifice and the region of interest. For NOTES procedures, the vagina may serve as another point of access, entering the abdomen via the posterior cul-de-sac of the pelvis. Similarly, the peritoneal cavity may be reached through the side wall of the stomach or colon.

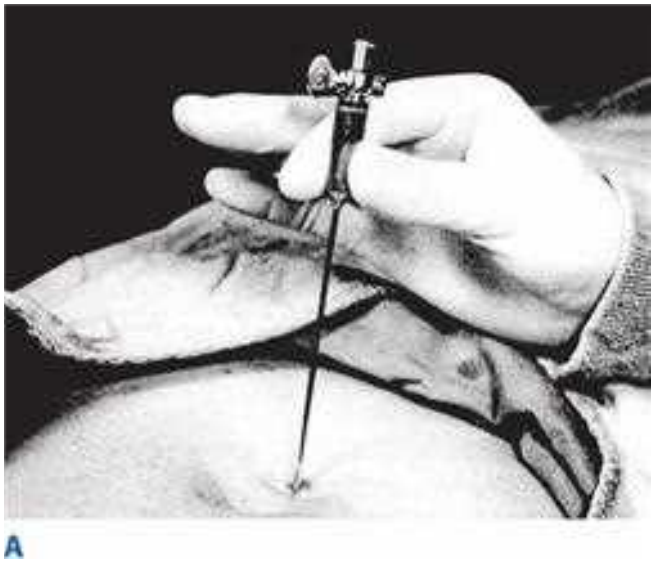
Access to the vascular system may be accomplished under local anesthesia by cutting down and exposing the desired vessel, usually in the groin. Increasingly, vascular access is obtained with percutaneous techniques using a small incision, a needle, and a guidewire, over which are passed a variety of different-sized access devices. This approach, known as the Seldinger technique, is most frequently used by general surgeons for placement of Hickman catheters, but also is used to gain access to the arterial and venous system for performance of minimally invasive procedures. Guidewire-assisted, Seldinger-type techniques also are helpful for gaining access to the gut for procedures such as PEG, for gaining access to the biliary system through the liver, and for gaining access to the upper urinary tract.

In thoracoscopic surgery, the access technique is similar to that used for placement of a chest tube. In these procedures, general anesthesia and single lung ventilation are essential. A small incision is made over the top of a rib and, under direct vision, carried down through the pleura. The lung is collapsed, and a trocar is inserted across the chest wall to allow access with a telescope. Once the lung is completely collapsed, subsequent access may be obtained with direct puncture, viewing all entry sites through the videoendoscope. Because insufflation of the chest is unnecessary, simple ports that keep the small incisions open are all that is required to allow repeated access to the thorax.

Laparoscopic Access

The requirements for laparoscopy are more involved, because the creation of a pneumoperitoneum requires that instruments of access (trocars) contain valves to maintain abdominal inflation.

Two methods are used for establishing abdominal access during laparoscopic procedures.[39,40] The first, direct puncture laparoscopy, begins with the elevation of the relaxed abdominal wall with two towel clips or a well-placed hand. A small incision is made in the umbilicus, and a specialized spring-loaded (Veress) needle is placed in the abdominal cavity (Fig. 14-5). With the Veress needle, two distinct pops are felt as the surgeon passes the needle through the abdominal wall fascia and the peritoneum. The umbilicus usually is selected as the preferred



A

B

Figure 14-5. **A.** Insufflation of the abdomen is accomplished with a Veress needle held at its serrated collar with a thumb and forefinger. **B.** Because the linea alba is fused to the umbilicus, the abdominal wall is grasped with fingers or penetrating towel clip to elevate the abdominal wall away from the underlying structures.

Figure 14-6. It is essential to be able to interpret the insufflator pressure readings and flow rates. These readings indicate proper intraperitoneal placement of the Veress needle.

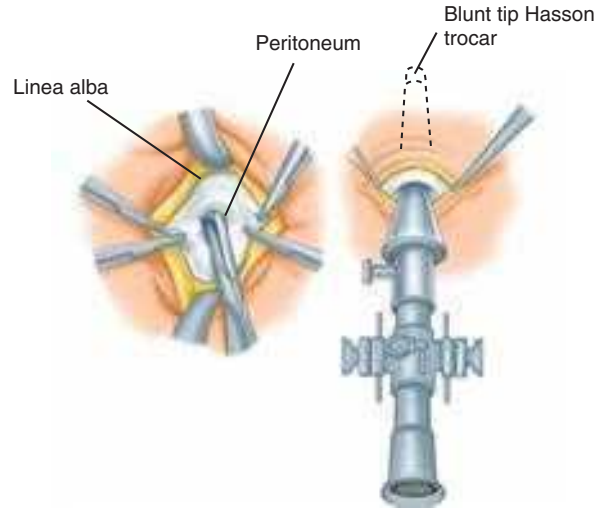


Figure 14-7. The open laparoscopy technique involves identification and incision of the peritoneum, followed by the placement of a specialized trocar with a conical sleeve to maintain a gas seal. Specialized wings on the trocar are attached to sutures placed through the fascia to prevent loss of the gas seal.

point of access because, in this location, the abdominal wall is quite thin, even in obese patients. The abdomen is inflated with a pressure-limited insufflator. CO_2 gas usually is used, with maximal pressures in the range of 14 to 15 mmHg. During the process of insufflation, it is essential that the surgeon observe the pressure and flow readings on the monitor to confirm an intraperitoneal location of the Veress needle tip (Fig. 14-6). Laparoscopic surgery can be performed under local anesthesia, but general anesthesia is preferable. Under local anesthesia, N_2O is used as the insufflating agent, and insufflation is stopped after 2 L of gas is insufflated or when a pressure of 10 mmHg is reached.

After peritoneal insufflation, direct access to the abdomen is obtained with a 5- or 10-mm trocar. The critical issues for safe direct-puncture laparoscopy include the use of a vented stylet for the trocar, or a trocar with a safety shield or dilating tip. The trocar must be pointed away from the sacral promontory and the great vessels.[41] Patient position should be surveyed before trocar placement to ensure a proper trajectory. For performance of laparoscopic cholecystectomy, the trocar is angled toward the right upper quadrant.

Occasionally, the direct peritoneal access (Hasson) technique is advisable.[42] With this technique, the surgeon makes a small incision just below the umbilicus and under direct vision locates the abdominal fascia. Two Kocher clamps are placed on the fascia, and with curved Mayo scissors, a small incision is made through the fascia and underlying peritoneum. A finger is placed into the abdomen to make sure that there is no adherent bowel. A sturdy suture is placed on each side of the fascia and secured to the wings of a specialized trocar, which is then passed directly into the abdominal cavity (Fig. 14-7). Rapid insufflation can make up for some of the time lost with the initial dissection. This technique is preferable for the abdomen of patients who have undergone previous operations in which small bowel may be adherent to the undersurface of the abdominal wound. The close adherence of bowel to the peritoneum in the previously operated abdomen does not eliminate the possibility of intestinal injury but should make great vessel injury extremely unlikely. Because of the difficulties in visualizing the abdominal region immediately adjacent to the primary trocar, it is recommended that the telescope be passed through a secondary trocar to inspect the site of initial abdominal access.[40] Secondary punctures are made with 5- and 10-mm trocars. For safe access to the abdominal cavity, it is critical to visualize all sites of trocar entry.[41,42] At the completion of the operation, all trocars are removed under direct vision, and the insertion sites are inspected for bleeding. If bleeding occurs, direct pressure with an instrument from another trocar site or balloon tamponade with a Foley catheter placed through the trocar site generally stops the bleeding within 3 to 5 minutes. When this is not successful, a full-thickness abdominal wall suture has been used successfully to tamponade trocar site bleeding.

It is generally agreed that 5-mm trocars need no site suturing. Ten-millimeter trocars placed off the midline and above the transverse mesocolon do not require repair. Conversely, if the fascia has been dilated to allow the passage of the gallbladder or other organ, it should be repaired at the fascial level with interrupted sutures. The port site may be closed with suture delivery systems similar to crochet needles enabling mass closure of the abdominal wall. This is especially helpful in obese patients where direct fascial closure may be challenging, through a small skin incision. Failure to close lower abdominal trocar sites that are 10 mm in diameter or larger can lead to an incarcerated hernia.

Access for Subcutaneous and Extraperitoneal Surgery

There are two methods for gaining access to nonanatomic spaces. For retroperitoneal locations, balloon dissection is effective. This access technique is appropriate for the extraperitoneal repair of inguinal hernias and for retroperitoneal surgery for adrenalectomy, nephrectomy, lumbar discectomy, pancreatic necrosectomy, or para-aortic lymph node dissection.[43,44] The initial access to the extraperitoneal space is performed in a way similar to direct puncture laparoscopy, except that the last layer (the peritoneum) is not traversed. Once the transversalis fascia has been punctured, a specialized trocar with a balloon on the end is introduced. The balloon is inflated in the extraperitoneal space to create a working chamber. The balloon then is deflated

and a Hasson trocar is placed. An insufflation pressure of 10 mmHg usually is adequate to keep the extraperitoneal space open for dissection and will limit subcutaneous emphysema. Higher gas pressures force CO_2 into the soft tissues and may contribute to hypercarbia. Extraperitoneal endosurgery provides less working space than laparoscopy but eliminates the possibility of intestinal injury, intestinal adhesion, herniation at the trocar sites, and ileus. These issues are important for laparoscopic hernia repair because extraperitoneal approaches prevent the small bowel from sticking to the prosthetic mesh.[34]

Subcutaneous surgery has been most widely used in cardiac, vascular, and plastic surgery.[36] In cardiac surgery, subcutaneous access has been used for saphenous vein harvesting, and in vascular surgery for ligation of subfascial perforating veins (Linton procedure). With minimally invasive techniques, the entire saphenous vein above the knee may be harvested through a single incision (Fig. 14-8).[45,46] Once the saphenous vein is located, a long retractor that holds a 5-mm laparoscope allows the coaxial dissection of the vein and coagulation or clipping of each side branch. A small incision above the knee also can be used to ligate perforating veins in the lower leg.

A

B

Figure 14-8. **A.** With two small incisions, virtually the entire saphenous vein can be harvested for bypass grafting. **B.** The lighted retractor in the subcutaneous space during saphenous vein harvest is seen illuminating the skin. *(Reproduced with permission of Taylor & Francis, LLC from Jones GE, Eaves FE III, Howell RL, et al. Harvest of muscle, nerve, fascia, and vein. In: Bostwick J III, Eaves FE III, Nahai F, eds.* Endoscopic Plastic Surgery. *St Louis: Quality Medical Publishing, Inc.: Quality Medical Publishing, Inc.; 1995:542. Permission conveyed through Copyright Clearance Center, Inc.)*

Subcutaneous access also is used for plastic surgery procedures.[46] Minimally invasive approaches are especially well suited to cosmetic surgery, in which attempts are made to hide the incision. It is easier to hide several 5-mm incisions than one long incision. The technique of blunt dissection along fascial planes combined with lighted retractors and endoscope-holding retractors is most successful for extensive subcutaneous surgery. Some prefer gas insufflation of these soft tissue planes. The primary disadvantage of soft tissue insufflation is that subcutaneous emphysema can be created.

Hand-Assisted Laparoscopic Access

Hand-assisted laparoscopic surgery is thought to combine the tactile advantages of open surgery with the minimal access of laparoscopy and thoracoscopy. This approach commonly is used to assist with difficult cases before conversion to celiotomy is necessary. Additionally, hand-assisted laparoscopic surgery is used to help surgeons negotiate the steep learning curve associated with advanced laparoscopic procedures.[47] This technology uses an entryway for the hand that preserves the pneumoperitoneum and enables laparoscopic visualization in combination with the use of minimally invasive instruments (Fig. 14-9). Formal investigation of this modality has been limited primarily to case reports and small series and has focused primarily on solid organ and colon surgery.

Intraperitoneal, intrathoracic, and retroperitoneal access for robotic surgery adheres to the principles of laparoscopic and thoracoscopic access; however, the port size for the primary puncture is 12 mm to allow placement of the stereo laparoscope. Remaining trocars are 8 mm.

Natural Orifice Transluminal Endoscopic Surgery Access

Multiple studies have shown safety in the performance of NOTES procedures. Transvaginal, transvesicle, transanal, transcolonic, transgastric, and transoral approaches have all been attempted with varying success. The ease of decontamination, entry, and closure of these structures create variable challenges. The transvaginal approach for resection of the uterus has been employed for many years by gynecologists and has been modified by laparoscopists with great success. Extraction of the gallbladder, kidney, bladder, large bowel, and stomach can be performed via the vagina. The esophagus can be traversed to enter the mediastinum. Leaving the orifice or organ of entry with an endoscope requires the use of an endoscopic needle knife followed by submucosal tunneling or direct puncture and balloon dilation (Fig. 14-10). Closure has been performed using endoscopic clips or sutures with advanced endoscopic platforms.

Single-Incision Laparoscopic Surgery Access

There is no standardized approach for SILS, and access techniques vary by surgeon preference. Traditionally, a single skin incision is made directly through the umbilical scar ranging from 1 to 3 cm. Through this single incision, multiple low-profile trocars can be placed separately into the fascia to allow insufflation, camera, and working instruments. The advantage of this technique is that conventional laparoscopic tools can be employed. The disadvantage becomes apparent when an extraction site

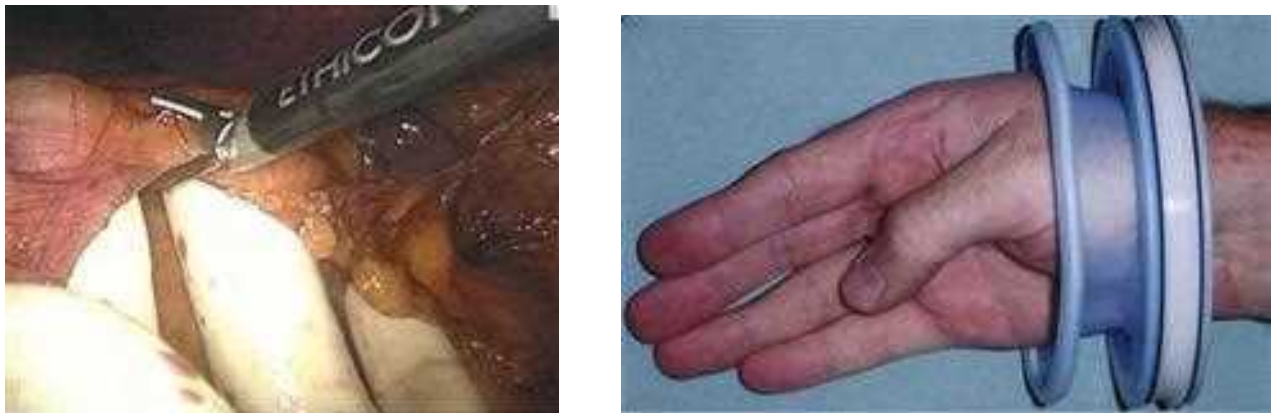

Figure 14-9. This is an example of hand-assisted laparoscopic surgery during left colectomy. The surgeon uses a hand to provide retraction and counter tension during mobilization of the colon from its retroperitoneal attachments, as well as during division of the mesocolon. This technique is particularly useful in the region of the transverse colon.

is needed. A variety of specialized multilumen trocars are on the market that can be placed through the umbilical ring[48] (Fig. 14-11A,B). The advantages of these devices include faster access, improved safety, minimization of air leaks, and platform-derived instrument triangulation. The major disadvantage is cost.

Port Placement

Trocars for the surgeon's left and right hand should be placed at least 10 cm apart. For most operations, it is possible to orient the telescope between these two trocars and slightly back from them. The ideal trocar orientation creates an equilateral triangle

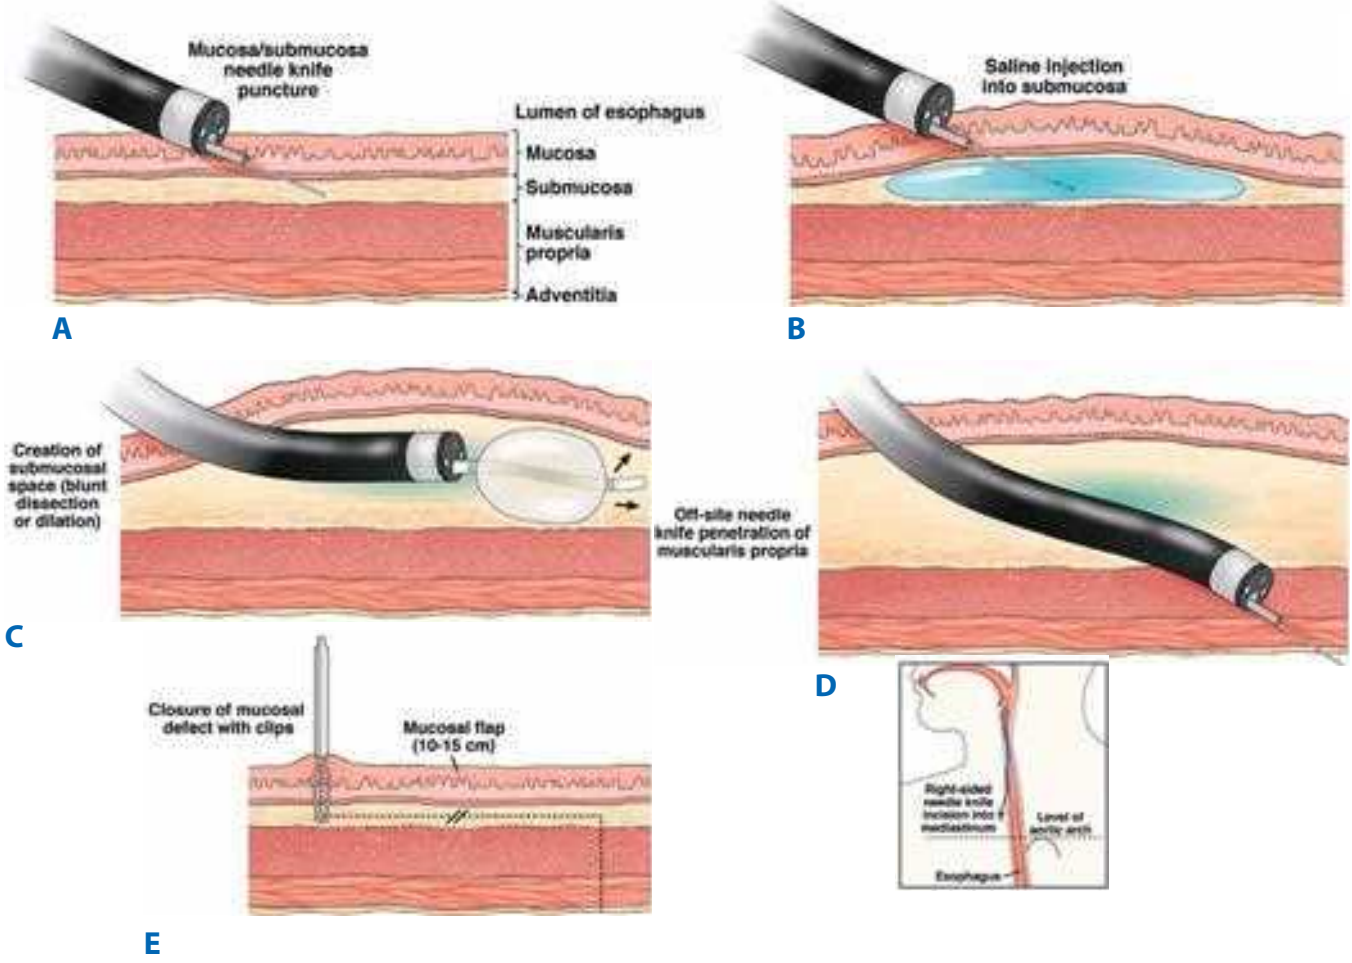

Figure 14-10. Submucosal tunnel technique for transesophageal mediastinoscopy. *(Reproduced with permission from Khashab MA, Kalloo AN. NOTES: current status and new horizons.* Gastroenterology. *2012;142:704-710. © 2012 by the AGA Institute.)*

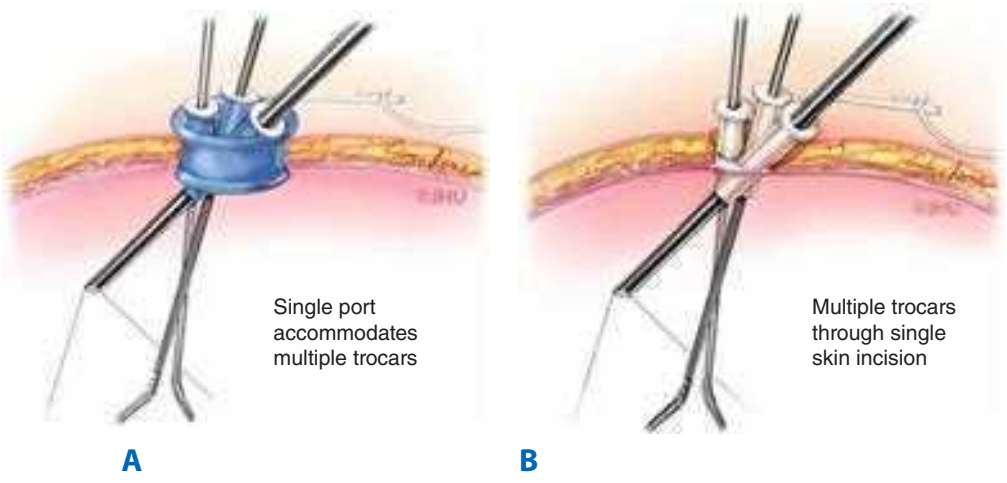

Figure 14-11. **A.** Specialized multilumen trocars can facilitate instrument placement. **B.** For single-incision laparoscopic surgery, multiple fascial punctures can be performed via a single skin incision. *(Illustration by Corinne Sandone. © 2014 JHU. Reprinted with permission.)*

between the surgeon's right hand, left hand, and the telescope, with 10 to 15 cm on each leg. If one imagines the target of the operation (e.g., the gallbladder or gastroesophageal junction) oriented at the apex of a second equilateral triangle built on the first, these four points of reference create a diamond (Fig. 14-12). The surgeon stands behind the telescope, which provides optimal ergonomic orientation but frequently requires that a camera operator (or mechanical camera holder) reach between the surgeon's hands to guide the telescope. SILS is challenging for even the experienced laparoscopist because it violates most of the aforementioned ergonomic principles. Having only a single point of entry into the abdominal cavity creates an inherently crowded port and hand position. The inability to space trocars severely limits the ability to triangulate the left and right hand instruments. As a result, the surgeon must often work in a crossed hands fashion (Fig. 14-13). Additionally, the axis of the camera view is often in line with the working instruments, making visualization difficult without a deflectable tip laparoscope.

The position of the operating table should permit the surgeon to work with both elbows in at the sides, with arms bent 90° at the elbow.[49] It usually is necessary to alter the operating table position with left or right tilt with the patient in the Trendelenburg or reverse Trendelenburg position, depending on the operative field.[50,51]

Imaging Systems

Two methods of videoendoscopic imaging are widely used. Both methods use a camera with a CCD, which is an array of photosensitive sensor elements (pixels) that convert the incoming light intensity to an electric charge. The electric charge is subsequently converted into a black-and-white image.[52]

With videoendoscopy, the CCD chip is placed on the internal end of a long, flexible endoscope. With older flexible endoscopes, thin quartz fibers are packed together in a bundle, and the CCD camera is mounted on the external end of the endoscope. Most standard GI endoscopes have the CCD chip at the distal

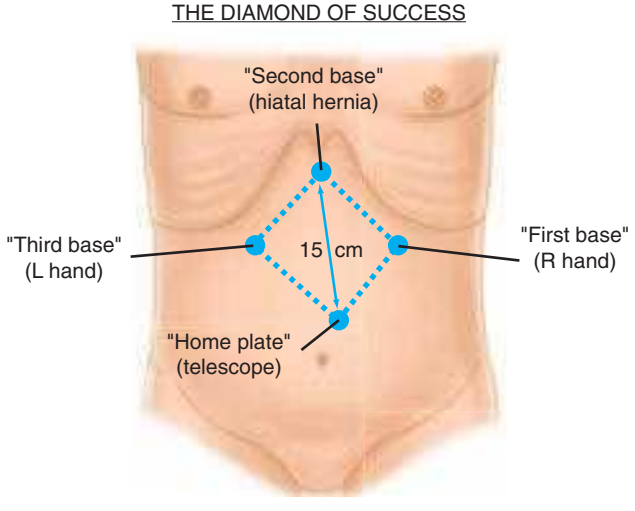

Figure 14-12. The diamond configuration created by placing the telescope between the left and the right hand, recessed from the target by about 15 cm. The distance between the left and the right hand is also ideally 10 to 15 cm. In this "baseball diamond" configuration, the surgical target occupies the second base position.

end, but small, delicate choledochoscopes and nephroscopes are equipped with fiber-optic bundles.[53] Distally mounted CCD chips were developed for laparoscopy as well but remain very expensive and therefore have not become as widely used.

Video cameras come in two basic designs. Nearly all laparoscopic cameras contain a red, green, and blue input, and are identical to the color cameras used for television production.[52] An additional feature of many video cameras is digital enhancement. Digital enhancement detects edges, areas where there are drastic color or light changes between two adjacent pixels.[54] By enhancing this difference, the image appears sharper and surgical resolution is improved. New laparoscopic cameras contain a high-definition (HD) chip, which increases the lines of resolution from 480 to 1080 lines. To enjoy the benefit of the clarity of HD video imaging, HD monitors also are necessary.

Priorities in a video imaging system for MIS are illumination first, resolution second, and color third. Without the first two attributes, video surgery is unsafe. Illumination and resolution are as dependent on the telescope, light source, and light cable as on the video camera used. Imaging for laparoscopy, thoracoscopy, and subcutaneous surgery uses a rigid metal telescope, usually 30 cm in length. Longer telescopes are available for obese patients and for reaching the mediastinum and deep in the pelvis from a periumbilical entry site. The standard telescope contains a series of quartz optical rods and focusing lenses.[55] Telescopes vary in size from 2 to 12 mm in diameter. Because light transmission is dependent on the cross-sectional area of the quartz rod, when the diameter of a rod/lens system is doubled, the illumination is quadrupled. Little illumination is needed in highly reflective, small spaces such as the knee, and a very small telescope will suffice. When working in the abdominal cavity, especially if blood is present, the full illumination of a 10-mm telescope usually is necessary.

Rigid telescopes may have a flat or angled end. The flat end provides a straight view (0°), and the angled end provides an oblique view (30° or 45°).[52] Angled telescopes allow greater flexibility in viewing a wider operative field through a single trocar site (Fig. 14-14A); rotating an angled telescope changes the field of view. The use of an angled telescope has distinct advantages for most videoendoscopic procedures, particularly in visualizing the common bile duct during laparoscopic cholecystectomy or visualizing the posterior esophagus or the tip of the spleen during laparoscopic fundoplication. Flexible tip laparoscopes offer even greater optical freedom.

Figure 14-14. A. The laparoscope tips come in a variety of angled configurations. All laparoscopes have a 70° field of view. A 30°-angled scope enables the surgeon to view this field at a 30° angle to the long axis of the scope.

Light is delivered to the endoscope through a fiber-optic light cable. These light cables are highly inefficient, losing >90% of the light delivered from the light source. Extremely bright light sources (300 watts) are necessary to provide adequate illumination for laparoscopic surgery.

The quality of the videoendoscopic image is only as good as the weakest component in the imaging chain (Fig. 14-15). Therefore, it is important to use a video monitor that has a resolution equal to or greater than the camera being used.[55] Resolution is the ability of the optical system to distinguish between line pairs. The larger the number of line pairs per millimeter, the sharper and more detailed the image. Most high-resolution monitors have up to 700 horizontal lines. HD television can deliver up to eight times more resolution than standard monitors; when combined with digital enhancement, a very sharp and well-defined image can be achieved.[52,55] A heads-up display is a high-resolution liquid crystal monitor that is built into eyewear worn by the surgeon.[56] This technology allows the surgeon to view the endoscopic image and operative field simultaneously. The proposed advantages of heads-up display include a high-resolution monocular image, which affords the surgeon mobility and reduces vertigo and eyestrain. However, this technology has not yet been widely adopted.

Interest in three-dimensional (3-D) laparoscopy has waxed and waned. 3-D laparoscopy provides the additional depth of field that is lost with two-dimensional endosurgery and improves performance of novice laparoscopists performing complex tasks of dexterity, including suturing and knot tying.[57] The advantages of 3-D systems are less obvious to experienced laparoscopists. Additionally, because 3-D systems require the flickering of two similar images, which are resolved with special glasses, the images' edges become fuzzy and resolution is lost. The optical accommodation necessary to rectify these slightly differing images is tiring and may induce headaches when one uses these systems for a long period of time. The da Vinci robot uses a specialized laparoscope with two optical bundles on opposite sides of the telescope. A specialized binocular eyepiece receives input from two CCD chips, each capturing the image from one of the two quartz rod lens systems, thereby creating true 3-D imaging without needing to employ active or passive technologies that have made 3-D laparoscopy so disappointing.

Single-incision laparoscopy presents new challenges to visualization of the operative field. In the traditional laparoscope, the light source enters the scope at a 90° angle. That position coupled with a bulky scope handle creates crowding in an already limited space. Additionally, because the scope and instruments enter the abdomen at the same point, an adequate perspective is often unobtainable even with a 30° scope. The advent of increased length laparoscopes with lighting coming from the end and a deflectable tip now allows the surgeon to re-create a sense of internal triangulation with little compromise externally. The ability to move the shaft of the scope off line while maintaining the same image provides a greater degree of freedom for the working ports.

Energy Sources for Endoscopic and Endoluminal Surgery

Many MIS procedures use conventional energy sources, but the benefits of bloodless surgery to maintain optimal visualization

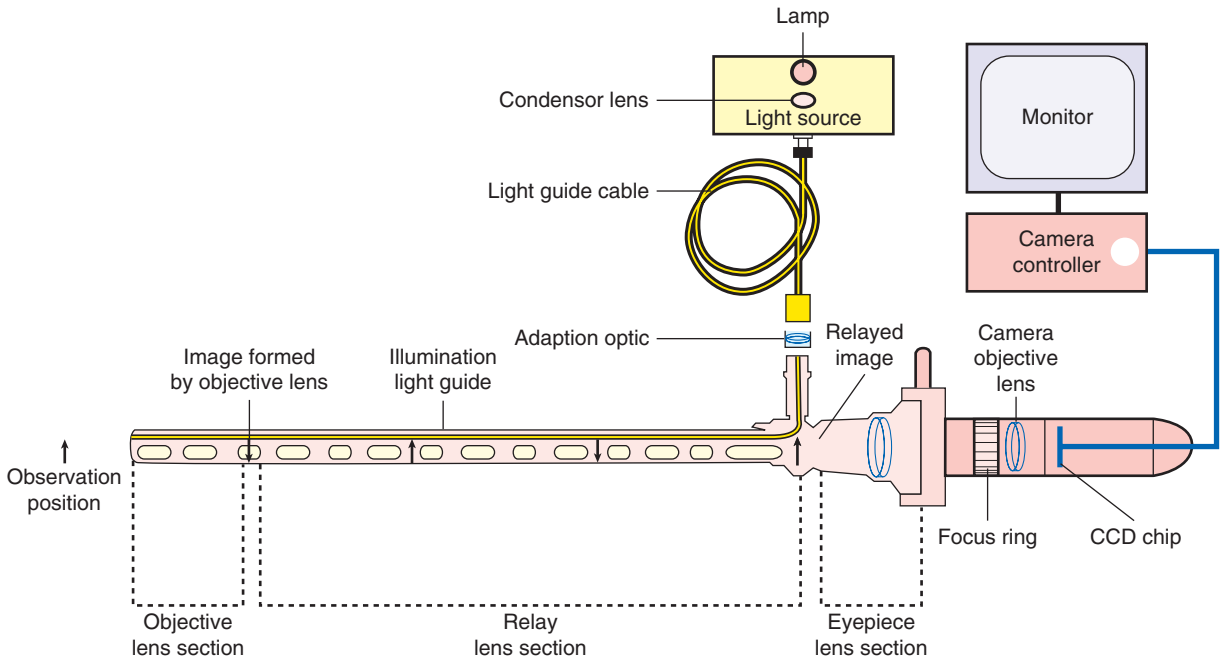

Figure 14-15. The Hopkins rod lens telescope includes a series of optical rods that effectively transmit light to the eyepiece. The video camera is placed on the eyepiece to provide the working image. The image is only as clear as the weakest link in the image chain. CCD = charge-coupled device. have spawned new ways of applying energy. The most common energy source is RF electrosurgery using an alternating current with a frequency of 500,000 cycles/s (Hz). Tissue heating progresses through the well-known phases of coagulation (60°C [140°F]), vaporization and desiccation (100°C [212°F]), and carbonization (>200°C [392°F]).[58]

The two most common methods of delivering RF electrosurgery are with monopolar and bipolar electrodes. With monopolar electrosurgery, a remote ground plate on the patient's leg or back receives the flow of electrons that originate at a point source, the surgical electrode. A fine-tipped electrode causes a high current density at the site of application and rapid tissue heating. Monopolar electrosurgery is inexpensive and easy to modulate to achieve different tissue effects.[59] A short-duration, high-voltage discharge of current (coagulation current) provides extremely rapid tissue heating. Lower-voltage, higher-wattage current (cutting current) is better for tissue desiccation and vaporization. When the surgeon desires tissue division with the least amount of thermal injury and least coagulation necrosis, a cutting current is used.

With bipolar electrosurgery, the electrons flow between two adjacent electrodes. The tissue between the two electrodes is heated and desiccated. There is little opportunity for tissue cutting when bipolar current is used alone, but the ability to coapt the electrodes across a vessel provides the best method of small-vessel coagulation without thermal injury to adjacent tissues[60] (Fig. 14-16). Advanced laparoscopic device manufacturers have leveraged the ability to selectively use bipolar energy and combined it with compressive force and a controllable blade to create a number of highly functional dissection and vessel-sealing tools.

To avoid thermal injury to adjacent structures, the laparoscopic field of view must include all uninsulated portions of the electrosurgical electrode. In addition, the integrity of the insulation must be maintained and assured. Capacitive coupling occurs when a plastic trocar insulates the abdominal wall from the current; in turn, the current is bled off of a metal sleeve or laparoscope into the viscera[54] (Fig. 14-17A). This may result in thermal necrosis and a delayed fecal fistula. Another potential mechanism for unrecognized visceral injury may occur with the direct coupling of current to the laparoscope and adjacent bowel[58] (Fig. 14-17B).

Another method of delivering RF electrosurgery is argon beam coagulation. This is a type of monopolar electrosurgery in which a uniform field of electrons is distributed across a tissue surface by the use of a jet of argon gas. The argon gas jet distributes electrons more evenly across the surface than does spray

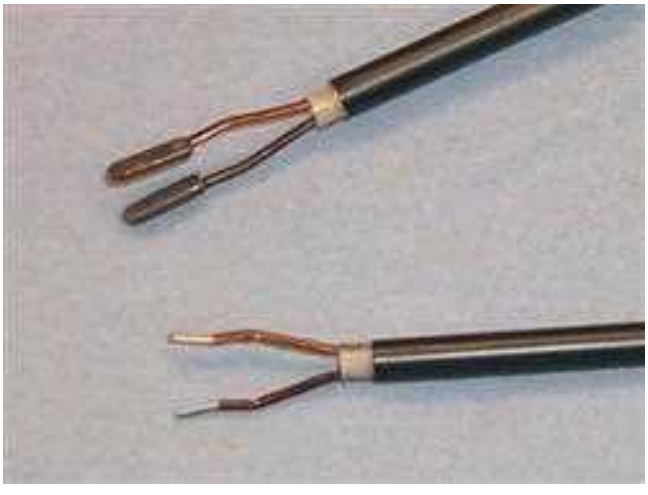

Figure 14-16. An example of bipolar coagulation devices. The flow of electrons passes from one electrode to the other, and the intervening tissue is heated and desiccated.

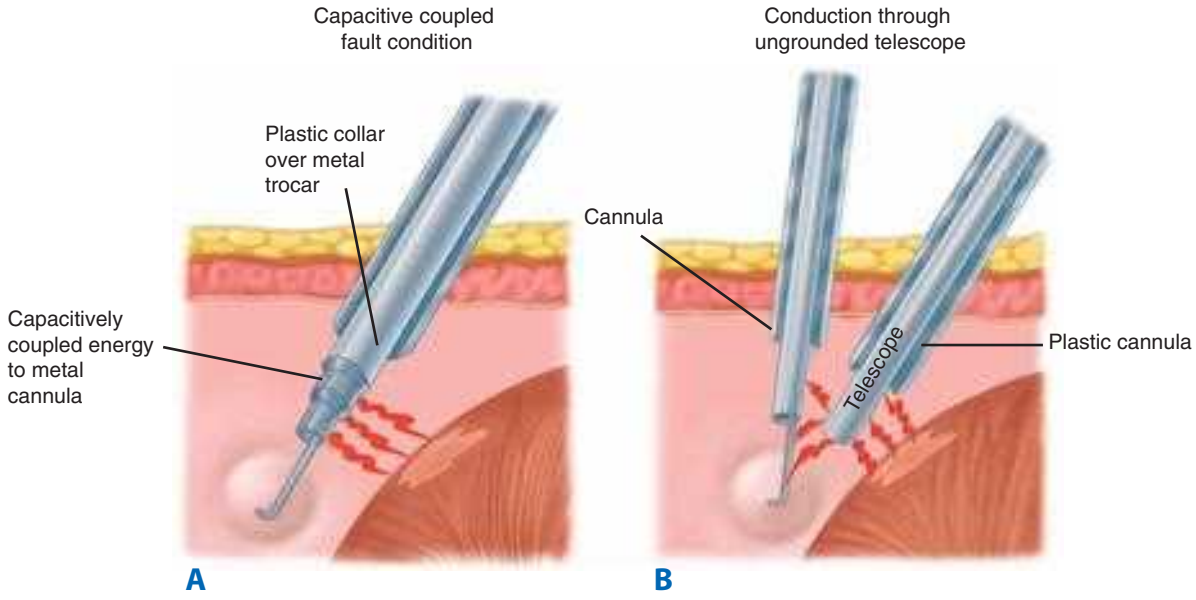

Figure 14-17. **A.** Capacitive coupling occurs as a result of high current density bleeding from a port sleeve or laparoscope into adjacent bowel. **B.** Direct coupling occurs when current is transmitted directly from the electrode to a metal instrument or laparoscope, and then into adjacent tissue. *(Reproduced with permission from Odell.*[58]*)*

electrofulguration. This technology has its greatest application for coagulation of diffusely bleeding surfaces such as the cut edge of liver or spleen. It is of less value in laparoscopic procedures because the increased intra-abdominal pressures created by the argon gas jet can increase the chances of a gas embolus. It is paramount to vent the ports and closely monitor insufflation pressure when using this source of energy within the context of laparoscopy.

With endoscopic endoluminal surgery, RF alternating current in the form of a monopolar circuit represents the mainstay for procedures such as snare polypectomy, sphincterotomy, lower esophageal sphincter ablation, and biopsy.[61,62] A grounding (return) electrode is necessary for this form of energy. Bipolar electrocoagulation is used primarily for thermal hemostasis. The electrosurgical generator is activated by a foot pedal so the endoscopist may keep both hands free during the endoscopic procedure.

Gas, liquid, and solid-state lasers have been available for medical application since the mid-1960s.[63] The CO_2 laser (wavelength 10.6 μm) is most appropriately used for cutting and superficial ablation of tissues. It is most helpful in locations unreachable with a scalpel such as excision of vocal cord granulomas. The CO_2 laser beam must be delivered with a series of mirrors and is therefore somewhat cumbersome to use. The next most popular laser is the neodymium yttrium-aluminum garnet (Nd:YAG) laser. Nd:YAG laser light is 1.064 μm (1064 nm) in wavelength. It is in the near-infrared portion of the spectrum and, like CO_2 laser light, is invisible to the naked eye. A unique feature of the Nd:YAG laser is that 1064-nm light is poorly absorbed by most tissue pigments and therefore travels deep into tissue.[64] Deep tissue penetration provides deep tissue heating (Fig. 14-18). For this reason, the Nd:YAG laser is capable of the greatest amount of tissue destruction with a single application.[63] Such capabilities make it the ideal laser for destruction of large fungating tumors of the rectosigmoid, tracheobronchial tree, or esophagus. A disadvantage is that the deep tissue heating may cause perforation of a hollow viscus.

When it is desirable to coagulate flat lesions in the cecum, a different laser should be chosen. The frequency-doubled Nd:YAG laser, also known as the KTP laser (potassium thionyl phosphate crystal is used to double the Nd:YAG frequency), provides 532-nm light. This is in the green portion of the spectrum, and at this wavelength, selective absorption by red pigments in tissue (such as hemangiomas and arteriovenous malformations) is optimal. The depth of tissue heating is intermediate, between those of the CO_2 and the Nd:YAG lasers. Coagulation (without vaporization) of superficial vascular lesions can be obtained without intestinal perforation.[64]

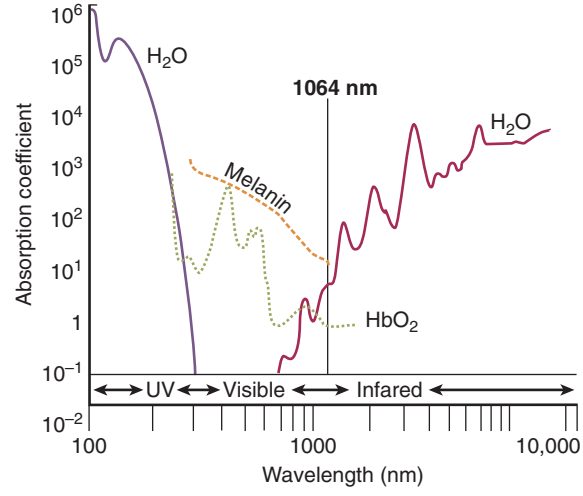

Figure 14-18. This graph shows the absorption of light by various tissue compounds (water, melanin, and oxyhemoglobin) as a function of the wavelength of the light. The nadir of the oxyhemoglobin and melanin curves is close to 1064 nm, the wavelength of the neodymium yttrium-aluminum garnet laser. (*Reproduced with permission from Hunter JG, Sackier JM, eds.* Minimally Invasive Surgery. *New York: McGraw-Hill; 1993:28.*)

In flexible GI endoscopy, the CO_2 and Nd:YAG lasers have largely been replaced by heater probes and endoluminal stents. The heater probe is a metal ball that is heated to a temperature (60–100°C [140°–212°F]) that allows coagulation of bleeding lesions without perforation.

Photodynamic therapy is a palliative treatment for obstructing cancers of the GI tract.[65] Patients are given an IV dose of porfimer sodium, which is a photosensitizing agent that is taken up by malignant cells. Two days after administration, the drug is endoscopically activated using a laser. The activated porfimer sodium generates oxygen free radicals, which kill the tumor cells. The tumor is later endoscopically débrided. The use of this modality for definitive treatment of early cancers is in experimental phases and has yet to become established.

A unique application of laser technology provides extremely rapid discharge ($<10^{-6}$ s) of large amounts of energy ($>10^3$ volts). These high-energy lasers, of which the pulsed dye laser has seen the most clinical use, allow the conversion of light energy to mechanical disruptive energy in the form of a shock wave. Such energy can be delivered through a quartz fiber, and with rapid repetitive discharges, can provide sufficient shock-wave energy to fragment kidney stones and gallstones.[66] Shock waves also may be created with miniature electric spark-plug discharge systems known as electrohydraulic lithotriptors. These devices also are inserted through thin probes for endoscopic application. Lasers have the advantage of pigment selectivity, but electrohydraulic lithotriptors are more popular because they are substantially less expensive and are more compact.

Methods of producing shock waves or heat with ultrasonic energy are also of interest. Extracorporeal shockwave lithotripsy creates focused shock waves that intensify as the focal point of the discharge is approached. When the focal point is within the body, large amounts of energy are capable of fragmenting stones. Slightly different configurations of this energy can be used to provide focused internal heating of tissues. Potential applications of this technology include the ability to noninvasively produce sufficient internal heating to destroy tissue without an incision.

A third means of using ultrasonic energy is to create rapidly oscillating instruments that are capable of heating tissue with friction; this technology represents a major step forward in energy technology.[67] An example of its application is the laparoscopic coagulation shears device (Harmonic Scalpel), which is capable of coagulating and dividing blood vessels by first occluding them and then providing sufficient heat to weld the blood vessel walls together and to divide the vessel. This nonelectric method of coagulating and dividing tissue with a minimal amount of collateral damage has facilitated the performance of numerous endosurgical procedures.[68] It is especially useful in the control of bleeding from medium-sized vessels that are too big to manage with monopolar electrocautery and require bipolar desiccation followed by cutting.

Instrumentation

Hand instruments for MIS usually are duplications of conventional surgical instruments made longer, thinner, and smaller at the tip. It is important to remember that when grasping tissue with laparoscopic instruments, a greater force is applied over a smaller surface area, which increases the risk for perforation or injury.[69]

Certain conventional instruments such as scissors are easy to reproduce with a diameter of 3 to 5 mm and a length of 20 to 45 cm, but other instruments such as forceps and clamps cannot provide remote access. Different configurations of graspers were developed to replace the various configurations of surgical forceps and clamps. Standard hand instruments are 5 mm in diameter and 30 cm in length, but smaller and shorter hand instruments are now available for pediatric surgery, for microlaparoscopic surgery, and for arthroscopic procedures.[69] A unique laparoscopic hand instrument is the monopolar electrical hook. This device usually is configured with a suction and irrigation apparatus to eliminate smoke and blood from the operative field. The monopolar hook allows tenting of tissue over a bare metal wire with subsequent coagulation and division of the tissue.

Instrumentation for NOTES is still evolving, but many long micrograspers, microscissors, electrocautery adapters, suturing devices, clip appliers, and visceral closure devices are in design and application. These instruments often require an entirely different endoscopic platform requiring manipulation by a surgeon and assistant to accomplish complex maneuvers. Techniques such as mucosotomy, hydrodissection, and clip application require specialized training. The sheer size of the instrumentation often requires an overtube to allow easy exchange throughout the procedure. Instrumentation for SILS seeks to restore the surgeon's ability to triangulate the left and right hands through variation in length, mechanical articulation, or curved design. Additionally, a lower profile camera head helps reduce the instrument crowding that occurs at the single point of abdominal entry.

Robotic Surgery

The term robot defines a device that has been programmed to perform specific tasks in place of those usually performed by people. The devices that have earned the title "surgical robots" would be more aptly termed computer-enhanced surgical devices, as they are controlled entirely by the surgeon for the purpose of improving performance. The first computer-assisted surgical device was the laparoscopic camera holder (Aesop, Computer Motion, Goleta, CA), which enabled the surgeon to maneuver the laparoscope either with a hand control, foot control, or voice activation. Randomized studies with such camera holders demonstrated a reduction in operative time, steadier image, and a reduction in the number of required laparoscope cleanings.[70] This device had the advantage of eliminating the need for a human camera holder, which served to free valuable OR personnel for other duties. This technology has now been eclipsed by simpler systems using passive positioning of the camera with a mechanical arm, but the benefits of a steadier image and fewer members of the OR team remain.

The major revolution in robotic surgery was the development of a master-slave surgical platform that returned the wrist to laparoscopic surgery and improved manual dexterity by developing an ergonomically comfortable work station, with 3-D imaging, tremor elimination, and scaling of movement (e.g., large, gross hand movements can be scaled down to allow suturing with microsurgical precision) (Fig. 14-19). The most recent iteration of the robotic platform features a second console slave enabling greater assisting and teaching opportunities. The surgeon is physically separated from the operating table, and the working arms of the device are placed over the patient (Fig. 14-20). An assistant remains at the bedside and changes the instruments as needed, providing retraction as needed to facilitate the procedure. The robotic platform (da Vinci, Intuitive Surgical, Sunnyvale, CA) was initially greeted with

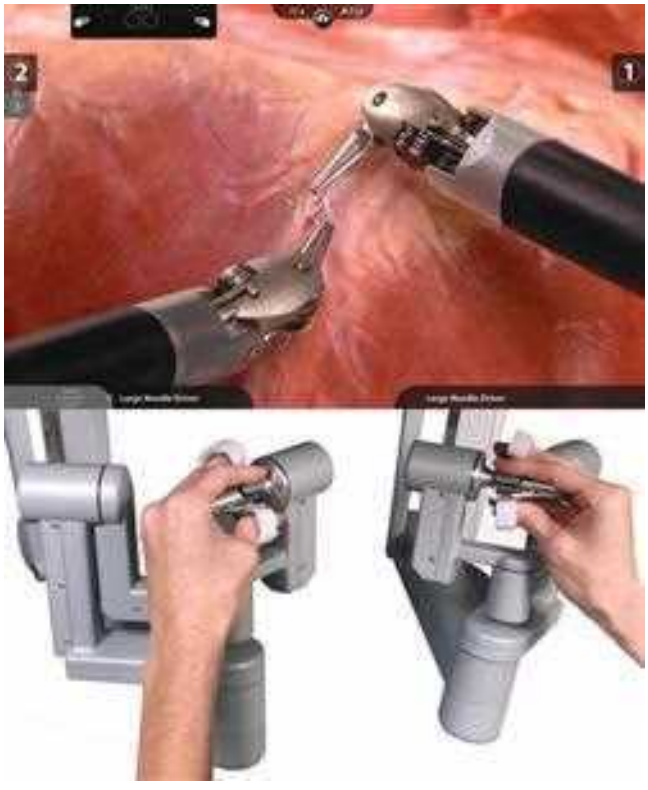

Figure 14-19. Robotic instruments and hand controls. The surgeon is in a sitting position, and the arms and wrists are in an ergonomic and relaxed position.

some skepticism by expert laparoscopists, as it was difficult to prove additional value for operations performed with the da Vinci robot. Not only were the operations longer and the equipment more expensive, but additional quality could not be demonstrated. Two randomized controlled trials compared robotic and conventional laparoscopic approaches to Nissen fundoplication.[71,72] In both of these trials, the operative time was longer for robotic surgery, and there was no difference in ultimate outcome. Similar results were achieved for laparoscopic cholecystectomy.[73] Nevertheless, the increased dexterity provided by the da Vinci robot convinced many surgeons and health administrators that robotic platforms were worthy of investment, for marketing purposes if for no other reason. The success story for computer-enhanced surgery with the da Vinci started with cardiac surgery and migrated to the pelvis. Mitral valve surgery, performed with right thoracoscopic access, became one of the more popular procedures performed with the robot.[74]

3▶

To date, a myriad of publications have demonstrated success performing procedures from thyroidectomies to colectomies with total mesorectal excision. Almost any procedure performed laparoscopically has been attempted robotically, although true advantage is demonstrated only very sparingly. In most cases, increased cost and operative time challenge the notion of "better."

The tidal wave of enthusiasm for robotic surgery came when most minimally invasive urologists declared robotic prostatectomy to be preferable to laparoscopic and open prostatectomy.[75] The great advantage—it would appear—of robotic

Figure 14-20. Room setup and position of surgeon and assistant for robotic surgery. (*©2013 Intuitive Surgical, Inc. Reprinted with permission.*)

prostatectomy is the ability to visualize and spare the pelvic nerves responsible for erectile function. In addition, the creation of the neocystourethrotomy, following prostatectomy, was greatly facilitated by needle holders and graspers with a wrist in them. Female pelvic surgery with the da Vinci robot is also reaching wide appeal. The magnified imaging provided makes this approach ideal for microsurgical tasks such as reanastomosis of the Fallopian tubes.

The final frontier for computer-enhanced surgery is the promise of telesurgery, in which the surgeon is a great distance from the patient (e.g., combat or space). This application has rarely been used, as the safety provided by having the surgeon at bedside cannot be sacrificed to prove the concept. However, remote laparoscopic cholecystectomy has been performed when a team of surgeons located in New York performed a cholecystectomy on a patient located in France.[76]

Endoluminal and Endovascular Surgery

The fields of vascular surgery, interventional radiology, neuroradiology, gastroenterology, general surgery, pulmonology, and urology all encounter clinical scenarios that require the urgent restoration of luminal patency. Based on this need, fundamental techniques have been pioneered that are applicable to all specialties and virtually every organ system. As a result, all minimally invasive surgical procedures, from coronary artery angioplasty to palliation of pancreatic malignancy, involve the use of access devices, catheters, guidewires, balloon dilators, stents, and other devices (e.g., lasers, atherectomy catheters) that are capable of opening up the occluded biologic cylinder[77] (Table 14-2). Endoluminal balloon dilators may be inserted through an endoscope, or they may be fluoroscopically guided. Balloon dilators all have low compliance—that is, the balloons do not stretch as the pressure within the balloon is increased. The high pressures achievable in the balloon create radial expansion of the narrowed vessel or orifice, usually disrupting the atherosclerotic plaque, the fibrotic stricture, or the muscular band (e.g., esophageal achalasia).[78]

Once the dilation has been attained, it is frequently beneficial to hold the lumen open with a stent.[79] Stenting is particularly valuable in treating malignant lesions and atherosclerotic occlusions or aneurysmal disease (Fig. 14-21). Stenting is also of value to seal leaky cylinders, including aortic dissections, traumatic vascular injuries, leaking GI anastomoses, and fistulas. Stenting usually is not applicable for long-term management of benign GI strictures except in patients with limited life expectancy (Fig. 14-22).[79–81]

A variety of stents are available that are divided into six basic categories: plastic stents, metal stents, drug-eluting stents (to decrease fibrovascular hyperplasia), covered metal stents, anchored stent grafts, and removable covered plastic stents[80] (Fig. 14-23). Plastic stents came first and are used widely as endoprostheses for temporary bypass of obstructions in the biliary or urinary systems. Metal stents generally are delivered over a balloon and expanded with the balloon to the desired size. These metal stents usually are made of titanium or nitinol and are still used in coronary stenting. A chemotherapeutic agent

was added to coronary stents several years ago to decrease endothelial proliferation. These drug-eluting stents provide greater long-term patency but require long-term anticoagulation with antiplatelet agents to prevent thrombosis.[82] Coated metal stents are use to prevent tissue ingrowth. Ingrowth may be an advantage in preventing stent migration, but such tissue ingrowth may occlude the lumen and cause obstruction anew. This is a particular problem when stents are used for palliation of GI malignant growth and may be a problem for the long-term use of stents in vascular disease. Filling the interstices with Silastic or other materials may prevent tumor ingrowth but also makes stent migration more likely. In an effort to minimize stent migration, stents have been incorporated with hooks and barbs at the proximal end of the stent to anchor it to the wall of the vessel. Endovascular stenting of aortic aneurysms has nearly replaced open surgery for this condition. Lastly, self-expanding plastic stents have been developed as temporary devices to be used in the GI tract to close internal fistulas and bridge leaking anastomoses.

Figure 14-23. Covered self-expanding metal stents. These devices can be placed fluoroscopically or endoscopically.

Natural Orifice Transluminal Endoscopic Surgery

The use of the flexible endoscope to enter the GI, urinary, or reproductive tracts and then traverse the wall of the structure to enter the peritoneal cavity, the mediastinum, or the chest has strong appeal to patients wishing to avoid scars and pain caused by abdominal wall trauma. In truth, transluminal surgery has been performed in the stomach for a long time, either from the inside out (e.g., percutaneous, PEG, and transgastric pseudocyst drainage) or from the outside in (e.g., laparoscopic assisted intragastric tumor resection). The catalyzing events for NOTES were the demonstration that a porcine gallbladder could be removed with a flexible endoscope passed through the wall of the stomach and then removed through the mouth, and the demonstration in a series of 10 human cases from India of the ability to perform transgastric appendectomy. Since that time, a great deal of money has been invested by endoscopic and MIS companies to help surgeons and gastroenterologists explore this new territory. Systemic inflammatory markers such as C-reactive protein, tumor necrosis factor-alpha, interleukin (IL)-1β, and IL-6 have been shown to be similar in transgastric and transcolonic NOTES when compared to laparoscopy in porcine models.[83] Concerns about the safety of transluminal access and limitations in equipment remain the greatest barriers to expansion. To date, the most headline-grabbing procedures have been the transvaginal and transgastric removal of the gallbladder[84–86] (Fig. 14-24). To ensure safety, all human cases thus far have involved laparoscopic assistance to aid in retraction and ensure adequate closure of the stomach or vagina. To date, thousands of transvaginal and transgastric procedures have been performed internationally, with two large registries demonstrating noninferiority to conventional laparoscopy.[87] The fact that the vast majority of these procedures are being done transvaginally creates an obvious limitation in applicability.

4▶

The rapid growth of endoscopic technology catalyzed by NOTES has already spun off new technologies capable of performing a wide variety of endoscopic surgical procedures from EMR, to ablation of Barrett's esophagus, to creation of competent antireflux valves in patients with gastroesophageal reflux disease.

POEM has shown promise as a NOTES treatment for esophageal achalasia.[88] In this procedure, a 1.5- to 2-cm mucosotomy is created within the anterior esophagus 10 cm proximal to the gastroesophageal junction. A submucosal tunnel is then created using a combination of electrocautery, hydrodissection, and carbon dioxide insufflation. The scope is advanced

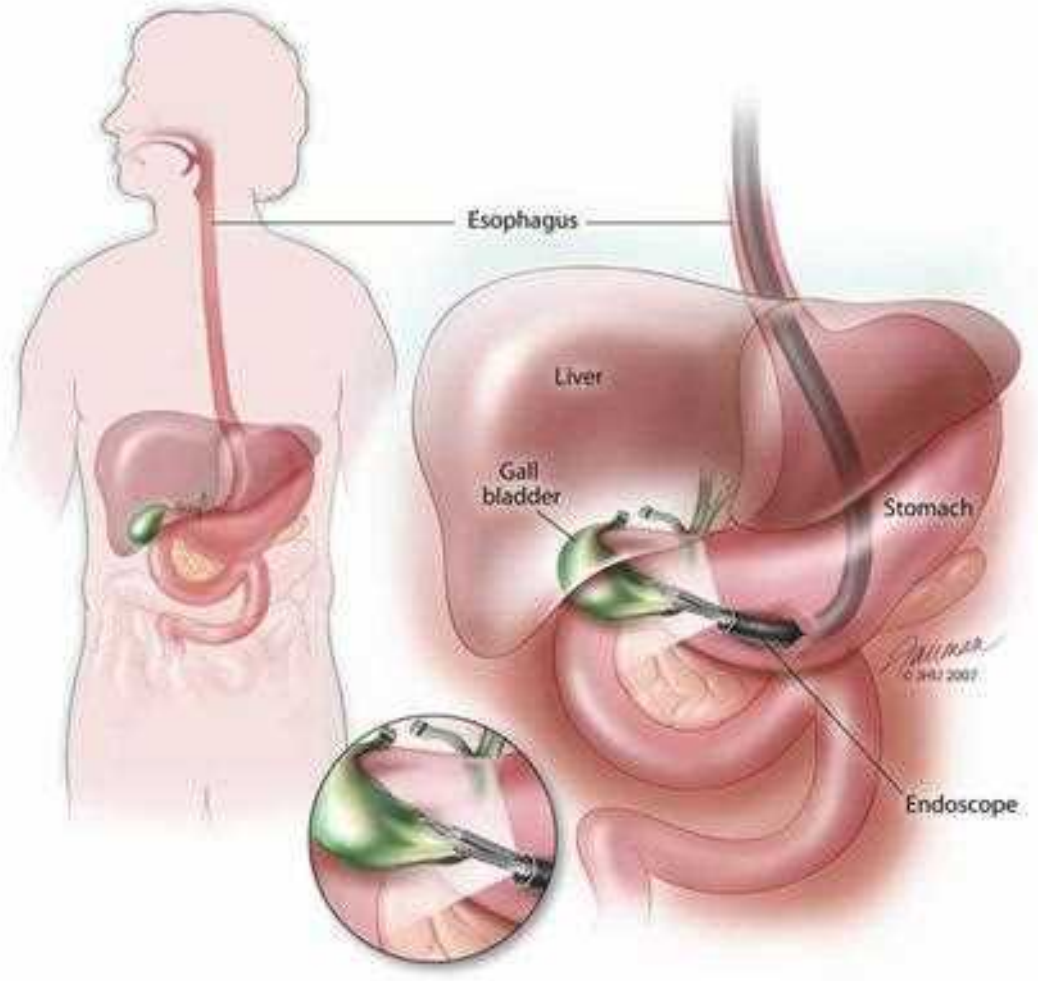

Figure 14-24. Transgastric cholecystectomy using natural orifice transluminal endoscopic surgery technology and one to three laparoscopic ports has been performed occasionally in several locations around the world. *(Illustration by Jennifer Fairman. © 2007 JHU. Reprinted with permission.)*

beyond the gastroesophageal junction, and a circular myotomy is performed avoiding disruption of the longitudinal fibers. The mucosotomy is then closed using endoscopic clips (Fig. 14-25). Over 1000 clinical POEM cases have been performed worldwide. Data from expert NOTES surgeons suggest that this selective myotomy avoids abdominal trauma and minimally disrupts the normal anatomic characteristics of the gastroesophageal junction while providing significant relief of symptoms.[89] Randomized clinical trials and long-term follow-up need to be performed to further evaluate efficacy.

Although this application is still considered experimental, there is little doubt that when equivalent operations can be performed with less pain, fewer scars, and less disability, patients will flock to it. NOTES procedures are associated with an increased mental workload and significant learning curve for even experienced surgical endoscopists. Surgeons should engage only when they can perform these procedures with the safety and efficacy demanded by our profession.

Single-Incision Laparoscopic Surgery

As a surgical technique, SILS seems to be a natural progression from conventional laparoscopic surgery. As surgeons sought to reduce the number and size of abdominal wall trocars and NOTES procedures necessitated laparoscopic surveillance, the idea of a hybridization took off. An incision in the umbilicus, a preexisting scar, is thought to be less painful, have fewer wound complications, lead to quicker return to activity, and have a better cosmetic appearance than conventional laparoscopy. Perhaps one of the earliest examples of SILS is the application of laparoscopic instrumentation to resect lesions in the rectum or sigmoid colon. Using the anus as the portal of entry, transanal endoscopic microsurgery (TEMS) employs a specialized multichannel trocar to reach lesions located 8 to 18 cm away from the anal verge (Fig. 14-26).

More deformable versions of these complex trocars have been developed with features to allow insufflation and be amenable to maintaining a seal within the natural orifice of the umbilicus (see Fig. 14-11). Ports typically contain three or four channels. The latter often affords the ability to place a dedicated retractor.

There are many challenges faced by the operating surgeon in SILS procedures. These include crowded trocar placement, a lack of triangulation of left and right hand instruments, frequent crossing or clashing of instruments, limited visualization, and limited retraction ability. These challenges are mitigated by surgeon experience and the development of specialized instruments. Articulating or curved instruments of varying lengths and an extended length can improve working space.

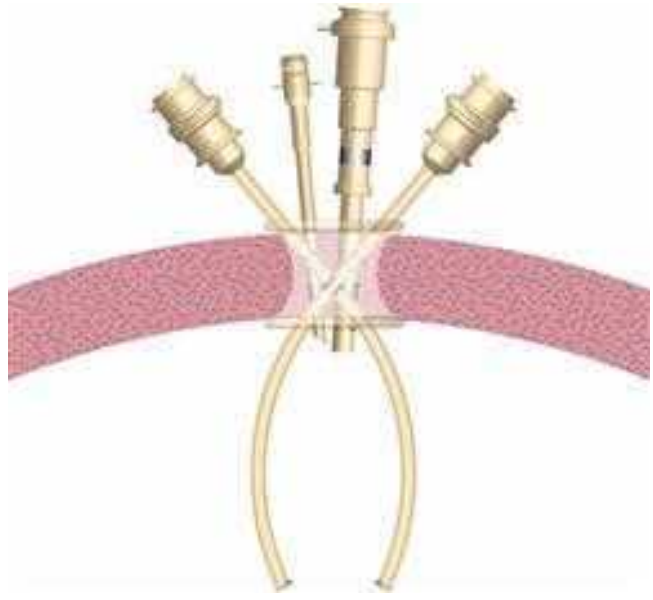

Figure 14-27. Example of curved instruments used in single-incision laparoscopic surgery. *(©2013 Intuitive Surgical, Inc. Reprinted with permission.)*

Curved instruments are typically reusable and offer less clutter than their more sophisticated counterparts, providing some cost reduction (Fig. 14-27). A low-profile HD scope with or without a deflectable tip can improve visualization greatly. Even with such instrumentation, the learning curve is very steep, particularly when the surgeon is forced to work in a cross-handed technique. The accomplished SILS surgeon will possess a tool bag of innovative strategies to retract structures like the gallbladder away from the operative field. These tricks may range from the use of percutaneous needlescopic instruments to the application of transfascial sutures. Expert consensus recommendations for efficient SILS are shown in Tables 14-3 and 14-4.[8] When performing SILS procedures, it is imperative to follow proven tenets of operative conduct such as visualizing the "critical view" of safety in a laparoscopic cholecystectomy. As safety should always be the paramount concern, the addition of extra trocars or conversion to traditional laparoscopy should not be considered a failure.

Contraindications include those true of traditional laparoscopy. Relative contraindications include previous surgery and high body mass index (BMI). Patients with a high BMI or

Table 14-3

Expert panel recommendations for accomplishing single-incision laparoscopic surgery efficiently

Multichannel port preferably to be placed intraumbilically, but an extraumbilical approach can be used in certain cases
Extra ports should be used where there is a clinical need
When applicable, sutures can be useful for added retraction
Closure should be accomplished using sutures of absorbable material placed either continuously or interrupted
Skin should be closed with absorbable sutures or glue

Table 14-4

Expert panel recommendations for single-incision laparoscopic surgery equipment and instrumentation

RECOMMENDED EQUIPMENT/ INSTRUMENTATION	BENEFIT TO SURGEON
Slimline instruments with low-profile design	Reduces internal and external clashing
Varied-length instruments	Reduces extracorporeal clashing
Longer instruments	Advantageous for reaching the surgical field
Articulating (or prebent) instruments	Restore triangulation
Small-diameter, low-profile angle scope	Reduces clashing by providing additional space
High-definition camera	Achieves high-quality images for intraoperative visualization

Source: Ahmed I, Cianco F, Ferrar V, et al. Current status of single-incision laparoscopic surgery: European experts' views. *Surg Laparosc Endosc Percutan Tech*. 2012;22(3):194-199.

central obesity can pose a challenge because the umbilicus may be located far from operative target. Size and morphology of the target organ should always be considered when doing SILS.

Many studies have demonstrated equivalency to standard laparoscopic procedures regarding intraoperative and postoperative complications. However, it is questionable what the full benefit of the dramatic reduction in ergonomics and the increase in complexity provide beyond an improved cosmetic appearance. This is in large part due to the already improved benefits of laparoscopic surgery.

A meta-analysis performed by Ahmed and colleagues in 2010 found the conversion rate from SILS to conventional laparoscopy to be 0% to 24% for cholecystectomies, 0% to 41% for appendectomies, and 0% to 33% for nephrectomies.[90] The most common complications were intra-abdominal abscesses and wound infections. The recently released robotics application may provide the bridge necessary to bypass the significant technical skills learning curve required to operate through a single site (Fig. 14-28).

SPECIAL CONSIDERATIONS

Pediatric Laparoscopy

The advantages of MIS in children may be more significant than in the adult population. MIS in the adolescent is little different from that in the adult, and standard instrumentation and trocar positions usually can be used. However, laparoscopy in the infant and young child requires specialized instrumentation. The instruments are shorter (15–20 cm), and many are 3 mm in diameter rather than 5 mm. Because the abdomen of the child is much smaller than that of the adult, a 5-mm telescope provides sufficient illumination for most operations. The development of 5-mm clippers and bipolar devices has obviated the need for 10-mm trocars in pediatric laparoscopy.[91] Because the abdominal wall is much thinner in infants, a pneumoperitoneum pressure of 8 mmHg can provide adequate exposure. DVT is rare in children, so prophylaxis against thrombosis probably is unnecessary. A wide variety of pediatric surgical procedures are frequently performed with MIS access, from pull-through procedures for colonic aganglionosis (Hirschsprung's disease) to repair of congenital diaphragmatic hernias.[92]

Laparoscopy during Pregnancy

Concerns about the safety of laparoscopic cholecystectomy or appendectomy in the pregnant patient have been thoroughly investigated and are readily managed. Access to the abdomen in the pregnant patient should take into consideration the height of the uterine fundus, which reaches the umbilicus at

6▶ 20 weeks. In order not to damage the uterus or its blood supply, most surgeons feel that the open (Hasson) approach should be used in favor of direct puncture laparoscopy. The patient should be positioned slightly on the left side to avoid compression of the vena cava by the uterus. Because pregnancy poses a risk for thromboembolism, sequential compression devices are essential for all procedures. Fetal acidosis induced by maternal hypercarbia also has been raised as a concern. The arterial pH of the fetus follows the pH of the mother linearly; and therefore, fetal acidosis may be prevented by avoiding a respiratory acidosis in the mother.[93] The pneumoperitoneum pressure induced by laparoscopy is not a safety issue either as it has been proved that midpregnancy uterine contractions provide a much greater pressure in utero than a pneumoperitoneum of 15 mmHg. More than 100 cases of laparoscopic cholecystectomy in pregnancy have been reported with uniformly good results.[94] The operation should be performed during the second trimester of pregnancy if possible. Protection of the fetus against intraoperative x-rays is imperative. Some believe it advisable to track fetal pulse rates with a transvaginal ultrasound probe; however, the significance of fetal tachycardia or bradycardia is a bit unclear in the second trimester of pregnancy. To be prudent, however, heart rate decelerations reversibly associated with pneumoperitoneum creation might signal the need to convert to open cholecystectomy or appendectomy.

Minimally Invasive Surgery and Cancer Treatment

MIS techniques have been used for many decades to provide palliation for the patient with an obstructive cancer. Laser treatment, intracavitary radiation, stenting, and dilation are outpatient techniques that can be used to reestablish the continuity of an obstructed esophagus, bile duct, ureter, or airway. MIS techniques also have been used in the staging of cancer. Mediastinoscopy is still used occasionally before thoracotomy to assess the status of the mediastinal lymph nodes. Laparoscopy also is used to assess the liver in patients being evaluated for pancreatic, gastric, or hepatic resection. New technology and greater surgical skills allow for accurate minimally invasive staging of cancer.[95] Occasionally, it is appropriate to perform palliative measures (e.g., laparoscopic gastrojejunostomy to bypass a pancreatic cancer) at the time of diagnostic laparoscopy if diagnostic findings preclude attempts at curative resection.

Initially controversial, the role of MIS to provide a safe curative treatment of cancer has proven to be no different from

7▶ the principles of open surgery. All gross and microscopic tumor should be removed (an R0 resection), and an adequate lymphadenectomy should be performed to allow accurate staging. Generally, this number has been 10 to 15 lymph nodes, although there is still debate as to the value of more extensive lymphadenectomy. All of the major abdominal cancer operations have been performed with laparoscopy. Of the three major cancer resections of GI cancer (liver lobe, pancreatic head, and esophagus), only esophagectomy is routinely performed by a fair number of centers.[96,97] Laparoscopic hepatectomy has attracted a loyal following, and distal pancreatectomy frequently is performed with laparoscopic access. In Japan, laparoscopic-assisted gastrectomy has become quite popular for early gastric cancer, an epidemic in Japan far exceeding that of colon cancer in North America and Northern Europe. The most common cancer operation performed laparoscopically is segmental colectomy, which has proven itself safe and efficacious in a multicenter controlled randomized trial.[98]

Considerations in the Elderly and Infirm

Laparoscopic cholecystectomy has made possible the removal of a symptomatic gallbladder in many patients previously thought to be too elderly or too ill to undergo a laparotomy. Older patients are more likely to require conversion to celiotomy because of disease chronicity.[98]

Operations on these patients require close monitoring of anesthesia. The intraoperative management of these patients may be more difficult with laparoscopic access than with open access. The advantage of MIS lies in what happens after the operation. Much of the morbidity of surgery in the elderly is a result of impaired mobility. In addition, pulmonary complications, urinary tract sepsis, DVT, pulmonary embolism, congestive heart failure, and myocardial infarction often are the result of improper fluid management and decreased mobility. By allowing rapid and early mobilization, laparoscopic surgery has made possible the safe performance of procedures in the elderly and infirm.

Cirrhosis and Portal Hypertension

Patients with hepatic insufficiency pose a significant challenge for any type of surgical intervention.[99] The ultimate surgical outcome in this population relates directly to the degree of underlying hepatic dysfunction.[100] Often, this group of patients has minimal reserve, and the stress of an operation will trigger complete hepatic failure or hepatorenal syndrome. These patients are at risk for major hemorrhage at all levels, including trocar insertion, operative dissection in a field of dilated veins, and secondary to an underlying coagulopathy. Additionally, ascitic leak from a port site may occur, leading to bacterial peritonitis. Therefore, a watertight port site closure should be carried out in all patients.

It is essential that the surgeon be aware of the severity of hepatic cirrhosis as judged by a Model of End-Stage Liver Disease (MELD) score or Child's classification. Additionally, the presence of portal hypertension is a relative contraindication to laparoscopic surgery until the portal pressures are reduced with portal decompression. For example, if a patient has an incarcerated umbilical hernia and ascites, a preoperative paracentesis or transjugular intrahepatic portosystemic shunt procedure in conjunction with aggressive diuresis may be considered. Because these patients commonly are intravascularly depleted, insufflation pressures should be reduced to prevent a decrease in cardiac output, and minimal amounts of Na^+-sparing IV fluids should be given.

Economics of Minimally Invasive Surgery

Minimally invasive surgical procedures reduce the costs of surgery most when length of hospital stay can be shortened and return to work is quickened. For example, shorter hospital stays can be demonstrated in laparoscopic cholecystectomy, Nissen fundoplication, splenectomy, and adrenalectomy. Procedures such as inguinal herniorrhaphy that are already performed as outpatient procedures are less likely to provide cost savings. Procedures that still require a 4- to 7-day hospitalization, such as laparoscopy-assisted colectomy, are less likely to deliver a lower bottom line than their open surgery counterparts. Nonetheless, with responsible use of disposable instrumentation and a commitment to the most effective use of the inpatient setting, most laparoscopic procedures can be made less expensive than their conventional equivalents.

Education and Skill Acquisition

Historically, surgeons in training (residents, registrars, and fellows) acquired their skills in minimally invasive techniques through a series of operative experiences of graded complexity. This training occurred on patients. Although such a paradigm did not compromise patient safety, learning in the OR is costly. In addition, the recent worldwide constraint placed on resident work hours makes it attractive to teach laparoscopic skills outside of the OR.

Skills labs started at nearly every surgical training center in the 1990s with low fidelity box-type trainers. These were rudimentary simulated abdominal cavities with a video camera, monitor, trocars, laparoscopic instruments, and target models. These targets were often as simple as a pegboard and rubber rings, or a latex drain to practice suturing and knot tying. Virtual reality training devices present a unique opportunity to improve and enhance experiential learning in endoscopy and laparoscopy for all surgeons. This technology has the advantage of enabling objective measurement of psychomotor skills, which can be used to determine progress in skill acquisition and, ultimately, technical competency.[101] Several of these devices have been validated as a means of measuring proficiency in skill performance. More importantly, training on virtual reality platforms has proven to translate to improved operative performance in randomized trials.[102,103] Currently surgical skills labs are mandatory for Residency Review Committee credentialing. Successful completion of the Fundamentals of Laparoscopic Surgery (FLS) technical and cognitive examination became a mandatory prerequisite for the American Board of Surgery qualification examination in general surgery in 2010. In the future, institutions may require simulator training to the expert level as a prerequisite for performance of laparoscopic procedures in the OR. The Fundamental of Endoscopic Surgery (FES) and Fundamentals of Robotic Surgery (FRS) high stakes exams are both on the horizon for future surgical trainees. The American College of Surgeons has taken a leadership position in accrediting skills labs across the world as American College of Surgeons–accredited educational institutes.

Telementoring

In response to the Institute of Medicine's call for the development of unique technologic solutions to deliver health care to rural and underserved areas, surgeons are beginning to explore the feasibility of telementoring. Teleconsultation or telementoring is two-way audio and visual communication between two geographically separated providers. This communication can take place in the office setting or directly in the OR when complex scenarios are encountered. Although local communication channels may limit its performance in rural areas, the technology is available and currently is being used, especially in states and provinces with large geographically remote populations.[103]

Innovation and Introduction of New Procedures

The revolution in minimally invasive general surgery, which occurred in 1990, created ethical challenges for the profession. The problem was this: If competence is gained from experience, how was the surgeon to climb the competence curve (otherwise known as the learning curve) without injuring patients? If it was indeed impossible to achieve competence without making mistakes along the way, how should one effectively communicate this to patients such that they understand the weight of their decisions? Even more fundamentally important is determining the path that should be followed before one recruits the first patient for a new procedure.

Although procedure development is fundamentally different than drug development (i.e., there is great individual variation in the performance of procedures, but no difference between one tablet and the next), adherence to a process similar to that used to develop a new drug is a reasonable path for a surgical innovator. At the outset, the surgeon must identify the problem that is not solved with current surgical procedures. For example, although the removal of a gallbladder through a Kocher incision is certainly effective, it creates a great deal of disability, pain, and scarification. As a result of those issues, many patients with very symptomatic biliary colic delayed operation until life-threatening complications occurred. Clearly, there was a need for developing a less invasive approach (Fig. 14-29).

Once the opportunity has been established, the next step involves a search through other disciplines for technologies and techniques that might be applied. Again, this is analogous to the drug industry, where secondary drug indications have often turned out to be more therapeutically important than the primary indication for drug development. The third step is in vivo studies in the most appropriate animal model. These types of studies are controversial because of the resistance to animal experimentation, and yet without such studies, many humans would be

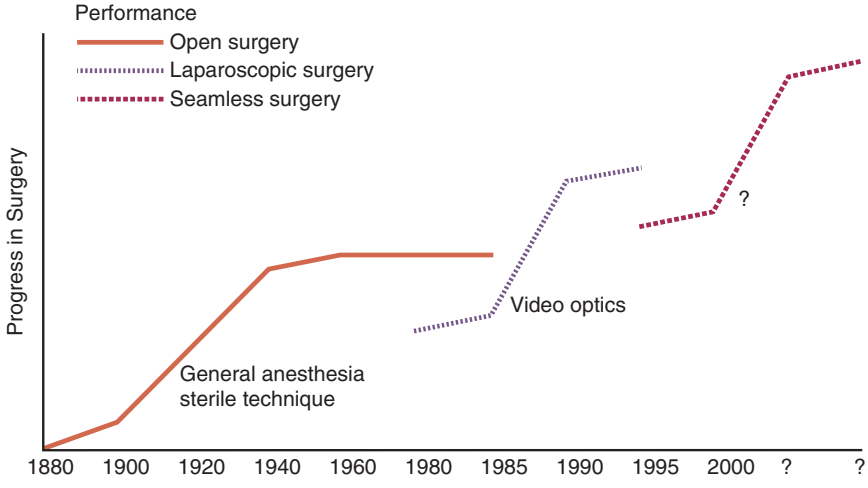

Figure 14-29. The progress of general surgery can be reflected by a series of performance curves. General anesthesia and sterile technique allowed the development of maximally invasive open surgery over the last 125 years. Video optics allowed the development of minimally invasive surgery over the last 25 years. Noninvasive (seamless) surgery will result when a yet undiscovered transformational event allows surgery to occur without an incision, and perhaps without anesthesia.

injured or killed during the developmental phase of medical drugs, devices, and techniques. These steps often are called the preclinical phase of procedure development.

The decision as to when such procedures are ready to come out of the lab is a difficult one. Put simply, the procedure should be reproducible, provide the desired effect, and not have serious side effects. Once these three criteria are reached, the time for human application has arrived. Before the surgeon discusses the new procedure with patients, it is important to achieve full institutional support. Involvement of the medical board, the chief of the medical staff, and the institutional review board is essential before commencing on a new procedure. These bodies are responsible for the use of safe, high-quality medical practices within their institution, and they will demand that great caution and all possible safeguards are in place before proceeding.

The dialogue with the patient who is to be first must be thorough, brutally honest, and well documented. The psychology that allows a patient to decide to be first is quite interesting, and may, under certain circumstances, require psychiatric evaluation. Certainly if a dying cancer patient has a chance with a new drug, this makes sense. Similarly, if the standard surgical procedure has a high attendant morbidity and the new procedure offers a substantially better outcome, the decision to be first is understandable. On the other hand, when the benefits of the new approach are small and the risks are largely unknown, a more complete psychological profile may be necessary before proceeding.

For new surgical procedures, it generally is wise to assemble the best possible operative team, including a surgeon experienced with the old technique, and assistants who have participated in the earlier animal work. This initial team of experienced physicians and nurses should remain together until full competence with the procedure is attained. This may take 10 procedures, or it may take 50 procedures. The team will know that it has achieved competence when the majority of procedures take the same length of time and the team is relaxed and sure of the flow of the operation. This will complete phase I of the procedure development.

In phase II, the efficacy of the procedure is tested in a nonrandomized fashion. Ideally, the outcome of new techniques must be as good as or better than the procedure that is being replaced. This phase should occur at several medical centers to prove that good outcomes are achievable outside of the pioneering institution. These same requirements may be applied to the introduction of new technology into the OR. The value equation requires that the additional measurable procedure quality exceeds the additional measurable cost to the patient or healthcare system. In phase III, a randomized trial pits the new procedure against the old.

Once the competence curve has been climbed, it is appropriate for the team to engage in the education of others. During the ascension of the competence curve, other learners in the institution (i.e., surgical residents) may not have the opportunity to participate in the first case series. Although this may be difficult for them, the best interest of the patient must be put before the education of the resident.

The second stage of learning occurs when the new procedure has proven its value and a handful of experts exist, but the majority of surgeons have not been trained to perform the new procedure. In this setting, it is relatively unethical for surgeons to forge ahead with a new procedure in humans as if they had spent the same amount of time in intensive study that the first team did. The fact that one or several surgical teams were able to perform an operation does not ensure that all others with the same medical degrees can perform the operation with equal skill. It behooves the learners to contact the experts and request their assistance to ensure an optimal outcome at the new center. Although it is important that the learners contact the experts, it is equally important that the experts be willing to share their experience with their fellow professionals. As well, the experts should provide feedback to the learners as to whether they feel the learners are equipped to forge ahead on their own. If not, further observation and assistance from the experts are required. Although this approach may sound obvious, it is fraught with difficulties. In many situations, ego, competitiveness, and monetary concerns have short-circuited this process and led to poor patient outcomes. To a large extent, MIS has recovered from the black eye it received early in development, when inadequately trained surgeons caused an excessive number of significant complications.

If innovative procedures and technologies are to be developed and applied without the mistakes of the past, surgeons must be honest when they answer these questions: Is this procedure safe? Would I consider undergoing this procedure if I developed a surgical indication? Is the procedure as good as or better than the procedure it is replacing? Do I have the skills to apply this procedure safely and with equivalent results to the more experienced surgeon? Answering these questions in the affirmative should be a professional obligation. A negative response should motivate the surgeon to seek an alternative procedure or outside assistance before subjecting a patient to the new procedure.

Molecular and Genomic Surgery

Xin-Hua Feng, Xia Lin, Juehua Yu, John Nemunaitis, and F. Charles Brunicardi

OVERVIEW OF MOLECULAR CELL BIOLOGY

The beginning of modern medicine can be traced back to centuries ago when physicians and scientists began studying human anatomy from cadavers in morgues and animal physiology following hunting expeditions. Gradually, from the study of animals and plants in greater detail and the discovery of microbes, scientific principles governing life lead to the emergence of the biological sciences. As biological science developed and expanded, scientists and physicians began to utilize the principles of biological sciences to solve challenges of human diseases while continuing to explore the fundamentals of life in greater detail. With ever-evolving state-of-the-art scientific tools, our understanding of how cells, tissues, organs, and entire organisms function, down to the level of molecular and subatomic structure, has resulted in modern biology with an enormous impact on modern healthcare and the discovery of amazing treatments for disease at an exponential pace. Significant progress has been made in molecular studies of organ development, cell signaling, and gene regulation. The advent of recombinant DNA technology, polymerase chain reaction (PCR) techniques, and next-generation genomic sequencing, which resulted in the sequencing of the human genome, holds the potential to have a transformational influence on healthcare and society this century by not only broadening our understanding of the pathophysiology of disease, but also by bringing about necessary changes in personalized medicine.

Today's practicing surgeons are becoming increasingly aware that many modern surgical procedures rely on the information gained through molecular research (i.e., personalized surgery). Genomic information, such as deleterious *BRCA* and *RET* proto-oncogene mutations, is being used to help direct prophylactic procedures to remove potentially harmful tissues before they do damage to patients. Molecular engineering has led to cancer-specific gene therapy that could serve in the near future as a more effective adjunct to surgical debulking of tumors than radiation or chemotherapy, so surgeons will benefit from a clear introduction to how basic biochemical and biological principles relate to the developing area of molecular biology. This chapter reviews the current information on modern molecular biology for the surgical community.

Basic Concepts of Molecular Research

The modern era of molecular biology, which has been mainly concerned with how genes govern cell activity, began in 1953 when James D. Watson and Francis H. C. Crick made one of the greatest scientific discoveries by deducing the double-helical structure of deoxyribonucleic acid (DNA).[1,2] The year 2003 marked the 50th anniversary of this great discovery. In the same year, the Human Genome Project completed with sequencing approximately 20,000 to 25,000 genes and 3 billion base pairs in human DNA.[3] Before 1953, one of the most mysterious aspects of biology was how genetic material was precisely duplicated from one generation to the next. Although DNA had been implicated as genetic material, it was the base-paired structure of DNA that provided a logical interpretation of how a double helix could "unzip" to make copies of itself. This DNA synthesis, termed *replication*, immediately gave rise to the notion that a template was involved in the transfer of information between generations, and thus confirmed the suspicion that DNA carried an organism's hereditary information.

Within cells, DNA is packed tightly into chromosomes. One important feature of DNA as genetic material is its ability to encode important information for all of a cell's functions (Fig. 15-1). Based on the principles of base complementarity, scientists also discovered how information in DNA is accurately transferred into the protein structure. DNA serves as a template for RNA synthesis, termed *transcription*, including messenger RNA (mRNA, or the protein-encoding RNA), ribosomal RNA (rRNA), and transfer RNA (tRNA). mRNA carries the information from DNA to make proteins, termed *translation*, with the assistance of rRNA and tRNA. Each of these steps is precisely controlled in such a way that genes are properly expressed in each cell at a specific time and location. In recent years, new

Key Points

1. Biological sciences developed drastically in last 60 years after the uncovering of DNA structure by Watson and Crick
2. The completion of the human genome sequence in 2003 represents a great milestone in modern science.
3. The technology emerging from molecular and cellular biology has revolutionized the understanding of disease and will radically transform the practice of surgery.
4. The use of genetically modified mouse models and cell lines using gene therapy and RNA interference therapy has greatly contributed to the understanding of the molecular basis for human diseases and targeted therapies.
5. The sequencing of each individual's genome has the potential to improve the predication, prevention, and targeted treatment of disease, resulting in personalized medicine and surgery.
6. The use of functional genomics and modern molecular analyses will facilitate the discovery of actionable genes to guide choice of care.

classes of noncoding RNAs (ncRNA), for example, microRNA (or miRNA), Piwi-interacting RNA (or piRNA), and long intergenic noncoding RNA (or lincRNA), have been identified. Although the number of ncRNAs encoded in the human genome is unknown and a lot of ncRNAs have not been validated for their functions, ncRNAs have been associated to regulate gene expression through posttranscriptional gene regulation such as mRNA degradation or epigenetic regulation such as chromatin structure modification and DNA methylation induction.[4] Consequently, the differential gene activity in a cell determines its actions, properties, and functions.

Molecular Approaches to Surgical Research

Rapid advances in molecular and cellular biology over the past half century have revolutionized the understanding of disease and will radically transform the practice of surgery. In the future, molecular techniques will be increasingly applied to surgical disease and will lead to new strategies for the selection and implementation of operative therapy. Surgeons should be familiar with the fundamental principles of molecular and cellular biology so that emerging scientific breakthroughs can be translated into improved care of the surgical patient.

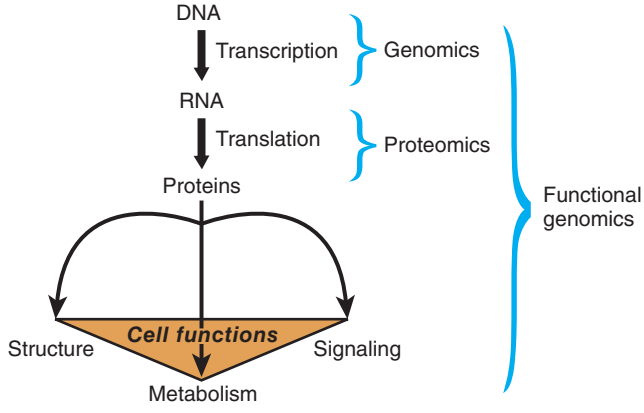

Figure 15-1. The flow of genetic information from DNA to protein to cell functions. The process of transmission of genetic information from DNA to RNA is called *transcription*, and the process of transmission from RNA to protein is called *translation*. Proteins are the essential controlling components for cell structure, cell signaling, and metabolism. *Genomics* and *proteomics* are the study of the genetic composition of a living organism at the DNA and protein level, respectively. The study of the relationship between genes and their cellular functions is called *functional genomics*.

The greatest advances in the field of molecular biology have been in the areas of analysis and manipulation of DNA.[1] Since Watson and Crick's discovery of DNA structure, an intensive effort has been made to unlock the deepest biologic secrets of DNA. Among the avalanche of technical advances, one discovery in particular has drastically changed the world of molecular biology: the uncovering of the enzymatic and microbiologic techniques that produce recombinant DNA. Recombinant DNA technology involves the enzymatic manipulation of DNA and, subsequently, the cloning of DNA. DNA molecules are cloned for a variety of purposes including safeguarding DNA samples, facilitating sequencing, generating probes, and expressing recombinant proteins in one or more host organisms. DNA can be produced by a number of means, including restricted digestion of an existing vector, PCR, and cDNA synthesis. As DNA cloning techniques have developed over the last quarter century, researchers have moved from studying DNA to studying the functions of proteins, and from cell and animal models to molecular therapies in humans. Expression of recombinant proteins provides a method for analyzing gene regulation, structure, and function. In recent years, the uses for recombinant proteins have expanded to include a variety of new applications, including gene therapy and biopharmaceuticals. The basic molecular approaches for modern surgical research include DNA cloning, cell manipulation, disease modeling in animals, and clinical trials in human patients.

FUNDAMENTALS OF MOLECULAR AND CELL BIOLOGY

DNA and Heredity

DNA forms a right-handed, double-helical structure that is composed of two antiparallel strands of unbranched polymeric deoxyribonucleotides linked by phosphodiester bonds between the 5′ carbon of one deoxyribose moiety to the 3′ carbon of the next (Fig. 15-2). DNA is composed of four types of deoxyribonucleotides: adenine (A), cytosine (C), guanine (G), and thymine (T). The nucleotides are joined together by phosphodiester bonds. In the double-helical structure deduced by Watson and Crick, the two strands of DNA are complementary to each other. Because of size, shape, and chemical composition, A always pairs with T, and C with G, through the formation of hydrogen bonds between complementary bases that stabilize the double helix.

Recognition of the hereditary transmission of genetic information is attributed to the Austrian monk, Gregor Mendel. His seminal work, ignored upon publication until its rediscovery in 1900, established the laws of segregation and of independent

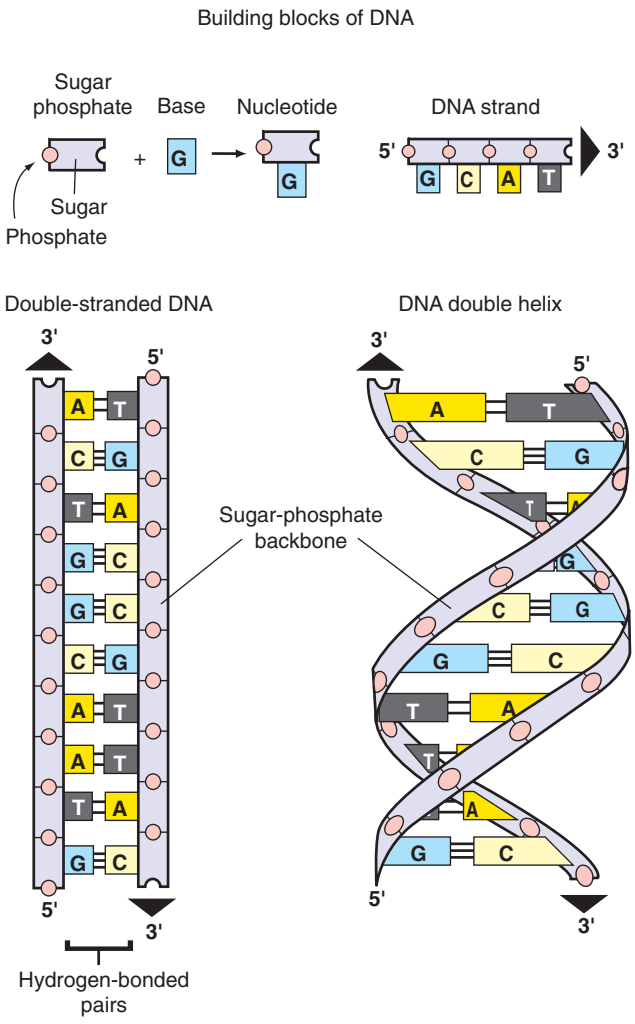

Figure 15-2. Schematic representation of a DNA molecule forming a double helix. DNA is made of four types of nucleotides, which are linked covalently into a DNA strand. A DNA molecule is composed of two DNA strands held together by hydrogen bonds between the pair bases. The arrowheads at the ends of the DNA strands indicate the polarities of the two strands, which run antiparallel to each other in the DNA molecule. The diagram at the bottom left of the figure shows the DNA molecule straightened out. In reality, the DNA molecule is twisted into a double helix, of which each turn of DNA is made up of 10.4 nucleotide pairs, as shown on the right. *(Republished with permission of Garland Publishing, Inc. from Alberts B, Johnson A, Lewis J, et al.* Molecular Biology of the Cell, *5th ed. New York: Garland Science; 2008. Permission conveyed through Copyright Clearance Center, Inc.)*

assortment. These two principles established the existence of paired elementary units of heredity and defined the statistical laws that govern them.[5] DNA was isolated in 1869, and a number of important observations of the inherited basis of certain diseases were made in the early part of the twentieth century. Although today it appears easy to understand how DNA replicates, before the 1950s, the idea of DNA as the primary genetic material was not appreciated. The modern era of molecular biology began in 1944 with the demonstration that DNA was the substance that carried genetic information. The first experimental evidence that DNA was genetic material came from simple transformation experiments conducted in the 1940s using *Streptococcus pneumoniae*. One strain of the bacteria could be converted into another by incubating it with DNA from the other, just as the treatment of the DNA with deoxyribonuclease would inactivate the transforming activity of the DNA. Similarly, in the early 1950s, before the discovery of the double-helical structure of DNA, the entry of viral DNA and not the protein into the host bacterium was believed to be necessary to initiate infection by the bacterial virus or bacteriophage. Key historical events concerning genetics are outlined in Table 15-1.

Table 15-1

Historical events in genetics and molecular biology

YEAR	INVESTIGATOR	EVENT
1865	Mendel	Laws of genetics established
1869	Miescher	DNA isolated
1905	Garrod	Human inborn errors of metabolism
1913	Sturtevant	Linear map of genes
1927	Muller	X-rays cause inheritable genetic damage
1928	Griffith	Transformation discovered
1941	Beadle and Tatum	"One gene, one enzyme" concept
1944	Avery, MacLeod, McCarty	DNA as material of heredity
1950	McKlintock	Existence of transposons confirmed
1953	Watson and Crick	Double-helical structure of DNA
1957	Benzer and Kornberg	Recombination and DNA polymerase
1966	Nirenberg, Khorana, Holley	Genetic code determined
1970	Temin and Baltimore	Reverse transcriptase
1972	Cohen, Boyer, Berg	Recombinant DNA technology
1975	Southern	Transfer of DNA fragments from sizing gel to nitrocellulose (Southern blot)
1977	Sanger, Maxim, Gilbert	DNA sequencing methods
1982	—	GenBank database established
1985	Mullis	Polymerase chain reaction
1986	—	Automated DNA sequencing
1989	Collins	Cystic fibrosis gene identified by positional cloning and linkage analysis
1990	—	Human Genome Project initiated
1997	Roslin Institute	Mammalian cloning (Dolly)
2001	IHGSC and Celera Genomics	Draft versions of human genome sequence published
2003	—	Human Genome Project completed

IHGSC = International Human Genome Sequencing Consortium.

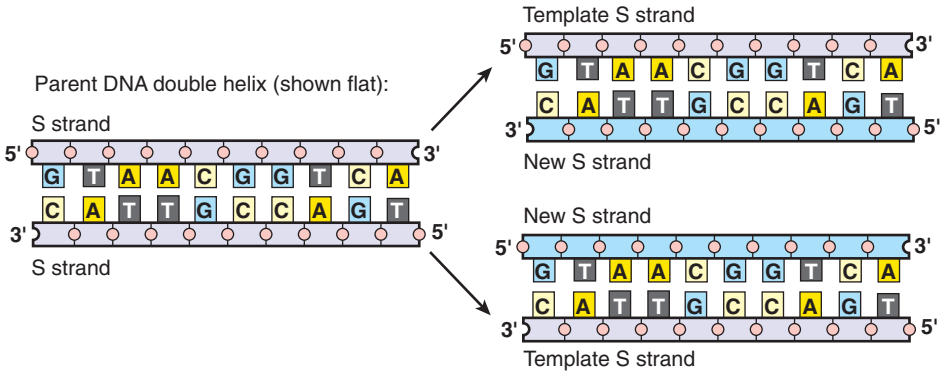

Figure 15-3. DNA replication. As the nucleotide A only pairs with T, and G with C, each strand of DNA can determine the nucleotide sequence in its complementary strand. In this way, double-helical DNA can be copied precisely. *(Republished with permission of Garland Publishing, Inc. from Alberts B, Johnson A, Lewis J, et al.* Molecular Biology of the Cell, *5th ed. New York: Garland Science; 2008. Permission conveyed through Copyright Clearance Center, Inc.)*

For cells to pass on the genetic material (DNA) to each progeny, the amount of DNA must be doubled. Watson and Crick recognized that the complementary base-pair structure of DNA implied the existence of a template-like mechanism for the copying of genetic material.[1] The transfer of DNA material from the mother cell to daughter cells takes place during somatic cell division (also called *mitosis*). Before a cell divides, DNA must be precisely duplicated. During replication, the two strands of DNA separate, and each strand creates a new complementary strand by precise base-pair matching (Fig. 15-3). The two, new, double-stranded DNAs carry the same genetic information, which can then be passed on to two daughter cells. Proofreading mechanisms ensure that the replication process occurs in a highly accurate manner. The fidelity of DNA replication is absolutely crucial to maintaining the integrity of the genome from generation to generation. However, mistakes can still occur during this process, resulting in *mutations*, which may lead to a change of the DNA's encoded protein and, consequently, a change of the cell's behavior. The reliable dependence of many features of modern organisms on subtle changes in genome is linked to Mendelian inheritance and also contributes to the processes of Darwinian evolution. In addition, massive changes, so-called *genetic instability*, can occur in the genome of somatic cells such as cancer cells.

Gene Regulation

Living cells have the necessary machinery to enzymatically transcribe DNA into RNA and translate the mRNA into protein. This machinery accomplishes the two major steps required for gene expression in all organisms: transcription and translation (Fig. 15-4). However, gene regulation is far more complex, particularly in eukaryotic organisms. For example, many gene transcripts must be spliced to remove the intervening sequences. The sequences that are spliced off are called *introns*, which appear to be useless, but in fact may carry some regulatory information. The sequences that are joined together, and are eventually translated into protein, are called *exons*. Additional regulation of gene expression includes modification of mRNA, control of mRNA stability, and its nuclear export into cytoplasm (where it is assembled into ribosomes for translation). After mRNA is translated into protein, the levels and functions of the proteins can be further regulated posttranslationally. However, the following sections will mainly focus on gene regulation at transcriptional and translational levels.

Transcription. Transcription is the enzymatic process of RNA synthesis from DNA.[6] In bacteria, a single RNA polymerase carries out all RNA synthesis, including that of mRNA, rRNA, and tRNA. Transcription often is coupled with translation in such a way that an mRNA molecule is completely accessible to

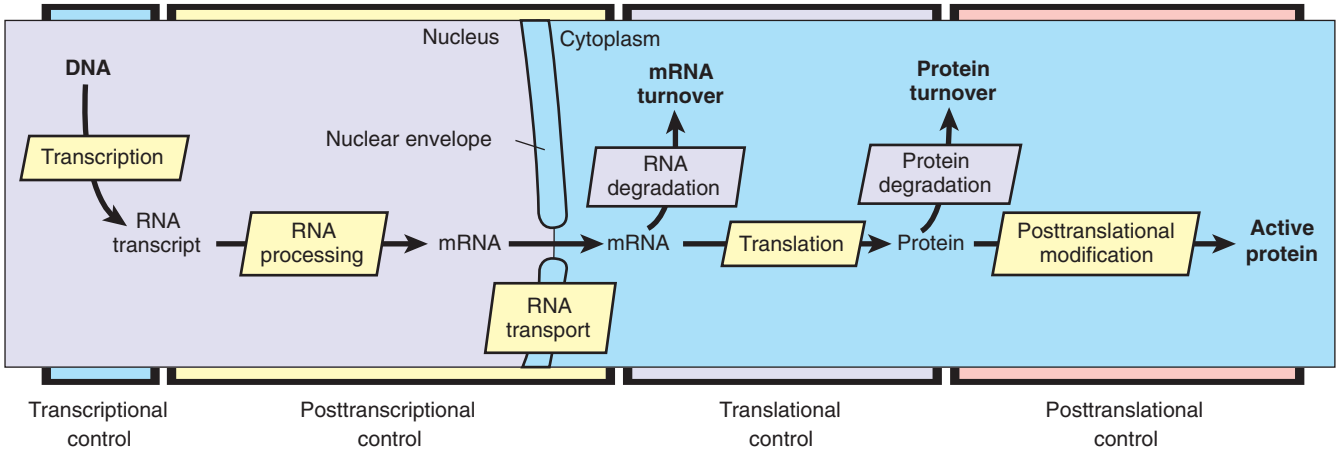

Figure 15-4. Four major steps in the control of eukaryotic gene expression. Transcriptional and posttranscriptional control determine the level of messenger RNA (mRNA) that is available to make a protein, while translational and posttranslational control determine the final outcome of functional proteins. Note that posttranscriptional and posttranslational controls consist of several steps.

ribosomes, and bacterial protein synthesis begins on an mRNA molecule even while it is still being synthesized. Therefore, a discussion of gene regulation with a look at the simpler prokaryotic system precedes that of the more complex transcription and posttranscriptional regulation of eukaryotic genes.

Transcription in Bacteria Initiation of transcription in prokaryotes begins with the recognition of DNA sequences by RNA polymerase. First, the bacterial RNA polymerase catalyzes RNA synthesis through loose binding to any region in the double-stranded DNA and then through specific binding to the *promoter* region with the assistance of accessory proteins called σ factors (sigma factors). A promoter region is the DNA region upstream of the transcription initiation site. RNA polymerase binds tightly at the promoter sites and causes the double-stranded DNA structure to unwind. Consequently, few nucleotides can be base-paired with the DNA template to begin transcription. Once transcription begins, the σ factor is released. The growing RNA chain may begin to peel off as the chain elongates. This occurs in such a way that there are always about 10 to 12 nucleotides of the growing RNA chains that are base-paired with the DNA template.

The bacterial promoter contains a region of about 40 bases that include two conserved elements called *–35 region* and *–10 region*. The numbering system begins at the initiation site, which is designated +1 position, and counts backward (in negative numbers) on the promoter and forward on the transcribed region. Although both regions on different promoters are not the same sequences, they are fairly conserved and very similar. This conservation provides the accurate and rapid initiation of transcription for most bacterial genes. It is also common in bacteria that one promoter serves to transcribe a series of clustered genes, called an *operon*. A single transcribed mRNA contains a series of coding regions, each of which is later independently translated. In this way, the protein products are synthesized in a coordinated manner. Most of the time, these proteins are involved in the same metabolic pathway, thus demonstrating that the control by one operon is an efficient system. After initiation of transcription, the polymerase moves along the DNA to elongate the chain of RNA, although at a certain point, it will stop. Each step of RNA synthesis, including initiation, elongation, and termination, will require the integral functions of RNA polymerase as well as the interactions of the polymerase with regulatory proteins.

Transcription in Eukaryotes Transcription mechanisms in eukaryotes differ from those in prokaryotes. The unique features of eukaryotic transcription are as follows: (a) Three separate RNA polymerases are involved in eukaryotes: RNA polymerase I transcribes the precursor of 5.8S, 18S, and 28S rRNAs; RNA polymerase II synthesizes the precursors of mRNA as well as microRNA; and RNA polymerase III makes tRNAs and 5S rRNAs. (b) In eukaryotes, the initial transcript is often the precursor to final mRNAs, tRNAs, and rRNAs. The precursor is then modified and/or processed into its final functional form. RNA splicing is one type of processing to remove the noncoding introns (the region between coding exons) on an mRNA. (c) In contrast to bacterial DNA, eukaryotic DNA often is packaged with histone and nonhistone proteins into chromatins. Transcription will only occur when the chromatin structure changes in such a way that DNA is accessible to the polymerase. (d) RNA is made in the nucleus and transported into cytoplasm, where translation occurs. Therefore, unlike bacteria, eukaryotes undergo uncoupled transcription and translation.

Eukaryotic gene transcription also involves the recognition and binding of RNA polymerase to the promoter DNA. However, the interaction between the polymerase and DNA is far more complex in eukaryotes than in prokaryotes. Because the majority of studies have been focused on the regulation and functions of proteins, this chapter primarily focuses on how protein-encoding mRNA is made by RNA polymerase II.

Translation. DNA directs the synthesis of RNA; RNA in turn directs the synthesis of proteins. Proteins are variable-length polypeptide polymers composed of various combinations of 20 different amino acids and are the working molecules of the cell. The process of decoding information on mRNA to synthesize proteins is called *translation* (see Fig. 15-1). Translation takes place in ribosomes composed of rRNA and ribosomal proteins. The numerous discoveries made during the 1950s made it easy to understand how DNA replication and transcription involve base-pairing between DNA and DNA or DNA and RNA. However, at that time, it was still impossible to comprehend how mRNA transfers the information to the protein-synthesizing machinery. The genetic information on mRNA is composed of arranged sequences of four bases that are transferred to the linear arrangement of 20 amino acids on a protein. Amino acids are characterized by a central carbon unit linked to four side chains: an amino group ($–NH_2$), a carboxy group (–COOH), a hydrogen, and a variable (–R) group. The amino acid chain is assembled via peptide bonds between the amino group of one amino acid and the carboxy group of the next. Because of this decoding, the information carried on mRNA relies on tRNA. Translation involves all three RNAs. The precise transfer of information from mRNA to protein is governed by *genetic code*, the set of rules by which codons are translated into an amino acid (Table 15-2). A *codon*, a triplet of three bases, codes for one amino acid. In this case, random combinations of the four bases form $4 \times 4 \times 4$, or 64 codes. Because 64 codes are more than enough for 20 amino acids, most amino acids are coded by more than one codon. The start codon is AUG, which also corresponds to methionine; therefore, almost all proteins begin with this amino acid. The sequence of nucleotide triplets that follows the start codon signal is termed the *reading frame*. The codons on mRNA are sequentially recognized by tRNA adaptor proteins. Specific enzymes termed *aminoacyl-tRNA synthetases* link a specific amino acid to a specific tRNA. The translation of mRNA to protein requires the ribosomal complex to move stepwise along the mRNA until the initiator methionine sequence is identified. In concert with various protein initiator factors, the methionyl-tRNA is positioned on the mRNA and protein synthesis begins. Each new amino acid is added sequentially by the appropriate tRNA in conjunction with proteins called *elongation factors*. Protein synthesis proceeds in the amino-to-carboxy-terminus direction.

The biologic versatility of proteins is astounding. Among many other functions, proteins serve as enzymes that catalyze critical biochemical reactions, carry signals to and from the extracellular environment, and mediate diverse signaling and regulatory functions in the intracellular environment. They also transport ions and various small molecules across plasma membranes. Proteins make up the key structural components of cells and the extracellular matrix and are responsible for cell motility. The unique functional properties of proteins are largely determined by their structure (Fig. 15-5).

Regulation of Gene Expression. The human organism is made up of a myriad of different cell types that, despite their vastly

Table 15-2

The genetic code

		SECOND BASE IN CODON

		GUG	Val	[V]	GCG	Ala	[A]	GAG	Glu	[E]	GGG	Gly	[G]	*G*	

A = adenine; C = cytosine; G = guanine; U = uracil; Ala = alanine; Arg = arginine; Asn = asparagine; Asp = aspartic acid; Cys = cysteine; Glu = glutamic acid; Gln = glutamine; Gly = glycine; His = histidine; Ile = isoleucine; Leu = leucine; Lys = lysine; Met = methionine; Phe = phenylalanine; Pro = proline; Ser = serine; Thr = threonine; Trp = tryptophan; Tyr = tyrosine; Val = valine. Letter in [ ] indicates single letter code for amino acid.

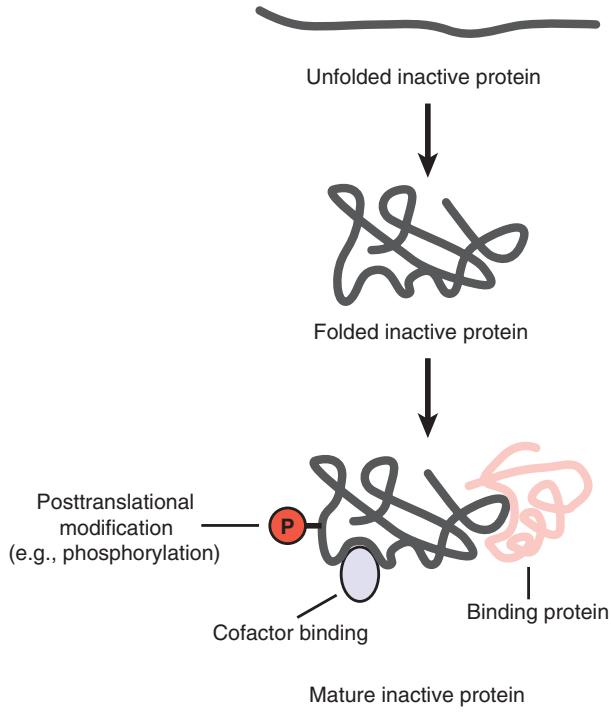

Figure 15-5. Maturation of a functional protein. Although the linear amino acid sequence of a protein often is shown, the function of a protein also is controlled by its correctly folded three-dimensional structure. In addition, many proteins also have covalent posttranslational modifications such as phosphorylation or noncovalent binding to a small molecule or a protein.

different characteristics, contain the same genetic material. This cellular diversity is controlled by the *genome* and accomplished by tight regulation of gene expression. This leads to the synthesis and accumulation of different complements of RNA and, ultimately, to the proteins found in different cell types. For example, muscle and bone express different genes or the same genes at different times. Moreover, the choice of which genes are expressed in a given cell at a given time depends on signals received from its environment. There are multiple levels at which gene expression can be controlled along the pathway from DNA to RNA to protein (see Fig. 15-4). *Transcriptional control* refers to the mechanism for regulating when and how often a gene is transcribed. Splicing of the primary RNA transcript (*RNA processing control*) and selection of completed mRNAs for nuclear export (*RNA transport control*) represent additional potential regulatory steps. The mRNAs in the cytoplasm can be selectively translated by ribosomes (*translational control*) or selectively stabilized or degraded (*mRNA degradation control*). Finally, the resulting proteins can undergo selective activation, inactivation, or compartmentalization (*protein activity control*).

Because a large number of genes are regulated at the transcriptional level, regulation of gene transcripts (i.e., mRNA) often is referred to as *gene regulation* in a narrow definition. Each of the steps during transcription is properly regulated in eukaryotic cells. Because genes are differentially regulated from one another, one gene can be differentially regulated in different cell types or at different developmental stages. Therefore, gene regulation at the level of transcription is largely context

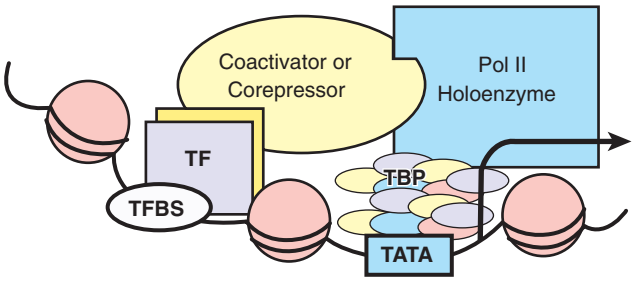

Figure 15-6. Transcriptional control by RNA polymerase. DNA is packaged into a chromatin structure. TATA = the common sequence on the promoter recognized by TBP and polymerase II holoenzyme; TBP = TATA-binding protein and associated factors; TF = hypothetical transcription factor; TFBS = transcription factor binding site; ball-shaped structures = nucleosomes. Coactivator or corepressor is a factor linking the TF with the Pol II complex.

dependent. However, there is a common scheme that applies to transcription at the molecular level (Fig. 15-6). Each gene promoter possesses unique sequences called *TATA boxes* that can be recognized and bound by a large complex containing RNA polymerase II, forming the basal transcription machinery. Usually located upstream of the TATA box (but sometimes longer distances) are a number of regulatory sequences referred to as *enhancers* that are recognized by regulatory proteins called *transcription factors*. These transcription factors specifically bind to the enhancers, often in response to environmental or developmental cues, and cooperate with each other and with basal transcription factors to initiate transcription. Regulatory sequences that negatively regulate the initiation of transcription also are present on the promoter DNA. The transcription factors that bind to these sites are called *repressors*, in contrast to the *activators* that activate transcription. The molecular interactions between transcription factors and promoter DNA, as well as between the cooperative transcription factors, are highly regulated and context-dependent. Specifically, the recruitment of transcription factors to the promoter DNA occurs in response to physiologic signals. A number of structural motifs in these DNA-binding transcription factors facilitate this recognition and interaction. These include the helix-turn-helix, the homeodomain motif, the zinc finger, the leucine zipper, and the helix-loop-helix motifs.

Human Genome

Genome is a collective term for all genes present in one organism. The human genome contains DNA sequences of 3 billion base pairs, carried by 23 pairs of chromosomes. The human genome has an estimated 25,000 to 30,000 genes, and overall, it is 99.9% identical in all people.[7,8] Approximately 3 million locations where single-base DNA differences exist have been identified and termed *single nucleotide polymorphisms*. Single nucleotide polymorphisms may be critical determinants of human variation in disease susceptibility and responses to environmental factors.

The completion of the human genome sequence in 2003 represented another great milestone in modern science. The Human Genome Project created the field of *genomics*, which is the study of genetic material in detail (see Fig. 15-1). The medical field is building on the knowledge, resources, and technologies emanating from the human genome to further the understanding of the relationship of the genes and their mutations to human health and disease. This expansion of genomics into human health applications resulted in the field of genomic medicine.

3▶ The emergence of genomics as a science will transform the practice of medicine and surgery in this century. This breakthrough has allowed scientists the opportunity to gain remarkable insights into the lives of humans. Ultimately, the goal is to use this information to develop new ways to treat, cure, or even prevent the thousands of diseases that afflict humankind. In the twenty-first century, work will begin to incorporate the information embedded in the human genome sequence into surgical practices. By doing so, the genomic information can be used for diagnosing and predicting disease and disease susceptibility. Diagnostic tests can be designed to detect errant genes in patients suspected of having particular diseases or of being at risk for developing them. Furthermore, exploration into the function of each human gene is now possible, which will shed light on how faulty genes play a role in disease causation. This knowledge also makes possible the development of a new generation of therapeutics based on genes. Drug design is being revolutionized as researchers create new classes of medicines based on a reasoned approach to the use of information on gene sequence and protein structure function rather than the traditional trial-and-error method. Drugs targeted to specific sites in the body promise to have fewer side effects than many of today's medicines. Finally, other applications of genomics will involve the transfer of genes to replace defective versions or the use of gene therapy to enhance normal functions such as immunity.

Proteomics refers to the study of the structure and expression of proteins as well as the interactions among proteins encoded by a human genome (see Fig. 15-1).[9] A number of Internet-based repositories for protein sequences exist, including Swiss-Prot (http://www.expasy.ch). These databases allow comparisons of newly identified proteins with previously characterized sequences to allow prediction of similarities, identification of splice variants, and prediction of membrane topology and posttranslational modifications. Tools for proteomic profiling include two-dimensional gel electrophoresis, time-of-flight mass spectrometry, matrix-assisted laser desorption/ionization, and protein microarrays. *Structural proteomics* aims to describe the three-dimensional structure of proteins that is critical to understanding function. *Functional genomics* seeks to assign a biochemical, physiologic, cell biologic, and/or developmental function to each predicted gene. An ever-increasing arsenal of approaches, including transgenic animals, RNA interference (RNAi), and various systematic mutational strategies, will allow dissection of functions associated with newly discovered genes. Although the potential of this field of study is vast, it is in its early stages.

It is anticipated that a genomic and proteomic approach to human disease will lead to a new understanding of pathogenesis that will aid in the development of effective strategies for early diagnosis and treatment.[10] For example, identification of altered protein expression in organs, cells, subcellular structures, or protein complexes may lead to development of new biomarkers for disease detection. Moreover, improved understanding of how protein structure determines function will allow rational identification of therapeutic targets, and thereby not only accelerate drug development, but also lead to new strategies to evaluate therapeutic efficacy and potential toxicity.[9]

Cell Cycle and Apoptosis

Every organism is composed of many different cell types at different developmental stages. Some cell types continue to grow, while some cells stop growing after a developmental stage or resume growth after a break. For example, embryonic stem cells grow continuously, while nerve cells and striated muscle cells stop dividing after maturation. Cell cycle is the process for every cell including DNA replication and protein synthesis, DNA segregation in half, and package DNA and protein in two newly formed cells to enable passage of identical genetic information from one parental cell to two daughter cells. Thus, the cell cycle is the fundamental mechanism to maintain tissue homeostasis. A cell cycle comprises four periods: G_1 (first gap phase before DNA synthesis), S (synthesis phase when DNA replication occurs), G_2 (the gap phase before mitosis), and M (mitosis, the phase when two daughter cells with identical DNA are generated) (Fig. 15-7). After a full cycle, the daughter cells enter G_1 again, and when they receive appropriate signals, undergo another cycle, and so on. The machinery that drives cell cycle progression is made up of a group of enzymes called *cyclin-dependent kinases* (CDKs). Cyclin expression fluctuates during the cell cycle, and cyclins are essential for CDK activities and form complexes with CDK. The cyclin A/CDK1 and cyclin B/CDK1 drive the progression for the M phase, while cyclin A/CDK2 is the primary S phase complex. Early G_1 cyclin D/CDK4/6 or late G_1 cyclin E/CDK2 controls the G_1-S transition. There also are negative regulators for CDK termed *CDK inhibitors*, which inhibit the assembly or activity of the cyclin-CDK complex. Expression of cyclins and CDK inhibitors often is regulated by developmental and environmental factors.

The cell cycle is connected with signal transduction pathways as well as gene expression. Although the S and M phases rarely are subjected to changes imposed by extracellular signals, the G_1 and G_2 phases are the primary periods when cells decide whether or not to move on to the next phase. During the G_1 phase, cells receive green- or red-light signals, S phase entry or G_1 arrest, respectively. Growing cells proliferate only when supplied with appropriate mitogenic growth factors. Cells become committed to entry of the cell cycle only toward the end of G_1. Mitogenic signals stimulate the activity of early G_1 CDKs (e.g., cyclin D/CDK4) that inhibit the activity of pRb protein and activate the transcription factor called *E2F* to induce the expression of batteries of genes essential for G_1-S progression. Meanwhile, cells also receive antiproliferative signals such as those from tumor suppressors. These antiproliferative signals also act in the G_1 phase to stop cells' progress into the S phase by inducing CKI production. For example, when DNA is damaged, cells will repair the damage before entering the S phase. Therefore, G_1 contains one of the most important checkpoints for cell cycle progression. If the analogy is made that CDK is to a cell as an engine is to a car, then cyclins and CKI are the gas pedal and brake, respectively. Accelerated proliferation or improper cell cycle progression with damaged DNA would be disastrous. Genetic gain-of-function mutations in oncogenes (that often promote expression or activity of the cyclin/CDK complex) or loss-of-function mutations in tumor suppressor (that stimulate production of CKI) are causal factors for malignant transformation.

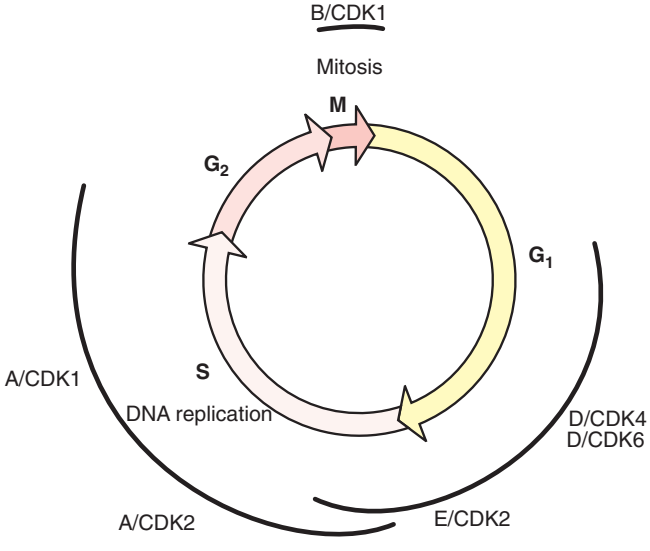

Figure 15-7. The cell cycle and its control system. M is the mitosis phase, when the nucleus and the cytoplasm divide; S is the phase when DNA is duplicated; G_1 is the gap between M and S; G_2 is the gap between S and M. A complex of cyclin and cyclin-dependent kinase (CDK) controls specific events of each phase. Without cyclin, CDK is inactive. Different cyclin/CDK complexes are shown around the cell cycle. A, B, D, and E stand for cyclin A, cyclin B, cyclin D, and cyclin E, respectively.

In addition to cell cycle control, cells use genetically programmed mechanisms to kill cells. This cellular process, called *apoptosis* or *programmed cell death*, is essential for the maintenance of tissue homeostasis (Fig. 15-8).

Normal tissues undergo proper apoptosis to remove unwanted cells, those that have completed their jobs or have been damaged or improperly proliferated. Apoptosis can be activated by many physiologic stimuli such as death receptor signals (e.g., Fas or cytokine tumor necrosis factor), growth factor deprivation, DNA damage, and stress signals. Two major pathways control the biochemical mechanisms governing apoptosis: the death receptor and mitochondrial. However, recent advances in apoptosis research suggest an interconnection of the two pathways. What is central to the apoptotic machinery is the activation of a cascade of proteinases called caspases. Similarly to CDK in the cell cycle, activities and expression of caspases are well controlled by positive and negative regulators. The complex machinery of apoptosis must be tightly controlled. Perturbations of this process can cause neoplastic transformation or other diseases.

Signal Transduction Pathways

Gene expression in a genome is controlled in a temporal and spatial manner, at least in part by signaling pathways.[11] A signaling pathway generally begins at the cell surface and, after a signaling relay by a cascade of intracellular effectors, ends up in the nucleus (Fig. 15-9). All cells have the ability to sense changes in their external environment. The bioactive substances to which cells can respond are many and include proteins, short peptides, amino acids, nucleotides/nucleosides, steroids, retinoids, fatty acids, and dissolved gases. Some of these substances are lipophilic and thereby can cross the plasma membrane by diffusion to bind to a specific target protein within the cytoplasm (intracellular receptor). Other substances bind directly with a transmembrane protein (cell-surface receptor). Binding of ligand to receptor initiates a series of biochemical reactions (*signal transduction*) typically involving protein-protein interactions and the transfer of high-energy phosphate groups, leading to various cellular end responses.

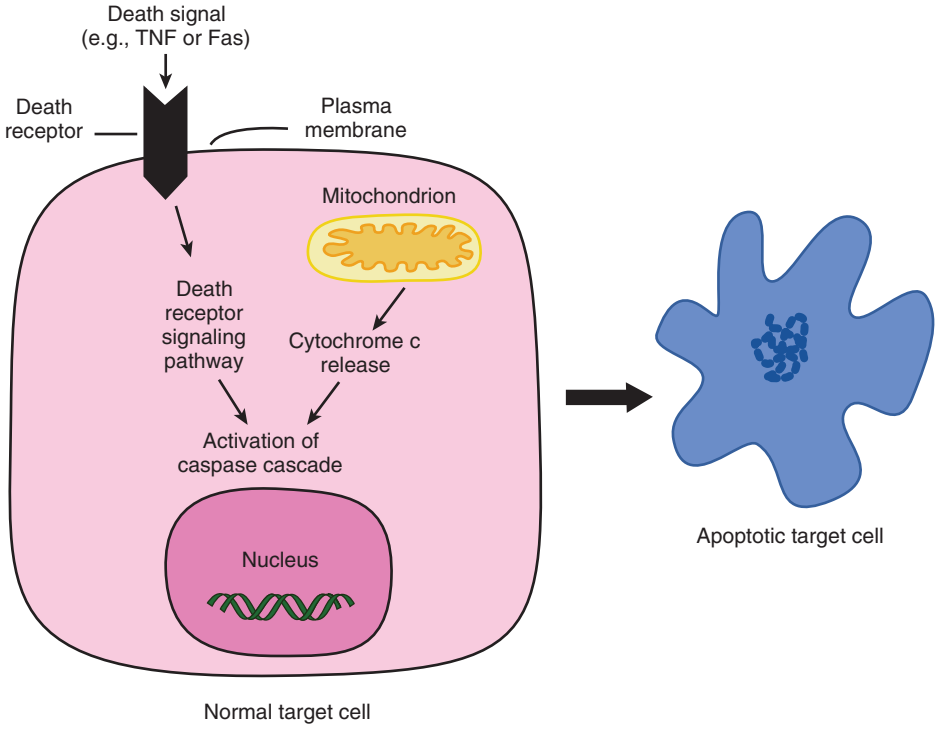

Figure 15-8. A simplified view of the apoptosis pathways. Extracellular death receptor pathways include the activation of Fas and tumor necrosis factor (TNF) receptors, and consequent activation of the caspase pathway. Intracellular death pathway indicates the release of cytochrome c from mitochondria, which also triggers the activation of the caspase cascade. During apoptosis, cells undergo DNA fragmentation and nuclear and cell membrane breakdown, and are eventually digested by other cells.

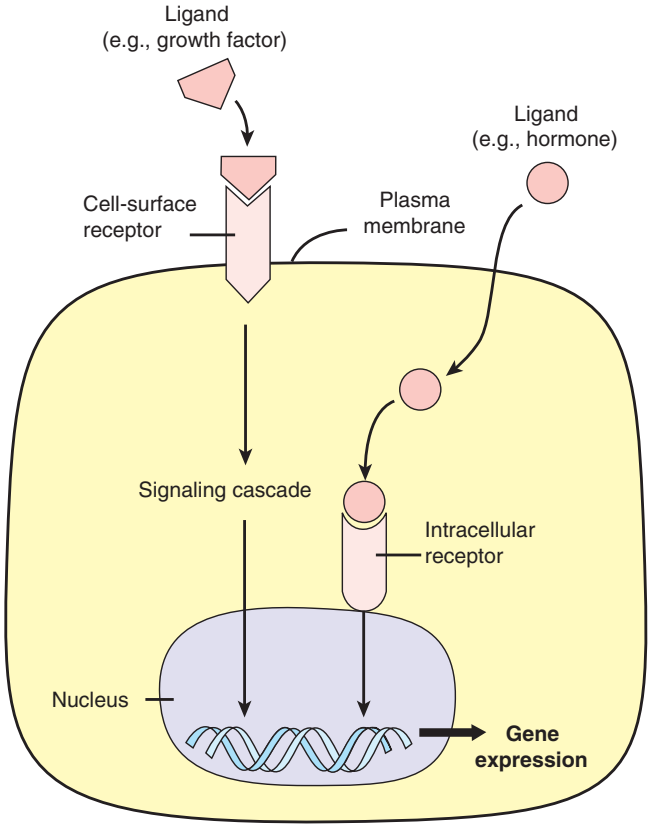

Figure 15-9. Cell-surface and intracellular receptor pathways. Extracellular signaling pathway: Most growth factors and other hydrophilic signaling molecules are unable to move across the plasma membrane and directly activate cell-surface receptors such as G-protein–coupled receptors and enzyme-linked receptors. The receptor serves as the receiver, and in turn activates the downstream signals in the cell. Intracellular signaling pathway: Hormones or other diffusible molecules enter the cell and bind to the intracellular receptor in the cytoplasm or in the nucleus. Either extracellular or intracellular signals often reach the nucleus to control gene expression.

Control and specificity through simple protein-protein interactions—referred to as *adhesive interactions*—is a common feature of signal transduction pathways in cells.[12] Signaling also involves catalytic activities of signaling molecules, such as protein kinases/phosphatases, that modify the structures of key signaling proteins. Upon binding and/or modification by upstream signaling molecules, downstream effectors undergo a conformational (allosteric) change and, consequently, a change in function. The signal that originates at the cell surface and is relayed by the cytoplasmic proteins often ultimately reaches the transcriptional apparatus in the nucleus. It alters the DNA binding and activities of transcription factors that directly turn genes on or off in response to the stimuli. Abnormal alterations in signaling activities and capacities in otherwise normal cells can lead to diseases such as cancer.

Advances in biology in the last two decades have dramatically expanded the view on how cells are wired with signaling pathways. In a given cell, many signaling pathways operate simultaneously and crosstalk with one another. A cell generally may react to a hormonal signal in a variety of ways: (a) by changing its metabolite or protein, (b) by generating an electric current, or (c) by contracting. Cells continually are subject to multiple input signals that simultaneously and sequentially activate multiple receptor- and non–receptor-mediated signal transduction pathways, which form a signaling network. Although the regulators responsible for cell behavior are rapidly identified as a result of genomic and proteomic techniques, the specific functions of the individual proteins, how they assemble, and the networks that control cellular behavior remain to be defined. An increased understanding of cell regulatory pathways—and how they are disrupted in disease—will likely reveal common themes based on protein interaction domains that direct associations of proteins with other polypeptides, phospholipids, nucleic acids, and other regulatory molecules. Advances in the understanding of signaling networks will require methods of investigation that move beyond traditional "linear" approaches into

medical informatics and computational biology. The bewildering biocomplexity of such networks mandates multidisciplinary and transdisciplinary research collaboration. The vast amount of information that is rapidly emerging from genomic and proteomic data mining will require the development of new modeling methodologies within the emerging disciplines of medical mathematics and physics.

Signaling pathways often are grouped according to the properties of signaling receptors. Many hydrophobic signaling molecules are able to diffuse across plasma membranes and directly reach specific cytoplasmic targets. Steroid hormones, thyroid hormones, retinoids, and vitamin D are examples that exert their activity upon binding to structurally related receptor proteins that are members of the *nuclear hormone receptor superfamily*. Ligand binding induces a conformational change that enhances transcriptional activity of these receptors. Most extracellular signaling molecules interact with transmembrane protein receptors that couple ligand binding to intracellular signals, leading to biologic actions.

There are three major classes of cell-surface receptors: *transmitter-gated ion channels*, *seven-transmembrane G-protein–coupled receptors (GPCRs)*, and *enzyme-linked receptors*. The superfamily of GPCRs is one of the largest families of proteins, representing over 800 genes of the human genome. Members of this superfamily share a characteristic seven-transmembrane configuration. The ligands for these receptors are diverse and include hormones, chemokines, neurotransmitters, proteinases, inflammatory mediators, and even sensory signals such as odorants and photons. Most GPCRs signal through *heterotrimeric G proteins*, which are guanine-nucleotide regulatory complexes. Thus the receptor serves as the receiver, the G protein serves as the transducer, and the enzyme serves as the effector arm. *Enzyme-linked receptors* possess an extracellular ligand-recognition domain and a cytosolic domain that either has intrinsic enzymatic activity or directly links with an enzyme. Structurally, these receptors usually have only one transmembrane-spanning domain. Of at least five forms of enzyme-linked receptors classified by the nature of the enzyme activity to which they are coupled, the growth factor receptors such as tyrosine kinase receptor or serine/threonine kinase receptors mediate diverse cellular events including cell growth, differentiation, metabolism, and survival/apoptosis. Dysregulation (particularly mutations) of these receptors is thought to underlie conditions of abnormal cellular proliferation in the context of cancer. The following sections will further review two examples of growth factor signaling pathways and their connection with human diseases.

Insulin Pathway and Diabetes.[13] The discovery of insulin in the early 1920s is one of the most dramatic events in the treatment of human disease. *Insulin* is a peptide hormone that is secreted by the β-cell of the pancreas. Insulin is required for the growth and metabolism of most mammalian cells, which contain cell-surface insulin receptors (InsR). Insulin binding to InsR activates the kinase activity of InsR. InsR then adds phosphoryl groups, a process referred to as *phosphorylation*, and subsequently activates its immediate intracellular effector, called *insulin receptor substrate* (IRS). IRS plays a central role in coordinating the signaling of insulin by activating distinct signaling pathways, the PI3K-Akt pathway and MAPK pathway, both of which possess multiple protein kinases that can control transcription, protein synthesis, and glycolysis (Fig. 15-10).

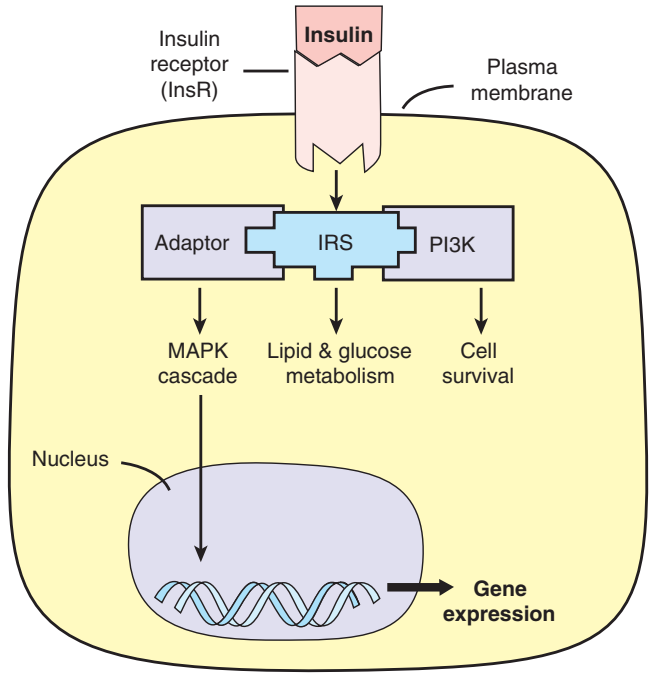

Figure 15-10. Insulin-signaling pathway. Insulin is a peptide growth factor that binds to and activates the heterotetrameric receptor complex (InsR). InsR possesses protein tyrosine kinase activity and is able to phosphorylate the downstream insulin receptor substrate (IRS). Phosphorylated IRS serves as a scaffold and controls the activation of multiple downstream pathways for gene expression, cell survival, and glucose metabolism. Inactivation of the insulin pathway can lead to type 2 diabetes.

The primary physiologic role of insulin is in glucose homeostasis, which is accomplished through the stimulation of glucose uptake into insulin-sensitive tissues such as fat and skeletal muscle. Defects in insulin synthesis/secretion and/or responsiveness are major causal factors in diabetes, one of the leading causes of death and disability in the United States, affecting an estimated 16 million Americans. Type 2 diabetes accounts for about 90% of all cases of diabetes. Clustering of type 2 diabetes in certain families and ethnic populations points to a strong genetic background for the disease. More than 90% of affected individuals have insulin resistance, which develops when the body is no longer able to respond correctly to insulin circulating in the blood. Although relatively little is known about the biochemical basis of this metabolic disorder, it is clear that the insulin-signaling pathways malfunction in this disease. It is also known that genetic mutations in the InsR or IRS cause type 2 diabetes, although which one is not certain. The majority of type 2 diabetes cases may result from defects in downstream-signaling components in the insulin-signaling pathway. Type 2 diabetes also is associated with declining β-cell function, resulting in reduced insulin secretion; these pathways are under intense study. A full understanding of the basis of insulin resistance is crucial for the development of new therapies for type 2 diabetes. Furthermore, apart from type 2 diabetes, insulin resistance is a central feature of several other common human disorders, including atherosclerosis and coronary artery disease, hypertension, and obesity.

Transforming Growth Factor-β (TGF-β) Pathway and Cancers.[14] Growth factor signaling controls cell growth, differentiation, and apoptosis. Although insulin and many mitogenic

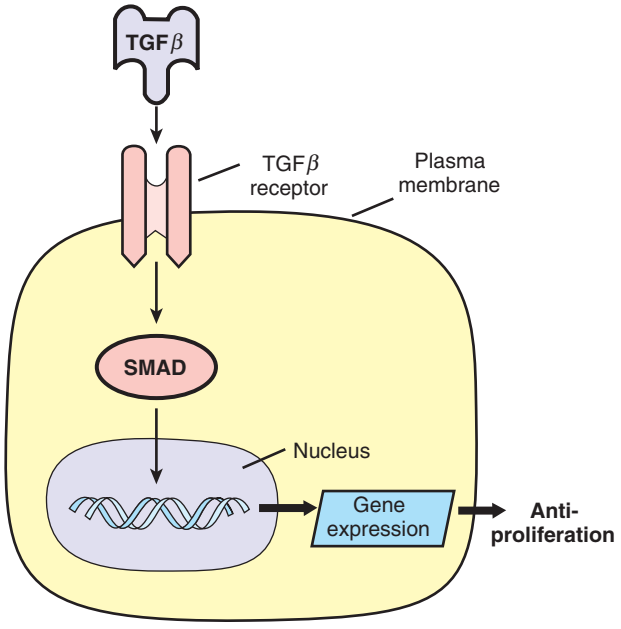

Figure 15-11. TGF-β signaling pathway. The TGF-β family has at least 29 members encoded in the human genome. They are also peptide growth factors. Each member binds to a heterotetrameric complex consisting of a distinct set of type I and type II receptors. TGF-β receptors are protein serine/threonine kinases and can phosphorylate the downstream substrates called *SMAD proteins*. Phosphorylated SMADs are directly transported into the nucleus, where they bind to the DNA and regulate gene expression that is responsible for inhibition of cell proliferation. Inactivation of the TGF-β pathway through genetic mutations in the TGF-β receptors or SMADs is frequent in human cancer, leading to the uncontrolled proliferation of cancer cells.

growth factors promote cell proliferation, some growth factors and hormones inhibit cell proliferation. TGF-β is one of them. The balance between mitogens and TGF-β plays an important role in controlling the proper pace of cell cycle progression. The growth inhibition function of TGF-β signaling in epithelial cells plays a major role in maintaining tissue homeostasis.

The TGF-β superfamily comprises a large number of structurally related growth and differentiation factors that act through a receptor complex at the cell surface (Fig. 15-11). The complex consists of transmembrane serine/threonine kinases. The receptor signals through activation of heterotrimeric complexes of intracellular effectors called SMADs (which are contracted from homologous *Caenorhabditis elegans* Sma and *Drosophila* Mad, two evolutionarily conserved genes for TGF-β signaling). Upon phosphorylation by the receptors, SMAD complexes translocate into the nucleus, where they bind to gene promoters and cooperate with specific transcription factors to regulate the expression of genes that control cell proliferation and differentiation. For example, TGF-β strongly induces the transcription of a gene called *p15*^{INK4B} (a type of CKI) and, at the same time, reduces the expression of many oncogenes such as *c-Myc*. The outcome of the altered gene expression leads to the inhibition of cell cycle progression. Meanwhile, the strength and duration of TGF-β signaling is fine-tuned by a variety of positive or negative modulators, including protein phosphatases. Therefore, controlled activation of TGF-β signaling is an intrinsic mechanism for cells to ensure controlled proliferation.

Resistance to TGF-β's anticancer action is one hallmark of human cancer cells. TGF-β receptors and SMADs are identified as tumor suppressors. The TGF-β signaling circuit can be disrupted in a variety of ways and in different types of human tumors. Some lose TGF-β responsiveness through downregulation or mutations of their TGF-β receptors. The cytoplasmic SMAD4 protein, which transduces signals from ligand-activated TGF-β receptors to downstream targets, may be eliminated through mutation of its encoding gene. The locus encoding cell cycle inhibitor p15^{INK4B} may be deleted. Alternatively, the immediate downstream target of its actions, cyclin-dependent kinase 4 (CDK4), may become unresponsive to the inhibitory actions of p15^{INK4B} because of mutations that block p15^{INK4B} binding. The resulting cyclin D/CDK4 complexes constitutively inactivate tumor suppressor pRb by hyperphosphorylation. Finally, functional pRb, the end target of this pathway, may be lost through mutation of its gene. For example, in pancreatic and colorectal cancers, 100% of cells derived from these cancers carry genetic defects in the TGF-β signaling pathway. Therefore, the antiproliferative pathway converging onto pRb and the cell division cycle is, in one way or another, disrupted in a majority of human cancer cells. Besides cancer, dysregulation of TGF-β signaling also has been associated with other human diseases such as Marfan's syndrome and thoracic aortic aneurysm.

Gene Therapy and Molecular Drugs in Cancer

Modern advances in the use of molecular biology to manipulate genomes have greatly contributed to the understanding of the molecular basis for how cells live, die, or differentiate. Given the fact that human diseases arise from improper changes in the genome, the continuous understanding of how the genome functions will make it possible to tailor medicine on an individual basis. Although significant hurdles remain, the course toward therapeutic application of molecular biology already has been mapped out by many proof-of-principle studies in the literature. In this section, cancer is used as an example to elaborate some therapeutic applications of molecular biology. Modern molecular medicine includes gene therapy and molecular drugs that target genes or gene products that wire human cells.

Cancer is a complex disease, involving uncontrolled growth and spread of tumor cells (Fig. 15-12). Cancer development depends on the acquisition and selection of specific characteristics that set the tumor cell apart from normal somatic cells. Cancer cells have defects in regulatory circuits that govern normal cell proliferation and homeostasis. Many lines of evidence indicate that tumorigenesis in humans is a multistep process and that these steps reflect genetic alterations that drive the progressive transformation of normal human cells into highly malignant derivatives. The genomes of tumor cells are invariably altered at multiple sites, having suffered disruption through lesions as subtle as point mutations and as obvious as changes in chromosome complement. A succession of genetic changes, each conferring one or another type of growth advantage, leads to the progressive conversion of normal human cells into cancer cells.

Cancer research in the past 20 years has generated a rich and complex body of knowledge, revealing cancer to be a disease involving dynamic changes in the genome. The causes of cancer include genetic predisposition, environmental influences, infectious agents, and aging. These transform normal cells into cancerous ones by derailing a wide spectrum of regulatory pathways including signal transduction pathways, cell

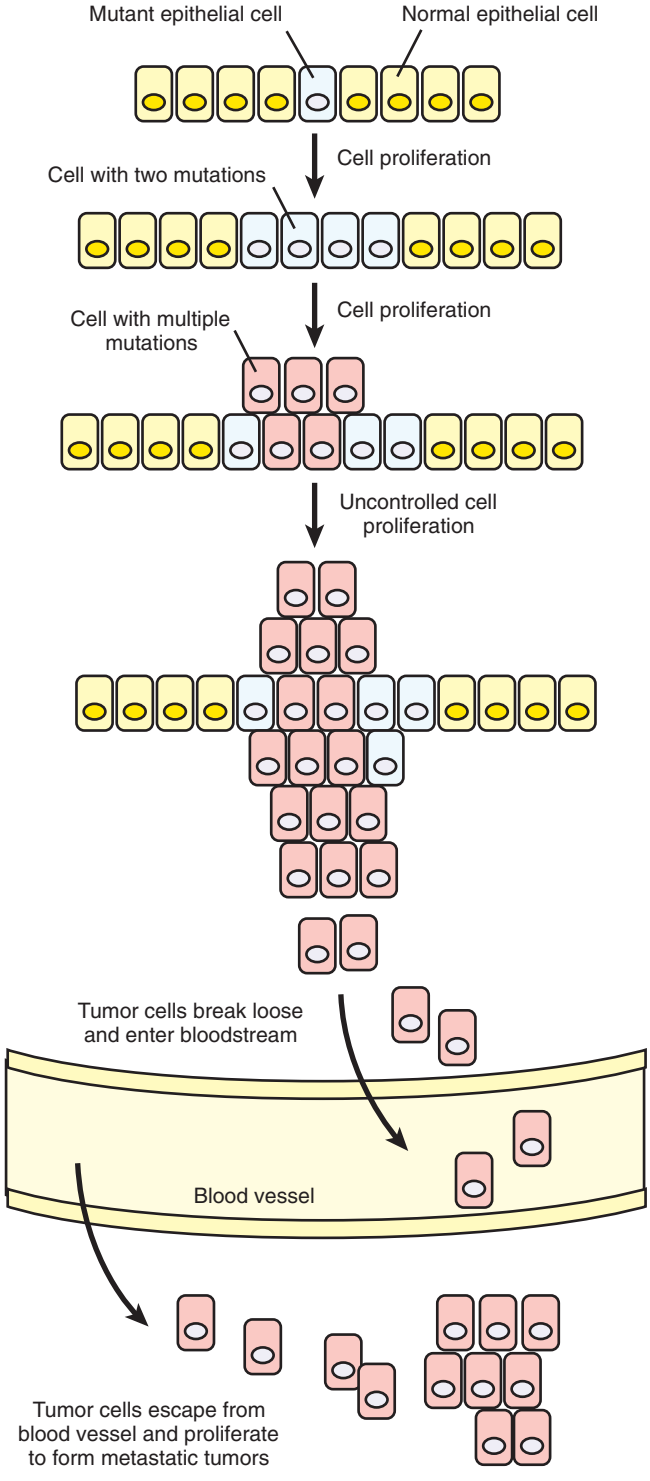

Figure 15-12. Tumor clonal evolution and metastasis. A tumor develops from mutant cells with multiple genetic mutations. Through repeated alterations in the genome, mutant epithelial cells are able to develop into a cluster of cells (called a *tumor clone*) that proliferates in an uncontrollable fashion. Further changes in the tumor cells can transform the tumor cells into a population of cells that can enter the blood vessels and repopulate in a new location.

cycle machinery, or apoptotic pathways.[15,16] The early notion that cancer was caused by mutations in genes critical for the control of cell growth implied that genome stability is important for preventing oncogenesis. There are two classes of cancer genes in which alteration has been identified in human and animal cancer cells: oncogenes, with dominant gain-of-function mutations, and tumor suppressor genes, with recessive loss-of-function mutations. In normal cells, oncogenes promote cell growth by activating cell cycle progression, whereas tumor suppressors counteract oncogenes' functions. Therefore, the balance between oncogenes and tumor suppressors maintains a well-controlled state of cell growth.

During the development of most types of human cancer, cancer cells can break away from primary tumor masses, invade adjacent tissues, and hence travel to distant sites where they form new colonies. This spreading process of tumor cells, called *metastasis*, is the cause of 90% of human cancer deaths. Metastatic cancer cells that enter the bloodstream can reach virtually all tissues of the body. Bones are one of the most common places for these cells to settle and start growing again. Bone metastasis is one of the most frequent causes of pain in people with cancer. It also can cause bones to break and create other symptoms and problems for patients.

The progression in the knowledge of cancer biology has been accelerating in recent years. All of the scientific knowledge acquired through hard work and discovery has made it possible for cancer treatment and prevention. As a result of explosive new discoveries, some modern treatments were developed. The success of these therapies, together with traditional treatments such as surgical procedures, is further underscored by the fact that in 2002 the cancer rate was reduced in the United States. Current approaches to the treatment of cancer involve killing cancer cells with toxic chemicals, radiation, or surgery. Alternatively, several new biologic- and gene-based therapies are aimed at enhancing the body's natural defenses against invading cancers. Understanding the biology of cancer cells has led to the development of designer therapies for cancer prevention and treatment. Gene therapy, immune system modulation, genetically engineered antibodies, and molecularly designed chemical drugs are all promising fronts in the war against cancer.

Immunotherapy. The growth of the body is controlled by many natural signals through complex signaling pathways. Some of these natural agents have been used in cancer treatment and have been proven effective for fighting several cancers through the clinical trial process. These naturally occurring biologic agents, such as interferons, interleukins, and other cytokines, can now be produced in the laboratory. These agents, as well as the synthetic agents that mimic the natural signals, are given to patients to influence the natural immune response agents either by directly altering the cancer cell growth or by acting indirectly to help healthy cells control the cancer. One of the most exciting applications of immunotherapy has come from the identification of certain tumor targets called *antigens* and the aiming of an antibody at these targets. This was first used as a means of localizing tumors in the body for diagnosis and was more recently used to attack cancer cells. Trastuzumab (Herceptin) is an example of such a drug.[17] Trastuzumab is a monoclonal antibody that neutralizes the mitogenic activity of cell-surface growth factor receptor HER-2, which is overexpressed in approximately 25% of breast cancers. HER-2–overexpressing tumors tend to grow faster and generally are more likely to recur than tumors that do not overproduce HER-2. Trastuzumab is designed to attack cancer cells that overexpress HER-2 by slowing or preventing the growth of these cells, resulting in increased survival of HER-2–positive breast cancer patients. Another significant example is the administration of interleukin-2 (IL-2) to patients with metastatic melanoma or kidney cancer, which has been

shown to mediate the durable regression of metastatic cancer. IL-2, a cytokine produced by human helper T lymphocytes, has a wide range of immune regulatory effects, including the expansion of lymphocytes following activation by a specific antigen. Although IL-2 has no direct impact on cancer cells, the impact of IL-2 on cancers in vivo derives from its ability to expand lymphocytes with antitumor activity. The expanded lymphocyte pool enables recognition of the antigen on cancer cells. Thus, the molecular identification of cancer antigens has opened new possibilities for the development of effective immunotherapies for patients with cancer. Clinical studies using immunization with peptides derived from cancer antigens have shown that high levels of lymphocytes with antitumor activity can be produced in cancer-bearing patients. Highly avid antitumor lymphocytes can be isolated from immunized patients and grown in vitro for use in cell-transfer therapies.

Chemotherapy. The primary function of anticancer chemicals is to block different steps involved in cell growth and replication. These chemicals often block a critical chemical reaction in a signal transduction pathway or during DNA replication or gene expression. For example, STI571, also known as *Gleevec*, is one of the first molecularly targeted drugs based on the changes that cancer causes in cells.[18] STI571 offers promise for the treatment of chronic myeloid leukemia (CML) and may soon surpass interferon-γ as the standard treatment for the disease. In CML, STI571 is targeted at the Bcr-Abl kinase, an activated oncogene product in CML (Fig. 15-13). Bcr-Abl is an overly activated protein kinase resulting from a specific genetic abnormality generated by chromosomal translocation that is found in the cells of patients with CML. STI571-mediated inhibition of Bcr-Abl kinase activity not only prevents cell growth of Bcr-Abl–transformed leukemic cells, but also induces apoptosis. Clinically, the drug quickly corrects the blood cell abnormalities caused by the leukemia in a majority of patients, achieving a complete disappearance of the leukemic blood cells and the return of normal blood cells. Additionally, the drug appears to have some effect on other cancers including certain brain tumors and gastrointestinal (GI) stromal tumors, a very rare type of stomach cancer.

Gene Therapy. Gene therapy is an experimental treatment that involves genetically altering a patient's own tumor cells or lymphocytes (cells of the immune system, some of which can attack cancer cells). For years, the concept of gene therapy has held promise as a new, potentially potent weapon to attack cancer. Although a rapid progression in the understanding of the molecular and clinical aspects of gene therapy has been witnessed in the past decade, gene therapy treatment has not yet been shown to be superior to standard treatments in humans.

Several problems must be resolved to transform it into a clinically relevant form of therapy. The major issues that limit its translation to the clinic are improving the selectivity of tumor targeting, improving the delivery to the tumor, and the enhancement of the transduction rate of the cells of interest. In most gene therapy trials for malignant diseases, tumors can be accessed and directly injected (in situ gene therapy). The in situ gene therapy also offers a better distribution of the vector virus throughout the tumor. Finally, a combination of gene therapy strategies will be more effective than the use of a single gene therapy system. An important aspect of effective gene therapy involves the choice of appropriate genes for manipulation. Genes that promote the production of messenger chemicals or other immune-active substances can be transferred into the patient's cells. These include genes that inhibit cell cycle progression, induce apoptosis, enhance host immunity against cancer cells, block the ability of cancer cells to metastasize, and cause tumor cells to undergo suicide. Recent development of RNAi technology, which uses a loss-of-function approach to block gene functions, ensures a new wave of hopes for gene therapy. Nonetheless, gene therapy is still experimental and is being studied in clinical trials for many different types of cancer. The mapping of genes responsible for human cancer is likely to provide new targets for gene therapy in the future. The preliminary results of gene therapy for cancer are encouraging, and as advancements are made in the understanding of the molecular biology of human cancer, the future of this rapidly developing field holds great potential for treating cancer.

It is noteworthy that the use of multiple therapeutic methods has proven more powerful than a single method. The use of chemotherapy after surgery to destroy the few remaining cancerous cells in the body is called *adjuvant* therapy. Adjuvant therapy was first tested and found to be effective in breast cancer. It was later adopted for use in other cancers. A major discovery in chemotherapy is the advantage of multiple chemotherapeutic agents (known as *combination* or *cocktail chemotherapy*) over single agents. Some types of fast-growing leukemias and lymphomas (tumors involving the cells of the bone marrow and lymph nodes) responded extremely well to combination chemotherapy, and clinical trials led to gradual improvement of the drug combinations used. Many of these tumors can be cured today by combination chemotherapy. As

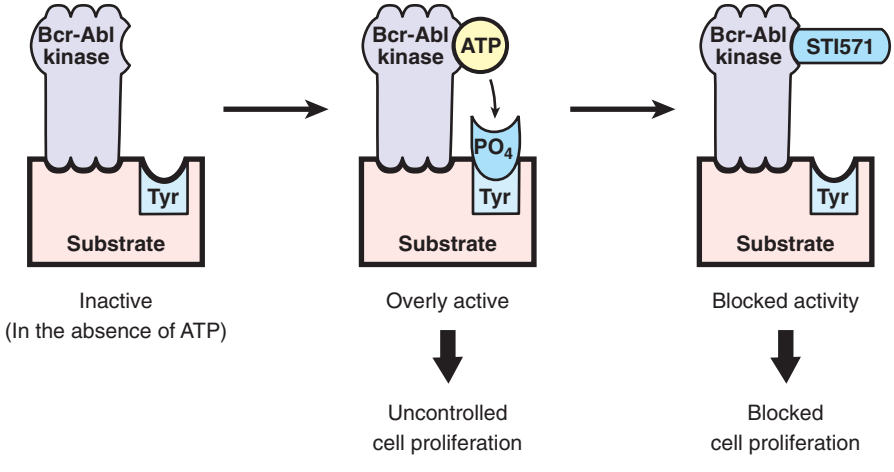

Figure 15-13. Mechanism of STI571 as a molecular drug. Bcr-Abl is an overly activated oncogene product resulting from a specific genetic abnormality generated by chromosomal translocation that is found in cells of patients with chronic myeloid leukemia. Bcr-Abl is an activated protein kinase and thus requires adenosine triphosphate (ATP) to phosphorylate substrates, which in turn promote cell proliferation. STI571 is a small molecule that competes with the ATP-binding site and thus blocks the transfer of phosphoryl group to substrate. PO_4 = phosphate; Tyr = tyrosine.

cancer cells carry multiple genetic defects, the use of combination chemotherapy, immunotherapy, and gene therapies may be more effective in treating cancers.

Stem Cell Research

Stem cell biology represents a cutting-edge scientific research field with potential clinical applications.[19] It may have an enormous impact on human health by offering hope for curing human diseases such as diabetes mellitus, Parkinson's disease, neurologic degeneration, and congenital heart disease. Stem cells are endowed with two remarkable properties (Fig. 15-14). First, stem cells can proliferate in an undifferentiated but pluripotent state and, as a result, can self-renew. Second, they have the ability to differentiate into many specialized cell types. There are two groups of stem cells: embryonic stem (ES) cells and adult stem cells. Human ES cells are derived from early preimplantation embryos called *blastocysts* (5 days postfertilization) and are capable of generating all differentiated germ layers in the body—ectoderm, mesoderm, and endoderm—and therefore are considered pluripotent. Adult stem cells are present in and can be isolated from adult tissues. They often are tissue specific and only can generate the cell types comprising a particular tissue in the body; therefore, they are considered multipotent. However, in some cases, they can transdifferentiate into cell types found in other tissues, called transdifferentiation. For example, hematopoietic stem cells are adult stem cells. They reside in bone marrow and are capable of generating all cell types of the blood and immune system.

Stem cells can be grown in culture and be induced to differentiate into a particular cell type, either in vitro or in vivo. With the recent and continually increasing improvement in culturing stem cells, scientists are beginning to understand the molecular mechanisms of stem cell self-renewal and differentiation in response to environmental cues. It is believed that discovery of the signals that control self-renewal vs. differentiation will be extremely important for the therapeutic use of stem cells in treating disease. It is possible that success in the study of the changes in signal transduction pathways in stem cells will lead to the development of therapies to replace diseased or damaged cells in the body using stem cell derivatives. Recently, stem cell research has been transformed by the discovery from the Shinya Yamanaka group and the James Thomsen group, who have found that a simple genetic manipulation can reprogram adult differentiated cells back into pluripotent stem cells.[20,21] This exciting discovery not only bypasses the ethical issues of using early embryos to generate ES cells, but also ensures a potentially limitless source of patient-specific stem cells for tissue engineering and regenerative medicine.

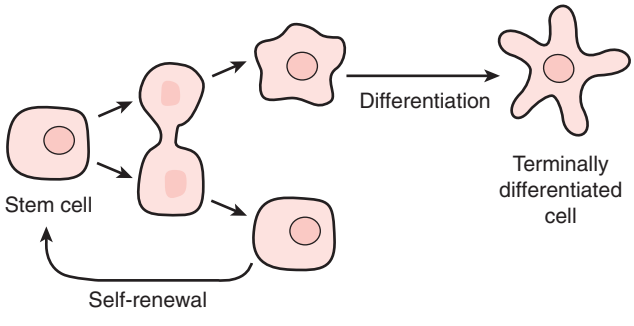

Figure 15-14. Stem cells. A stem cell is capable of self-renewal (unlimited cell cycle) and differentiation (becoming nondividing cells with specialized functions). Differentiating stem cells often undergo additional cell divisions before they become fully mature cells that carry out specific tissue functions.

The Atomic Theory of Disease[22]

The staggering advances in anatomy, physiology, and molecular biology over the past centuries have led us to our current state in which the atom is now the anatomy of the twenty-first century. As 99% of the body is composed of six elements (oxygen, carbon, hydrogen, nitrogen, calcium, and phosphorus), the next great advance in medicine will be bridging the subatomic, molecular, and genomic levels by forming an atomic theory of disease, which states that alterations in the composition of subatomic particles are the root cause of disease. The atomic theory of disease would include genetic alterations at the atomic/subatomic level that are akin to single nucleotide polymorphisms (SNPs), in which alleles for a gene differ on the exact nucleotide in a single location, which can change the ultimate protein structure. This can lead to subtle changes in function or dramatic results that cause pathology. We hypothesize that on a subatomic level, there could potentially be polymorphisms as well, in which there are subtle changes in the sea of subatomic particles. Isotopes, discovered 100 years ago, would fall into this category of subatomic polymorphism, as they differ in the number of neutrons present in the atom. Differences in other particles may not change the mass of the atom, but may alter some of the characteristics of the atom.

A known example of a change in the subatomic milieu of an element leading to a disease process is that of methemoglobinemia, a disorder characterized by an overabundance of methemoglobin. Methemoglobin contains an oxidized form of iron (carrying an extra electron), as opposed to the reduced form in normal hemoglobin. This results in a shift in the oxygen-hemoglobin dissociation curve to the left, causing hypoxia. Methemoglobinemia can be congenital, due to a defect in an enzyme that normally reduces methemoglobin back to hemoglobin, or acquired, caused by breakdown products of drugs that can oxidize hemoglobin. Although there is less than 1% of methemoglobin normally present in human tissues, affecting local blood flow and inflammation through its effects on nitric oxide and heme, large quantities can lead to respiratory failure and death.

TECHNOLOGIES OF MOLECULAR AND CELL BIOLOGY

DNA Cloning

Since the advent of recombinant DNA technology three decades ago, hundreds of thousands of genes have been identified. Recombinant DNA technology is the technology that uses advanced enzymatic and microbiologic techniques to manipulate DNA.[23] Pure pieces of any DNA can be inserted into bacteriophage DNA or other carrier DNA such as plasmids to produce recombinant DNA in bacteria. In this way, DNA can be reconstructed, amplified, and used to manipulate the functions of individual cells or even organisms. This technology, often referred to as *DNA cloning*, is the basis of all other DNA analysis methods. It is only with the awesome power of recombinant DNA technology that the completion of the Human Genome Project was possible. It also has led to the identification of the entire gene complements of organisms such as viruses, bacteria, worms, flies, and plants.

Molecular cloning refers to the process of cloning a DNA fragment of interest into a DNA vector that ultimately

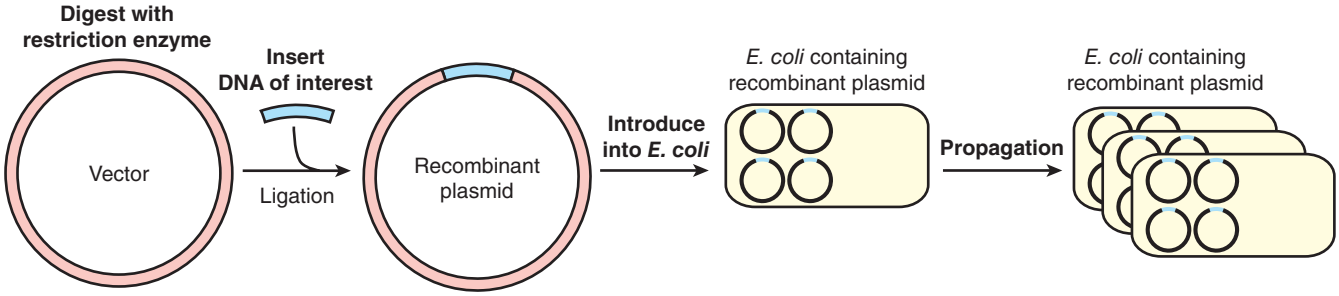

Figure 15-15. Generation of recombinant DNA. The vector is a circular DNA molecule that is capable of replicating in *Escherichia coli* cells. Insert DNA (often your favorite gene) is ligated to the vector after ends of both DNA are properly treated with restriction enzymes. Ligated DNA (i.e., the recombinant plasmid DNA) is then transformed into *E. coli* cells, where it replicates to produce recombinant progenies. *E. coli* cells carrying the recombinant plasmid can be propagated to yield large quantities of plasmid DNA.

is delivered into bacterial or mammalian cells or tissues[24,25] (Fig. 15-15). This represents a very basic technique that is widely used in almost all areas of biomedical research. DNA vectors often are called *plasmids*, which are extrachromosomal molecules of DNA that vary in size and can replicate and be transmitted from bacterial cell to cell. Plasmids can be propagated either in the cytoplasm or after insertion, as part of the bacterial chromosome in *Escherichia coli*. The process of molecular cloning involves several steps of manipulation of DNA. First, the vector plasmid DNA is cleaved with a restriction enzyme to create compatible ends with the foreign DNA fragment to be cloned. The vector and the DNA fragment are then joined in vitro by a DNA ligase. Alternatively, DNA cloning can be simply done through the so-called *Gateway Technology* that allows for the rapid and efficient transfer of DNA fragments between different cloning vectors while maintaining reading frame and orientation, without the use of restriction endonucleases and DNA ligase. The technology, which is based on the site-specific recombination system of bacteriophage l, is simple, fast, robust, and automatable and thus compatible for high-throughput DNA cloning.

Finally, the ligation product or the Gateway reaction product is introduced into competent host bacteria; this procedure is called *transformation*, which can be done by either calcium/heat shock or electroporation. Precautions must be taken in every step of cloning to generate the desired DNA construct. The vector must be correctly prepared to maximize the creation of recombinants; for example, it must be enzymatically treated to prevent self-ligation. Host bacteria must be made sufficiently competent to permit the entry of recombinant plasmids into cells. The selection of desired recombinant plasmid-bearing *E. coli* normally is achieved by the property of drug resistance conferred by the plasmid vectors. The plasmids encoding markers provide specific resistance to (i.e., the ability to grow in the presence of) antibiotics such as ampicillin, kanamycin, and tetracycline. The foreign component in the plasmid vector can be a mammalian expression cassette, which can direct expression of foreign genes in mammalian cells. The resulting plasmid vector can be amplified in *E. coli* to prepare large quantities of DNA for its subsequent applications such as transfection, gene therapy, transgenics, and knockout mice.

Detection of Nucleic Acids and Proteins

Southern Blot Hybridization. Southern blotting refers to the technique of transferring DNA fragments from an electrophoresis gel to a membrane support and the subsequent analysis of the fragments by hybridization with a radioactively or chemiluminescently labeled probe (Fig. 15-16).[26] Southern blotting is named after E. M. Southern, who in 1975 first described the technique of DNA analysis. It enables reliable and efficient analysis of size-fractionated DNA fragments in an immobilized membrane support. Southern blotting is composed of several steps. It normally begins with the digestion of the DNA samples with appropriate restriction enzymes, which will discriminate wild-type and mutant DNA by size and the separation of DNA samples in an agarose gel by electrophoresis with appropriate DNA size markers, called the DNA ladder. The DNA gel is stained with a dye, usually ethidium

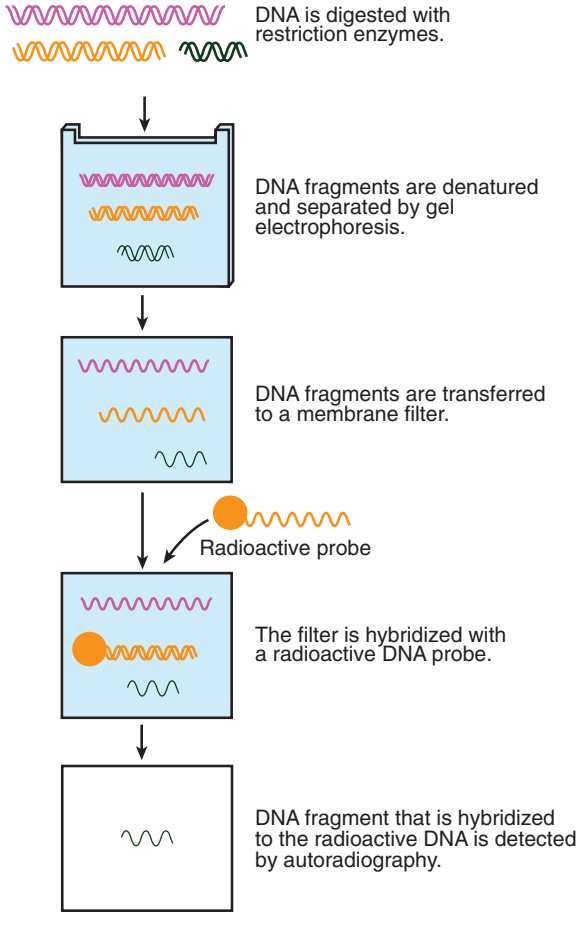

Figure 15-16. Southern blotting. Restriction enzymatic fragments of DNA are separated by agarose gel electrophoresis, transferred to a membrane filter, and then hybridized to a radioactive probe.

bromide, and photographed with a ruler laid alongside the gel so that band positions can later be identified on the membrane. The DNA gel then is treated so the DNA fragments are denatured (i.e., strand separation). The DNA then is transferred onto a nitrocellulose membrane by capillary diffusion or under electricity. After immobilization, the DNA can be subjected to hybridization analysis, enabling bands with sequence similarity to a radioactively or chemiluminescently labeled probe to be identified.

The development of Southern transfer and the associated hybridization techniques made it possible for the first time to obtain information about the physical organization of single and multicopy sequences in complex genomes. The later application of Southern blotting hybridization to the study of restriction fragment length polymorphisms opened up new possibilities such as genetic fingerprinting and prenatal diagnosis of genetic diseases.

Northern Blot Hybridization. Northern blotting refers to the technique of size fractionation of RNA in a gel and the transferring of an RNA sample to a solid support (membrane) in such a manner that the relative positions of the RNA molecules are maintained. The resulting membrane then is hybridized with a labeled probe complementary to the mRNA of interest. Signals generated from detection of the membrane can be used to determine the size and abundance of the target RNA. In principle, Northern blot hybridization is similar to Southern blot hybridization (and hence its name), with the exception that RNA, not DNA, is on the membrane. Although reverse-transcriptase PCR has been used in many applications (described in the next section, Polymerase Chain Reaction), Northern analysis is the only method that provides information regarding mRNA size and has remained a standard method for detection and quantitation of mRNA. The process of Northern hybridization involves several steps, as does Southern hybridization, including electrophoresis of RNA samples in an agarose-formaldehyde gel, transfer to a membrane support, and hybridization to a radioactively labeled DNA probe. Data from hybridization allow quantification of steady-state mRNA levels and, at the same time, provide information related to the presence, size, and integrity of discrete mRNA species. Thus, Northern blot analysis, also termed *RNA gel blot analysis*, commonly is used in molecular biology studies relating to gene expression.

Polymerase Chain Reaction. PCR is an in vitro method for the polymerase-directed amplification of specific DNA sequences using two oligonucleotide primers that hybridize to opposite strands and flank the region of interest in the target DNA (Fig. 15-17).[27] One cycle of PCR reaction involves template denaturation, primer annealing, and the extension of the annealed primers by DNA polymerase. Because the primer extension products synthesized in one cycle can serve as a template in the next, the number of target DNA copies nearly doubles at each cycle. Thus, a repeated series of cycles result in the exponential accumulation of a specific fragment in which the termini are sharply defined by the 5′ ends of the primers. The introduction of the thermostable DNA polymerase (e.g., Taq polymerase) transforms the PCR into a simple and robust reaction. The reaction components (e.g., template, primers, Taq polymerase, 2′-deoxynucleoside 5′-triphosphates, and buffer) could all be assembled and the amplification reaction carried out by simply cycling the temperatures within the reaction tube. The specificity and yield in amplifying a particular DNA fragment by PCR reaction are affected by the proper setting of the reaction parameters (e.g., enzyme, primer, and Mg^{2+} concentration, as well as the temperature cycling profile). Modifying various PCR parameters to optimize the specificity of amplification yields more homogenous products, even in rare template reactions.

The emergence of the PCR technique has dramatically altered the approach to both fundamental and applied biologic problems. The capability of amplifying a specific DNA fragment from a gene or the whole genome greatly advances the study of the gene and its function. It is simple, yet robust, speedy, and most of all, flexible. As a recombinant DNA tool, it underlies almost all of molecular biology. This revolutionary technique enabled the modern methods for the isolation of genes, construction of a DNA vector, introduction of alterations into DNA, and quantitation of gene expression, making it a fundamental cornerstone of genetic and molecular analysis.

Immunoblotting and Immunoprecipitation. Analyses of proteins are primarily carried out by antibody-directed immunologic techniques. For example, Western blotting, also called *immunoblotting*, is performed to detect protein levels in a population of cells or tissues, whereas immunoprecipitation is used to concentrate proteins from a larger pool. Using specific antibodies, microscopic analysis called *immunofluorescence* and *immunohistochemistry* is possible for the subcellular localization and expression of proteins in cells or tissues, respectively.

Immunoblotting refers to the process of identifying a protein from a mixture of proteins (Fig. 15-18). It consists of five steps: (a) sample preparation; (b) electrophoresis (separation of a protein mixture by sodium dodecyl sulfate-polyacrylamide gel electrophoresis); (c) transfer (the electrophoretic transfer of proteins from gel onto membrane support [e.g., nitrocellulose, nylon, or polyvinylidene difluoride]); (d) staining (the subsequent immunodetection of target proteins with specific antibody); and (e) development (colorimetric, chemiluminescent, and recently fluorescent visualization of the antibody-recognized protein). Thus, immunoblotting combines the resolution of gel electrophoresis with the specificity of immunochemical detection. Immunoblotting is a powerful tool used to determine a number of important characteristics of proteins. For example, immunoblotting analysis will determine the presence and the quantity of a protein in a given cellular condition and its relative molecular weight. Immunoblotting also can be used to determine whether posttranslational modification such as phosphorylation has occurred on a protein. Importantly, through immunoblotting analysis, a comparison of the protein levels and modification states in normal vs. diseased tissues is possible.

Immunoprecipitation, another widely used immunochemical technique, is a method that uses antibody to enrich a protein of interest and any other proteins that are associated with it (Fig. 15-19). The principle of the technique lies in the property of a strong and specific affinity between antibodies and their antigens to locate and pull down target proteins in solution. Once the antibody-antigen (target protein) complexes are formed in the solution, they are collected and purified using small agarose beads with covalently attached protein A or protein G. Both protein A and protein G specifically interact with the antibodies, thus forming a large immobilized complex of antibody-antigen bound to beads. The purified protein can then be analyzed by a number of biochemical methods. When immunoprecipitation is combined with immunoblotting, it can

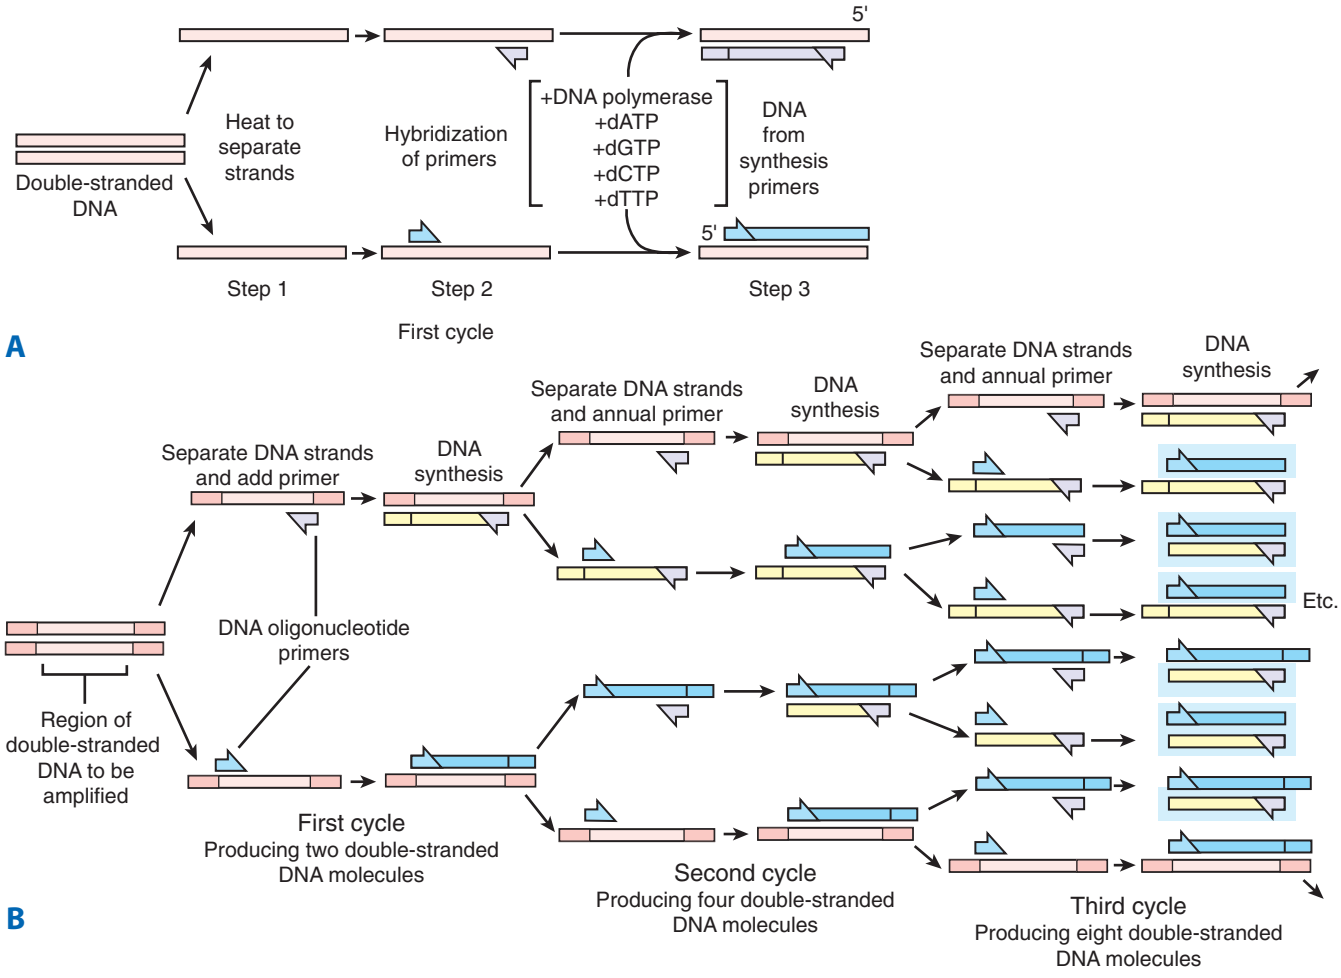

Figure 15-17. Amplification of DNA using the polymerase chain reaction (PCR) technique. Knowledge of the DNA sequence to be amplified is used to design two synthetic DNA oligonucleotides, each complementary to the sequence on one strand of the DNA double helix at opposite ends of the region to be amplified. These oligonucleotides serve as primers for in vitro DNA synthesis, which is performed by a DNA polymerase, and they determine the segment of the DNA that is amplified. **A.** PCR starts with a double-stranded DNA, and each cycle of the reaction begins with a brief heat treatment to separate the two strands (*Step 1*). After strand separation, cooling of the DNA in the presence of a large excess of the two primer DNA oligonucleotides allows these primers to hybridize to complementary sequences in the two DNA strands (*Step 2*). This mixture is then incubated with DNA polymerase and the four deoxyribonucleoside triphosphates so that DNA is synthesized, starting from the two primers (*Step 3*). The entire cycle is then begun again by a heat treatment to separate the newly synthesized DNA strands. **B.** As the procedure is performed over and over again, the newly synthesized fragments serve as templates in their turn, and, within a few cycles, the predominant DNA is identical to the sequence bracketed by and including the two primers in the original template. Of the DNA put into the original reaction, only the sequence bracketed by the two primers is amplified because there are no primers attached anywhere else. In the example illustrated in **B**, three cycles of reaction produce 16 DNA chains, eight of which (*boxed in brown*) are the same length as and correspond exactly to one or the other strand of the original bracketed sequence shown at the far left; the other strands contain extra DNA downstream of the original sequence, which is replicated in the first few cycles. After three more cycles, 240 of the 256 DNA chains correspond exactly to the original bracketed sequence, and after several more cycles, essentially all of the DNA strands have this unique length. *(Republished with permission of Garland Publishing, Inc. from Alberts B, Johnson A, Lewis J, et al.* Molecular Biology of the Cell, *5th ed. New York: Garland Science; 2008. Permission conveyed through Copyright Clearance Center, Inc.)*

be used for the sensitive detection of proteins in low concentrations, which would otherwise be difficult to detect. Moreover, combined immunoprecipitation and immunoblotting analysis is very efficient in analyzing the protein-protein interactions or determining the posttranslational modifications of proteins. In addition, immunoprecipitated proteins can be used as preparative steps for assays such as intrinsic or associated enzymatic activities. The success of immunoprecipitation is influenced by two major factors: (a) the abundance of the protein in the original preparation and (b) the specificity and affinity of the antibody for this protein.

Recently, *immunoprecipitation* is even used to enrich modified DNA (for example, 5-methylcytosine) for bisulfite sequencing. Besides proteins of interest, specific antibodies can also be raised against specially modified DNA. Like the protein immunoprecipitation, modified DNA can be pulled down, taking advantage of the specificity and affinity of antibody to antigen.

DNA Microarray. Now that the human genome sequence is completed, the primary focus of biologists is rapidly shifting toward gaining an understanding of how genes function. One of the interesting findings about the human genome is that there are only approximately 25,000 to 30,000 protein-encoding genes. However, it is known that genes and their products function in a complicated and yet orchestrated fashion and that the surprisingly small number of genes from the genome sequence is sufficient to

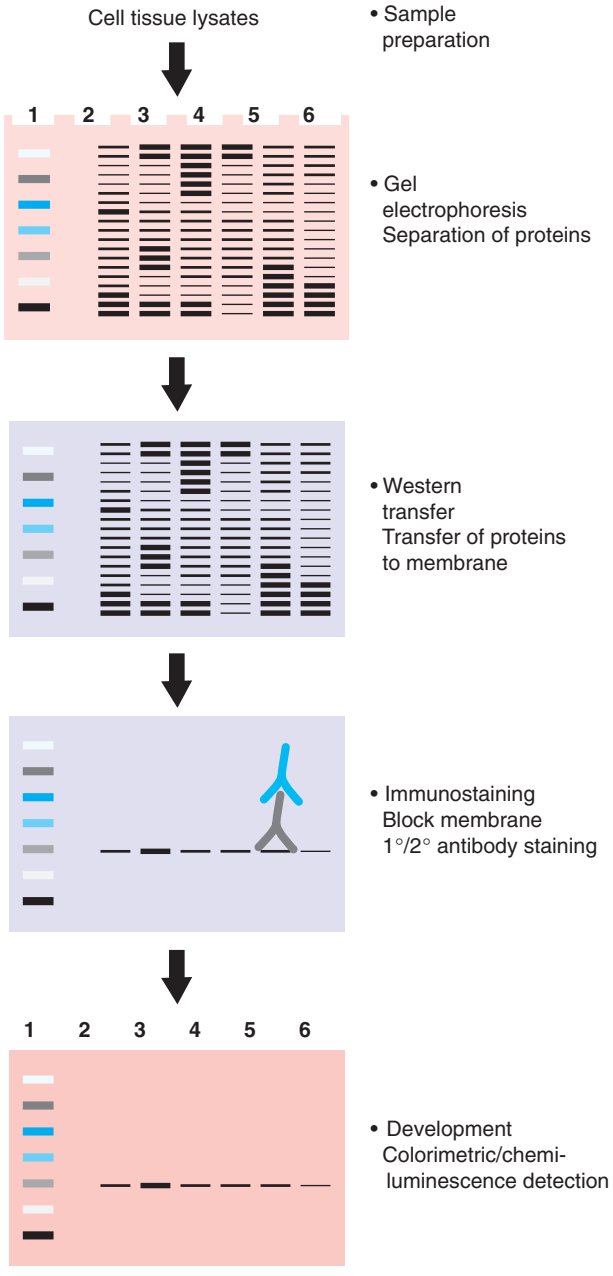

Figure 15-18. Immunoblotting. Proteins are prepared from cells or tissues, separated according to size by sodium dodecyl sulfate-polyacrylamide gel electrophoresis, and transferred to a membrane filter. Detection of a protein of interest can be done by sequential incubation with a primary antibody directed against the protein, and then with an enzyme-conjugated secondary antibody that recognizes the primary antibody. Visualization of the protein is carried out by using colorimetric or luminescent substrates for the conjugated enzyme.

make a human being. Nonetheless, with the tens of thousands of genes present in the genome, traditional methods in molecular biology, which generally work on a one-gene-in-one-experiment basis, cannot generate the whole picture of genome function. In the past several years, a new technology called *DNA microarray* has attracted tremendous interest among biologists as well as clinicians. This technology promises to monitor the whole genome on a single chip so researchers can have a better picture of the interactions among thousands of genes simultaneously.

DNA microarray, also called *gene chip*, *DNA chip*, and *gene array*, refers to large sets of probes of known sequences orderly arranged on a small chip, enabling many hybridization reactions to be carried out in parallel in a small device (Fig. 15-20).[28] Like Southern and Northern hybridization, the underlying principle of this technology is the remarkable ability of nucleic acids to form a duplex between two strands with complementary base sequences. DNA microarray provides a medium for matching known and unknown DNA samples based on base-pairing rules and automating the process of identifying the unknowns. Microarrays require specialized robotics and imaging equipment that spot the samples on a glass or nylon substrate, carry out the hybridization, and analyze the data generated. DNA microarrays containing different sets of genes from a variety of organisms are now commercially available, allowing biologists to simply purchase the chips and perform hybridization and data collection. The massive scale of microarray experiments requires the aid of computers. They are used during the capturing of the image of the hybridized target, the conversion of the image into usable measures of the extent of hybridization, and the interpretation of the extent of hybridization into a meaningful measure of the amount of the complementary sequence in the target. Some data-analysis packages are available commercially or can be found in the core facility of certain institutions.

DNA microarray technology has produced many significant results in quite different areas of application. There are two major application forms for the technology: identification of sequence (gene/gene mutation) in multiple regions of a genome and determination of expression level (abundance) of large numbers of genes simultaneously. For example, analysis of genomic DNA detects amplifications and deletions found in human tumors. Differential gene expression analysis also has uncovered networks of genes differentially present in cancers that cannot be distinguished by conventional means. Significantly, recent advancements in next-generation sequencing (e.g., Solexa and 454 technology) have demonstrated the precision and speed to analyze gene expression in any genome.

Next-Generation Sequencing.[29,30] The recombinant DNA technology greatly impacts the completion of the Human Genome Project due to the invention of shotgun sequencing, which includes breaking the genome DNA into small pieces and randomly cloning those pieces into DNA vectors that are easily sequenced. Based on the overlapping sequence of each clone, computer analysis can be programmed to map and align the DNA sequence that will ultimately cover the whole human genome.

Based on shotgun sequencing, as the sequencing technologies advance, next-generation sequencing has become one of the most powerful tools to analyze DNA mutation, to identify epigenetic modification, and to profile gene expression or ncRNA expression.[31] The next-generation sequencing process usually includes library construction, sequencing, and data analysis. Take the Illumina next-generation sequencing as an example: DNA are shared or digested into small pieces and then used to generate a DNA library with adapters on both ends of each DNA piece. Then, the DNA library is diluted and loaded on a chamber of a slide, called a *lane*, for cluster amplification. Cycled fluorescent deoxyribonucleotide triphosphates (dNTPs) are then added to the chamber to enable DNA polymerization, resulting in different fluorescent emission representing different dNTP reading on different clusters, into a microscope. The fluorescent

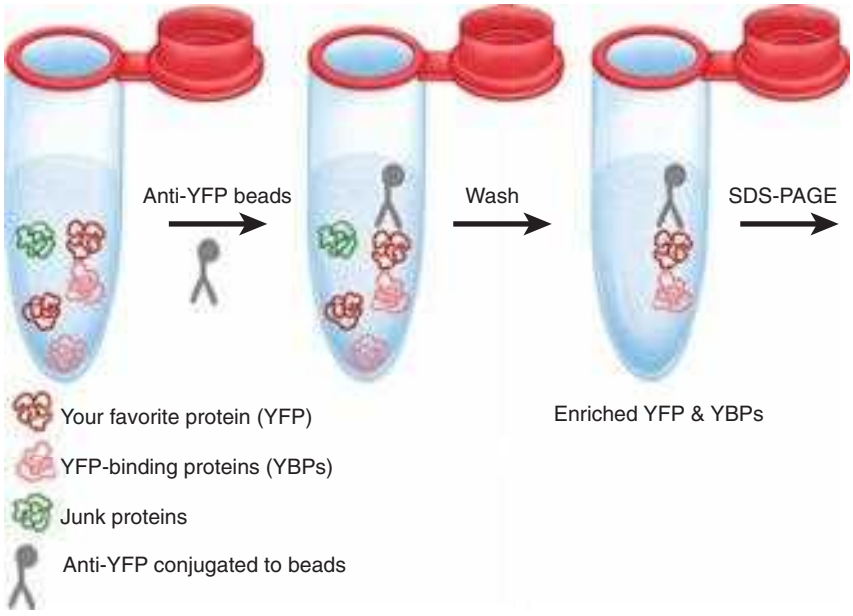

Figure 15-19. Immunoprecipitation. Proteins prepared from cells or tissues can be enriched using an antibody directed against them. The antibody is first conjugated to agarose beads and then incubated with protein mixture. Due to the specific high-affinity interaction between antibody and its antigen (the protein), the antigen-antibody complex can be collected on beads by centrifugation. The immunoprecipitated protein can then be analyzed by immunoblotting. Alternatively, if proteins are radiolabeled in cells or tissues, detection of immunoprecipitated proteins can be achieved by simple sodium dodecyl sulfate-polyacrylamide gel electrophoresis followed by autoradiography.

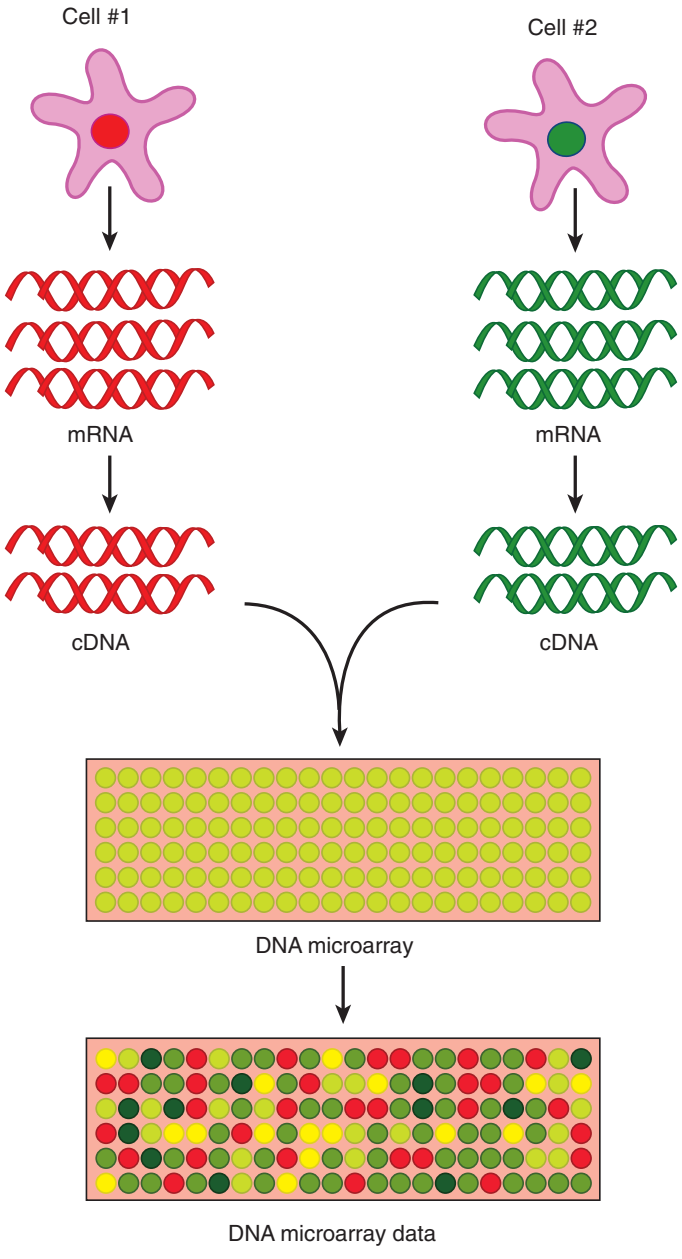

Figure 15-20. DNA microarrays. DNA microarrays, also referred to as *gene chips*, have arrayed oligonucleotides or complementary DNAs (cDNAs) corresponding to tens or hundreds of distinct genes. DNA microarray is used to comparatively analyze gene expression in different cells or tissues. Messenger RNAs (mRNAs) extracted from different sources are converted into cDNAs, which are then labeled with different fluorescent dyes. The two fluorescent cDNA probes are mixed and hybridized to the same DNA microarrays. The ratio of red to green fluorescence at each spot on the chip represents the relative expression of levels of that gene between two different cells. In the example shown in the figure, cDNA from cell #1 is labeled with red fluorescence and that from cell #2 is labeled with green fluorescence. On the microarray, red spots demonstrate that the gene in the cell sample #1 is expressed at a higher level than the corresponding gene in cell sample #2. The green spots indicate that the gene in the cell sample #2 is expressed at a higher level than the corresponding gene in the cell sample #1. Yellow spots represent equal expression of the gene in both cell samples.

signal is transformed into sequencing data that will be aligned and mapped to a standard genome database. The advantages of next-generation sequencing include the following: no necessity of DNA cloning; fast and cost-effective; and a huge amount of data to give a good depth and accuracy of the sequence.

Based on the applications, the most common next-generation sequencing technologies for whole-genome sequencing are whole-genome DNA sequencing, whole-genome bisulfite sequencing (BS-seq), RNA sequencing (RNA-seq), and chromatin immunoprecipitation (ChIP) sequencing (ChIP-seq). Whole-genome DNA sequencing is purely to sequence the DNA sequence of a genome without any preprocessing of the DNA, reflecting any deletions, replications, and mutations within the genomic DNA. BS-seq is commonly used to identify DNA methylation on the genome (5-methylcytosine [5mC]). The process always involves a bisulfite treatment of DNA before library construction, during which the unmethylated cytosine will be transformed to a uracil, resulting in reading as a thymine in data output, whereas 5mC is protected and remains as cytosine in data output. Thus, 5mC and cytosine are distinguished by this way. RNA-seq is usually performed to analyze transcription for the same purpose as performing a microarray. However, RNA-seq is more accurate and provides more information such as splicing variants than traditional microarray. Usually, cDNA that is reversely transcribed from extracted RNA is used to generate libraries. Depending on the needs, mRNA and ncRNA can be enriched in different protocols for RNA extraction. ChIP-seq is always used to map the location of a DNA-binding protein in the genome. Prior to library construction, ChIP is performed to enrich DNA bound by the protein of interest (POI). First, POI and DNA are cross-linked before sonication. Then, a specific antibody is used to pull down POI and attached DNA fragments. After the protein and DNA are reverse cross-linked, DNA will be purified to make the ChIP-seq library.

By using next-generation sequencing technology, any potential mutations in a patient will be scrutinized as well as any defects in epigenetic modification, which will greatly facilitate the diagnosis of patients and personalization of medicine in a fast and economic way.

Cell Manipulations

Cell Culture. Cell culture has become one of the most powerful tools in biomedical laboratories, as cultured cells are being used in a diversity of biologic fields ranging from biochemistry to molecular and cellular biology.[32] Through their ability to be maintained in vitro, cells can be manipulated by the introduction of genes of interest (cell transfection) and be transferred into in vivo biologic receivers (cell transplantation) to study the biologic effect of the interested genes (Fig. 15-21). In the common laboratory settings, cells are cultured either as a monolayer (in which cells grow as one layer on culture dishes) or in suspension.

It is important to know the wealth of information concerning cell culturing before attempting the procedure. For example, conditions of culture will depend on the cell types to be cultured (e.g., origins of the cells such as epithelial or fibroblasts, or primary vs. immortalized/transformed cells). It is also necessary to use cell type-specific culture medium that varies in combination of growth factors and serum concentrations. If primary cells are derived from human patients or animals, some commercial resources have a variety of culture media available for testing. Generally, cells are manipulated in a sterile hood, and the working surfaces are wiped with 70% to 80% ethyl alcohol solution. Cultured cells are usually maintained in a humidified carbon dioxide incubator at 37°C (98.6°F) and need to be examined daily under an inverted microscope to check for possible contamination and confluency (the area cells occupy on the dish). As a general rule, cells should be fed with fresh medium every 2 to 3 days and split when they reach confluency. Depending on the growth rate of cells, the actual time and number of plates required to split cells in two varies from cell line to cell line. Splitting a monolayer requires the detachment of cells from plates by using a trypsin or collagenase treatment, of which concentration and time period vary depending on cell lines. If cultured cells grow continuously in suspension, they are split or subcultured by dilution.

Because cell lines may change their properties when cultured, it is not possible to maintain cell lines in culture indefinitely. Therefore, it is essential to store cells at various time

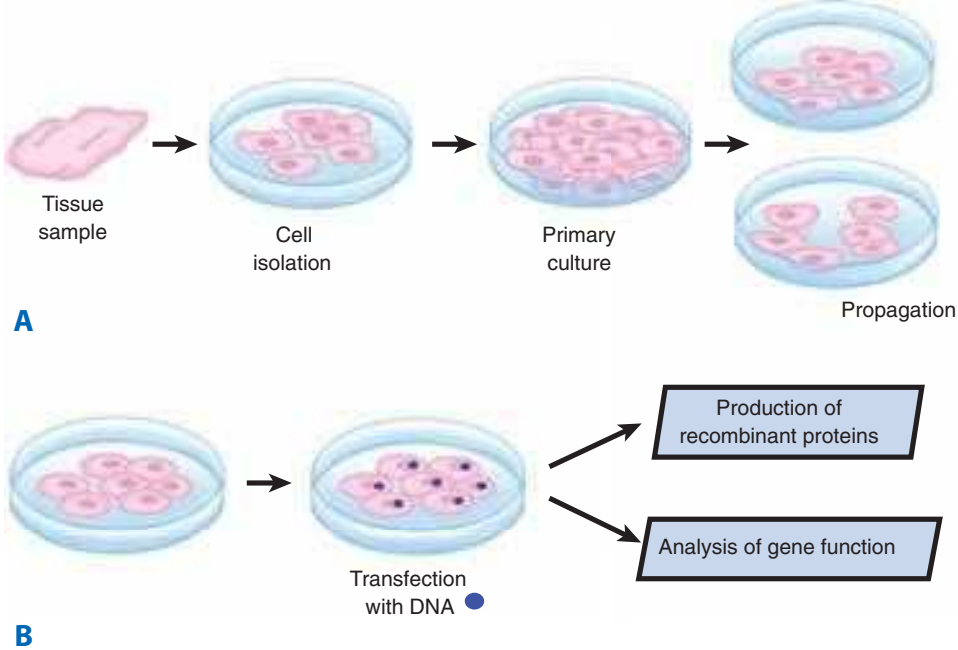

Figure 15-21. Cell culture and transfection. **A.** Primary cells can be isolated from tissues and cultured in medium for a limited period of time. After genetic manipulations to overcome the cell aging process, primary cells can be immortalized into cell lines for long-term culture. **B.** DNA can be introduced into cells to produce recombinant gene products or to analyze the biologic functions of the gene.

passages for future use. The common procedure to use is cryopreservation. The solution for cryopreservation is usually fetal calf serum containing 10% dimethyl sulfoxide or glycerol, stored in liquid nitrogen (−196°C [−320.8°F]) for years of preservation. However, the viability and health of cells when thawed will decrease over time even in liquid nitrogen.

Cell Transfection. Cells are cultured for two reasons: to maintain and to manipulate them (see Fig. 15-21). The transfer of foreign macromolecules, such as nucleic acid, into living cells provides an efficient method for studying a variety of cellular processes and functions at the molecular level. DNA transfection has become an important tool for studying the regulation and function of genes. The cDNA to be expressed should be in a plasmid vector, behind an appropriate promoter working in mammalian cells (e.g., the constitutively active cytomegalovirus promoter or inducible promoter). Depending on the cell type, many ways of introducing DNA into mammalian cells have been developed. Commonly used approaches include calcium phosphate, electroporation, liposome-mediated transfection, the nonliposomal formulation, and the use of viral vectors. These methods have shown variable success when attempting to transfect a wide variety of cells. Transfection can be performed in the presence or absence of serum. It is suggested to test the transfection efficiency of cell lines of interest by comparing transfection with several different approaches. For a detailed transfection protocol, it is best to follow the manufacturer's instructions for the particular reagent. General considerations for a successful transfection depend on several parameters, such as the quality and quantity of DNA and cell culture (type of cell and growth phase). To minimize variations in both of these in transfection experiments, it is best to use cells that are healthy, proliferate well, and are plated at a constant density.

Depending on the transfection method, DNA expression can be transient or stable. Using calcium phosphate and liposome-mediated transfection, after DNA is introduced into the cells, it is normally maintained epitopically in cells and will be diluted while host cells undergo cell division. Therefore, functional assays should be performed 24 to 72 hours after transfection, also termed *transient transfection*. In many applications, it is important to study the long-term effects of DNA in cells by stable transfection. Thus, electroporation and viral vector are often used in these situations to enable integration of ectopic DNA into the host genome. Stable cell clones can be selected when plasmids carry an antibiotic-resistant marker. In the presence of antibiotics, only those cells that continuously carry the antibiotic-resistant marker (after generations of cell division) can survive. One application of stable transfection is the generation of transgenic or knockout mouse models, in which the transgene has to be integrated in the mouse genome in the ES cells, followed by microinjection of those transgenic ES cells into blastocysts to generate chimera mice. Stable cells also can be transplanted into host organs to test the effect of transgenic cells in vivo.

Genetic Manipulations

Understanding how genes control the growth and differentiation of the mammalian organism has been the most challenging topic of modern research. It is essential for us to understand how genetic mutations and chemicals lead to the pathologic condition of human bodies. The knowledge and ability to change the genetic program will inevitably make a great impact on society and have far-reaching effects on how we think of ourselves.

The mouse has become firmly established as the primary experimental model for studying how genes control mammalian development. Genetically altered mice are powerful tools to study the function and regulation of genes as well as modeling human diseases.[33] The gene function can be studied by creating mutant mice through homologous recombination (gene knockout). A gene of interest (GOI) also can be introduced into the mouse (transgenic mouse) to study its effect on development or diseases. Because mouse models do not precisely represent human biology, genetic manipulations of human somatic or ES cells provide a great means for the understanding of the molecular networks in human cells in addition to mouse models. In all cases, the gene to be manipulated must first be cloned. Gene cloning has been made easy by recombinant DNA technology and the availability of human and mouse genomes (see the Human Genome section). The following section briefly describes the technologies and the principles behind how to combine both mouse genetics and human cell culture in exploring gene function and disease mechanisms.

4▶

Transgenic Mice. During the past 20 years, DNA cloning and other techniques have allowed the introduction of new genetic material into the mouse germline. As early as 1980, the first genetic material was successfully introduced into the mouse germline by using pronuclear microinjection of DNA (Fig. 15-22). These animals, called *transgenic*, contain foreign DNA within their genomes. In simple terms, a transgenic mouse is created by the microinjection of ectopic DNA into the one-celled mouse embryo to induce integration, allowing the efficient introduction of cloned genes into the following developing mouse somatic tissues, as well as into the germline.

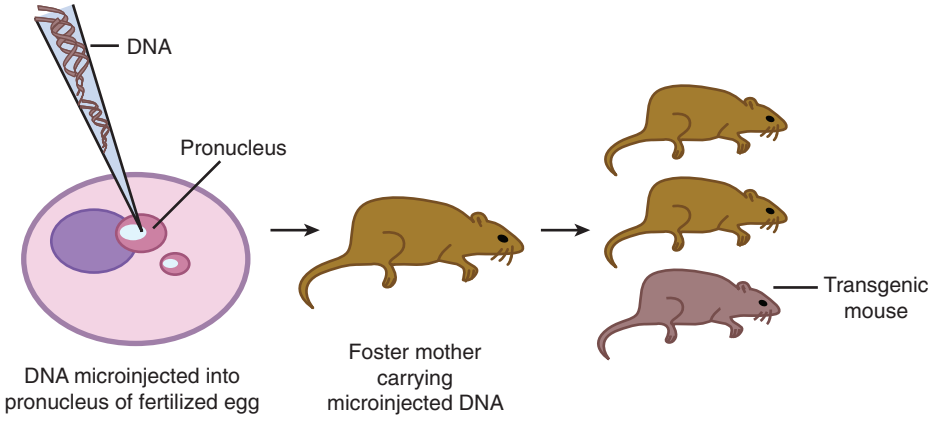

Figure 15-22. Transgenic mouse technology. DNA is microinjected into a pronucleus of a fertilized egg, which is then transplanted into a foster mother. The microinjected egg develops offspring mice. Incorporation of the injected DNA into offspring is indicated by the different coat color of offspring mice.

Designs of a Transgene The transgenic technique has proven to be extremely important for basic investigations of gene regulation, creation of animal models of human disease, and genetic engineering of livestock. The design of a transgene construct is a simple task. Like constructs used in cell transfection, a simple transgene construct consists of a protein-encoding gene and a promoter that precedes it. The most common applications for the use of transgenic mice are similar to those in the cell culture system: (a) to study the functions of proteins encoded by the transgene, (b) to analyze the tissue-specific and developmental-stage–specific activity of a gene promoter, and (c) to generate reporter lines to facilitate biomedical studies. Examples of the first application include overexpression of oncogenes, growth factors, hormones, and other key regulatory genes, as well as genes of viral origins. Overexpression of the transgene normally represents gain-of-function mutations. The tissue distribution or expression of a transgene is determined primarily by *cis*-acting promoter enhancer elements within or in the immediate vicinity of the genes themselves. Thus, controlled expression of the transgene can be made possible by using an inducible or tissue-specific promoter. Furthermore, transgenic mice carrying dominant negative mutations of a regulatory gene also have been generated. For example, a truncated growth factor receptor that can bind to the ligand, but loses its catalytic activity when expressed in mice, can block the growth factor binding to the endogenous protein. In this way, the transgenic mice exhibit a loss of function of phenotype, possibly resembling the knockout of the endogenous gene. The second application of the transgenic expression is to analyze the gene promoter of interest. The gene promoter of interest normally is fused to a reporter gene that encodes β-galactosidase (also called *LacZ*), luciferase, or green fluorescence protein. Chemical staining of LacZ activity or detection of chemiluminescence/fluorescence can easily visualize the expression of the reporter gene. The third application originates from the second: when the activity of the promoter is known, a fluorescent reporter gene (such as *GFP*) will be driven by the tissue-specific promoter, therefore labeling a particular type of cells at a particular stage. This application is generally used to isolate a special cell type expressing the *GFP* reporter by fluorescence-activated cell sorting (FACS), as well as lineage-tracing experiments.

Production of Transgenic Mice The success of generating transgenic mice is largely dependent on the proper quality and concentration of the DNA supplied for microinjection. For DNA to be microinjected into mouse embryos, it should be linearized by restriction digestion to increase the chance of proper transgene integration. Concentration of DNA should be accurately determined. Mice that develop from injected eggs often are termed *founder* mice.

Genotyping of Transgenic Mice The screening of founder mice and the transgenic lines derived from the founders is accomplished by determining the integration of the injected gene into the genome. This normally is achieved by performing PCR or Southern blot analysis with a small amount of DNA extracted from the mouse tail. Once a given founder mouse is identified to be transgenic, it will be mated to begin establishing a transgenic line. Usually, for a given gene, more than one transgenic line is generated to assure that the phenotype is due to transgene but not to the interruption of the gene where the transgene integrates into.

Analysis of Phenotype of Transgenic Mice Phenotypes of transgenic mice are dictated by both the expression pattern and biologic functions of the transgene. Depending on the promoter and the transgene, phenotypes can be predictable or unpredictable. Elucidation of the functions of the transgene-encoded protein in vitro often offers some clue to what the protein might function to do in vivo. When a constitutively active promoter is used to drive the expression of transgenes, mice should express the gene in every tissue; however, this mouse model may not allow the identification and study of the earliest events in disease pathogenesis. Ideally, the use of tissue-specific or inducible promoter allows one to determine if the pathogenic protein leads to a reversible or irreversible disease process in a cell-autonomous manner. For example, rat insulin promoter can target transgene expression exclusively in the β-cells of pancreatic islets. The phenotype of insulin promoter-mediated transgenic mice is projected to affect the function of human β-cells.

Gene Knockout in Mice. The first recorded knockout mouse was created by Mario R. Capecchi, Sir Martin J. Evans, and Oliver Smithies in 1989. They were awarded the 2007 Nobel Prize in Physiology or Medicine. The isolation and genetic manipulation of mouse ES cells represent one of the most important milestones for modern genetic technologies.[34] Several unique properties of ES cells, such as the pluripotency to differentiate into all germ layers in an embryo, including the germline, make them an efficient vehicle to introduce genetic alterations in mice. An important breakthrough from this idea is to generate gene-targeted mutation in mice, first by introducing the targeting vector into the ES cells, allowing selection for successful homologous recombination in a dish, then introducing the selected ES clone into the blastocysts, and finally recovering animals bearing the mutant allele from the germline (Fig. 15-23). This not only makes mouse genetics a powerful approach for addressing important gene functions, but also identifies the mouse as a great system to model human disease.

Targeting Vector The basic concept in building a target vector to knock out a gene is to use two segments of homologous sequence to a GOI that flank a part of the gene essential for functions (e.g., the coding region). In the targeting vector, a positive selectable marker (e.g., the *neo* gene) is placed between the homology arms. Upon the homologous recombination between the arms of the vector and the corresponding genomic regions of the GOI in ES cells, the positive selectable marker will replace the essential segment of the target gene, thus creating a null allele. In addition, a negative selectable marker also can be used alone or in combination with the positive selectable marker, but must be placed outside of the homologous arms to enrich for homologous recombination. To create a conditional knockout (i.e., gene knockout in a spatiotemporal fashion), site-specific recombinases such as the popular cre-loxP system are used. If the consensus loxP sequences that are recognized by cre recombinases are properly designed into targeting loci, controlled expression of the recombinase as a transgene can result in the site-specific recombination at the right time and in the right place (i.e., cell type or tissue). This method, often referred as conditional knockout, is markedly useful to prevent developmental compensations and to introduce null mutations in the adult mouse that would otherwise be lethal. Overall, this cre-loxP system allows for spatial and temporal control over transgene expression and takes advantage of inducers with minimal pleiotropic effects.

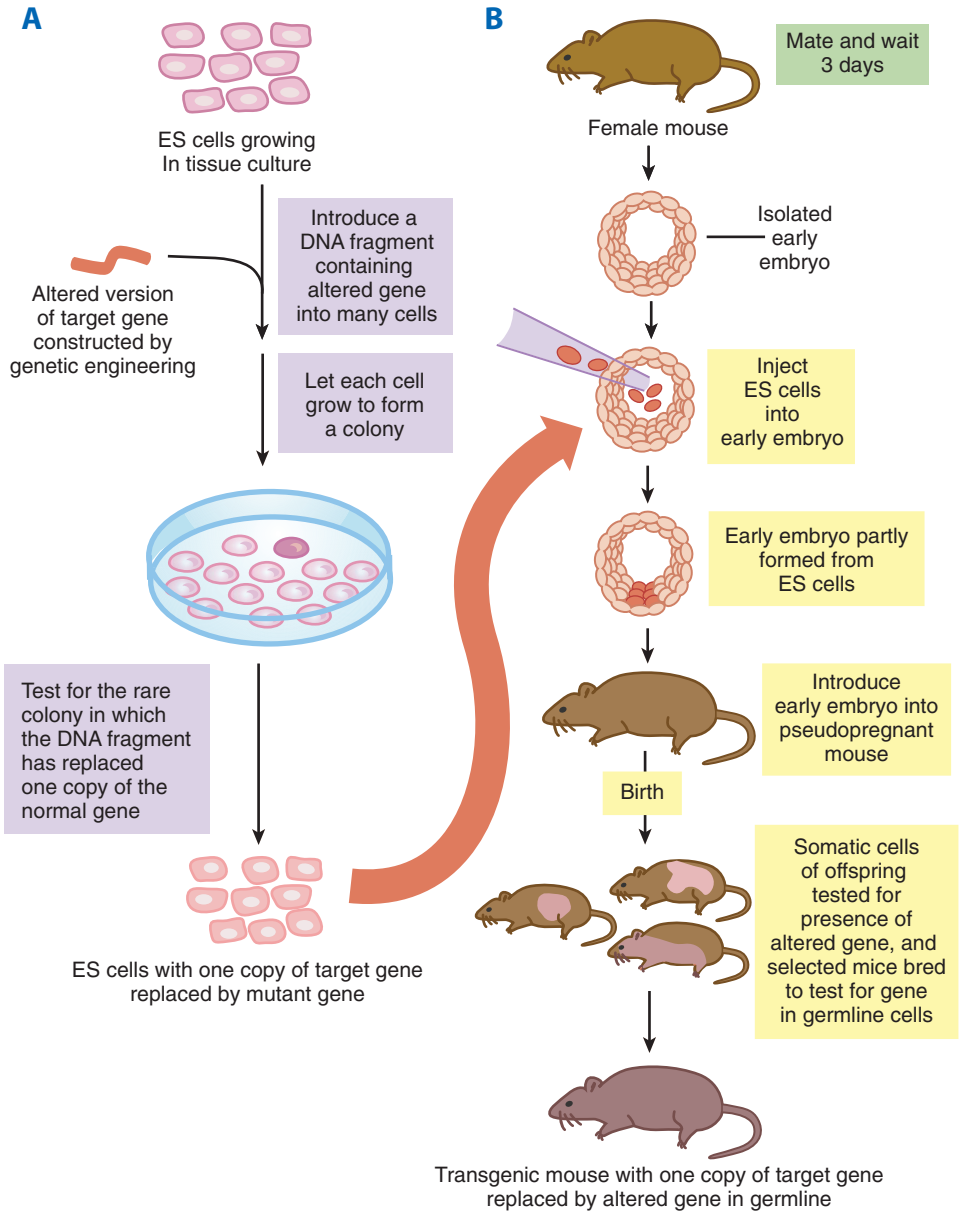

Figure 15-23. Knockout mouse technology. Summary of the procedures used for making gene replacements in mice. In the first step (**A**), an altered version of the gene is introduced into cultured embryonic stem (ES) cells. Only a few rare ES cells will have their corresponding normal genes replaced by the altered gene through a homologous recombination event. Although the procedure is often laborious, these rare cells can be identified and cultured to produce many descendants, each of which carries an altered gene in place of one of its two normal corresponding genes. In the next step of the procedure (**B**), these altered ES cells are injected into a very early mouse embryo; the cells are incorporated into the growing embryo, and a mouse produced by such an embryo will contain some somatic cells that carry the altered gene. Some of these mice also will contain germline cells that contain the altered gene. When bred with a normal mouse, some of the progeny of these mice will contain the altered gene in all of their cells. If two such mice are in turn bred (not shown), some of the progeny will contain two altered genes (one on each chromosome) in all of their cells. If the original gene alteration completely inactivates the function of the gene, these mice are known as *knockout mice*. When such mice are missing genes that function during development, they often die with specific defects long before they reach adulthood. These defects are carefully analyzed to help decipher the normal function of the missing gene. *(Republished with permission of Garland Publishing, Inc. from Alberts B, Johnson A, Lewis J, et al.* Molecular Biology of the Cell, *5th ed. New York: Garland Science; 2008. Permission conveyed through Copyright Clearance Center, Inc.)*

Introduction of the Targeting Vector into ES Cells ES cell lines can be obtained from other investigators or commercial sources or established from blastocyst-stage embryos. To maintain ES cells at their full developmental potential, optimal growth conditions should be provided in culture. If culture conditions are inappropriate or inadequate, ES cells may acquire genetic lesions or alter their gene expression patterns, and consequently decrease their pluripotency. Excellent protocols are available in public domains or in mouse facilities in most institutions.

To alter the genome of ES cells, the targeting vector DNA then is transfected into ES cells. Electroporation is the most widely used and the most efficient transfection method for ES cells. Similar procedures for stable cell transfection are used for

selecting ES cells that carry the targeting vector. High-quality, targeting-vector DNA free of contaminating chemicals is first linearized and then electroporated into ES cells. Stable ES cells are selected in the presence of a positive selectable antibiotic drug. After a certain period of time and depending on the type of antibiotics, all sensitive cells die and the resistant cells grow into individual colonies of the appropriate size for subcloning by picking. It is extremely important to minimize the time during which ES cells are in culture between selection and injection into blastocysts. Before injecting the ES cells, DNA is prepared from ES colonies to screen for positive ES cells that exhibit the correct integration or homologous recombination of the targeting vector. Positive ES colonies are then expanded and used for creation of chimeras.

Creation of the Chimera A chimeric organism is one in which cells originate from more than one embryo source. Here, chimeric mice are denoted as those that contain some tissues from the ES cells with an altered genome. When these ES cells give rise to the lineage of the germ layer, the germ cells carrying the altered genome can be passed on to the offspring, thus creating the germline transmission from ES cells. There are two methods for introducing ES cells into preimplantation-stage embryos: injection and aggregation. The injection of embryonic cells directly into the cavity of blastocysts is one of the fundamental methods for generating chimeras, but aggregation chimeras also have become an important alternative for transmitting the ES cell genome into mice. Since every tissue type of a chimera should contain cells from different origins, the mixture of recognizable markers (e.g., coat color) that are specific for each the donor mouse and ES cells can be used to identify chimeric mice. However, most experimenters probably use existing mouse core facilities already established in some institutions, or contract a commercial vendor for the creation of a chimera.

Genotyping and Phenotyping of Knockout Animals The next step is to analyze whether germline transmission of targeted mutation occurs in mice. DNA from a small amount of tissue from offspring of the chimera is extracted and subjected to genomic PCR or Southern blot DNA hybridization. Positive mice (i.e., those with properly integrated targeting vector into the genome) will be used for the propagation of more knockout mice for phenotype analysis. When the knockout genes are crucial for early embryogenesis, mice often die in utero, an occurrence called *embryonic lethality*. When this happens, only the phenotype of the homozygous (both alleles ablated) knockout mouse embryos and the phenotype of the heterozygous (only one allele ablated) adult mice can be studied. Because most are interested in the phenotype of adult mice, in particular when using mice as disease models, it is recommended to create the conditional knockout using the cre-loxP system so that the GOI can be knocked out at will.

To date, more than 5000 genes have been disrupted by homologous recombination and transmitted through the germline. The phenotypic studies of these mice provide ample information on the functions of these genes in growth and differentiation of organisms and during development of human diseases.

RNA Interference. Although gene ablation in animal models provides an important means to understand the in vivo functions of GOI, animal models may not adequately represent human biology. Alternatively, gene targeting can be used to knock out genes in human cells, including human ES cells. Gene targeting in human ES cells by homologous recombination has been extremely low efficiency, although there are more new techniques emerging aimed at increasing the targeting efficiency. A number of recent advances have made gene targeting in somatic cells as easy as in murine ES cells.[33] However, gene targeting (knocking out both alleles) in somatic cells is a time-consuming process.

Development of RNAi technology in the past few years has provided a more promising approach to understanding the biologic functions of human genes in human cells.[35] RNAi is an ancient natural mechanism by which small, double-stranded RNA (dsRNA) acts as a guide for an enzyme complex that destroys complementary RNA and downregulates gene expression in a sequence-specific manner. Although the mechanism by which dsRNA suppresses gene expression is not entirely understood, experimental data provide important insights. In nonmammalian systems such as *Drosophila*, it appears that longer dsRNA is processed into 21–23 nt dsRNA (called *small interfering RNA* or *siRNA*) by an enzyme called *Dicer* containing RNase III motifs. The siRNA apparently then acts as a guide sequence within a multicomponent nuclease complex to target complementary mRNA for degradation. Because long dsRNA induces a potent antiviral response pathway in mammalian cells, short siRNAs are used to perform gene silencing experiments in mammalian cells (Fig. 15-24).

For siRNA studies in mammalian cells, researchers have used two 21-mer RNAs with 19 complementary nucleotides and 3′ terminal noncomplementary dimers of thymidine or uridine. The antisense siRNA strand is fully complementary to the mRNA target sequence. Target sequences for an siRNA are identified visually or by software.

The target 19 nucleotides should be compared to an appropriate genome database to eliminate any sequences with significant homology to other genes. Those sequences that appear to be specific to the GOI are the potential siRNA target sites. A few of these target sites are selected for siRNA design. The antisense siRNA strand is the reverse complement of the target sequence. The sense strand of the siRNA is the same sequence as the target mRNA sequence. A deoxythymidine dimer is routinely incorporated at the 3′ end of the sense strand siRNA, although it is unknown whether this noncomplementary dinucleotide is important for the activity of siRNAs.

There are two ways to introduce siRNA to knock down gene expression in human cells:

1. RNA transfection: siRNA can be made chemically or using an in vitro transcription method. Like DNA oligos, chemically synthesized siRNA oligos can be commercially ordered. However, synthetic siRNA is expensive, and several siRNAs may have to be tried before a particular gene is successfully silenced. In vitro transcription provides a more economic approach. Both short and long RNA can be synthesized using bacteriophage RNA polymerase T7, T3, or SP6. In the case of long dsRNAs, RNase such as recombinant Dicers will be used to process the long dsRNA into a mixture of 21–23 nt siRNA. siRNA oligos or mixtures can be transfected into a few characterized cell lines such as HeLa (human cervical carcinoma) and 293T cells (human kidney carcinoma). Transfection of siRNA directly into primary cells may be difficult.
2. DNA transfection: Expression vectors for expressing siRNA have been made using RNA polymerase III promoters such as U6 and H1. These promoters precisely transcribe a hairpin structure of dsRNA, which will be processed into siRNA in

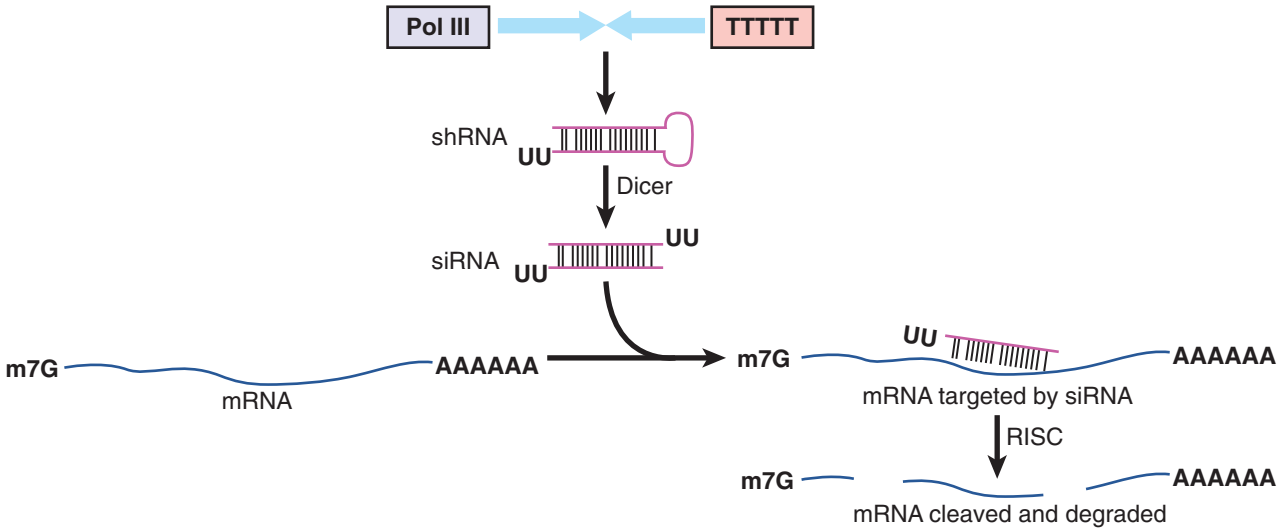

Figure 15-24. RNA interference in mammalian cells. Small interfering RNA (siRNA) can be produced from a polymerase III–driven expression vector. Such a vector first synthesizes a 19–29 nt double-stranded (ds)RNA stem and a loop (labeled as *shRNA* in the figure), and then the RNase complex called *Dicer* processes the hairpin RNA into a small dsRNA (labeled as *siRNA* in the figure). siRNA can be chemically synthesized and directly introduced into the target cell. In the cell, through RNA-induced silencing complex (RISC), siRNA recognizes and degrades target messenger RNAs (mRNAs).

the cell (see Fig. 15-24). Therefore, properly designed DNA oligos corresponding to the desired siRNA will be inserted downstream of the U6 or H1 promoter. There are two advantages of the siRNA expression vectors over siRNA oligos. First, it is easier to transfect DNA into cells. Second, stable populations of cells can be generated that maintain the long-term silencing of target genes. Furthermore, the siRNA expression cassette can be incorporated into a retroviral or adenoviral vector to provide a wide spectrum of applications in gene therapy.

There has been a fast and fruitful development of RNAi tools for in vitro and in vivo use in mammals. These novel approaches, together with future developments, will be crucial to put RNAi technology to use for effective disease therapy or to exert the awesome power of mammalian genetics. Therefore, the applications of RNAi to human health are enormous. siRNA can be applied as a new tool for sequence-specific regulation of gene expression in functional genomics and biomedical studies. With the availability of the human genome sequences, RNAi approaches hold tremendous promise for unleashing the dormant potential of sequenced genomes.

Practical applications of RNAi will possibly result in new therapeutic interventions. In 2002, the concept of using siRNA in battling infectious diseases and carcinogenesis was proven effective. These include notable successes in blocking replication of viruses, such as HIV, hepatitis B virus, and hepatitis C virus, in cultured cells using siRNA targeted at the viral genome or the human gene encoding viral receptors. RNAi has been shown to antagonize the effects of hepatitis C virus in mouse models. In cancers, silencing of oncogenes such as *c-Myc* or *Ras* can slow down the proliferation rate of cancer cells. Finally, siRNA also has potential applications for some dominant genetic disorders.

The twenty-first century, already heralded as the "century of the gene," carries great promise for alleviating suffering from disease and improving human health. On the whole, completion of the human genome blueprint, the promise of gene therapy and molecular therapies, and the existence of stem cells have captured the imagination of the public and the biomedical community. Aside from their potential in curing human diseases, these emerging technologies also have provoked many political, economic, religious, and ethical discussions. As more is discerned about the technologic scientific advances, more attention must also be paid to concerns for their inherent risks and social implications. It is important for surgeons to play a leadership role in the emergence of personalized medicine and surgery, as surgeons have access to the diseased tissues. Surgeons should be establishing collaborations with the genomic and molecular scientists to develop genomic biobanks in order to study the genome and molecular signaling of the disease tissues that will help with an understanding of the underlying cause of an individual's disease and ultimately lead to effective, targeted therapies. Surgeons must take this enormous opportunity to collaborate with basic and clinical scientists to develop the field of personalized genomic medicine and surgery this century. 5▶

Bifunctional RNAi Technology.[36] Over the last 20 years, the field has worked to define oncogene and nononcogene addiction, discriminate between driver and passenger genes, and appreciate the complexity of complex, robust, network interactions. These insights have led to a preliminary understanding of therapeutically relevant sensitivity and resistance pathway signal patterns requiring *multiple* target modulation. However, this knowledge has not been effectively or reproducibly clinically translated. Clinical response is usually far greater when a combination of single-target molecular therapy is administered. However, it must also be realized that targeting two or more pathways may also increase the toxicity profile, particularly if target specificity is limited. When attempted, off-target toxicity has been demonstrated with combination small-molecule therapy. In contrast, multitargeting bifunctional short hairpin (bi-shRNA) DNA vectors are designed to limit off-target effect given the high specificity for the genes they are designed to target.

Exogenously applied hairpin constructs can be designed to be incorporated into cleavage-dependent RISC or cleavage-independent RISC complexes, or both. The concept of a bifunctional shRNA[37] is to increase knockdown efficiency without loss of sequence specificity by engaging both siRNA and miRNA-like (i.e., common biogenic pathway but complementary to target sequence) RISCs, thereby concurrently activating nucleolytic (Ago2-RISC) and nonnucleolytic (Ago1, 3, 4 ± Ago2-RISC) processes.[38] Each bi-shRNA contains both a matched stem sequence to promote Ago2-mediated passenger strand cleavage and a second partial mismatched stem sequence for cleavage-independent passenger strand departure. Thus, functionality of the effectors is set by programmed passenger strand guided RISC loading rather than Ago subset distribution in the cancer cell. Both component Ago2 and Ago [1, 2, 4 ± 3] RNAi moieties are fully complementary to the mRNA target sequence. Preliminary data indicate reduced "off-target effects" by shRNA compared with target-identical siRNAs. More than two mismatches in sequences within the target region drastically reduce knockdown effect to undetectable levels (unpublished results). The design process involves in silico scanning of the entire human mRNA RefSeq database to avoid any potential sequence-related "off-target effects." Published data also indicate persistent susceptibility to shRNA-mediated gene knockdown despite recent evidence of reduced Dicer expression in human cancer cells.[39]

The first clinical experience with the bi-shRNA platform involved the ex vivo knockdown of furin, a Ca^{2+}-dependent, nonredundant proprotein convertase that is essential for proteolytic maturational processing of immunosuppressive TGF-β isoforms (β1 and β2). An autologous whole-cell cancer vaccine, FANG™ (*f*urin-knockdown *an*d *G*MCSF-augmented),[40] was produced based on a dual function immunosensitization principle of augmenting tumor antigen expression, presentation, and processing via granulocyte-macrophage colony-stimulating factor (GMCSF) cytokine transgene expression and attenuating secretory immunosuppressive TGF-β. Harvested, autologous cancer cells are transfected with the GMCSF/bi-shRNA^{furin} (FANG) expression plasmid via electroporation. A phase I clinical trial (BB-IND 14205) involving 52 cancer patients was recently completed. Results demonstrated better than 90% knockdown of the bi-shRNA target, furin, and better than 90% knockdown of furin-regulated proteins TGF-β1 and TGF-β2, thereby confirming the mechanistic expectation of this novel RNAi platform. Moreover, predicted extensive GMCSF expression verified our ability to successfully construct multi-cassette vectors with good manufacturing practice techniques fulfilling Food and Drug Administration requirements for clinical testing.

Twenty-seven patients received one or more vaccine dose, and 23 patients achieved stable disease as their best response. No toxic effect was identified. Median survival of the FANG™-treated patients from time of procurement was 554 days and has not been reached from time of treatment. Expected survival of similar patients is historically less than 1 year. Sequential enzyme-linked immunosorbent spot (ELISPOT) analysis revealed a dramatic and significant increase in immune response from baseline to month 4 in half of the FANG™-treated patients. Comparison of survival between ELISPOT-positive and ELISPOT-negative patients demonstrated a statistically significant increase in survival from time of procurement (P = .045) and time of treatment (P = .025).

These phase I study results demonstrated mechanism, safety, and effectiveness of the bi-shRNA technology and clinical functionality of a multitargeting (dual) DNA expression vector. Further utilization of bi-shRNAi technology is under way clinically (targeting STMN1, a microtubule modulation critical to cancer program) and preclinically targeting PDX1[41] (an oncogene-like transcription factor for pancreatic embryogenesis using nonviral nanoparticle delivery mechanisms).[42]

Personalized Genomic Medicine and Surgery[43]

Genes determine our susceptibility to diseases and direct our body's response to medicine. Because an individual's genes differ from those of another, the determination of each individual's genome has the potential to improve the predication, prevention, and treatment of disease. Sequencing of individual genomes holds the key to realize this revolution called *personalized genomic medicine and surgery*. Next-generation sequencing, such as Illumina sequencing and 454 pyrosequencing technology, is promising to reduce the time and cost so that genome sequencing can be affordable within healthcare systems. The goal of personalized genomic medicine and surgery is to identify the gene variations in each individual and to target the specific gene variations causing the disease by choosing personalized treatments that effectively work in association with the individual's genomic profile. The importance of surgeons in this transformational field of biomedical science is that surgeons have access to the diseased tissues on a daily basis. Surgeons should partner with the genomic scientists to develop genomic biobanks in order to study the genome of the disease tissues. These discovery studies are rapidly leading to the uncovering of mutations and SNPs that are the underlying cause of an individual's disease and ultimately lead to targeted therapies. Although personalized genomic medicine and surgery holds the potential to revolutionize the practice of modern medicine, there currently exists a gap between our ability to sequence any given individual's genome and how clinicians can apply this information to guide care. There is a rapidly growing list of single genes that are currently guiding care, and these genes are listed as type 1 personalized genes. Examples of these genes are *BRCA1*, *RET* proto-oncogene, and *CHD1* mutation, which guide potential use of mastectomy, thyroidectomy, and gastrectomy, respectively; however, the great challenge before the scientific and medical community this century is to learn to use the entire genome to guide personalized care.

chapter 16

The Skin and Subcutaneous Tissue

Sajid A. Khan, Jonathan Bank, David H. Song, and Eugene A. Choi

INTRODUCTION

The skin is a complex organ encompassing the body's surface and continuous with the mucous membranes. Accounting for approximately 15% of total body weight, it is the largest organ in the human body. Enabled by an array of tissue and cell types, intact skin protects the body from external insults. However, the skin is also the source of a myriad of pathologies that include inflammatory disorders, mechanical and thermal injuries, infectious diseases, and benign and malignant tumors. The intricacies of this organ and associated pathologies are reasons the skin and subcutaneous tissue remain of great interest and require the attention of various surgical disciplines that include plastic surgery, dermatology, general surgery, and surgical oncology.

ANATOMY AND HISTOLOGY

Background

Components of epithelial, connective, vascular, muscular, and nervous tissue are organized into three histologic layers (epidermis, dermis, and hypodermis), which vary in consistency between various body parts (Fig. 16-1). The thickness of each layer, distribution of dermal appendages, density and type of nerve endings, and melanocyte distribution are just some of the variables that differ by location and purpose. The epidermis and its appendages are of ectodermal origin, whereas the dermis and hypodermis are of mesodermal origin.[1]

Epidermis

The epidermis consists of stratified epithelium that undergoes continuous regeneration. Ninety to ninety-five percent of these epithelial cells are ectodermally derived keratinocytes. During their differentiation, keratinocytes form flattened, anucleate cells that are ultimately shed from the skin surface. This process results in the formation of distinct cell layers (from deep to superficial): stratum basale (single cell layer), stratum spinosum (5 to 15 cells thick), stratum granulare (1 to 3 cells), and stratum corneum (5 to 10 cells), which is further subdivided into a deep, compact stratum compactum layer and a more superficial, loose stratum disjunctum layer. In the palmoplantar region, an additional layer, the stratum lucidum, can be seen between strata granulare and corneum (see Fig. 16-1). Transit time (keratinization) is approximately 30 days. Epidermal thickness differs between skin regions, ranging from 50 μm on the eyelids to 1 mm on the soles. Interventions such as tissue expansion result in thickening of the epidermis (and thinning of the dermis).

Epidermal Components

Keratinocytes. Basal layer keratinocytes are columnar or cubical cells with a basophilic cytoplasm and large nucleus, and they are aligned with an underlying basement membrane and anchored by hemidesmosomes. Melanosomes are positioned over the nucleus. The cytoplasm includes bundles of filaments comprised of keratin polypeptides; these insert into the desmosomes and contribute to the formation of the cytoskeleton,

Key Points

1. The epidermis consists of continually regenerating stratified epithelium, and 90% of cells are comprised of ectodermally derived keratinocytes.
2. Dermal fibers are predominantly made of type I and III collagen in a 4:1 ratio. They are responsible for the mechanical resistance of skin.
3. *Staphylococcus aureus* is the most common isolate of all skin infections. Impetigo, cellulitis, erysipelas, folliculitis, furuncles, and simple abscesses are examples of uncomplicated infections, whereas deep-tissue infections, extensive cellulitis, necrotizing fasciitis, and myonecrosis are examples of complicated infections.
4. Hemangiomas arise from benign proliferation of endothelial cells surrounding blood-filled cavities. They most commonly present after birth, rapidly grow during the first year of life, and gradually involute in most cases.
5. Basal cell carcinoma represents the most common tumor diagnosed in the United States, and the nodular variant is the most common subtype.
6. Squamous cell carcinoma is the second most common skin cancer, and primary treatment modalities are surgical excision and Moh's microsurgery. Cautery and ablation, cryotherapy, drug therapy, and radiation therapy are alternative treatments.
7. Tumor thickness, ulceration, and mitotic rate are the most important prognostic indicators of survival in melanoma. If a sentinel node contains metastatic cancer, prognosis is determined by the number of positive nodes, the primary tumor thickness, mitotic rate and ulceration, and the age of the patient.

conferring mechanical resistance to the epidermis as a whole. Other types of intercellular junctions (including gap and adherens junctions) are present as well. Proliferation occurs at this cell layer. Spinosum layer keratinocytes are polygonal, with an eosinophilic cytoplasm. Ultrastructurally, they contain coarse bundles of tonofilaments, cytoplasmic protein found in epithelial cells.

Granular layer keratinocytes are flattened cells, lying parallel to the skin surface, with a diameter of 25 µm; they contain keratohyalin granules and keratin and lamellar bodies. The latter are involved in the process of desquamation and in the formation of a lipid pericellular coat that acts as a penetration barrier against foreign (hydrophilic) substances.

Corneum layer keratinocytes are highly flattened, hexagonal, eosinophilic cells, containing mainly keratin matrix, that are eventually shed from the skin surface and contribute to the skin's barrier function. The superficial part of eccrine sweat glands and hair follicles are considered part of the epidermis as well. The epithelial cells comprising these units have separate biologic properties with regard to regeneration, differentiation, and response to various stimuli. Five to ten percent of epidermal cells are nonkeratinocytes, including primarily Langerhans cells, melanocytes, and Merkel cells.

Langerhans Cells. These are mobile, dendritic, antigen-presenting cells present in all stratified epithelia that originate from bone marrow precursors. These cells are capable of uptaking exogenous antigens (by use of Birbeck granules), processing them and presenting them to T cells; they represent 3% to 6% of all cells in the epidermis.[2]

Melanocytes. Originating from the neural crest, these cells migrate into the epidermis where they produce melanin, the main natural pigment of the skin. They are distributed regularly among basal keratinocytes, at a ratio of 1 melanocyte for every 4 to 10 keratinocytes. Their density reaches 500 to 2000 cells per mm^2 of cutaneous surface, with regional variations (maximal density on genital skin).

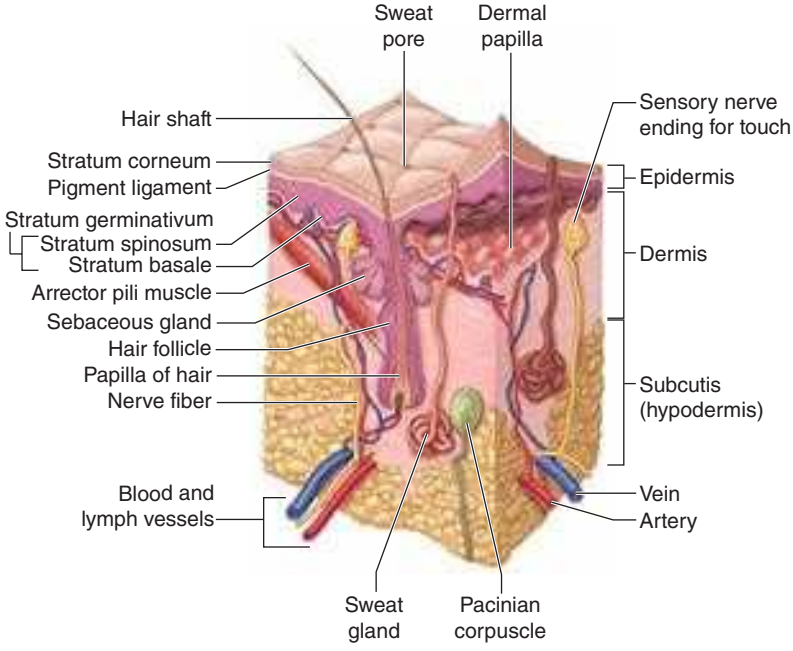

Figure 16-1. Schematic representation of the skin and its appendages. Note that the root of the hair follicle may extend beneath the dermis into the subcutis.

Melanin is produced through the enzymatic activity of tyrosinase on the substrate tyrosine and is then stored in melanosomes; these are transported along the dendritic processes of melanocytes and are eventually transferred to adjacent keratinocytes where they form an umbrella-like cap over the nucleus, protecting it from the effects of ultraviolet (UV) light. Melanocytes express the bcl-2 oncoprotein, S100 protein, and vimentin.

Ethnic variations in pigmentation are due to differences in activity of melanocytes and distribution of melanosomes within the epidermis and not differences in the number of melanocytes.

Merkel Cells. Merkel cells display both neuroendocrine and epithelial features. They function as mechanoreceptors and synapse with dermal sensory axons in the basal layer of the epidermis and the epithelial sheath of hair follicles.

Lymphocytes. The normal human epidermis contains a small percentage (<1%) of lymphocytes, present mainly in the basal layer. They express predominantly a T-memory/effector phenotype.[3]

Toker Cells. These are cells with a clear cytoplasm and are located within the nipple epidermis in 10% of both males and females. Their role in normal skin and pathology remains poorly understood, but they may be precursors of Paget's cell carcinoma.[4]

Epidermal Appendages. These are specialized epithelial structures, connected to the surface epidermis but located mainly within the dermis and hypodermis. Appendages serve functions that include lubrication, sensation, contractility, and heat loss.

Sweat Glands. Sweat glands are tubular exocrine glands, consisting of a secretory coil and an excretory duct. Eccrine sweat glands are the main sweat glands in humans, playing a vital role in the process of thermoregulation. They are present almost everywhere on the skin (except mucous membranes), with a maximal density over the palms, soles, axillae, and forehead.

Apocrine sweat glands are less abundant in humans and are derived embryologically from the germ cells that produce the pilosebaceous follicle and are, therefore, structurally associated with it. These glands are found in the axillary, anogenital, and nipple regions. They consist of a secretory coil that is larger and more irregular in shape than that of eccrine glands.

A third type of sweat gland was more recently described in the axillary region. The so-called "apoeccrine" glands are atrichial glands, opening directly to the skin surface, but their secretory coil is similar to that of apocrine glands and they present during puberty.[5]

Pilosebaceous Follicles. These structures are derived from the epithelial germ layer and lie obliquely in the dermis, with their deepest part reaching the hypodermis. They are present throughout the integument, excluding the glabrous skin (palms, soles) and portions of the genitalia. Their size and morphology are variable (terminal, vellus, lanugo, and intermediary hair). Their growth is cyclic and proceeds through three distinct phases of uneven duration (anagen, catagen, and telogen) during which their histology varies considerably.

Nails. The nails overlie the dorsal aspect of the distal phalanges of the fingers and toes. They consist of three parts: (a) the root, covered by the proximal nail fold, continuous with the lateral nail folds; (b) the nail plate, comprised of hard keratin; and (c) the free edge, overlying the hyponychium, a thickened epidermis. The nail lies on the nail bed, a richly vascular connective tissue containing numerous arteriovenous shunts. The proximal part of the nail bed is continuous with the nail matrix, responsible for nail growth and adhesion.

Dermis

Architecture. The dermis is a compressible, elastic connective tissue that supports and protects the epidermis, dermal appendages, and neurovascular plexuses. It consists of cells, fibrous molecules, and a ground substance. It turns over continuously, regulated by mechanisms controlling the synthesis and degradation of its protein components. The thickness of the dermis varies considerably with the anatomic location (being much thicker on the back, palms, and soles than on the eyelids).

The papillary (superficial) dermis forms conic upward projections (dermal papillae) alternating with epidermal rete ridges, thus increasing the surface of contact between the dermis and epidermis and allowing for better adhesion between these layers. It contains several cell types (fibroblasts, dermal dendrocytes, and mast cells), vessels, and nerve endings. It is made of collagen fibers arranged in loose bundles and thin elastic fibers stretching perpendicularly to the dermal-epidermal junction. In the distal extremities, dermal papillae contain tactile corpuscles, specialized nerve endings acting as mechanoreceptors. The reticular (deep) dermis is made of coarser collagen bundles, tending to lie parallel to the skin surface. The elastic network is also thicker in this layer. The reticular dermis contains the deep part of cutaneous appendages and vascular and nerve plexuses.

Dermal Fibers. The majority (>90%) of dermal fibers are collagen, predominantly types I and III, which are responsible for the mechanical resistance of the skin. Collagen accounts for 98% of the total mass of dry dermis. Collagen fibers are arranged in bundles that are loose in the papillary dermis and become thicker in the deep dermis. Other collagens found in the dermis include type IV collagen (at the dermo-epidermal junction and in the basement membranes of cutaneous appendages, vessels, muscles, and nerves) and type VII collagen (anchoring fibers of the dermo-epidermal junction).

2▶

Elastic fibers are responsible for the retractile properties of the skin due to their ability to stretch to twice their resting length and return to their baseline shape after the deforming force is relieved. In the papillary dermis, they are thin; they become thicker in the reticular dermis, where they tend to run horizontally. By electron microscopy, elastic fibers show variations depending on age and the area studied (sun-exposed or not). They have irregular contours and are made of a central amorphous matrix composed of elastin, an insoluble protein. This core is surrounded by a varying number of microfibrils made of fibrillin. Reticulin fibers consist biochemically of an assembly of thin collagen fibers (types I and III) and fibronectin.

Cells. Fibroblasts are the fundamental cells of the dermis and all connective tissues that synthesize all types of fibers and the ground substance. They appear as spindle-shaped or stellate cells, containing a well-developed rough endoplasmic reticulum. Myofibroblasts are cells derived from fibroblasts, namely during the process of wound healing; they contain myofilaments, visible by electron microscopy, and express (smooth) muscle actin and more rarely desmin.[6]

Dermal dendrocytes represent a heterogeneous population of mesenchymal dendritic cells, recognizable mainly by immunohistochemistry. They are present around capillaries of the papillary dermis, around sweat gland coils, and within the

connective tissue septa of the hypodermis. Dermal dendrocytes complement the immunologically functional cells of the epidermis. Mast cells are mononuclear cells of bone marrow origin, sparsely distributed in the perivascular and periadnexal dermis.

Cutaneous Vasculature. Excluding the epidermis, which is a nonvascular tissue, the skin possesses a rich vascular network that largely exceeds the skin metabolic requirements. This network plays a role in thermoregulation, wound healing, immune reactions, and blood pressure control. Cutaneous vessels belong to the arterial, venous, or lymphatic system; they originate from perforating arteries arising from underlying vessels of the muscles and form two distinct horizontal plexuses that communicate via vessels traversing the dermis vertically. The deep plexus lies close to the dermal-hypodermal junction and provides nutritional arteries to sweat glands and hair follicles. The superficial plexus, derived from terminal arterioles, lies at the interface between the papillary and reticular dermis and provides a vascular loop to every dermal papilla toward the surface (except in the nail bed). This consists of an ascending precapillary arteriole, arterial and venous capillaries forming a hairpin turn, and a descending postcapillary venule (these account for the majority of vessels in the papillary dermis).[7]

Cutaneous Enervation. The skin contains a rich and complex enervation, consisting of an afferent and an efferent limb. The afferent limb is responsible for the perception of eternal stimuli (touch, pressure, vibration, pain, temperature, itch) via a network of sensory myelinated and nonmyelinated fibers, free terminal nerve endings, and tactile corpuscles. The efferent limb is supported by nonmyelinated fibers of the sympathetic system that regulate vasomotricity, sweat secretion, and piloerection.

Hypodermis (Subcutaneous Fat, Panniculus Adiposus)

Fatty tissue is the deepest part of the skin, separating it from the underlying muscle fascia or the periosteum. It plays an important role in thermoregulation, insulation, storage of energy, and protection from mechanical injuries.

The main cells of the hypodermis are the adipocytes—large, rounded cells with a lipid-laden cytoplasm (triglycerides, fatty acids) compressing the nucleus against the cell membrane. Adipocytes are arranged in primary and secondary lobules, the morphology of which varies according to gender and body region. These lobules are separated by connective tissue septa containing cells (fibroblasts, dendrocytes, mast cells), the deepest part of sweat glands, and vessels and nerves contributing to the formation of the corresponding dermal plexuses.

INFLAMMATORY CONDITIONS

Hidradenitis Suppurativa

Hidradenitis suppurativa is a chronic inflammatory disease presenting as painful subcutaneous nodules. Patients experience appreciable physical, psychological, and economical hardship and decreased quality of life when compared to patients who suffer from other chronic dermatologic disease such as psoriasis and alopecia.[8] It is characterized by multiple abscesses, internetworking sinus tracts, foul-smelling exudate from draining sinuses, inflammation in the dermis, both atrophic and hypertrophic scars, ulceration, and infection, which may extend deep into the fascia. The diagnosis is made clinically without the need for imaging or laboratory tests. Affected sites are axillary, inguinal, perineal, mammary, and inframammary areas corresponding to a "milk-line" distribution.

The current pathophysiologic mechanism is that there is follicular occlusion, and not an apocrine disorder as previously believed. Hyperandrogenism does not have a proven role in the disease; poor hygiene, smoking, alcohol consumption, and bacterial involvement are thought to exacerbate rather than initiate the disease process.

Treatment varies depending on disease severity and extent. The majority of patients with early-stage disease (abscesses without significant scarring) respond to topical or systemic antibiotics (clindamycin is first-line therapy). Antiandrogens have an equivocal role in therapy. Application of various anti-inflammatory agents has been successful in limited accounts and with questionable long-term efficacy. With the goal of ablating hair follicles, radiation therapy, radiofrequency ablation, and carbon dioxide (CO_2) laser ablation have been employed, again with less than satisfactory long-term results.[9-12]

Refractory cases respond best to wide surgical debridement of the affected sites. Recurrence rates tend to be higher in the inframammary and inguino-perineal regions, reaching up to 50%. Primary wound closure after debridement bears a high risk of recurrence and is therefore discouraged. Locoregional flaps, split-thickness skin grafting, and healing by secondary intention are other alternatives. Skin grafting has a faster healing rate compared with secondary wound closure. However, the cost of having a painful donor site and limb immobilization led most patients in one reported study to prefer secondary healing.[13] Topical antimicrobial creams should be used during the healing process.

Pyoderma Gangrenosum

Pyoderma gangrenosum (PG) is a relatively uncommon noninfectious neutrophilic dermatosis. This disease is commonly associated with inflammatory bowel disease, rheumatoid arthritis, hematologic malignancies, and monoclonal gammopathies. Clinically, the condition is characterized by the presence of sterile pustules, which progress and ulcerate to variable depths and dimensions. The lower extremities are the most commonly affected site, although all other parts of the skin can be involved. Extracutaneous manifestations include the upper airway, eye, genitalia mucosa, lungs, spleen, and muscle. Secondary infection is common. PG is more common in women and peaks in the third to sixth decades of life. Lesion borders are purplish in color with erythematous edges. Five clinical types are identified: ulcerative, pustular, bullous, vegetative, and peristomal. Treatment of this condition is centered on treatment of the inciting disease (i.e., management of Crohn's disease) and often includes systemic steroids or calcineurin inhibitors. Treatment of PG combines systemic, topical, and surgical modalities. Systemic therapy is instituted in widespread and progressing cases and revolves around anti-inflammatory medications. Calcineurin inhibitors (inhibitors of T-cell activation) and corticosteroids are the mainstay of therapy. Other immunomodulators include sulfa drugs (dapsone), clofazimine, thalidomide, colchicine, azathioprine, cyclophosphamide, and mycophenolate mofetil. Patients with Crohn's disease and PG treated with infliximab (tumor necrosis factor [TNF]-α inhibitor) and etanercept (TNF-α antagonist) had a marked improvement in their PG.[14,15] Once ulcers develop, topical antimicrobials should be used to decrease the likelihood of secondary infections. Wound care should be geared toward debridement of purulent exudate

and devitalized tissue, while maintaining a moist environment to facilitate healing. Topical calcineurin inhibitors have been shown to be useful in peristomal PG.[16] Surgical debridement should be used concomitantly with systemic therapy, as the surgical insult may trigger further PG. Wound closure can usually be achieved with split-thickness skin grafting and temporary coverage with allografts or bioengineered skin substitutes.

Toxic Epidermal Necrolysis and Steven-Johnson Syndrome

These inflammatory diseases represent a spectrum of an autoimmune reaction to stimuli such as drugs that result in structural defects in the epidermal-dermal junction. The cutaneous manifestations of toxic epidermal necrolysis syndrome (TENS) follow a prodromal period reminiscent of an upper respiratory tract infection.[17] A symmetrical macular eruption follows starting from the face and trunk and spreading to the extremities. Typically, a Nikolsky sign develops in which lateral pressure causes the epidermis to detach from the basal layer. The macular eruption evolves into blisters, causing an extensive superficial partial-thickness skin injury with exposed dermis (Fig. 16-2). The process progresses for 7 to 10 days; re-epithelialization occurs over 1 to 3 weeks. Mucosal and ocular surfaces may be involved in a similar fashion. Immunosuppressed patients are at higher risk.

TENS historically was considered to be the extreme of a spectrum, with erythema multiforme and Stevens-Johnson syndrome (SJS) being less extensive forms of disease. Currently, erythema multiforme is thought to be a separate entity, related to herpetic and *Mycoplasma pneumoniae* infection. TENS involves more than 30% total body surface area; between 10% and 30% is considered the SJS-TEN overlap syndrome. Prognosis is related to the extent of disease and related primarily to secondary infection and other intensive care unit (ICU)-associated morbidity. With modern-day burn and ICU care, the mortality has declined significantly.[17] The mildest form of the disease is SJS, which clinically presents as second-degree burns appearing as erythema and blisters/bullae of the oropharynx, anoderm, and torso. Less than 10% of total body surface area is involved with this disease. TENS is driven by the same dermo-epidermal structural defects but consists of greater than 30% total body surface area. In addition to the aforementioned, it affects the mouth, esophagus, small bowel, and colon, resulting in sloughing of mucosa that may present as gastrointestinal bleeding and intestinal malabsorption.[18] It also affects the eyes, genitalia, and other mucosal surfaces.

Figure 16-2. Blisters on the forearm of a patient several days after exposure to vancomycin. Note the clear antishear dressing and the dark silver-impregnated antimicrobial dressing (Acticoat™).

The drugs most commonly associated with TENS-SJS include aromatic anticonvulsants, sulfonamides, allopurinol, oxicams (nonsteroidal anti-inflammatory drugs), and nevirapine. The pathophysiology of TENS is not completely understood; current theories involve apoptosis due to Fas-mediated mechanisms (a soluble or a membrane-bound protein that causes apoptosis upon activation), granulysin (a proapoptotic protein that permits cell-mediated cytotoxicity), and reactive oxygen species. There appears to be a genetic component, and genetic testing before carbamazepine treatment is recommended in people of Han Chinese ancestry to exclude carriers of HLA-B1502.[19]

The two principles of TENS management include early withdrawal of the offending drug and supportive care (i.e., pain control, intravenous fluid, electrolyte repletion, prevention of skin infections, enteral feeds, and possible respiratory support) in a burn unit. Despite drug withdrawal, noxious metabolites may persist. Wound care differs between centers and focuses on debridement of devitalized tissue and coverage with nonadherent dressings. Temporary skin coverage is sometimes needed until re-epithelialization is allowed to progress, reducing the probability of skin infections and dehydration. Coverage can be achieved with biologic dressing (allograft skin), biosynthetic dressings (Biobrane), and antimicrobial dressings (antibiotic or silver-impregnated such as Acticoat). A Wood's lamp examination every 1 hour should be performed to look for corneal sloughing. It should be noted that these diseases should be distinguished from staphylococcal scalded skin syndrome, which clinically appears similar but is a result of exotoxins produced after staphylococcal infections of nasopharynx or otitis media.

Systemic treatment with steroids has fallen out of favor due to increased sepsis rates, prolonged admission, and potentially higher mortality rates. Intravenous immunoglobulin (IVIG) is thought to be a treatment given the presence of anti-Fas antibodies within IVIG. The antagonistic antibodies inhibit Fas-mediated cell apoptosis.[20] However, a high variability exists between batches with this regard. There are mixed reports of IVIG treatment efficacy. A 2007 meta-analysis of nine IVIG trials concluded that high-dose IVIG does, in fact, improve survival.[21] Other treatment protocols include plasmapheresis aimed at decreasing cytokine and drug load, cyclosporine, cyclophosphamide, and anti–TNF-α antibodies.[17]

INJURIES

Radiation-Induced Injuries

Radiation-induced injuries can be the result of environmental exposure, industrial/occupational applications, and medical etiologies. Surgeons must be aware of the role radiation plays in oncologic multidisciplinary care. In addition to radiation treatment for cancers such as lymphoma and head and neck squamous cell carcinomas, radiotherapy plays a role in the adjuvant setting either before or after surgical resection in diseases such as rectal, esophageal, and cervical cancers. Although the newer modalities and principles of radiation oncology have allowed for more precise administration of this therapy with theoretically fewer side

effects, there still are complications and clinical entities related to the skin (and deeper viscera) that the surgeon needs to be attuned to.

The replicating basal keratinocytes, hair follicle stem cells, and melanocytes are the most radiosensitive components of the skin. Damage to basal keratinocytes and hair follicle cells causes an immediate burst of free radicals, irreversible double-stranded breaks in nuclear and mitochondrial DNA, and inflammation. The first dose of radiation destroys a percentage of basal keratinocytes, hindering the regenerative capacity of the epidermis; repeated exposures do not allow time for cells to repair.

Acute skin changes are the result of injury to the basal epithelium in the radiated region. Within weeks, this manifests as erythema, edema, and alopecia. As the cells of the skin and subcutaneous tissue undergo repair, permanent hyperpigmentation is clinically apparent. Histologically, the epidermis appears thickened, but the functional integrity is compromised. Severe radiation injury results in complete loss of the epidermis with persistent edema and fibrinous exudate. Re-epithelialization from unaffected wound edges and from recuperating dermal adnexa begins within 10 to 14 days of exposure, provided other parameters are optimized (nutrition, infection, etc.). Chronic changes result from thrombosis and necrosis of capillaries, presenting months to years after the inciting event, ultimately leading to fibrosis and possible ulcers. Chronic skin changes include thinning, hypovascularization, telangiectasia of remaining vessels, ulceration, fibrosis with loss of elasticity, and increased susceptibility to trauma and infection. Chronic radiation skin injury includes delayed ulcers, fibrosis, and telangiectasias that present weeks to years after exposure.

Treatment of minor radiation skin injury consists primarily of maintaining the integrity of remaining skin with moisturizers until recovery of skin adnexa. Management of severe radiation includes surgical excision of damaged tissues as well as control of the typically opiate-resistant pain.

Environmental-induced injuries are from UV radiation and solar-induced skin toxicity and are the most common forms of radiation exposure skin injuries. Radiation reaching the surface of the earth contains infrared (700–2500 nm), visible (400–700 nm), and invisible UV radiation (290–400 nm).[22] UVC rays are filtered by the ozone layer of the atmosphere. UVB rays (290–320 nm) and UVA rays (320–400 nm) reach the earth's surface and have cutaneous effects. UVB radiation reaches the earth in relatively low amounts but is highly energetic. UVA rays are lower in energy, but are more abundant, constituting approximately 95% of UV rays reaching the ground. Seasonal, temporal, geo-orbital, and environmental parameters affect solar irradiance. Seventy percent of UVB radiation that reaches the skin is absorbed by the stratum corneum, 20% reaches deeper in the epidermis, and only 10% penetrates the upper part of the dermis. UVA rays are more penetrant, with 20% to 30% reaching the deep dermis. The major chromophores are nucleic acids, aromatic amino acids, and melanin.

Short-term solar radiation effects include erythema and pigmentation. UVB is more effective than UVA in causing a dermal inflammatory response resulting in erythema in a delayed phenomenon, peaking at 6 to 24 hours (dose and skin type dependent). Pigmentation occurs as a result of photo-oxidation of melanin by UVA. Partial fading occurs rapidly within 1 hour after the end of exposure. For higher UVA doses, a stable residual pigmentation is observed after the transient effect. Neomelanization is characterized by a visible brown pigmentation in UV-exposed skin, which represents an increase in epidermal melanin content. It becomes visible after about 72 hours. An acute erythemogenic dose of UVB is necessary to induce delayed pigmentation; UVA is less effective in tanning and in radiation protection. UVB pigmentation results in a homogeneous tan and UVA protection. However, melanization produced by cumulative UVA exposures appears to be longer lasting than that acquired with UVB exposures.[22]

Long-term effects of UV pigmentation can lead to irregular pigmentation and hyperpigmented areas, melasma, postinflammatory pigmentation, and actinic lentigines (sun spots). Radiation damage results from an increase in lysozyme activity, which inhibits the activity of collagenase and elastase and prevents the elastic fibers from proteolysis. The collagen fibril network is impaired and causes an accumulation of an amorphous, elastin-containing material. There is also a loss of collagen and a change in collagen composition (increase in collagen III to collagen I ratio). This structural disarrangement manifests as a loss of firmness and resilience of skin, leading to an older appearance to the skin.

Trauma-Induced Injuries

Mechanical Injury. Skin injuries may occur as a result of penetrating, blunt, and shear forces, or a combination of these. Clean lacerations may be closed primarily after irrigation, debridement, and exploration. Many surgeons will primarily close clean wounds if the injury is treated within 6 hours of the inciting event. However, there is no systematic evidence regarding the timing of closure[23]; practitioners are advised to use their judgment. Contaminated or infected wounds should be allowed to heal by secondary intention or delayed primary closure.[24]

Tangential abrasions should be approached similarly to burns injuries, with management dependent on the depth of the injury incurred. Superficial partial-thickness wounds may be left to heal spontaneously while providing topical antimicrobial prophylaxis or sterile biologic dressings. Deeper wounds may require split-thickness skin grafting to avoid prolonged need for dressing changes and hypertrophic scarring that might result from a prolonged healing period. Degloved skin may be used to provide coverage similar to a skin graft, or as a temporary dressing, provided the wound bed has been cleaned.

Bite Wounds. Accounting for over 4.5 million injuries each year, with many more presumably unreported, seemingly innocuous punctures may lead to severe deep-tissue infections if unrecognized and not treated appropriately.[25]

Bite bacteriology is influenced by normal mouth flora, as well as the content of the offending animal's food. Early presentation bite wounds yield polymicrobial cultures. Common aerobic bacterial genera include *Pasteurella multocida*, *Streptococcus*, *Staphylococcus*, *Neisseria*, and *Corynebacterium*; anaerobic organisms include *Fusobacterium*, *Porphyromonas, Prevotella, Propionibacterium, Bacteroides,* and *Peptostreptococcus. Capnocytophaga canimorsus* bacteria after a dog bite are rare. It appears that immunocompromised patients are most susceptible to this type of infection and its complications. Cultures from an infected bite wound that presents late usually will grow a single organism type. Bacterial load in dog bites is heavily dependent on the content and timing of the last meal and can range between 10^3 with a dry meal (biscuits) to 10^7 within 8 hours of a wet meat meal (Fig. 16-3).[26] The bacterial spectrum found in cat bites is very similar to that of dog bites, with a

A B

Figure 16-3. **A.** Dog bite to the face involving the lip and left oral commissure. **B.** Primary closure following debridement and irrigation. Closure was performed due to aesthetic and functional considerations.

slightly higher prevalence of *Pasteurella* species. Rare infections acquired from cats have been with *Francisella tularensis* (tularemia) and *Yersinia pestis* (human plague).

Bacteria colonizing human bites are those present on the skin or in the mouth. These include the gram-positive aerobic organisms *Staphylococcus aureus*, *Staphylococcus epidermidis,* and *Streptococcus* species, and anaerobes including *Peptococcus* species, *Peptostreptococcus* species, *Bacteroides* species, and *Eikenella corrodens* (facultative anaerobe). Antibiotic coverage must cover gram-positive and anaerobic organisms. A first-generation cephalosporin in combination with penicillin or ampicillin in combination with clavulanic acid provides adequate coverage. Clindamycin is an alternative, but additional coverage for *Eikenella corrodens* should be administered.

Most wounds are amenable to standard wound care protocols. Irrigation (preferably with sterile saline solution) should be performed, although it will reduce surface bacteria only if done with nonpulsatile irrigation. To significantly reduce bacterial load and eliminate particulate debris in the wound, pressure irrigation should be performed. Eighty percent of wounds presenting to the emergency department have a bacterial load under 10^5, and superficial irrigation will suffice. Larger wounds with signs of infection will require pulse irrigation. Rapid quantitative cultures should be used to guide treatment in wounds with suspected infection. Human bites typically are characterized by higher bacteria load ($>10^5$).

In select cases, bite wounds may be closed primarily, particularly in areas of aesthetic significance such as the face, where secondary intention healing will result in unsightly scarring. This approach should follow initial management as outlined earlier, along with close follow-up to permit early detection of infection.

Rabies in domestic animals in the United States is rare, and the majority of cases are contracted from bat bites. In developing countries, dog bites remain the most common source of rabies. Management of this is beyond the scope of this chapter.

Caustic Injury

Between 2.4% and 10.7% of burns are due to chemical exposure[27]; however, approximately 30% of burn deaths are related to chemical burns. Damage from chemical burns is related to the concentration, duration, and quantity of acidic or alkaline solution. Acidic injuries typically cause a more superficial burn pattern due to eschar formation as a result of coagulation necrosis of the skin. This limits subsequent tissue penetration. Exothermic chemical reactions associated with acid burns may cause a combined thermal and chemical injury. Without treatment, this injury will result in erythema and ulcers through the subcutaneous tissue. Injuries related to basic fluids result from liquefactive necrosis starting with fat saponification and result in longer more sustained injuries causing a deeper pattern of injury (Fig. 16-4). Common examples are sodium hydroxide (drain decloggers, paint remover) and calcium hydroxide (cement). This permits further penetration of the unattached molecules, causing further tissue destruction.

The treatment for both types of injuries is based on neutralization of the inciting solution and starts with running distilled water or saline over the affected skin for at least 30 minutes for acidic solutions and 2 hours for alkaline injuries. It should be noted that neutralizing agents do not offer a significant advantage over dilution with water, may delay treatment, and may worsen the injury due to the exothermic reaction that may occur. The clinician observes and treats based on the degree of presentation. Many cases are successfully managed conservatively with topical emollients and oral analgesics, and most cases result in edema, erythema, and induration. If signs of deep second-degree burns develop, local wound care may include debridement, Silvadene, and protective petroleum gauze. In severe cases, injury to the underlying vessels, bones, muscle, and tendon may occur, and these cases may be managed within 24 hours by liposuction through a small catheter and then saline injection. Surgery is indicated for tissue necrosis, uncontrolled pain, or deep-tissue damage. Antibiotics should not be administered unless signs of infection are present.

Injuries that have specific additional treatments include hydrofluoride burns Hydrofluoride is found in air conditioning cleaners and petroleum refineries. Treatment of hydrofluoride burns should include topical or locally injected calcium gluconate to bind fluorine ions. Intra-arterial calcium gluconate can provide pain relief and preserves arteries from necrosis, whereas intravenous (IV) calcium repletes resorbed calcium stores. Topical calcium carbonate gel and quaternary

Figure 16-4. Self-inflicted alkali burn with cleaner fluid.

ammonium compounds detoxify fluoride ions. This mitigates the leaching of calcium and magnesium ions by the hydrofluoric acid from the affected tissues and prevents potentially severe hypocalcemia and hypomagnesemia that predispose to cardiac arrhythmias.

IV fluid extravasation results in yet another type of chemical injury and occurs in 0.1% to 0.7% of all cytotoxic drug administrations (Fig. 16-5). The dorsum of the hand is the most common location of this type of injury, predisposing exposure of the extensor tendon. There is a higher risk in patients receiving chemotherapy, and the risk increases dramatically in the pediatric population (11%–58%). Doxorubicin is often the offending agent, and its effects are attributable to direct toxicity resulting in cellular death, perpetuated by release of doxorubicin from cell lysis and failed wound healing. Resultant tissue injury depends on several factors, including solution osmolality, tissue toxicity, vasoconstrictive properties, infusion pressure, and regional anatomic properties.[28] Although most extravasations do not culminate in significant injuries, skin and subcutaneous damage is more likely in the critically ill and neonates. This is due, in part, to the type of infusions employed in these patients, the thin skin at the IV site (dorsum of hands and feet), fragility of veins, and the relatively poorly perfused tissue in these locations. Initial presentation may include erythema, blistering, and pain. The true extent of the injury may be beyond the apparent external margins, and this may take days to manifest completely (longer in the case of calcium carbonate infiltrations). Injury to deeper structures should be excluded. Treatment varies from conservative management with limb elevation to saline infiltration (for dilution) and aspiration with liposuction cannula.[28] These methods have been shown to be effective only in the early period following extravasation. Cold or warm compresses should be avoided because they may add a thermal injury component to an area in which thermoregulatory mechanism are impeded due to vasoconstriction, pressure, and inflammation. Surgical intervention includes debridement of devitalized tissue and reconstruction with appropriate technique (i.e., skin substitutes, skin grafting, flaps, or secondary intention). Topical antimicrobial therapy is encouraged until surgery is possible.

Thermal Injury

Exposure of the skin to thermal extremes disrupts its primary function as a barrier to heat loss, evaporation, and microbial invasion. The depth and extent of injury are dependent on the duration and temperature of the exposure. The pathophysiology and management are discussed elsewhere in this book. Briefly, the epicenter of the injury undergoes a varying extent of necrosis (depending on the exposure), otherwise referred to as the zone of coagulation, which is surrounded by the zone of stasis, which has marginal perfusion and questionable viability.[29] This is the area of tissue that is most amenable to salvage by appropriate resuscitative and wound management techniques, which would theoretically limit the extent of injury. The outermost area of skin shows characteristics similar to other inflamed tissues and has been designated the zone of hyperemia. The degree of burn corresponds to histologic layers of the affected dermis and correlates with management and prognosis pertaining to timeline of healing and magnitude of scarring (Fig. 16-6).

Hypothermic skin injury (frostbite) can result from direct cellular damage or the secondary effects of microvascular

thrombosis and subsequent ischemia.[30] Freezing of tissue leads to intracellular and extracellular ice formation, intracellular ice formation, cell dehydration and crenation, local electrolyte abnormalities, and disturbances in lipid-protein complexes. With rewarming, the ice melts and damaged cells take up water; affected capillaries leak fluid into the interstitium. Subsequently, this edema and concomitant inflammatory process result in epidermal blistering and microvasoconstriction, propagating further tissue injury. Treatment includes rapid rewarming to 40 to 42°C, analgesia, debridement of blisters, hydrotherapy, elevation, topical antimicrobials, topical antithromboxanes (aloe vera), and systemic antiprostaglandins (aspirin).

Figure 16-6. Scald burn of upper arm, back, and buttock. Pink areas are superficial partial-thickness burn, whereas whiter areas are deeper burns in the dermis.

Pressure Injury

Tissue pressures that exceed the pressure of the microcirculation (30 mmHg) result in tissue ischemia. Frequent or prolonged ischemic insults will ultimately result in tissue damage (Fig. 16-7). Areas of bony prominence are particularly prone to ischemia, the most common areas being ischial tuberosity (28%), trochanter (19%), sacrum (17%), and heel (9%). Tissue pressures can measure up to 300 mmHg in the ischial region during sitting and 150 mmHg over the sacrum while lying supine.[31] Muscle is more susceptible than skin to ischemic insult due to its relatively high metabolic demand. Wounds are staged as follows: stage 1, nonblanching erythema over intact skin; stage 2, partial-thickness injury (epidermis or dermis)—blister or crater; stage 3, full-thickness injury extending down to, but not including, fascia and without undermining of adjacent tissue; and stage 4, full-thickness skin injury with destruction or necrosis of muscle, bone, tendon, or joint capsule.

Management principles for pressure sores should include pressure relief (air mattresses and gel cushions for redistribution of pressure), systemic optimization (particularly nutritional support), and wound care.[32,33] Goals of surgical intervention are drainage of fluid collections, wide debridement of devitalized and scarred tissue, excision of pseudobursa, ostectomy of involved bones, hemostasis, and tension-free closure of dead space with well-vascularized tissue (muscle, musculocutaneous, or fasciocutaneous flaps). Stage 2 and 3 ulcers may be left to heal secondarily after debridement. Subatmospheric pressure wound therapy devices (vacuum-assisted closure) play a role in wound management by removing excess interstitial fluid, promoting capillary circulation, decreasing bacterial colonization, increasing vascularity and granulation tissue formation, and contributing to wound size reduction.[34]

BIOENGINEERED SKIN SUBSTITUTES

Recent work in surgical laboratories has provided surgeons with advancements in bioengineered skin substitutes. Different types of skin substitutes arise from xenograft, autologous, synthetic, and allogeneic sources.[35] An example of a xenograft substitute is the porcine dermis Permacol (Tissue Sciences Laboratory), whereas the cultured keratinocyte Epicel (Genzyme Tissue

Repair Corp) grafts represent an autologous substitute. Some examples of synthetic skin substitutes include Biobrane (UDL Laboratories) and Integra (Integra Life Science Corp). Biobrane is a silicon and nylon mesh layer bound with porcine collagen. Integra is a two-layered membrane composed of a silicon layer to maintain hydration and a porous bovine collagen and chondroitin sulfate layer that provides an environment for fibroblasts, macrophages, and capillaries to lay down a vascularized collagen matrix dermal layer. The more superficial silicon layer can be removed, and an autograft can subsequently be applied. AlloDerm (Life Cell) is an allogeneic substitute made of acellular dermal matrix derived from human skin tissue. It provides a matrix for revascularization, incorporating into host tissue, and provides additional strength. In contrast to Integra, it does not provide a dermal matrix to support a skin graft, and thus is not often used as a skin substitute. Several other skin substitutes are also available.

BACTERIAL INFECTIONS OF THE SKIN AND SUBCUTANEOUS TISSUE

In 1998, the Food and Drug Administration (FDA) categorized infections of the skin and skin structures for the purpose of clinical trials. A revision of this categorization in 2010 excluded specific diagnoses such as bite wounds, decubitus ulcers, diabetic foot ulcers, perirectal abscesses, and necrotizing fasciitis. The general division into "uncomplicated" and "complicated" skin infections can be applied to help guide management.[36]

Staphylococcus aureus is the most common isolate (~44%).[37] Other gram-positive bacteria such as *Enterococcus* species (9%), β-hemolytic streptococci (4%), and coagulase-negative staphylococci (3%) are less common. Gram-negative species, including *Pseudomonas aeruginosa* (11%), *Escherichia coli* (7.2%), and *Enterobacter* (5%), *Klebsiella* (4%), and *Serratia* (2%) species, among others, should be considered in complicated infections in patients with diabetes, neutropenia, and cirrhosis. 3▶

Uncomplicated Skin Infections

Disease processes included in this category are limited to the epidermis or its appendages and involve a surface area that is less than 75 cm^2. Impetigo, cellulitis, erysipelas, folliculitis, furuncles, and simple abscesses are included in this category. Folliculitis is an infection of a hair follicle that may progress to a furuncle or a carbuncle (abscess with multiple draining sinuses). Folliculitis and furuncles resolve with adequate hygiene and warm soaks.

Minor primary infections, or a secondarily infected lesion, should be treated with topical ointments such as 2% mupirocin to provide coverage for methicillin-resistant *Staphylococcus aureus* (MRSA). For an uncomplicated furuncle or carbuncle (simple abscess), incision and drainage are sufficient, and antibiotics are not warranted. For nonpurulent, uncomplicated cellulitis β-hemolytic streptococci coverage is recommended (β-lactam such as cephalexin), with MRSA coverage to be added if no response is seen within 48 to 72 hours or in the presence of chills, fevers, expanding erythema, or uncontrolled pain. Dual coverage can be achieved with clindamycin, trimethoprim-sulfamethoxazole, linezolid, or the combination of a tetracycline and a β-lactam. Purulent cellulitis that does not meet criteria for a complicated infection requires MRSA coverage. Need for empiric coverage for streptococci is unlikely. Clindamycin, trimethoprim-sulfamethoxazole, linezolid, and tetracyclines are options. The infections can be managed on an outpatient basis in the vast majority of cases.

Complicated Skin Infections

Deep-tissue infections (below the dermis), extensive cellulitis, necrotizing fasciitis, and myonecrosis are considered complicated skin infections. A thorough history and exam should be performed to elicit information (e.g., history of trauma, diabetes mellitus, cirrhosis, neutropenia, bites, IV or subcutaneous drug abuse) as well as physical findings such as crepitus (gas-forming organism), fluctuance (abscess), purpura (sepsis in streptococcal infections), bullae (streptococci, *Vibrio vulnificus*), lymphangitis, and signs of a systemic inflammatory response. Aspirated fluid from suspected infected collection should be cultured. Swabs and aspirates in cellulitis have a low yield (10%), whereas tissues cultures may have a higher rate of organism recovery (20%–30%). The utility of computed tomography (CT) or magnetic resonance imaging (MRI) in diagnosing a deep infection is limited and should not delay surgical evaluation and debridement.

Treatment of nonpurulent, complicated cellulitis can begin with a β-lactam, with MRSA coverage added if no response is observed. Empiric MRSA coverage is warranted in all other complicated skin and subcutaneous infections. Vancomycin is the mainstay of therapy, although it is inferior to β-lactams for methicillin-sensitive *Staphylococcus aureus* (MSSA) and has a relatively slow onset of efficacy in vitro. Linezolid, daptomycin, tigecycline, and telavancin are other FDA-approved alternatives for MRSA treatment. Clindamycin is also approved for *S. aureus*; however, resistance may develop, and diarrhea can occur in up to 20% (*Clostridium difficile* related).

Necrotizing infections can manifest with bullae, skin necrosis, pain beyond the margins of erythema, crepitus, gas on imaging, hypotension, or other signs of systemic inflammatory response syndrome (SIRS). These signs are late findings and are frequently absent. Due to substantial morbidity and mortality associated with these infections, the index for suspicion should be high, and the threshold for surgical exploration should be low, particularly in a weakened host, such as diabetic patients, the malnourished, alcoholics, neutropenic or functionally neutropenic patients, cirrhotic patients, renal failure patients, and individuals with peripheral vascular disease.

Common sites of origin are the genitalia, perineum (Fournier's gangrene), and abdominal wall. Classification is based on the anatomic site, the involved tissue planes (e.g., adipose, fascia, muscle), the offending organisms, and the velocity of the infection. Involvement of the deep fascia (necrotizing fasciitis—deep to the adipose tissue, overlying the muscle) results in a rapidly progressing infection with bacteria spreading along low-resistance tissue planes (Fig. 16-8). Necrotizing myositis primarily involves the muscle but can spread to surrounding tissue as well.

Three types of necrotizing infections can be distinguished based on the organisms involved. Type 1 is the most common, with a polymicrobial source including gram-positive cocci, gram-negative rods, and anaerobes (*Bacteroides* species, *Clostridium perfringens* and *septicum*), occurring in the perineum and trunk of the immunocompromised host. Occasionally an entry site can be identified (incisions, lines, or intestinal perforation), but in 20% to 50% of cases, a risk factor is not

A

B

Figure 16-8. **A.** Initial presentation of necrotizing soft issue infection in an obese, diabetic patient. **B.** Following operative debridement to muscle layer.

identified. Type 2 is a less common, monomicrobial infection with β-hemolytic streptococci or staphylococci (MRSA rising in frequency to 40%). It can be associated with toxic shock and occur in a previously healthy host, typically on the trunk or extremities, with a history of trauma commonly elicited. Type 3 is a rare but fulminant subset resulting from a *V. vulnificus* infection of traumatized skin in sea divers.

Laboratory findings are nonspecific. Leukocytosis, low calcium, and elevated lactate, creatine kinase, and creatinine may be seen. Advanced illness may bring on coagulopathy and acidemia. Blood cultures may or may not be positive. A retrospectively developed scoring system, called the Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score, which includes C-reactive protein (CRP), white blood cell (WBC) count, hemoglobin, plasma sodium, creatinine, and glucose, can be of diagnostic assistance with a high sensitivity and specificity. Tissue samples will demonstrate necrosis, WBC count infiltration, thrombosis, angiitis, and microorganisms.

Management of patients with suspected necrotizing infections should begin with proper patient triage to an ICU for initial evaluation, resuscitation, and treatment. If the diagnosis is clear, operative exploration and debridement should not be delayed. Broad-spectrum IV antibiotics should be started as soon as possible, with vancomycin (for MRSA) in addition to clindamycin or linezolid (to inhibit toxin synthesis) and gram-negative rod coverage (in the form of a third-generation cephalosporin or a quinolone). Surgery is the definitive treatment. Incisions should be made over the involved skin, parallel to neurovascular bundles, extending to and exposing the deep fascia to assess tissue viability. Necrotic tissue will appear dull, gray, and avascular and should be excised. Characteristic "murky dishwater"–like fluid may be encountered at the affected sites. Borders for debridement are where tissue planes cease to readily separate. Rapid quantitative tissue cultures (if available) and frozen section analysis may help guide the debridement. In Fournier's gangrene, one should aim to preserve the anal sphincter as well as the testicles (blood supply is independent of the overlying tissue; usually not infected). Revision surgery should be planned ("second look") within 24 to 48 hours. Adjuncts to surgery include topical antimicrobial creams, subatmospheric pressure wound dressings, and optimization of nutrition. Controversial topics are the role of hyperbaric oxygen (may inhibit infection by creating an oxidative burst, with anecdotally fewer debridements required and improved survival, but the availability is limited) and IVIG (may modulate the immune response to streptococcal superantigens). Wound closure is performed once bacteriologic, metabolic, and nutritional balances are obtained. Mortality ranges from 25% to 40% and is higher in truncal and perineal cases.

Actinomycosis

Actinomycosis should be considered in the differential diagnosis of any acute, subacute, or chronic cutaneous swelling of the head and neck. The cervicofacial form of *Actinomycetes* infection is the most common presentation, typically as an acute pyogenic infection in the submandibular or paramandibular area, but infection could be elsewhere in the mandibular and maxillary regions. The primary skin infection may spread to adjacent structures such as the scalp, orbit, ears, and other areas. Oral infection may spread to the hypopharynx, larynx, trachea, salivary glands, and sinuses. Actinomycosis can spread beyond boundaries of tissue planes and may also mimic chronic osteomyelitis. Treatment consists of a combination of penicillin therapy and surgical debridement. Debulking and debriding infected tissue arising from sinus tracts and abscess cavities inhibit actinomycosis growth in most cases.

VIRAL INFECTIONS WITH SURGICAL IMPLICATIONS

Human Papillomavirus Infections

Human papillomaviruses (HPV) are small DNA viruses of the papovavirus family. Over 100 different types have been described and can be classified as cutaneous or mucosal, depending on their tropism. The cutaneous types, HPV-1, -2 and -4, cause common warts, whereas HPV-5 and -8 are associated with epidermodysplasia verruciformis, an extremely rare autosomal recessive genetic disorder of the skin that entails a higher risk of malignant transformation. Mucosal types HPV-6 and -11 have a low malignant potential; lesions induced by HPV-16 and -18 have a higher malignancy potential. Regression of HPV lesions is frequently an immune-mediated, spontaneous event that is exemplified by the persistent and extensive manifestation of this virus in the immune-compromised patient.

Cutaneous manifestations of HPV can vary. Common warts (verruca vulgaris) are caused by HPV-1, -2 and -4, with a prevalence of up to 33% in schoolchildren and 3.5% in adults; prevalence is higher in the immunosuppressed patient.[38] The hands are the most commonly affected sites. Histologically, nonspecific findings of hyperkeratosis, papillomatosis, and acanthosis are found, as well as the hallmark koilocytes (clear halo around nucleus). Plantar warts occur on the soles of the feet, caused by HPV-1 and -4, commonly at pressure points, and are characterized by a keratotic plug surrounded by a hyperkeratotic ring, with black dots (thrombosed capillaries) on the surface. Plane warts occur on the face, dorsum of hands, and shins. They are caused by HPV-3 and -10 and tend to be multiple, flat-topped lesions with a smooth surface and light brown color. They regress spontaneously. Condyloma acuminatum manifests as multiple exophytic papillomatous lesions in the anogenital area. Sexually transmitted HPV-6 and -11 are responsible for 90% for genital wart cases, although other types have been implicated as well. Giant condyloma acuminatum of Buschke-Lowenstein is a large exophytic, cauliflower-like tumor and is now thought to be a variant of verrucous carcinoma. Epidermodysplasia verruciformis is a form of primary genetic immunodeficiency, rendering patients susceptible to infections with HPV-5 and -8. Recently, a similar clinical picture has been described in human immunodeficiency virus (HIV) and transplant patients.[39,40] Epidermodysplasia verruciformis presents clinically as multiple flat warts resembling seborrheic keratosis. There is a 30% to 50% risk of squamous cell carcinoma (SCC) transformation.

First-line therapy for single or multiple warts includes topical preparations of salicylic acid, silver nitrate, and glutaraldehyde. If these fail, cryotherapy may be considered. Treatment of recalcitrant lesions includes a variety of therapeutic options aimed at physically destroying the lesions by electrodessication, cryoablation, and pulsed dye laser therapy. Additional modalities such as H_2-antagonists and zinc sulfate may have a role in augmenting the immune response and reducing recurrence rates.

Cutaneous Manifestations of Human Immunodeficiency Virus

Skin involvement may result from HIV infection itself or from opportunistic disorders secondary to immune suppression.[41] Primary HIV may manifest as a generalized morbilliform rash. Kaposi's sarcoma may precede the onset of immunosuppression. During early stages of HIV infection, nonspecific skin changes occur, as well as common disorders with atypical clinical features, including recurrent varicella zoster, hyperkeratotic warts, and seborrheic dermatitis. Condylomata acuminata and verrucae appear early; however, their frequency and severity do not change with disease progression.

Cutaneous manifestations during later stages commonly include chronic herpes simplex virus and cytomegalovirus infections and, to a lesser extent, molluscum contagiosum, which is typically treatable with imiquimod.[41] Mycobacterial infections and mucocutaneous candidiasis also occur. Recurrent and persistent mucocutaneous candidiasis is common in patients with HIV infection. Bacterial infections such as impetigo and folliculitis may be more persistent and widespread.

Malignant lesions such as Kaposi's sarcoma occur in less than 5% of HIV-infected patients in the United States, although the worldwide prevalence in acquired immunodeficiency syndrome (AIDS) patients exceeds 30%. Other cutaneous cancers, particularly basal cell cancer, are becoming more common than Kaposi's sarcoma in patients adhering to highly active antiretroviral therapy (HAART). Approximately 6% of HIV patients will develop a cutaneous malignancy over a 7.5-year period.

With regard to general surgical considerations in HIV patients, contributing related morbidities such as malnutrition, decreased CD4 count, and presence of opportunistic infection may result in delayed and attenuated wound healing capacity.[42]

BENIGN TUMORS

Hemangioma

4▶ Hemangiomas result from benign proliferation of endothelial cells that surround blood-filled cavities. Their natural history most commonly is presentation soon after birth, rapid growth during the first year of life, and gradual involution in more than 90% of cases. Occasionally, their rapid growth directly interferes with the airway, gastrointestinal tract, or musculoskeletal function, and in these select cases, resection is indicated before tumor involution. These tumors may consume a large proportion of cardiac output, resulting in high-output cardiac failure, or may result in a consumptive coagulopathy. In both of these cases, resection is also indicated. Systemic prednisone and interferon-α can impede tumor progression. If these tumors persist into adolescence leaving a cosmetically undesirable telangiectasia, surgical resection may be considered. When surgical resection or debulking is considered, upfront selective embolization can help with planned resection. Finally, some vascular malformations, such as port wine stains of the trigeminal nerve distribution, may prompt the search for a systemic syndrome such as Sturge-Weber syndrome.

Nevi

Overgrowth of melanocytic nevus cells may be found in the epidermis (junctional), partially in the dermis (compound), or completely within the dermis (dermal). They are most commonly acquired, and most involute after migration into the dermis. Congenital nevi are found in less than 1% of neonates, and when characterized as giant congenital nevi, they have up to a 5% chance of developing into a malignant melanoma.[43,44] The treatment of choice is total excision, and at times, the large wound defect requires serial excisions and local tissue expanders.

Cystic Lesions

There are three types of cutaneous cysts: epidermal, dermoid, and trichilemmal.[45] All of these benign entities are comprised of epidermis that grows toward the center of the cyst, resulting in central accumulation of keratin to form a cyst. All clinically appear as a white, creamy substance-containing subcutaneous, thin-walled nodule. Epidermal cysts are the most common cutaneous cyst and histologically characterized by mature epidermis complete with granular layer. Trichilemmal cysts are the second most common lesion; they tend to form on the scalp of females, have a distinct odor after rupture, histologically lack a granular layer, and have an outer layer resembling the root sheath of a hair follicle. Dermoid cysts are congenital, found between the forehead to nose tip, and contain squamous epithelium, eccrine glands, and pilosebaceous units, occasionally developing bone, tooth, or nerve tissue. The eyebrow is the most frequent site of presentation. These cysts are commonly asymptomatic but can become inflamed and infected, thus necessitating incision and drainage. After the acute phase subsides, the entire cyst should be removed to prevent recurrence.

Keratosis

Actinic Keratosis. Actinic keratosis is a commonly detected abnormal proliferation of intraepidermal keratinocytes primarily found in fair-skinned individuals. The general behavior of this premalignant lesion is regression, progression, or persistence, and their calculated 10-year potential to transform into SCC is between 6.1% and 10%. In fact, 60% to 65% of SCCs are believed to originate from these precursor lesions.

Seborrheic Keratosis. These premalignant, light-brown lesions with velvet-like texture appear in the sun-exposed skin of older individuals. Histologically, the lesions are characterized by atypical-appearing keratinocytes, and their natural behavior typically is transformation into SCC that rarely metastasizes. Treatment options are excision, fluorouracil, cautery and destruction, and dermabrasion.[46,47] Interestingly, sudden eruptions of multiple seborrheic keratosis may be associated with other malignancies.

Soft Tissue Tumors

Acrochordons represent hyperplastic cells of the epidermis attached to a fibrous connective tissue stalk. They appear on the trunk, eyelids, and axilla as pedunculated masses and are resected usually for cosmesis.[48-50] Dermatofibromas are 1- to 2-cm, soft, solitary nodules consisting of predominantly nonencapsulated whorls of collagen laid down by fibroblasts located on the legs and trunks. These fibromas can be managed nonoperatively, but excision is the treatment of choice.[48-50] In rare cases, basal cell carcinomas may develop within the dermatofibromas. Lipomas are the most common subcutaneous neoplasm and have no malignant potential.[51] This soft and fleshy conglomeration of benign adipocytes can be appear almost anywhere on the body, but they are most often found on the trunk and commonly undergo rapid growth. Surgical excision can be considered for symptomatic or large lesions that compromise musculoskeletal function.

Neural Tumors

Benign cutaneous tumors that arise from the nerve sheath are collectively referred to as neural tumors. Dermal neurofibromas are benign neoplasms arising from nerve sheath that appear as fleshy and nontender sessile or pedunculated masses on the skin. They are most often associated with café-au-lait spots and Lisch nodules in neurofibromatosis type 1 (NF1) disease, also known as von Recklinghausen's disease.[49,50] Neurilemomas are discrete nodules consisting of Schwann cells of the peripheral nerve sheath, often causing pain along the distribution of the nerve, and are treated with simple resection. Granular cell tumors are derived from Schwann cells, infiltrate surrounding skeletal muscle, and are resected when symptomatic.[49,50,52]

MALIGNANT TUMORS

Basal Cell Carcinoma

Basal cell carcinoma (BCC) arises from the basal layer of nonkeratinocytes and represents the most common tumor diagnosed in the United States.[53,54] Annually it accounts for 25% of all diagnosed cancers and 75% of skin cancers.[55] The primary risk factor for disease development is sun exposure (UVB rays more than UVA rays) particularly during adolescence; however, other factors include immune suppression (i.e., organ transplant recipients, HIV), chemical exposure, and ionizing radiation exposure. BCC can also be a feature of inherited conditions such as xeroderma pigmentosa, unilateral basal cell nevus syndrome, and nevoid BCC syndrome.[55] The natural behavior of BCC is one of local invasion rather than distant metastasis. Untreated BCC can result in significant morbidity. Thirty percent of cases are found on the nose, and bleeding, ulceration, and itching are often part of the clinical presentation. 5▶

The most common form of BCC (60%) is the nodular variant, characterized by raised, pearly pink papules and occasionally a depressed tumor center with raised borders giving the classic "rodent ulcer" appearance. This variant tends to develop in sun-exposed areas of individuals over the age of 60. Superficial BCC accounts for 15% of BCC, is diagnosed at a mean age of 57 years, and typically appears on the trunk as a pink or erythematous plaque with a thin pearly border. The infiltrative form appears on the head and neck in the late 60s with similar clinical appearance to the nodular variant. An important variant to keep in mind is the pigmented variant of nodular BCC because this may be difficult to differentiate from nodular melanoma. Other important subtypes include the morpheaform variant, accounting for 3% of cases and characterized by indistinct borders with a yellow hue, and fibroepithelioma of Pinkus. Histologic subtypes of BCC include nodular and micronodular (50%), superficial (15%), and infiltrative.

Treatment options include Moh's microsurgery, excisional surgery, and cautery and destruction. Moh's microsurgery provides histologic confirmation of excision and maximal conservation of tissue, which is important to keep in mind in cosmetically sensitive areas such as facial lesions. It has also been shown to be cost-effective and associated with low recurrence rates (1%).[56,57] It is the treatment of choice for morpheaform, poorly delineated, recurrent, and infiltrative BCC, particularly facial lesions. Alternative treatment is excisional surgery with 4-mm margins with extension into subcutaneous tissue, which provides definitive treatment of nonmorpheaform lesions <2 cm in diameter. A common approach used by dermatologists is cautery and destruction, although it should be kept in mind that the results are operator and institution dependent as shown by a study showing inferior results for individuals having the procedure performed at academic training institutions as opposed to experienced private practitioners (local cure 81%

vs. 94%).[58] This option should only be considered in patients who are not candidates for the more extensive surgical options and for lesions not located in mid-face. Poor surgical candidates and patients without recurrent or morpheaform lesions may be treated with radiation therapy. Radiation also may be used in cases of questionable resection margins or microscopic positive margins after surgery. The practitioner must be aware of the potential consequences of radiation therapy, including poor cosmetic outcomes and future cancer risk.

Six to 12 weeks of imiquimod, an FDA-approved drug and immune modifier, is an option for small-diameter (<2 cm), superficial BCC of the neck, trunk, or extremities, with reported histologic clearance rates of 42% to 76%.[59-63] Topical fluorouracil is another FDA-approved treatment for superficial BCC, and one study of 31 tumors treated daily for 11 weeks showed a 90% histologic clearance rate. Lastly, topical photodynamic therapy has shown some benefit in treatment as well.

It is critical for each patient to have routine annual follow-up that includes full-body skin examinations. Sixty-six percent of recurrences develop within 3 years, and with a few exceptions occurring decades after initial treatment, the remaining recur within 5 years of initial treatment.[57,64] A second primary BCC may develop after treatment and, in 40% of cases, presents within the first 3 years after treatment.

Squamous Cell Carcinoma

SCC is the second most common skin cancer, accounting for approximately 100,000 cases each year and generally afflicting individuals of lighter skin color. The primary risk factor and driving force for the development of this common cancer is UV exposure; however, other risks include environmental factors such as chemical agents, physical agents (ionizing radiation), psoralen and UVA (PUVA), HPV-16 and -18 infections (immunosuppression), and smoking. Chronic nonhealing wounds, burn scars, and chronic dermatosis are other risk factors, and many darker skin individuals who develop SCC often have a history of one these risk factors (Fig. 16-9). Heritable conditions such as xeroderma pigmentosum, epidermolysis bullosa, and oculocutaneous albinism are predisposing risk factors.

SCC has in situ variants (including Bowen's disease and erythroplasia of Queyrat in situ lesions of the penis) and invasive variants. In situ disease presents as well-delineated pink papules or plaques, and invasive disease presents as slightly pink or skin-colored, raised plaques. Bleeding of the lesion with minimal trauma is not uncommon, and pain is rare. Most in situ cases grow slowly over time and do not progress to invasive disease, except for Bowen's disease and erythroplasia of Queyrat where the risk of malignant transformation is 3% to 5% and 10%, respectively.[65]

Figure 16-9. Squamous cell carcinoma forming in a chronic wound.

The natural history of invasive disease depends on location and inherent tumor characteristics. For example, lesions associated with chronic inflammation and located at mucocutaneous junctions may metastasize in 10% to 30% of cases, whereas lesions arising in sun-exposed areas without adverse risk factors are less likely to spread and have a better prognosis.[64] Clinical risk factors for recurrence include presentation with neurologic symptoms, immunosuppression, tumor with poorly defined borders, and tumor that arises at a site of prior radiation. Perineural involvement increases the incidence of local recurrence and lymph node metastasis and has a poorer survival. Other histologic features indicative of aggressive disease include poor differentiation, thickness greater than 4 mm, and adenoid, adenosquamous, and desmoplastic subtypes.[54]

Treatment modalities for SCC include cautery and ablation, cryotherapy, drug therapy including imiquimod, surgical excision, Moh's microsurgery, and radiation therapy. However, cautery and ablation carry the risk of leaving residual tumor behind; in a study of 291 patients with primary in situ lesions treated with cautery and ablation, all but two patients recurred.[66] This modality is not recommended in dense hair-bearing regions and for tumors extending into subcutaneous tissue.

Surgical excision is the treatment of choice, when feasible. For lesions less than 2 cm in diameter, wide excision with a 4-mm margin for low-grade lesions and a 6-mm margin for high-grade lesions is sufficient. Factors rendering tumors high risk are size >2 cm in diameter and involvement of subcutaneous tissue. Moh's microsurgery is indicated for lesions at sites where cosmesis or function preservation is critical, for poorly differentiated tumors, for invasive lesions, and for verrucous carcinomas. Lower recurrence rates are seen with this modality with primary lesions of the ear or lip, recurrent lesions, primaries with perineural invasion, lesions with diameters >2 cm, and poorly differentiated lesions.[64,67] It has also found use in nail bed lesions and in those arising in a background of osteomyelitis.

When patients are poor surgical candidates, radiation therapy can play a role in primary modality treatment. It may also act as an adjunct to surgical treatment in cases of lip carcinoma with 30% to 50% involvement, microscopic positive margins, perineural histology, underlying tissue invasion, and multiple recurrences.[55,68]

The role of lymph node dissection in the setting of SCC is evolving. Regional palpable nodes should be removed along with susceptible regional lymph node basins in patients with SCC in the setting of chronic wounds. Management of lymph node disease involves surgical resection and/or radiation therapy. Patients with parotid disease commonly benefit from a superficial or total parotidectomy (with facial nerve preservation) and adjuvant radiotherapy (60 Gy in 30 fractions). Isolated cervical lymph node involvement without adverse features is managed with follow-up surveillance for patients, which involves skin and regional lymph node examination every 1 to 3 months for the first year after treatment, every 2 to 4 months for the ensuing year, every 4 to 6 months for the next 3 years, and then every 6 to 12 months for the rest of life.[54]

Melanoma

Background. In 2013, an estimated 76,690 individuals were diagnosed with malignant melanoma, accounting for 9480 deaths.[53,69] The incidence of melanoma is rising faster than most other solid malignancies, and these numbers likely represent an underestimation given the many in situ and thin melanoma cases that are underreported. These tumors primarily arise from melanocytes at the epidermal-dermal junction but may also originate from mucosal surfaces of the oropharynx, nasopharynx, eyes, proximal esophagus, anorectum, and female genitalia. Their pathogenesis is not completely understood, but they are believed to originate from nests of melanocytes that have undergone dysplastic changes.

A well-known environmental risk factor is exposure to solar UV radiation. It was recently reported that greater than 10 tanning bed sessions by adolescents and young adults increased their relative risk of developing melanoma by twofold.[70] Nonenvironmental risk factors include a personal history of melanoma, which is associated with a 10-fold increase in risk. Individuals with dysplastic nevi have a 10% overall lifetime risk of melanoma, with tumors arising from pre-existing nevi or de novo. Dysplastic nevus syndrome (B-K mole syndrome) has an autosomal dominant transmission with high penetrance and is associated with a nearly 100% lifetime risk in being diagnosed with cutaneous melanoma. Congenital nevi increase risk for melanoma proportionally with size; giant congenital nevi are associated with a 5% to 8% lifetime risk. Five to ten percent of cutaneous melanomas occur in patients with a family history of melanoma, and these individuals have an earlier age of disease onset, commonly express dysplastic nevi, and more commonly have more than one primary lesion. Melanoma development is strongly associated with the p16/CDK4,6/Rb and p14ARF/HMD2/p53 tumor suppressor pathways and the RAF-MEK-ERK and PI3K-Akt oncogenic pathways.[71]

Pathogenesis and Clinical Presentation. Melanoma growth most commonly starts as a localized, radial growth phase followed by a vertical growth phase that determines metastatic risk. The subtypes of melanoma include lentigo maligna, superficial spreading, acral lentiginous, mucosal, nodular, polypoid, desmoplastic, amelanotic, and soft tissue. The most common subtype is superficial spreading, accounting for 70% of cases (Fig. 16-10). These melanomas are found anywhere on the body

Figure 16-10. Primary cutaneous melanoma seen in the scalp of a 61-year-old male.

Figure 16-11. Nodular melanoma seen in the leg of a 55-year-old male.

with the exception of the hands and feet. Nodular melanoma accounts for 15% to 30% of melanomas, and this variant is unique in that it begins with a vertical growth phase that partly accounts for its worse prognosis (Fig. 16-11). Lentigo maligna is typically found in older individuals and primarily located in the head and neck region. The acral lentiginous variant accounts for 29% to 72% of melanomas in dark-skinned individuals, is occasionally seen in Caucasians, and is found on palmar, plantar, and subungual surfaces.

Melanoma most commonly manifests as cutaneous disease, and clinical characteristics include an **A**symmetric outline, changing irregular **B**orders, **C**olor variations, **D**iameter greater than 6 mm, and **E**levation (ABCDE). Other key clinical characteristics include a pigmented lesion that has enlarged, ulcerated, or bled. Amelanotic lesions appear as raised pink, purple, or normal-colored skin papules and are often diagnosed late.

Diagnosis and Staging. Workup should begin with a history and physical exam. The entire skin should be checked for synchronous primaries, satellite lesions, and in-transit metastases, and all nodal basins should be examined for lymphadenopathy. Suspicious lesions should undergo excisional biopsy with 1- to 2-mm margins; however, tumors that are large or in a cosmetically or anatomically challenging area can be approached by incisional biopsy, including punch biopsy. Tissue specimen should include full thickness of the lesion and a small section of normal adjacent skin to aid the pathologist in diagnosis. Suspicious lymph nodes should undergo fine-needle aspiration (FNA).

Melanoma is characterized according to the American Joint Committee on Cancer (AJCC) as localized disease (stage I and II), regional disease (stage III), or distant metastatic disease (stage IV). Overall tumor thickness, ulceration, and mitotic rate are the most important prognostic indicators of survival.[72,73] If a sentinel node contains metastatic melanoma, the number of positive nodes; thickness, mitotic rate, and ulceration of the primary tumor; and patient age determine prognosis. With clinically positive nodes, the number of positive nodes, primary tumor ulceration, and patient age determine prognosis.[74] The site of metastasis is strongly associated with prognosis for stage IV disease, and elevated lactate dehydrogenase (LDH) is associated with a worse prognosis.[75]

7▶

There is no supporting evidence for chest x-ray or CT in the staging of patients unless there is positive regional lymph node disease (and even in this case, the indications are not so clear).[41] However, high-risk melanoma (i.e., T4b), especially of the lower extremities, may warrant further imaging to stage with modalities such as a positron emission tomography (PET)-CT or CT of the pelvis.[41] In addition, patients with clinically palpable regional lymph nodes are at high risk for distant metastases and should receive additional imaging that includes CT of the chest, abdomen, and pelvis; whole-body PET-CT; or brain MRI.

The sentinel lymph node biopsy (SLNB) technique for melanoma was introduced in 1992 and has become a cornerstone in the management of melanoma, although its role in management continues to be refined. SLNB is a standard staging procedure to evaluate the regional nodes for patients with clinically node-negative malignant melanoma. This technique identifies the first draining lymph node from the primary and has shown excellent accuracy and significantly less morbidity compared to complete resection of nodal basins. The SLNB technique involves preoperative lymphoscintigraphy with intradermal injections of technetium-sulfur colloid to delineate lymphatic drainage and intraoperative intradermal injection of 1 mL of isosulfan or methylene blue dye near the tumor or biopsy site (Figs. 16-12 and 16-13). The radioactive tracer-dye combination allows the sentinel node to be identified in 98% of cases. An incision over the lymph node basin of interest allows nodes to be excised and studied with hematoxylin and eosin and immunohistochemistry (S100, HMB45, and MART-1/Melan-A) staining (Fig. 16-14). Risks of this technique are uncommon but include skin necrosis near the site of injection, anaphylactic shock, lymphedema, surgical site infections, seromas, and hematomas.

Surgical Management of the Primary Tumor and Lymph Nodes. The appropriate excision margin is based on primary tumor depth. Although there are no randomized trials studying margins for melanoma in situ, most surgical oncologists believe

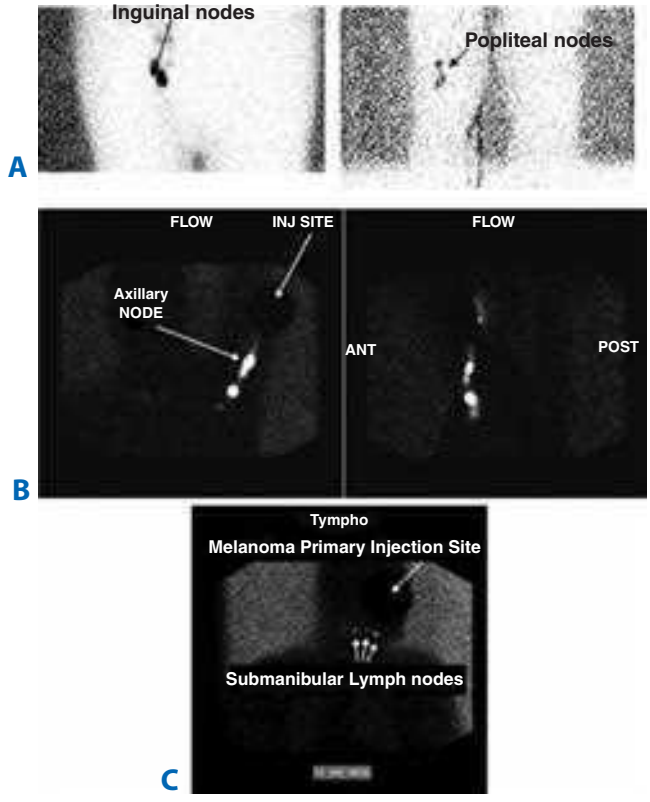

Figure 16-12. After injection of radioactive technetium-99–labeled sulfur colloid tracer at the primary cutaneous melanoma site, sentinel lymph node basins are identified. **A.** Lymphoscintigraphy of 67-year-old male with a malignant melanoma of the right heel; sentinel lymph nodes in both the right popliteal fossa and inguinal region. **B.** Lymphoscintigraphy of 52-year-old male with a malignant melanoma of the posterior right upper arm; sentinel lymph node in the right axillary region. **C.** Lymphoscintigraphy of 69-year-old male with a facial melanoma; sentinel lymph nodes in the submandibular region. ANT = anterior; INJ = injection; POST = posterior.

Figure 16-14. Operation of sentinel lymph node biopsy for cutaneous melanoma. After preoperative injection of radioactive technetium-99–labeled sulfur colloid tracer and intraoperative injection of Lymphazurin blue dye around the primary melanoma excision site, the nodal basin of interest is identified. An incision is made directly overlying the lymph node basin in the posterior axillary space. The sentinel lymph nodes are identified and excised.

that margins of 0.5 to 1.0 cm are sufficient. We believe that 1.0-cm margins should be obtained in anatomically feasible areas given the possibility of an incidental finding of a small invasive component in permanent sections. The World Health Organization (WHO) trial by Veronesi and colleagues provided the first prospective randomized controlled trial guiding appropriate margin management.[76] In this trial, 612 patients with melanoma <2 mm in thickness were randomized to 1- or 3-cm margins. The results demonstrated no difference in overall survival or recurrence-free survival between groups. A trial from the Swedish Melanoma Study Group supported the WHO trial. The Swedish study examined patients with <2-mm thick melanoma who were randomized to 2- or 5-cm margins.[77] There was no difference in recurrence-free survival (73% vs. 74%; $P = .88$) or overall survival (75% vs. 74%; $P = .77$) between the groups. The Intergroup Melanoma Trial randomized 468 patients with intermediate-thickness melanoma (1–4 mm) to 2- or 4-cm margins of excision.[78,79] They did not find a significant difference in 10-year overall survival (70% vs. 77%; $P = .074$) or local recurrence (2.1% vs. 2.6%) between the two cohorts. A British trial suggested that there is a limit to how narrow margins can be for melanomas >2 mm thick in showing that 1-cm margins provide worse outcomes compared to 3-cm margins.

Tumors <1 mm thick require 1-cm margins, tumors 1 to 2 mm thick require 1- to 2-cm margins, tumors 2 to 4 mm thick require 2-cm margins, and tumors >4 mm thick require 2-cm margins, although there are no randomized data to support this last point. Technically challenging locations should be treated in a similar fashion. For facial and scalp lesions, advancement flaps usually suffice for closure, as do wedge resections for lesions of the ear helix. When tumors are situated near critical structures (e.g., eye, lip), the best should be done to remove the primary tumor with adequate margins.

SLNBs are recommended for melanomas 1 to 4 mm thick according to the National Comprehensive Cancer Network (NCCN) guideline recommendations.[41] The incidence of regional lymph node metastasis in <1-mm thick melanomas is 5% or less. According to the NCCN guidelines, SLNB may be considered for thin melanoma with adverse features (i.e., >0.75 mm, >1 mitosis per mm, ulcerated), and literature that supports this approach states that SLNB provides prognostic information and is therapeutic for low-volume disease.[41,80] For tumors that are >4 mm, the incidence of regional lymph node positivity is 35% to 40% and SLNB may provide prognostic information for these thick melanomas.[81-83]

The role for SLNB is supported by the Multicenter Selective Lymphadenectomy Trial (MSLT)-1, which looked at patients with melanoma 1.5 to 4 mm thick and randomized them to SLNB (and completion lymphadenectomy if positive) vs. no SLNB (and delayed complete lymphadenectomy for recurrent lymph node disease).[84] SLNBs provided prognostic information but did not affect survival. However, when patients who were lymph node positive only were compared, 5-year overall survival was better if the lymphadenectomy was done at the time of a positive sentinel node vs. when it was delayed until the patients presented with clinical findings. Completion lymphadenectomy is commonly performed for sentinel nodes with metastatic disease, but it has been shown that most of these nodal basins do not have additional disease. Thus, many surgeons do not perform routine completion lymphadenectomy for positive nodes, and data from the MSLT-2 may provide guidance.

Several studies evaluated the indications and benefit for extended lymphadenectomy. Three retrospective studies showed a 12% to 24% improved 5-year overall survival in patients with micrometastasis in elective regional lymphadenectomy specimens compared with patients undergoing therapeutic lymphadenectomy for clinically palpable disease.[85-87] The last large prospective randomized controlled trial showed a trend toward improved survival in patients with intermediate-thickness (1.5–4 mm) melanomas who underwent immediate elective lymphadenectomy as opposed to nodal observation (77% vs. 73%; $P = .12$).[88] For patients with clinically evident local regional lymphadenopathy, FNA biopsies can confirm metastatic disease. If metastatic workup including PET-CT excludes

distant disease, resection of the primary melanoma lesion and a completion lymphadenectomy should be performed.

Individuals with face, anterior scalp, and ear primaries who have a positive SLNB should undergo a superficial parotidectomy in addition to a modified radical neck dissection. Patients with positive sentinel nodes in the inguino-femoral nodes should undergo an inguino-femoral lymphadenectomy that includes removal of Cloquet's node. If Cloquet's node is positive or the patient has three or more nodes that contain melanoma metastases, this is an indication for an ilio-obdurator lymphadenectomy.[41]

Surgery for Regional and Distant Metastasis. Nonmetastatic, in-transit disease should undergo excision to clear margins when feasible. However, disease not amenable to complete excision derives benefit from isolated limb perfusion (ILP) and isolated limb infusion (ILI) (Fig. 16-15). These two modalities are used to treat regional disease, and their purpose is to administer high doses of chemotherapy, commonly melphalan, to an affected limb while avoiding systemic drug toxicity. ILI was shown to provide a 31% response rate in one study, while hyperthermic ILP provided a 63% complete response rate in an independent study.[89-92]

The most common sites of distant metastasis are the lung and liver followed by the brain, gastrointestinal tract, distant skin, and subcutaneous tissue. A limited subset of patients with small-volume, limited distant metastases to the brain, gastrointestinal tract, or distant skin will be cured with resection or gamma knife radiation. Liver metastases are better dealt without surgical resection unless they arise from an ocular primary. Adjuvant therapy after resection of metastatic lesions is not standard of care; however, there are ongoing clinical trials addressing whether drugs and vaccines will be beneficial in this setting.[55] Surgery may provide palliation for patients with gastrointestinal obstruction, gastrointestinal hemorrhage, and nongastrointestinal hemorrhage. Radiotherapy for symptomatic bony or brain metastases provides palliation in diffuse disease.

Adjuvant and Palliative Therapies. Eastern Cooperative Oncology Group (ECOG) Trials 1684, 1690, and 1694 were prospective randomized controlled trials that demonstrated disease-free survival advantages in patients with melanoma thicker than 4 mm with or without lymph node involvement if they received adjuvant treatment with high-dose interferon (IFN).[93-95] A European Organization for Research and Treatment of Cancer (EORTC) trial also showed recurrence-free survival benefit with pegylated IFN.[96] It is important to note that IFN therapy is not well tolerated, and the pooled analysis of these trials did not show an improvement in overall survival benefit.

Most patients with metastatic melanoma will not be surgical candidates. Although the medical options for metastatic melanoma have historically been poor, several recent studies have shown promise in drug therapy for metastatic melanoma. BRAF inhibitors (sorafenib), anti-PD1 antibodies, CTLA antibodies (ipilimumab), and high-dose interleukin-2 (IL-2) with and without vaccines have been shown in randomized studies to provide survival benefit in metastatic disease.[97-101] Despite the excitement of recent drugs, surgery will likely play an adjunct role in treating individuals who develop resistance to these drugs over time.

Special Circumstances. Special circumstances of note are melanoma in pregnant women, melanoma of unknown primaries, and noncutaneous melanomas (i.e., ocular). The prognosis of pregnant patients is similar to women who are not pregnant. Extrapolation of studies examining the SLNB technique in pregnant women with breast cancer suggests lymphoscintigraphy may be done safely during pregnancy without risk to the fetus. (Blue dye is contraindicated.) General anesthesia should be avoided during the first trimester, and local anesthetics should be used at this time. It has been suggested by some that after excising the primary tumor during pregnancy, the SLNB may be performed after delivery.

Unknown primary melanoma most commonly presents in lymph nodes (2% of cases and <5% of metastatic presentation). A thorough search for the primary lesion should be sought, including eliciting a history about prior skin lesions, skin procedures (e.g., curettage and electrodesiccation, excision, laser), and review of any prior "benign" pathology. The surgeon should be aware that melanoma is known to spontaneously regress because of an immune response.

Ocular melanoma is the most common noncutaneous disease site, and treatment includes photocoagulation, partial resection, radiation, or enucleation.[102-104] Ocular melanomas exclusively metastasize to the liver and not regional lymph nodes, and some patients benefit from liver resection. Melanoma of the mucous membranes most commonly presents in

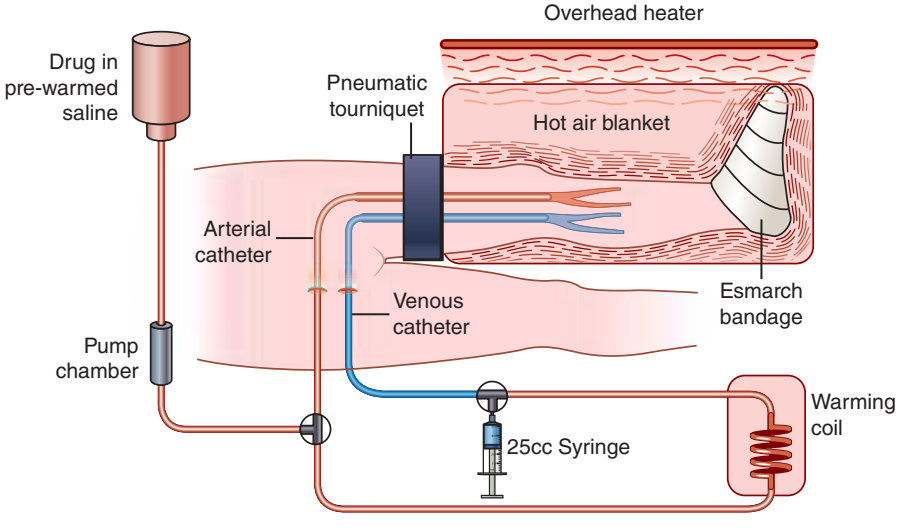

Figure 16-15. Isolated limb infusion. Schematic of isolated limb infusion of lower extremity. *(From Testori A, Verhoef C, Kroon HM, et al. Treatment of melanoma metastasis in a limb by isolated limb perfusion and isolated limb infusion.* J Surg Oncol. *2011;104:397-404. Copyright 2011 John Wiley and Sons. Reprinted with permission.)*

the oral cavity, oropharynx, nasopharynx, paranasal sinus, anus, rectum, and female genitalia. Patients with this presentation have a worse prognosis (10% 5-year survival) than individuals with cutaneous melanomas. Management should be excision to negative margins, and radical resections (i.e., abdominoperineal resection) should be avoided because the role of surgery is locoregional control, not cure. Generally speaking, lymph node dissection should be avoided because the benefit is unclear.

Merkel Cell Carcinoma

This is a rare and aggressive neuroendocrine tumor of the skin most commonly found in white men and diagnosed at a mean age of 70 years (Fig. 16-16). Risk factors include UV radiation, PUVA, and immunosuppression. Approximately one in three cases present on the face, with the remainder occurring on sun-exposed skin. A rapidly growing, flesh-colored papule or plaque characterizes the disease. Regional lymph nodes are involved in 30% of patients, and 50% will develop systemic disease (skin, lymph nodes, liver, lung, bone, brain).[105,106] There are no standardized diagnostic imaging studies for staging, but CT of the chest, abdomen, and pelvis and octreotide scans may provide useful information when clinically indicated.

After examining the entire skin for other lesions, treatment should begin by evaluating the nodal basins. Patients without clinical nodal disease should undergo an SLNB preceding a wide local excision because studies suggest a benefit.[107] In patients with sentinel lymph nodes with metastatic disease, completion lymphadenectomy and/or radiation therapy may follow, and in patients with node-negative disease, observation or radiation therapy should be considered.[107] SLNB is important for staging and treatment, and the literature suggests that it predicts recurrence and relapse-free survival. Elective lymph node dissection may decrease regional nodal recurrence and in-transit metastases. Patients with clinically positive nodes should have an FNA to confirm disease. If positive, a metastatic staging workup should follow, and if negative, treatment of the primary and nodal basin as managed for sentinel lymph node–positive disease should be considered. A negative FNA and open biopsy-negative disease should be managed by treatment of the primary disease alone. Patients with metastatic disease should be managed according to consensus from a multidisciplinary tumor board.

Figure 16-16. Merkel cell carcinoma seen just above the left knee in a 44-year-old female.

Important surgical principles for excision of the primary lesion are to excise with wide margins down to fascia and complete circumferential and peripheral deep-margin assessment. Recommended management for margins is 1- to 3-cm margins, and given the rarity of the tumor, there are no randomized trials further defining these margins. Moh's microsurgery may play a role to ensure negative margins. Chemotherapy is commonly used, but there are no data to support a specific regimen or that demonstrate a definitive survival benefit.

Recurrence is common, and one study of 95 patients showed a 47% recurrence, with 80% of recurrences occurring within 2 years and 96% occurring within 5 years.[108,109] Regional lymph node disease is common, and 70% of patients will have nodal spread within 2 years of disease presentation. Five-year overall survival of head and neck disease in surgically treated patients is between 40% and 68%.

Kaposi's Sarcoma

Kaposi's sarcoma is characterized by the proliferation and inflammation of endothelial-derived spindle cell lesions. There are five major forms of this angioproliferative disorder: classic (Mediterranean), African endemic, HIV-negative men having sex with men (MSM)–associated, AIDS-associated, and immunosuppression-associated; they are all driven by the human herpesvirus (HHV-8).[68] Kaposi's sarcoma is diagnosed after the fifth decade of life and predominantly found on the skin but can occur anywhere in the body. In North America, the Kaposi's sarcoma herpes virus is transmitted via sexual and nonsexual routes and predominantly affects individuals with compromised immune systems such as those with HIV and transplant recipients on immune-suppressing medications. Clinically, Kaposi's sarcoma appears as multifocal, rubbery blue nodules. Treatment of AIDS-associated Kaposi's sarcoma is with antiviral therapy, and many patients experience a dramatic treatment response.[110,111] Those individuals who do not respond and have limited mucocutaneous disease may benefit from cryotherapy, photodynamic therapy, radiation therapy, intralesional injections, and topical therapy. Surgical biopsy is important for disease diagnosis, but given the high local recurrence and the fact that Kaposi's sarcoma represents more of a systemic rather than local disease, the benefit of surgery is limited and generally should not be pursued except for palliation.

Dermatofibrosarcoma Protuberans

This rare, low-grade sarcoma of fibroblast origin commonly afflicts individuals during their third decade of life. It has low distant metastatic potential but behaves aggressively locally with finger-like extensions. Tumor depth is the most important prognostic variable. Presentation is characteristically a slow-growing, asymptomatic, violaceous plaque involving the trunk,

head, neck, or extremities. Treatment is wide local excision with 3-cm margins down to deep underlying fascia or Moh's microsurgery in cosmetically sensitive areas where maximum tissue preservation will benefit.[112] No nodal dissection is needed, and both approaches provide similar local control.[113] Some clinicians have used radiation therapy and biologic agents (imatinib) with some success in patients with advanced disease. Local recurrence occurs in 50% to 75% of cases, usually within 3 years of treatment, and thus, clinical follow-up is important. Recurrent tumors should be resected whenever possible.

Malignant Fibrous Histiocytoma (Undifferentiated Pleomorphic Sarcoma and Myxofibrosarcoma)

This uncommon, cutaneous, spindle-cell, soft tissue sarcoma occurs in the extremities, head, and neck of elderly patients. They present as solitary, soft to firm, skin-colored subcutaneous nodules. Complete surgical resection is the treatment of choice, and adjuvant radiation therapy provides local control; patients with positive margins benefit most from this combination. Nevertheless, patients undergoing complete gross resection will experience recurrence in 30% to 35% of cases.[71] Up to 50% of patients may present with distant metastasis, and this is a contraindication to surgical resection.

Angiosarcoma

Angiosarcoma is an uncommon, aggressive cancer that arises from vascular endothelial cells and occurs in four variants, all of which have a poor prognosis.[114] The head and neck variant presents in individuals older than 40 years as an ill-defined red patch on the face or scalp, often with satellite lesions and distant metastasis, and has a median survival of 18 to 28 months. Lymphedema-associated angiosarcoma (Stewart-Treves) develops on an extremity ipsilateral to an axillary lymphadenectomy. It appears on the upper, medial arm as a violaceous plaque in an individual with nonpitting edema and has a poor survival. Radiation-induced angiosarcoma occurs 4 to 25 years after radiation therapy for benign (acne) and malignant (i.e., breast cancer) conditions. Finally, the epithelioid variant of angiosarcoma involves the lower extremities and also has a poor prognosis. Surgical excision with wide margins is the treatment of choice for localized disease, but the rate of recurrence is high. Adjuvant radiation therapy can be considered in a multidisciplinary fashion. Cases of extremity disease can be considered for amputation. For widely metastatic disease, chemotherapy and radiation may provide palliation, but these modalities do not prolong overall survival.[55]

Extramammary Paget's Disease

This rare adenocarcinoma of apocrine glands arises in perianal and axillary regions and in genitalia of men and women.[115] Clinical presentation is that of erythematous or nonpigmented plaques with an eczema-like appearance that often persist after failed treatment from other therapies. An important characteristic and one that the surgeon must be acutely aware of is the high incidence of concomitant other malignancies with this cutaneous disease. Forty percent of cases are associated with primary gastrointestinal and genitourinary malignancies, and a diligent search should be made after a diagnosis of extramammary Paget's disease is made. Treatment is surgical resection with negative microscopic margins, and adjuvant radiation may provide additional locoregional control.

CONCLUSION

The skin is the largest organ in the human body and is composed of three organized layers that are the source of numerous pathologies. Recognition and management of cutaneous and subcutaneous diseases require an astute clinician to optimize clinical outcomes. Improvements in drugs therapies and healthcare practices have helped recovery from skin injuries. Skin and subcutaneous diseases are often managed medically, although surgery frequently complements treatment. Benign tumors are surgical diseases, while malignant tumors are primarily treated surgically, and additional modalities including chemotherapy and radiation therapy are sometimes required. The management of melanoma is at an exciting phase, requiring the coordinated multidisciplinary care of medical oncologists, surgical oncologists, radiation oncologists, dermatopathologists, and plastic and reconstructive surgeons. The advent of new drug therapies will redefine the role of surgery in this disease in the coming years.

chapter 17

The Breast

Kelly K. Hunt, John F.R. Robertson, and Kirby I. Bland

A BRIEF HISTORY OF BREAST CANCER THERAPY

Breast cancer has captured the attention of surgeons throughout the ages. The Smith Surgical Papyrus (3000–2500 B.C.) is the earliest known document to refer to breast cancer. The cancer was in a man, but the description encompassed most of the common clinical features. In reference to this cancer, the author concluded, "There is no treatment."[1] There were few other historical references to breast cancer until the first century. In *De Medicina,* Celsus commented on the value of operations for early breast cancer: "None of these may be removed but the cacoethes (early cancer), the rest are irritated by every method of cure. The more violent the operations are, the more angry they grow."[2] In the second century, Galen inscribed his classical clinical observation: "We have often seen in the breast a tumor exactly resembling the animal the crab. Just as the crab has legs on both sides of his body, so in this disease the veins extending out from the unnatural growth take the shape of a crab's legs. We have often cured this disease in its early stages, but after it has reached a large size, no one has cured it. In all operations we attempt to excise the tumor in a circle where it borders on the healthy tissue."[3]

The galenic system of medicine ascribed cancers to an excess of black bile and concluded that excision of a local bodily outbreak could not cure the systemic imbalance. Theories espoused by Galen dominated medicine until the Renaissance. In 1652 Tulp introduced the idea that cancer was contagious when he reported an elderly woman and her housemaid who both developed breast cancer (N. Tulp, Observationes medicae 1652).

Key Points

1. The breast receives its principal blood supply from perforating branches of the internal mammary artery, lateral branches of the posterior intercostal arteries, and branches from the axillary artery, including the highest thoracic, lateral thoracic, and pectoral branches of the thoracoacromial artery.
2. The axillary lymph nodes usually receive >75% of the lymph drainage from the breast, and the rest flows through the lymph vessels that accompany the perforating branches of the internal mammary artery and enters the parasternal (internal mammary) group of lymph nodes.
3. Breast development and function are initiated by a variety of hormonal stimuli, with the major trophic effects being modulated by estrogen, progesterone, and prolactin.
4. Benign breast disorders and diseases are related to the normal processes of reproductive life and to involution, and there is a spectrum of breast conditions that ranges from normal to disorder to disease (aberrations of normal development and involution classification).
5. To calculate breast cancer risk using the Gail model, a woman's risk factors are translated into an overall risk score by multiplying her relative risks from several categories. This risk score is then compared with an adjusted population risk of breast cancer to determine the woman's individual risk. This model is not appropriate for use in women with a known *BRCA1* or *BRCA2* mutation or women with lobular or ductal carcinoma in situ.
6. Routine use of screening mammography in women ≥50 years of age reduces mortality from breast cancer by 25%. MRI screening is recommended in women with BRCA mutations and may be considered in women with a greater than 20% to 25% lifetime risk of developing breast cancer.
7. Core-needle biopsy is the preferred method for diagnosis of palpable or nonpalpable breast abnormalities.
8. When a diagnosis of breast cancer is made, the surgeon should determine the clinical stage, histologic characteristics, and appropriate biomarker levels before initiating local therapy.
9. Sentinel node dissection is the preferred method for staging of the regional lymph nodes in women with clinically node-negative invasive breast cancer. Axillary dissection may be avoided in women with 1 to 2 positive sentinel nodes who are treated with breast conserving surgery, whole breast radiation and systemic therapy.
10. Local-regional and systemic therapy decisions for an individual patient with breast cancer are best made using a multidisciplinary treatment approach. The sequencing of therapies is dependent on patient and tumor related factors including breast cancer subtype.

This single incidence was accepted as conclusive evidence and started an idea which persisted into the 20th century among some lay people. The majority of respected surgeons considered operative intervention to be a futile and ill-advised endeavor. The Renaissance and the wars of the 16th and 17th centuries brought developments in surgery, particularly in anatomical understanding. However there were no new theories espoused in relation to cancer. Beginning with Morgagni, surgical resections were more frequently undertaken, including some early attempts at mastectomy and axillary dissection. The 17th century saw the start of the Age of Enlightenment which lasted until the 19th century. In terms of medicine, this resulted in the abandonment of Galen's humoral pathology which was repudiated by Le Dran and the subsequent rise in cellular pathology as espoused by Virchow. Le Dran stated that breast cancer was a local disease that spread by way of lymph vessels to axillary lymph nodes. When operating on a woman with breast cancer, he routinely removed any enlarged axillary lymph nodes.[4]

In the 19th century, Moore, of the Middlesex Hospital, London, emphasized complete resection of the breast for cancer and stated that palpable axillary lymph nodes also should be removed.[5] In a presentation before the British Medical Association in 1877, Banks supported Moore's concepts and advocated the resection of axillary lymph nodes even when palpable lymphadenopathy was not evident, recognizing that occult involvement of axillary lymph nodes was frequently present. In 1894, Halsted and Meyer reported their operations for treatment of breast cancer.[6] By demonstrating superior local-regional control rates after radical resection, these surgeons established radical mastectomy as state-of-the-art treatment for that era. Halsted and Meyer advocated complete dissection of axillary lymph node levels I to III. Both routinely resected the long thoracic nerve and the thoracodorsal neurovascular bundle with the axillary contents. In 1943, Haagensen and Stout described the grave signs of breast cancer, which included: (a) edema of the skin of the breast, (b) skin ulceration, (c) chest wall fixation, (d) an axillary lymph node >2.5 cm in diameter, and (e) fixed axillary lymph nodes. Women with two or more signs had a 42% local recurrence rate and only a 2% five-year disease-free survival rate.[7] Based on these findings, they declared that women with grave signs were beyond cure by radical surgery. In 1948, Patey and Dyson of the Middlesex Hospital, London, advocated a modified radical mastectomy for the management of advanced operable breast cancer, explaining, "Until an effective general agent for treatment of carcinoma of the breast is developed, a high proportion of these cases are doomed to die."[8] Their technique included removal of the breast and axillary lymph nodes with preservation of the pectoralis major muscle. They showed that removal of the pectoralis minor muscle allowed access to and clearance of axillary lymph node levels I to III.

During the 1970s, there was a transition from the Halsted radical mastectomy to the modified radical mastectomy as the surgical procedure most frequently used by American surgeons to treat breast cancer. This transition acknowledged that: (a) fewer patients were presenting with advanced local disease with or without the grave signs described by Haagensen, (b) extirpation of the pectoralis major muscle was not essential for local-regional control in stage I and II breast cancer, and (c) neither the modified radical mastectomy nor the Halsted radical mastectomy consistently achieved local-regional control of stage III

breast cancer. Radiation therapy was incorporated into the management of advanced breast cancer and demonstrated improvements in local-regional control. The National Surgical Adjuvant Breast and Bowel Project (NSABP) conducted a randomized trial in the early 1970s to determine the impact of local and regional treatments on survival in operable breast cancer. In the B-04 trial, 1665 women were enrolled and stratified by clinical assessment of the axillary lymph nodes. The clinically node-negative women were randomized into three treatment groups: (a) Halsted radical mastectomy; (b) total mastectomy plus radiation therapy; and (c) total mastectomy alone. Clinically node-positive women were randomized to Halsted radical mastectomy or total mastectomy plus radiation therapy. This trial accrued patients between 1971 and 1974, an era that predated widespread availability of effective systemic therapy for breast cancer and therefore reflect survival associated with local-regional therapy alone. There were no differences in survival between the three groups of node-negative women or between the two groups of node-positive women. These overall survival equivalence patterns have persisted at 25 years of follow-up.[9]

The next major advance in the surgical management of breast cancer was the development of breast conserving surgery. Breast conserving surgery and radium treatment was first reported by Geoffrey Keynes of St Bartholomew's Hospital, London in the British Medical Journal in 1937.[10] Several decades later, the NSABP launched the B-06 trial, a phase III study that randomized 1851 patients to total mastectomy, lumpectomy alone, or lumpectomy with breast irradiation. The results showed no difference in disease-free, distant disease-free, and overall survival among the three groups; however, the omission of radiation therapy resulted in significantly higher rates of ipsilateral breast tumor recurrence in those who received lumpectomy alone.[11] The B-06 trial excluded patients who had palpable axillary lymph nodes and those patients randomized to breast conserving surgery had frozen sections performed and if on frozen section the margins were involved the surgeon proceeded to perform a mastectomy but the patient was included in the analysis as though they had a breast conserving operation. Furthermore, in B-06 local in-breast recurrences were regarded as "non-events" in terms of disease-free survival. Both NSABP B-04 and B-06 trials were taken to refute the Halstedian concept that cancer spread throughout a region of the breast to lymphatics and then on to distant sites. Bernard Fisher proposed the "alternative hypothesis" that breast cancer was a systemic disease at diagnosis and that tumor cells had access to both the blood and lymphatic systems and that regional lymph nodes were a marker of systemic disease and not a barrier to the dissemination of cancer cells. He proposed that host factors were important in the development of metastasis and that variations in the local-regional approach to breast cancer were not likely to substantially impact survival. This idea was dominant for a number of years but has been challenged by the Early Breast Cancer Trialists' Collaborative Group overview analysis which reported that "the avoidance of recurrence in a conserved breast …. avoids about one breast cancer death over the next 15 years for every four such recurrences avoided."[12] Indicating that not all breast cancer is a systemic disease at presentation.

During the 1970s, clinical trials were initiated to determine the value of systemic therapy in the postoperative setting as an adjuvant to surgery. The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) was established in 1985 to coordinate the meta-analysis of data from randomized clinical trials in order to examine the impact of adjuvant treatments for breast cancer on recurrence and mortality. The EBCTCG overview has demonstrated that anthracycline containing regimens are superior to CMF, and more recently, that the addition of a taxane to an anthracycline-based regimen reduces breast cancer mortality by one third.[11] The overview has also demonstrated that tamoxifen is of benefit only in patients with estrogen receptor (ER) positive breast cancer and that tamoxifen may decrease mortality from breast cancer by as much as 50%.[13] Importantly, the EBCTCG data have shown that proportional reduction in risk was not significantly affected by standard clinical and pathologic factors such as tumor size, ER status, and nodal status.[14] This underscores the importance of stratification of risk in determining adjuvant therapy decisions in order to minimize the toxicities of therapies in those unlikely to benefit, yet realize the substantial benefits gained in local-regional control and survival in those at higher risk.

Many early randomized clinical trials considered all patients similarly in terms of treatment viewing breast cancer as more of a homogeneous disease. Breast cancer has traditionally been defined by pathologic determinants using conventional light microscopy and basic histologic techniques. In the 1980s immunohistochemistry allowed assessment of the expression of individual tumor markers (most commonly proteins) while DNA was initially assessed in terms of its ploidy status. Subsequently, breast cancer specimens have been interrogated at the level of the DNA by labeling genes of interest and allowing fluorescent dyes to quantify the abundance of a particular gene and comparing a large number of genes simultaneously in a single breast cancer specimen. Gene expression arrays have shown that breast cancers cluster according to their intrinsic gene expression patterns into at least five intrinsic subtypes and these intrinsic subtypes correlate with breast cancer outcomes.[15] Breast cancers are now classified by molecular subtypes and these are being used for risk stratification and decision making in terms of local-regional and systemic therapies.

Currently, 50% of American women will consult a surgeon regarding breast disease, 25% will undergo breast biopsy for diagnosis of an abnormality, and 12% will develop some variant of breast cancer. Considerable progress has been made in the integration of surgery, radiation therapy, and systemic therapy to control local-regional disease, enhance survival, and improve the quality of life of breast cancer survivors. Surgeons are traditionally the first physician consulted for breast care and it is critical for them to be well trained in all aspects of the breast from embryologic development, to growth and development, and to benign and malignant disease processes. This will allow the greatest opportunity to achieve optimal outcomes for patients and their families.

EMBRYOLOGY AND FUNCTIONAL ANATOMY OF THE BREAST

Embryology

At the fifth or sixth week of fetal development, two ventral bands of thickened ectoderm (mammary ridges, milk lines) are evident in the embryo.[16] In most mammals, paired breasts develop along these ridges, which extend from the base of the forelimb (future axilla) to the region of the hind limb (inguinal area). These ridges are not prominent in the human embryo and disappear after a short time, except for small portions that may

Figure 17-1. The mammary milk line (Visual Art: © 2012.The University of Texas MD Anderson Cancer Center.)

persist in the pectoral region. Accessory breasts (*polymastia*) or accessory nipples (*polythelia*) may occur along the milk line (Fig. 17-1) when normal regression fails. Each breast develops when an ingrowth of ectoderm forms a primary tissue bud in the mesenchyme. The primary bud, in turn, initiates the development of 15 to 20 secondary buds. Epithelial cords develop from the secondary buds and extend into the surrounding mesenchyme. Major (lactiferous) ducts develop, which open into a shallow mammary pit. During infancy, a proliferation of mesenchyme transforms the mammary pit into a nipple. If there is failure of a pit to elevate above skin level, an inverted nipple results. This congenital malformation occurs in 4% of infants. At birth, the breasts are identical in males and females, demonstrating only the presence of major ducts. Enlargement of the breast may be evident and a secretion, historically referred to as *witch's milk,* may be produced. These transitory events occur in response to maternal hormones that cross the placenta.

The breast remains undeveloped in the female until puberty, when it enlarges in response to ovarian estrogen and progesterone, which initiate proliferation of the epithelial and connective tissue elements. However, the breasts remain incompletely developed until pregnancy occurs. Absence of the breast (*amastia*) is rare and results from an arrest in mammary ridge development that occurs during the sixth fetal week. Poland's syndrome consists of hypoplasia or complete absence of the breast, costal cartilage and rib defects, hypoplasia of the subcutaneous tissues of the chest wall, and brachysyndactyly. Breast hypoplasia also may be iatrogenically induced before puberty by trauma, infection, or radiation therapy. *Symmastia* is a rare anomaly recognized as webbing between the breasts across the midline. Accessory nipples (*polythelia*) occur in <1% of infants and may be associated with abnormalities of the urinary tract (renal agenesis and cancer), abnormalities of the cardiovascular system (conduction disturbances, hypertension, congenital heart anomalies), and other conditions (pyloric stenosis, epilepsy, ear abnormalities, arthrogryposis). Supernumerary breasts may occur in any configuration along the mammary milk line but most frequently occur between the normal nipple location and the symphysis pubis. Turner's syndrome (ovarian agenesis and dysgenesis) and Fleischer's syndrome (displacement of the nipples and bilateral renal hypoplasia) may have polymastia as a component. Accessory axillary breast tissue is uncommon and usually is bilateral.

Functional Anatomy

The breast is composed of 15 to 20 lobes (Fig. 17-2), which are each composed of several lobules.[17] Fibrous bands of connective tissue travel through the breast (Cooper's suspensory ligaments), insert perpendicularly into the dermis, and provide structural support. The mature female breast extends from the level of the second or third rib to the inframammary fold at the sixth or seventh rib. It extends transversely from the lateral border of the sternum to the anterior axillary line. The deep or posterior surface of the breast rests on the fascia of the pectoralis major, serratus anterior, and external oblique abdominal muscles, and the upper extent of the rectus sheath. The retromammary bursa may be identified on the posterior aspect of the breast between the investing fascia of the breast and the fascia of the pectoralis major muscles. The axillary tail of Spence extends laterally across the anterior axillary fold. The upper outer quadrant of the breast contains a greater volume of tissue than do the other quadrants. The breast has a protuberant conical form. The base of the cone is roughly circular, measuring 10 to 12 cm in diameter. Considerable variations in the size, contour, and density of the breast are evident among individuals. The nulliparous breast has a hemispheric configuration with distinct flattening above the nipple. With the hormonal stimulation that accompanies pregnancy and lactation, the breast becomes larger and increases in volume and density, whereas with senescence, it assumes a flattened, flaccid, and more pendulous configuration with decreased volume.

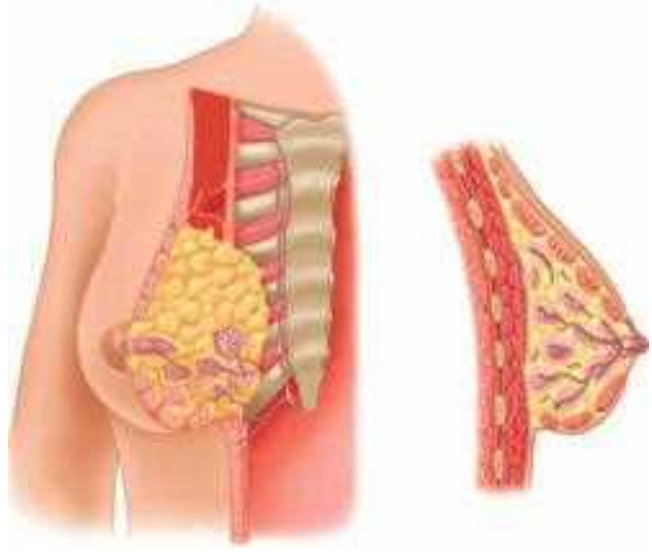

Figure 17-2. Anatomy of the breast. Tangential and cross-sectional (sagittal) views of the breast and associated chest wall. (*Reproduced with permission from Romrell LJ, Bland KI.* Anatomy of the breast, axilla, chest wall, and related metastatic sites. *In: Bland KI, Copeland EMI, eds. The Breast: Comprehensive Management of Benign and Malignant Diseases. Philadelphia: Saunders, 2009. Copyright Elsevier.*)

Nipple-Areola Complex. The epidermis of the nipple-areola complex is pigmented and is variably corrugated. During puberty, the pigment becomes darker and the nipple assumes an elevated configuration. Throughout pregnancy, the areola enlarges and pigmentation is further enhanced. The areola contains sebaceous glands, sweat glands, and accessory glands, which produce small elevations on the surface of the areola (Montgomery's tubercles). Smooth muscle bundle fibers, which lie circumferentially in the dense connective tissue and longitudinally along the major ducts, extend upward into the nipple, where they are responsible for the nipple erection that occurs with various sensory stimuli. The dermal papilla at the tip of the nipple contains numerous sensory nerve endings and Meissner's corpuscles. This rich sensory innervation is of functional importance, because the sucking of the infant initiates a chain of neurohumoral events that results in milk letdown.

Inactive and Active Breast. Each lobe of the breast terminates in a major (lactiferous) duct (2–4 mm in diameter), which opens through a constricted orifice (0.4–0.7 mm in diameter) into the ampulla of the nipple (see Fig. 17-2). Immediately below the nipple-areola complex, each major duct has a dilated portion (lactiferous sinus), which is lined with stratified squamous epithelium. Major ducts are lined with two layers of cuboidal cells, whereas minor ducts are lined with a single layer of columnar or cuboidal cells. Myoepithelial cells of ectodermal origin reside between the epithelial cells in the basal lamina and contain myofibrils. In the inactive breast, the epithelium is sparse and consists primarily of ductal epithelium (Fig. 17-3). In the early phase of the menstrual cycle, minor ducts are cordlike with small lumina. With estrogen stimulation at the time of ovulation, alveolar epithelium increases in height, duct lumina become more prominent, and some secretions accumulate. When the hormonal stimulation decreases, the alveolar epithelium regresses.

With pregnancy, the breast undergoes proliferative and developmental maturation. As the breast enlarges in response to hormonal stimulation, lymphocytes, plasma cells, and eosinophils accumulate within the connective tissues. The minor ducts branch and alveoli develop. Development of the alveoli is asymmetric, and variations in the degree of development may occur within a single lobule (Fig. 17-4). With parturition, enlargement of the breasts occurs via hypertrophy of alveolar epithelium and accumulation of secretory products in the lumina of the minor ducts. Alveolar epithelium contains abundant endoplasmic reticulum, large mitochondria, Golgi complexes, and dense lysosomes. Two distinct substances are produced by the alveolar epithelium: (a) the protein component of milk, which is synthesized in the endoplasmic reticulum (merocrine secretion); and (b) the lipid component of milk (apocrine secretion), which forms as free lipid droplets in the cytoplasm. Milk released in the first few days after parturition is called *colostrum* and has low lipid content but contains considerable quantities of antibodies. The lymphocytes and plasma cells that accumulate within the connective tissues of the breast are the source of the antibody component. With subsequent reduction in the number of these cells, the production of colostrum decreases and lipid-rich milk is released.

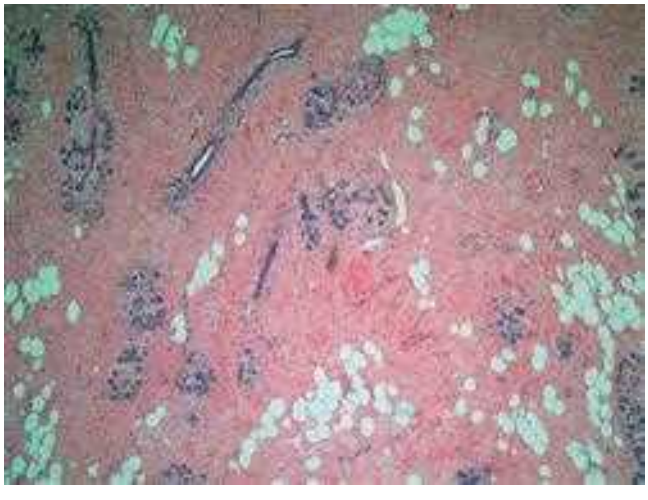

Figure 17-3. Inactive human breast (100x). The epithelium, which is primarily ductal, is embedded in loose connective tissue. Dense connective tissue surrounds the terminal duct lobular units (TDLU). Figure 17-4. Active human breast: pregnancy and lactation (160x). The alveolar epithelium becomes conspicuous during the early proliferative period. The alveolus is surrounded by cellular connective tissue. (Photo used with permission of Dr. Sindhu Menon, Consultant Histopathologist & Dr. Rahul Deb, Consultant Histopathologist and Lead Breast Pathologist, Royal Derby Hospital, Derby, UK.)

Blood Supply, Innervation, and Lymphatics. The breast receives its principal blood supply from: (a) perforating branches of the internal mammary artery; (b) lateral branches of the posterior intercostal arteries; and (c) branches from the axillary artery, including the highest thoracic, lateral thoracic, and pectoral branches of the thoracoacromial artery (Fig. 17-5).

1▶ The second, third, and fourth anterior intercostal perforators and branches of the internal mammary artery arborize in the breast as the medial mammary arteries. The lateral thoracic artery gives off branches to the serratus anterior, pectoralis major and pectoralis minor, and subscapularis muscles. It also gives rise to lateral mammary branches. The veins of the breast and chest wall follow the course of the arteries, with venous drainage being toward the axilla. The three principal groups of veins are: (a) perforating branches of the internal thoracic vein, (b) perforating branches of the posterior intercostal veins, and

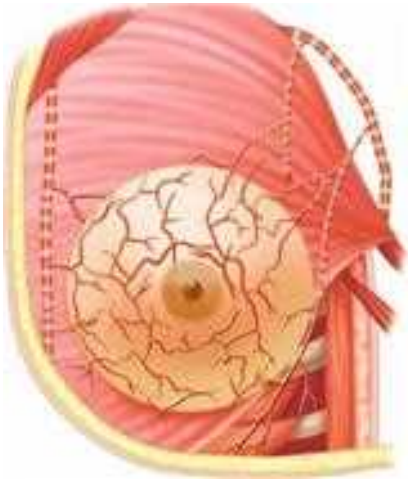

Figure 17-5. Arterial supply to the breast, axilla, and chest wall. (*Reproduced with permission from Romrell LJ, Bland KI.* Anatomy of the breast, axilla, chest wall, and related metastatic sites. *In: Bland KI, Copeland EMI, eds. The Breast: Comprehensive Management of Benign and Malignant Diseases. Philadelphia: Saunders, 2009. Copyright Elsevier.*)

(c) tributaries of the axillary vein. Batson's vertebral venous plexus, which invests the vertebrae and extends from the base of the skull to the sacrum, may provide a route for breast cancer metastases to the vertebrae, skull, pelvic bones, and central nervous system. Lymph vessels generally parallel the course of blood vessels.

Lateral cutaneous branches of the third through sixth intercostal nerves provide sensory innervation of the breast (lateral mammary branches) and of the anterolateral chest wall. These branches exit the intercostal spaces between slips of the serratus anterior muscle. Cutaneous branches that arise from the cervical plexus, specifically the anterior branches of the supraclavicular nerve, supply a limited area of skin over the upper portion of the breast. The intercostobrachial nerve is the lateral cutaneous branch of the second intercostal nerve and may be visualized during surgical dissection of the axilla. Resection of the intercostobrachial nerve causes loss of sensation over the medial aspect of the upper arm.

The boundaries for lymph drainage of the axilla are not well demarcated, and there is considerable variation in the position of the axillary lymph nodes. The six axillary lymph node groups recognized by surgeons (Figs. 17-6 and 17-7) are: (a) the axillary vein group (lateral), which consists of four to six lymph nodes that lie medial or posterior to the vein and receive most of the lymph drainage from the upper extremity; (b) the external mammary group (anterior or pectoral group), which consists of five to six lymph nodes that lie along the lower border of the pectoralis minor muscle contiguous with the lateral thoracic vessels and receive most of the lymph drainage from the lateral aspect of the breast; (c) the scapular group (posterior or subscapular), which consists of five to seven lymph nodes that lie along the posterior wall of the axilla at the lateral border of the scapula contiguous with the subscapular vessels and receive lymph drainage principally from the lower posterior neck, the posterior trunk, and the posterior shoulder; (d) the central group, which consists of three or four sets of lymph nodes that are

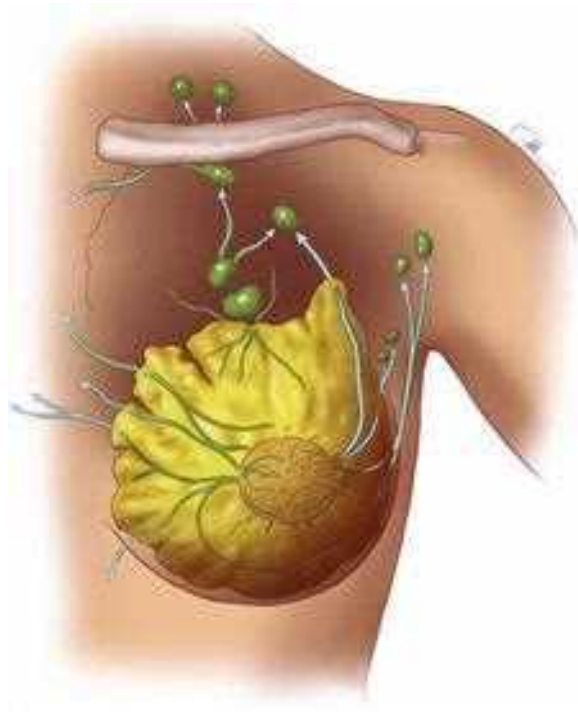

Figure 17-6. Lymphatic pathways of the breast. *Arrows* indicate the direction of lymph flow. (Visual Art: © 2012. The University of Texas MD Anderson Cancer Center.)

embedded in the fat of the axilla lying immediately posterior to the pectoralis minor muscle and receive lymph drainage both from the axillary vein, external mammary, and scapular groups of lymph nodes, and directly from the breast; (e) the subclavicular

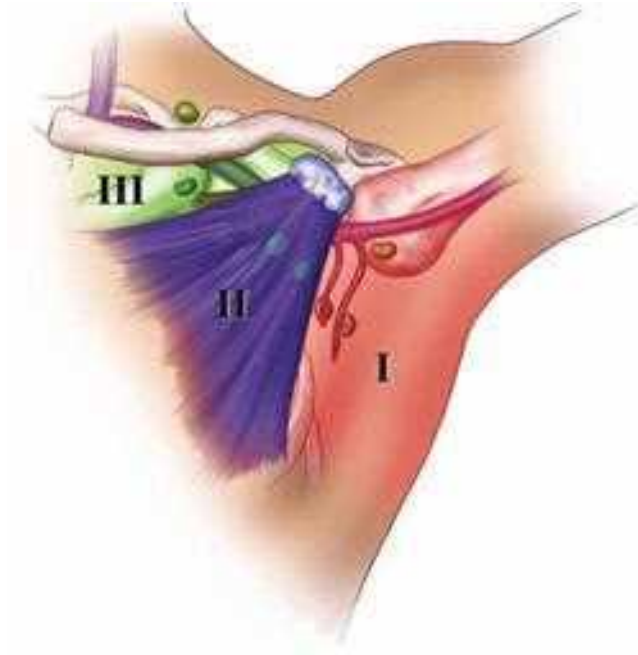

Figure 17-7. Axillary lymph node groups. Level I includes lymph nodes located lateral to the pectoralis minor muscle; level II includes lymph nodes located deep to the pectoralis minor; and level III includes lymph nodes located medial to the pectoralis minor. The axillary vein with its major tributaries and the supraclavicular lymph node group are also illustrated. (Visual Art: © 2012.The University of Texas MD Anderson Cancer Center.)

group (apical), which consists of six to twelve sets of lymph nodes that lie posterior and superior to the upper border of the pectoralis minor muscle and receive lymph drainage from all of the other groups of axillary lymph nodes; and (f) the interpectoral group (Rotter's lymph nodes), which consists of one to four lymph nodes that are interposed between the pectoralis major and pectoralis minor muscles and receive lymph drainage directly from the breast. The lymph fluid that passes through the interpectoral group of lymph nodes passes directly into the central and subclavicular groups.

As indicated in Fig.17-7, the lymph node groups are assigned levels according to their anatomic relationship to the pectoralis minor muscle. Lymph nodes located lateral to or below the lower border of the pectoralis minor muscle are referred to as *level I lymph nodes,* which include the axillary vein, external mammary, and scapular groups. Lymph nodes located superficial or deep to the pectoralis minor muscle are referred to as *level II lymph nodes,* which include the central and interpectoral groups. Lymph nodes located medial to or above the upper border of the pectoralis minor muscle are referred to as *level III lymph nodes,* which consist of the subclavicular group. The plexus of lymph vessels in the breast arises in the interlobular connective tissue and in the walls of the lactiferous ducts and communicates with the subareolar plexus of lymph vessels. Efferent lymph vessels from the breast pass around the lateral edge of the pectoralis major muscle and pierce the clavipectoral fascia, ending in the external mammary (anterior, pectoral) group of lymph nodes. Some lymph vessels may travel directly to the subscapular (posterior, scapular) group of lymph nodes. From the upper part of the breast, a few lymph vessels pass directly to the subclavicular (apical) group of lymph nodes. The axillary lymph nodes usually receive >75% of the lymph drainage from the breast. The rest is derived primarily from the medial aspect of the breast, flows through the lymph vessels that accompany the perforating branches of the internal mammary artery, and enters the parasternal (internal mammary) group of lymph nodes.

2▶

PHYSIOLOGY OF THE BREAST

Breast Development and Function

Breast development and function are initiated by a variety of hormonal stimuli, including estrogen, progesterone, prolactin, oxytocin, thyroid hormone, cortisol, and growth hormone.[17,18] Estrogen, progesterone, and prolactin especially have profound trophic effects that are essential to normal breast development and function. Estrogen initiates ductal development, whereas progesterone is responsible for differentiation of epithelium and for lobular development. Prolactin is the primary hormonal stimulus for lactogenesis in late pregnancy and the postpartum period. It upregulates hormone receptors and stimulates epithelial development. Figure 17-8 depicts the secretion of neurotrophic hormones from the hypothalamus, which

3▶

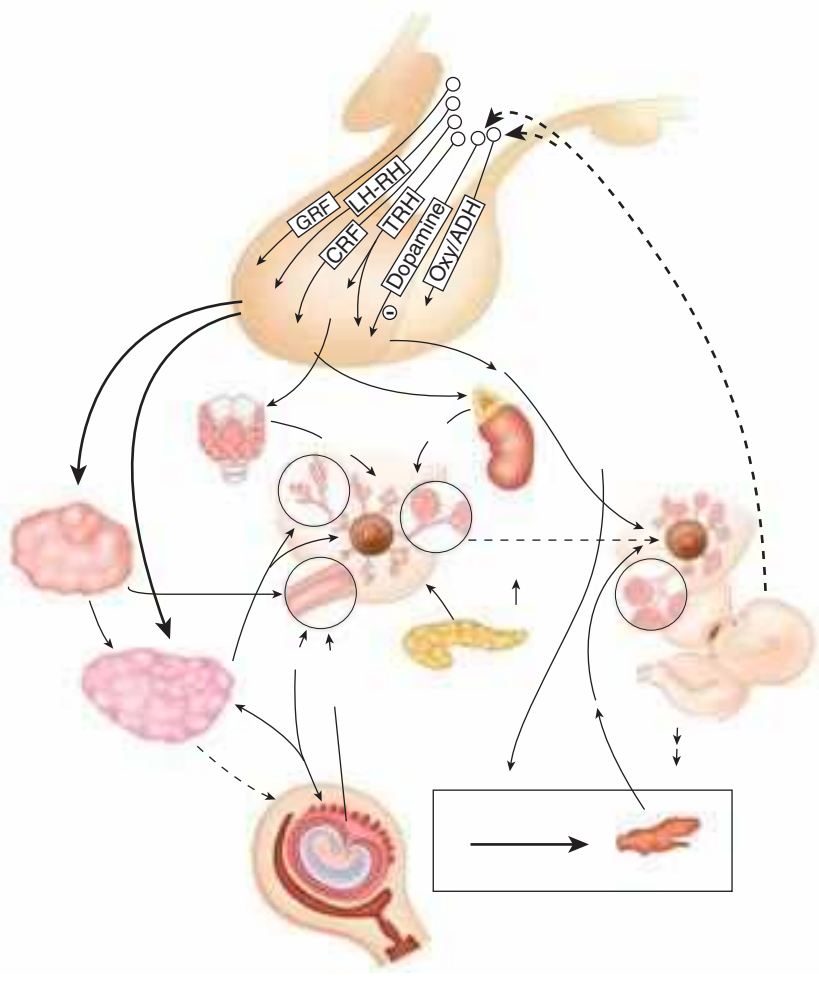

Figure 17-8. Overview of the neuroendocrine control of breast development and function. ADH = antidiuretic hormone; CRF = corticotropin-releasing factor; GRF = growth hormone releasing factor; LH-RH = luteinizing hormone–releasing hormone; Oxy = oxytocin; TRH = thyrotropin-releasing hormone. The Breast: Comprehensive Management of Benign and Malignant Diseases. Philadelphia: Saunders, 2009. Copyright Elsevier.*)

is responsible for regulation of the secretion of the hormones that affect the breast tissues. The gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH) regulate the release of estrogen and progesterone from the ovaries. In turn, the release of LH and FSH from the basophilic cells of the anterior pituitary is regulated by the secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus. Positive and negative feedback effects of circulating estrogen and progesterone regulate the secretion of LH, FSH, and GnRH. These hormones are responsible for the development, function, and maintenance of breast tissues (Fig. 17-9A). In the female neonate, circulating estrogen and progesterone levels decrease after birth and remain low throughout childhood because of the sensitivity of the hypothalamic-pituitary axis to negative feedback from these hormones. With the onset of puberty, there is a decrease in the sensitivity of the hypothalamic-pituitary axis to negative feedback and an increase in its sensitivity to positive feedback from estrogen. These physiologic events initiate an increase in GnRH, FSH, and LH secretion and ultimately an increase in estrogen and progesterone secretion by the ovaries, leading to establishment of the menstrual cycle. At the beginning of the menstrual cycle, there is an increase in the size and density of the breasts, which is followed by engorgement of the breast tissues and epithelial proliferation. With the onset of menstruation, the breast engorgement subsides and epithelial proliferation decreases.

Pregnancy, Lactation, and Senescence

A dramatic increase in circulating ovarian and placental estrogens and progestins is evident during pregnancy, which initiates striking alterations in the form and substance of the breast (see Fig. 17-9B).[17-19] The breast enlarges as the ductal and lobular epithelium proliferates, the areolar skin darkens, and the accessory areolar glands (Montgomery's glands) become prominent. In the first and second trimesters, the minor ducts branch and develop. During the third trimester, fat droplets accumulate in

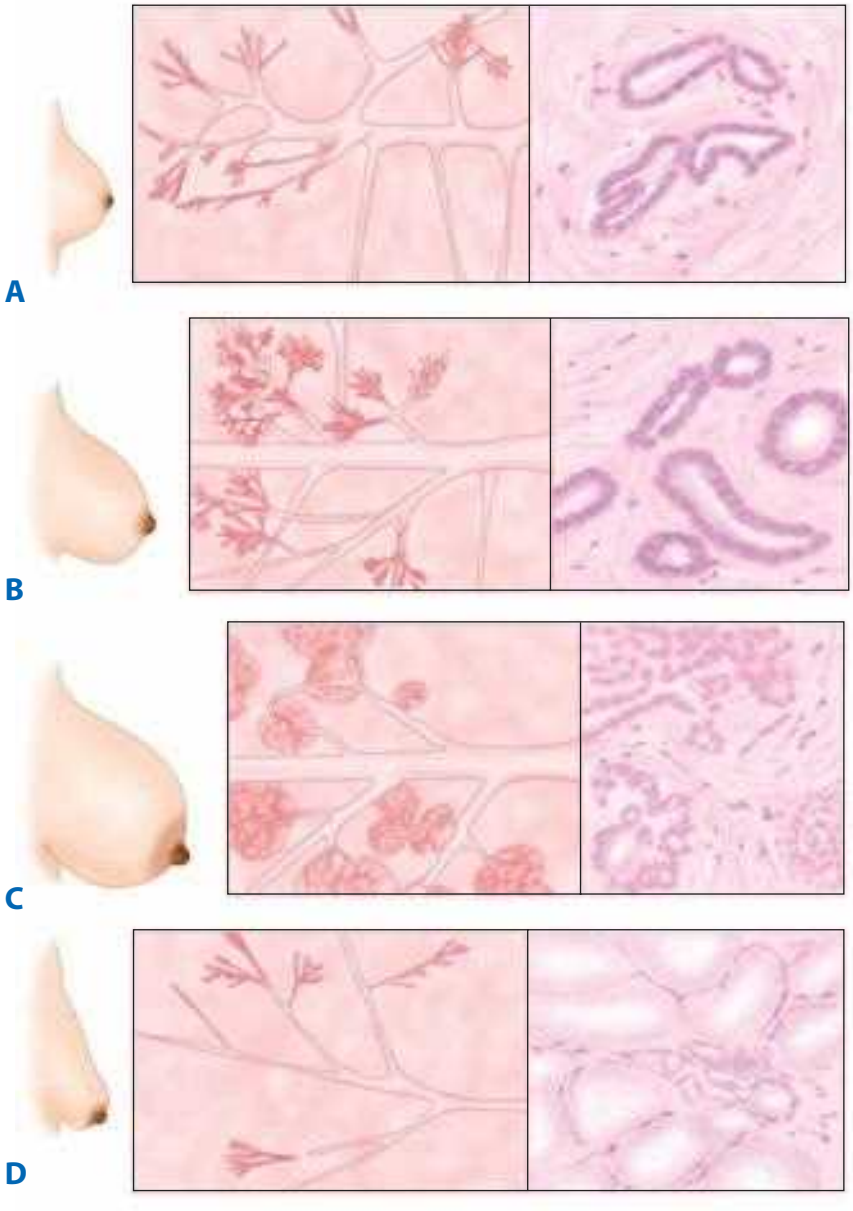

Figure 17-9. The breast at different physiologic stages. The central column contains three-dimensional depictions of microscopic structures. **A.** Adolescence. **B.** Pregnancy. **C.** Lactation. **D.** Senescence.

the alveolar epithelium and colostrum fills the alveolar and ductal spaces. In late pregnancy, prolactin stimulates the synthesis of milk fats and proteins.

After delivery of the placenta, circulating progesterone and estrogen levels decrease, permitting full expression of the lactogenic action of prolactin. Milk production and release are controlled by neural reflex arcs that originate in nerve endings of the nipple-areola complex. Maintenance of lactation requires regular stimulation of these neural reflexes, which results in prolactin secretion and milk letdown. Oxytocin release results from the auditory, visual, and olfactory stimuli associated with nursing. Oxytocin initiates contraction of the myoepithelial cells, which results in compression of alveoli and expulsion of milk into the lactiferous sinuses. After weaning of the infant, prolactin and oxytocin release decreases. Dormant milk causes increased pressure within the ducts and alveoli, which results in atrophy of the epithelium (Fig. 17-9C). With menopause there is a decrease in the secretion of estrogen and progesterone by the ovaries and involution of the ducts and alveoli of the breast. The surrounding fibrous connective tissue increases in density, and breast tissues are replaced by adipose tissues (Fig. 17-9D).

Gynecomastia

Gynecomastia refers to an enlarged breast in the male.[20] Physiologic gynecomastia usually occurs during three phases of life: the neonatal period, adolescence, and senescence. Common to each of these phases is an excess of circulating estrogens in relation to circulating testosterone. Neonatal gynecomastia is caused by the action of placental estrogens on neonatal breast tissues, whereas in adolescence, there is an excess of estradiol relative to testosterone, and with senescence, the circulating testosterone level falls, which results in relative hyperestrinism. In gynecomastia, the ductal structures of the male breast enlarge, elongate, and branch with a concomitant increase in epithelium. During puberty, the condition often is unilateral and typically occurs between ages 12 and 15 years. In contrast, senescent gynecomastia is usually bilateral. In the nonobese male, breast tissue measuring at least 2 cm in diameter must be present before a diagnosis of gynecomastia may be made. Mammography and ultrasonography are used to differentiate breast tissues. Dominant masses or areas of firmness, irregularity, and asymmetry suggest the possibility of a breast cancer, particularly in the older male. Gynecomastia generally does not predispose the male breast to cancer. However, the hypoandrogenic state of Klinefelter's syndrome (XXY), in which gynecomastia is usually evident, is associated with an increased risk of breast cancer. Gynecomastia is graded based on the degree of breast enlargement, the position of the nipple with reference to the inframammary fold and the degree of breast ptosis and skin redundancy: Grade 1: mild breast enlargement without skin redundancy; Grade IIa: moderate breast enlargement without skin redundancy; Grade IIb: moderate breast enlargement with skin redundancy; and Grade 3: marked breast enlargement with skin redundancy and ptosis.

Table 17-1 identifies the pathophysiologic mechanisms that may initiate gynecomastia: estrogen excess states; androgen deficiency states; pharmacologic causes; and idiopathic causes. Estrogen excess results from an increase in the secretion of estradiol by the testicles or by nontesticular tumors, nutritional alterations such as protein and fat deprivation, endocrine disorders (hyperthyroidism, hypothyroidism), and hepatic disease (nonalcoholic and alcoholic cirrhosis). Refeeding gynecomastia is related to the resumption of pituitary gonadotropin secretion after pituitary shutdown. Androgen deficiency may initiate gynecomastia. Concurrently occurring with decreased circulating testosterone levels is an elevated level of circulating testosterone-binding globulin, which results in a reduction of free testosterone. This senescent gynecomastia usually occurs in men aged 50 to 70 years. Hypoandrogenic states can be from primary testicular failure or secondary testicular failure. Klinefelter's syndrome (XXY) is an example of primary testicular failure which is manifested by gynecomastia, hypergonadotropic hypogonadism, and azoospermia. Secondary testicular failure may result from trauma, orchitis, and cryptorchidism. Renal failure, regardless of cause, also may initiate gynecomastia.

Table 17-1

Pathophysiologic mechanisms of gynecomastia

I. Estrogen excess states
  A. Gonadal origin
    1. True hermaphroditism
    2. Gonadal stromal (nongerminal) neoplasms of the testis
      a. Leydig cell (interstitial)
      b. Sertoli cell
      c. Granulosa-theca cell
    3. Germ cell tumors
      a. Choriocarcinoma
      b. Seminoma, teratoma
      c. Embryonal carcinoma
  B. Nontesticular tumors
    1. Adrenal cortical neoplasms
    2. Lung carcinoma
    3. Hepatocellular carcinoma
  C. Endocrine disorders
  D. Diseases of the liver—nonalcoholic and alcoholic cirrhosis
  E. Nutrition alteration states
II. Androgen deficiency states
  A. Senescence
  B. Hypoandrogenic states (hypogonadism)
    1. Primary testicular failure
      a. Klinefelter's syndrome (XXY)
      b. Reifenstein's syndrome
      c. Rosewater-Gwinup-Hamwi familial gynecomastia
      d. Kallmann syndrome
      e. Kennedy's disease with associated gynecomastia
      f. Eunuchoidal state (congenital anorchia)
      g. Hereditary defects of androgen biosynthesis
      h. Adrenocorticotropic hormone deficiency
    2. Secondary testicular failure
      a. Trauma
      b. Orchitis
      c. Cryptorchidism
      d. Irradiation
  C. Renal failure
III. Pharmacologic causes
IV. Systemic diseases with idiopathic mechanisms

Pharmacologic causes of gynecomastia include drugs with estrogenic activity (digitalis, estrogens, anabolic steroids, marijuana) or drugs that enhance estrogen synthesis (human chorionic gonadotropin). Drugs that inhibit the action or synthesis of testosterone (cimetidine, ketoconazole, phenytoin, spironolactone, antineoplastic agents, diazepam) also have been implicated. Drugs such as reserpine, theophylline, verapamil, tricyclic antidepressants, and furosemide induce gynecomastia through idiopathic mechanisms.

When gynecomastia is caused by androgen deficiency, then testosterone administration may cause regression. When it is caused by medications, then these are discontinued if possible. When endocrine defects are responsible, then these receive specific therapy. As soon asgynecomastia is progressive and does not respond to other treatments, surgical therapy is considered. Techniques include local excision, liposuction or subcutaneous mastectomy. Attempts to reverse gynecomastia with danazol have been successful, but the androgenic side effects of the drug are considerable.

INFECTIOUS AND INFLAMMATORY DISORDERS OF THE BREAST

Infections in the postpartum period remain proportionately the most common time for breast infections to occur. Infections of the breast unrelated to lactation are proportionately less common, however, are still a relatively common presentation to breast specialists. The latter are classified as intrinsic (secondary to abnormalities in the breast) or extrinsic (secondary to an infection in an adjacent structure, e.g., skin, thoracic cavity) the most common being probably periductal mastitis and infected sebaceous cyst, respectively.

Bacterial Infection

Staphylococcus aureus and *Streptococcus* species are the organisms most frequently recovered from nipple discharge from an infected breast.[17] Typically breast abscesses are seen in staphylococcal infections and present with point tenderness, erythema, and hyperthermia. When these abscesses are related to lactation they usually occur within the first few weeks of breastfeeding. If there is progression of a staphylococcal infection, this may result in subcutaneous, subareolar, interlobular (periductal), and retromammary abscesses (unicentric or multicentric). Previously almost all breast abscesses were treated by operative incision and drainage but now the initial approach is antibiotics and repeated aspiration of the abscess, usually ultrasound guided aspiration.[21] Operative drainage is now reserved for those cases which don't resolve with repeated aspiration and antibiotic therapy or if there is some other indication for incision and drainage (e.g., thinning or necrosis of the overlying skin). Preoperative ultrasonography is effective in delineating the required extent of the drainage procedure. While staphylococcal infections tend to be more localized and may be situated deep in the breast tissues, streptococcal infections usually present with diffuse superficial involvement. They are treated with local wound care, including application of warm compresses, and the administration of IV antibiotics (penicillins or cephalosporins). Breast infections may be chronic, possibly with recurrent abscess formation. In this situation, cultures are performed to identify acid-fast bacilli, anaerobic and aerobic bacteria, and fungi. Uncommon organisms may be encountered, and long-term antibiotic therapy may be required.

Biopsy of the abscess cavity wall should be considered at the time of incision and drainage to rule out underlying breast cancer in patients where antibiotics and drainage have been ineffective.

Nowadays hospital-acquired puerperal infections of the breast are much less common, but nursing women who present with milk stasis or noninfectious inflammation may still develop this problem. Epidemic puerperal mastitis is initiated by highly virulent strains of methicillin-resistant *S. aureus* that are transmitted via the suckling neonate and may result in substantial morbidity and occasional mortality. Purulent fluid may be expressed from the nipple. In this circumstance, breastfeeding is stopped, antibiotics are started, and surgical therapy is initiated. *Nonepidemic* (*sporadic*) *puerperal mastitis* refers to involvement of the interlobular connective tissue of the breast by an infectious process. The patient develops nipple fissuring and milk stasis, which initiates a retrograde bacterial infection. Emptying of the breast using breast suction pumps shortens the duration of symptoms and reduces the incidence of recurrences. The addition of antibiotic therapy results in a satisfactory outcome in >95% of cases.

Zuska's disease, also called *recurrent periductal mastitis,* is a condition of recurrent retroareolar infections and abscesses.[22,23] Smoking has been implicated as a risk factor for this condition.[24,25] This syndrome is managed symptomatically by antibiotics coupled with incision and drainage as necessary. Attempts to obtain durable long-term control by wide débridement of chronically infected tissue and/or terminal duct resection have been reported and can be curative but equally can be frustrated by postoperative infections.[26]

Mycotic Infections

Fungal infections of the breast are rare and usually involve blastomycosis or sporotrichosis.[27] Intraoral fungi that are inoculated into the breast tissue by the suckling infant initiate these infections, which present as mammary abscesses in close proximity to the nipple-areola complex. Pus mixed with blood may be expressed from sinus tracts. Antifungal agents can be administered for the treatment of systemic (noncutaneous) infections. This therapy generally eliminates the necessity of surgical intervention, but occasionally drainage of an abscess, or even partial mastectomy, may be necessary to eradicate a persistent fungal infection. *Candida albicans* affecting the skin of the breast presents as erythematous, scaly lesions of the inframammary or axillary folds. Scrapings from the lesions demonstrate fungal elements (filaments and binding cells). Therapy involves the removal of predisposing factors such as maceration and the topical application of nystatin.

Hidradenitis Suppurativa

Hidradenitis suppurativa of the nipple-areola complex or axilla is a chronic inflammatory condition that originates within the accessory areolar glands of Montgomery or within the axillary sebaceous glands.[27] Women with chronic acne are predisposed to developing hidradenitis. When located in and about the nipple-areola complex, this disease may mimic other chronic inflammatory states, Paget's disease of the nipple, or invasive breast cancer. Involvement of the axillary skin is often multifocal and contiguous. Antibiotic therapy with incision and drainage of fluctuant areas is appropriate treatment. Excision of the involved areas may be required. Large areas of skin loss may necessitate coverage with advancement flaps or split-thickness skin grafts.

Mondor's Disease

Mondor's disease is a variant of thrombophlebitis that involves the superficial veins of the anterior chest wall and breast.[28] In 1939, Mondor described the condition as "string phlebitis," a thrombosed vein presenting as a tender, cord-like structure.[29] Frequently involved veins include the lateral thoracic vein, the thoracoepigastric vein, and, less commonly, the superficial epigastric vein. Typically, a woman presents with acute pain in the lateral aspect of the breast or the anterior chest wall. A tender, firm cord is found to follow the distribution of one of the major superficial veins. Rarely, the presentation is bilateral, and most women have no evidence of thrombophlebitis in other anatomic sites. This benign, self-limited disorder is not indicative of a cancer. When the diagnosis is uncertain, or when a mass is present near the tender cord, biopsy is indicated. Therapy for Mondor's disease includes the liberal use of anti-inflammatory medications and application of warm compresses along the symptomatic vein. The process usually resolves within 4 to 6 weeks. When symptoms persist or are refractory to therapy, excision of the involved vein segment may be considered.

COMMON BENIGN DISORDERS AND DISEASES OF THE BREAST

Benign breast disorders and diseases encompass a wide range of clinical and pathologic entities. Surgeons require an in-depth understanding of benign breast disorders and diseases so that clear explanations may be given to affected women, appropriate treatment instituted, and unnecessary long-term follow up avoided.

Aberrations of Normal Development and Involution

The basic principles underlying the aberrations of normal development and involution (ANDI) classification of benign breast conditions are the following: (a) benign breast disorders and diseases are related to the normal processes of reproductive life and to involution; (b) there is a spectrum of breast conditions that ranges from normal to disorder to disease; and (c) the ANDI classification encompasses all aspects of the breast condition, including pathogenesis and the degree of abnormality .[30] 4▶ The horizontal component of Table 17-2 defines ANDI along a spectrum from normal, to mild abnormality (disorder), to severe abnormality (disease). The vertical component indicates the period during which the condition develops.

Early Reproductive Years. Fibroadenomas are seen and present symptomatically predominantly in younger women aged 15 to 25 years (Fig. 17-10).[31] Fibroadenomas usually grow to 1 or 2 cm in diameter and then are stable but may grow to a larger size. Small fibroadenomas (≤1 cm in size) are considered normal, whereas larger fibroadenomas (≤3 cm) are disorders and giant fibroadenomas (>3 cm) are disease. Similarly, multiple fibroadenomas (more than five lesions in one breast) are very uncommon and are considered disease. It is noted that with the introduction of mammographic screening, asymptomatic fibroadenomas are sometimes found in an older screened population. The precise etiology of adolescent breast hypertrophy is unknown. A spectrum of changes from limited to massive stromal hyperplasia (gigantomastia) is seen. Nipple inversion is a disorder of development of the major

Table 17-2

ANDI classification of benign breast disorders

	NORMAL	DISORDER	DISEASE
Early reproductive years (age 15–25 y)	Lobular development	Fibroadenoma	Giant fibroadenoma
	Stromal development	Adolescent hypertrophy	Gigantomastia
	Nipple eversion	Nipple inversion	Subareolar abscess
			Mammary duct fistula
Later reproductive years (age 25–40 y)	Cyclical changes of menstruation	Cyclical mastalgia	Incapacitating mastalgia
		Nodularity	
	Epithelial hyperplasia of pregnancy	Bloody nipple discharge	
Involution (age 35–55 y)	Lobular involution	Macrocysts	—
		Sclerosing lesions	
	Duct involution		
	Dilatation	Duct ectasia	Periductal mastitis
	Sclerosis	Nipple retraction	—
	Epithelial turnover	Epithelial hyperplasia	Epithelial hyperplasia with atypia

ducts, which prevents normal protrusion of the nipple. Mammary duct fistulas arise when nipple inversion predisposes to major duct obstruction, leading to recurrent subareolar abscess and mammary duct fistula.

Later Reproductive Years. Cyclical mastalgia and nodularity usually are associated with premenstrual enlargement of the breast and are regarded as normal. Cyclical pronounced mastalgia and severe painful nodularity are viewed differently than are physiologic discomfort and lumpiness. Painful nodularity that persists for >1 week of the menstrual cycle is considered a disorder. In epithelial hyperplasia of pregnancy, papillary projections sometimes give rise to bilateral bloody nipple discharge.

Involution. Involution of lobular epithelium is dependent on the specialized stroma around it. However, an integrated involution of breast stroma and epithelium is not always seen, and disorders of the process are common. When the stroma involutes too quickly, alveoli remain and form microcysts, which are precursors of macrocysts. The macrocysts are common, often subclinical, and do not require specific treatment. Sclerosing adenosis is considered a disorder of both the proliferative and the involutional phases of the breast cycle. Duct ectasia (dilated ducts) and periductal mastitis are other important components of the ANDI classification. Periductal fibrosis is a sequela of periductal mastitis and may result in nipple retraction. About 60% of women ≥70 years of age exhibit some degree of epithelial hyperplasia (Fig. 17-11). Atypical proliferative diseases include ductal and lobular hyperplasia, both of which display some features of carcinoma in situ. Women with atypical ductal or lobular hyperplasia have a fourfold increase in breast cancer risk (Table 17-3).

Pathology of Nonproliferative Disorders

Of paramount importance for the optimal management of benign breast disorders and diseases is the histologic differentiation of benign, atypical, and malignant changes.[32,33] Determining the clinical significance of these changes is a problem that is compounded by inconsistent nomenclature. The classification

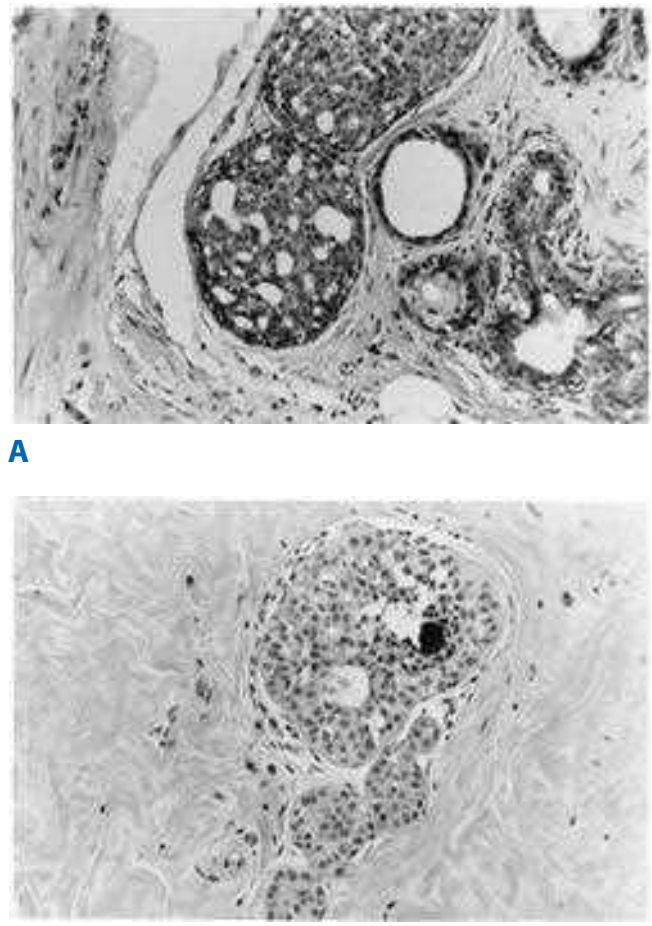

Figure 17-11. **A.** Ductal epithelial hyperplasia. The irregular intracellular spaces and variable cell nuclei distinguish this process from carcinoma in situ. **B.** Lobular hyperplasia. The presence of alveolar lumina and incomplete distention distinguish this process from carcinoma in situ. (*Photos used with permission of Dr. R.L. Hackett.*)

Table 17-3

Cancer risk associated with benign breast disorders and in situ carcinoma of the breast

ABNORMALITY	RELATIVE RISK
Nonproliferative lesions of the breast	No increased risk
Sclerosing adenosis	No increased risk
Intraductal papilloma	No increased risk
Florid hyperplasia	1.5 to 2-fold
Atypical lobular hyperplasia	4-fold
Atypical ductal hyperplasia	4-fold
Ductal involvement by cells of atypical ductal hyperplasia	7-fold
Lobular carcinoma in situ	10-fold
Ductal carcinoma in situ	10-fold

system originally developed by Page separates the various types of benign breast disorders and diseases into three clinically relevant groups: nonproliferative disorders, proliferative disorders without atypia, and proliferative disorders with atypia (Table 17-4). Nonproliferative disorders of the breast account for 70% of benign breast conditions and carry no increased risk for the development of breast cancer. This category includes cysts, duct ectasia, periductal mastitis, calcifications, fibroadenomas, and related disorders.

Breast macrocysts are an involutional disorder, have a high frequency of occurrence, and are often multiple. Duct ectasia is a clinical syndrome characterized by dilated subareolar ducts that are palpable and often associated with thick nipple discharge. Haagensen regarded duct ectasia as a primary event that led to stagnation of secretions, epithelial ulceration, and leakage of duct secretions (containing chemically irritating fatty acids) into periductal tissue.[34] This sequence was thought to produce a local inflammatory process with periductal fibrosis and subsequent nipple retraction. An alternative theory considers periductal mastitis to be the primary process, which leads to weakening of the ducts and secondary dilatation. It is possible that both processes occur and together explain the wide spectrum of problems seen, which include nipple discharge, nipple retraction, inflammatory masses, and abscesses.

Calcium deposits are frequently encountered in the breast. Most are benign and are caused by cellular secretions and debris or by trauma and inflammation. Calcifications that are associated with cancer include microcalcifications, which vary in shape and density and are <0.5 mm in size, and fine, linear calcifications, which may show branching. Fibroadenomas have abundant stroma with histologically normal cellular elements. They show hormonal dependence similar to that of normal breast lobules in that they lactate during pregnancy and involute in the postmenopausal period. Adenomas of the breast are well circumscribed and are composed of benign epithelium with sparse stroma, which is the histologic feature that differentiates them from fibroadenomas. They may be divided into tubular adenomas and lactating adenomas. Tubular adenomas are seen in young nonpregnant women, whereas lactating adenomas are seen during pregnancy or during the postpartum period. Hamartomas are discrete breast tumors that are usually 2 to 4 cm in diameter, firm, and sharply circumscribed. Adenolipomas consist of sharply circumscribed nodules of fatty tissue that contain normal breast lobules and ducts.

Fibrocystic Disease. The term *fibrocystic disease* is nonspecific. Too frequently, it is used as a diagnostic term to describe symptoms, to rationalize the need for breast biopsy, and to explain biopsy results. Synonyms include fibrocystic changes, cystic mastopathy, chronic cystic disease, chronic cystic mastitis, Schimmelbusch's disease, mazoplasia, Cooper's disease, Reclus' disease, and fibroadenomatosis. *Fibrocystic disease* refers to a spectrum of histopathologic changes that are best diagnosed and treated specifically.

Pathology of Proliferative Disorders Without Atypia

Proliferative breast disorders without atypia include sclerosing adenosis, radial scars, complex sclerosing lesions, ductal epithelial hyperplasia, and intraductal papillomas.[32,33] Sclerosing adenosis is prevalent during the childbearing and perimenopausal years and has no malignant potential. Histologic changes are both proliferative (ductal proliferation) and involutional (stromal fibrosis, epithelial regression). Sclerosing adenosis is characterized by distorted breast lobules and usually occurs in the context of multiple microcysts, but occasionally presents as a palpable mass. Benign calcifications are often associated with this disorder. Sclerosing adenosis can be managed by observation as long as the imaging features and pathologic findings are concordant. Central sclerosis and various degrees of epithelial proliferation, apocrine metaplasia, and papilloma formation characterize radial scars and complex sclerosing lesions of the breast. Lesions up to 1 cm in diameter are called *radial scars,* whereas larger lesions are called *complex sclerosing lesions.* Radial scars originate at sites of terminal duct branching where the characteristic histologic changes radiate from a central area of fibrosis. All of the histologic features of a radial scar are seen in the larger complex sclerosing lesions, but there is a greater disturbance of structure with papilloma formation, apocrine metaplasia, and occasionally sclerosing adenosis. Distinguishing between a radial scar and invasive breast carcinoma can be challenging based on core needle biopsy sampling. Often the imaging features of a radial scar (which can be quite similar to an invasive cancer) will dictate the need for either a vacuum assisted biopsy or surgical excision in order to exclude the possibility of carcinoma.

Mild ductal hyperplasia is characterized by the presence of three or four cell layers above the basement membrane. Moderate ductal hyperplasia is characterized by the presence of five or more cell layers above the basement membrane. Florid ductal epithelial hyperplasia occupies at least 70% of a minor duct lumen. It is found in >20% of breast tissue specimens, is either solid or papillary, and is associated with an increased cancer risk (see Table 17-3). Intraductal papillomas arise in the major ducts, usually in premenopausal women. They generally are <0.5 cm in diameter but may be as large as 5 cm. A common presenting symptom is nipple discharge, which may be serous or bloody. Grossly, intraductal papillomas are pinkish tan, friable, and usually attached to the wall of the involved duct by a stalk. They rarely undergo malignant transformation, and their presence does not increase a woman's risk of developing breast cancer (unless accompanied by atypia). However, multiple intraductal papillomas, which occur in younger women and are

less frequently associated with nipple discharge, are susceptible to malignant transformation.

Pathology of Atypical Proliferative Diseases

The atypical proliferative diseases have some of the features of carcinoma in situ but either lack a major defining feature of carcinoma in situ or have the features in less than fully developed form.[34] Atypical ductal hyperplasia (ADH) appears similar to low grade ductal carcinoma in situ (DCIS) histologically and is composed of monotonous round, cuboidal, or polygonal cells enclosed by basement membrane with rare mitoses. A lesion will be considered to be ADH if it is up to 2 or 3 mm in size but would be called DCIS if it is larger than 3 mm. The diagnosis can be difficult to establish with core needle biopsy specimen alone and most cases will require excisional biopsy specimen for classification. Individuals with a diagnosis of ADH are at increased risk for development of breast cancer and should be counseled appropriately regarding risk reduction strategies.

In 1978, Haagensen et al described lobular neoplasia, a spectrum of disorders ranging from atypical lobular hyperplasia to lobular carcinoma in situ (LCIS).[35]Atypical lobular hyperplasia (ALH) results in minimal distention of lobular units with cells that are similar to those seen in LCIS. The diagnosis of LCIS is made when small monomorphic cells that distend the terminal ductal lobular unit are noted. In cases of LCIS the acini are full and distended while the overall lobular architecture is maintained (Fig. 17-12). Classic LCIS is not associated with a specific mammographic or palpable abnormality but is an incidental finding noted on breast biopsy. There is a variant of LCIS that has been termed *pleomorphic LCIS*. In the case of pleomorphic LCIS, there can be calcifications or other suspicious mammographic changes that dictate the need for biopsy. Classic LCIS is not treated with excision as the patient is at risk for developing invasive breast cancer in either breast and therefore the patient is counseled regarding appropriate risk reduction strategies. Pleomorphic LCIS can be difficult to distinguish from high-grade DCIS and there are some proponents who have suggested that patients with pleomorphic LCIS be managed similar to those with DCIS with attention to margins and consideration for radiation therapy in the setting of breast conserving treatment. The use of immunohistochemical staining for E-cadherin can help to discriminate between LCIS and DCIS. In lobular neoplasias, such as ALH and LCIS, there is a lack of E-cadherin expression whereas the majority of ductal lesions will demonstrate E-cadherin reactivity.

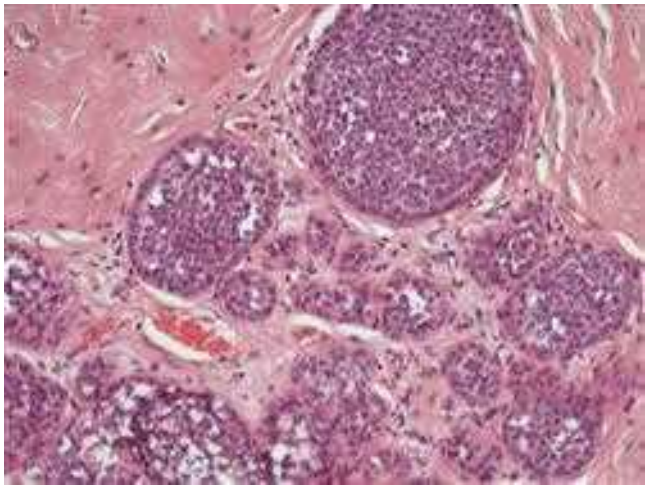

Figure 17-12. Lobular carcinoma in situ (100x). There are small monomorphic cells which distend the terminal duct lobular unit, without necrosis or mitoses. Treatment of Selected Benign Breast Disorders and Diseases

Cysts. Because needle biopsy of breast masses may produce artifacts that make mammography assessment more difficult, many multidisciplinary teams prefer to image breast masses before performing either fine needle aspiration or core needle biopsy.[36,37] In practice, however, the first investigation of palpable breast masses may be a needle biopsy, which allows for the early diagnosis of cysts. A 21-gauge needle attached to a 10-mL syringe is placed directly into the mass, which is fixed by fingers of the nondominant hand. The volume of a typical cyst is 5 to 10 mL, but it may be 75 mL or more. If the fluid that is aspirated is not bloodstained, then the cyst is aspirated to dryness, the needle is removed, and the fluid is discarded, because cytologic examination of such fluid is not cost effective. After aspiration, the breast is carefully palpated to exclude a residual mass. In most cases however imaging has been performed prior to a needle being introduced into the breast and indeed the majority of cysts are now aspirated under ultrasound guidance. If a mass was noted on initial ultrasound or there is a residual mass post-aspiration then a tissue specimen is obtained usually by core biopsy. When cystic fluid is bloodstained, fluid can be sent for cytologic examination. A simple cyst is rarely of concern, but a complex cyst may be the result of an underlying malignancy. A pneumocystogram can be obtained by injecting air into the cyst and then obtaining a repeat mammogram. When this technique is used, the wall of the cyst cavity can be more carefully assessed for any irregularities.

Fibroadenomas. Most fibroadenomas are self-limiting and many go undiagnosed, so a more conservative approach is reasonable. Careful ultrasound examination with core-needle biopsy will provide for an accurate diagnosis. Ultrasonography may reveal specific features that are pathognomonic for fibroadenoma and in a young woman (e.g., under 25 years) where the risk of breast cancer is already very low a core-needle biopsy may not be necessary. In patients where biopsy is performed, the patient is counseled concerning the ultrasound and biopsy results, and surgical excision of the fibroadenoma may be avoided. Cryoablation and ultrasound-guided vacuum assisted biopsy are approved treatments for fibroadenomas of the breast, especially lesions <3 cm. Larger lesions are often still best removed by excision. With short-term follow-up a significant percentage of fibroadenomas will decrease in size and will no longer be palpable.[38] However, many will remain palpable, especially those larger than 2 cm.[39] Therefore, women should be counseled that the options for treatment include surgical removal, cryoablation, vacuum assisted biopsy, or observation.

Sclerosing Disorders. The clinical significance of sclerosing adenosis lies in its imitation of cancer. On physical examination, it may be confused with cancer, by mammography, and at gross pathologic examination. Excisional biopsy and histologic examination are frequently necessary to exclude the diagnosis of cancer. The diagnostic work-up for radial scars and complex

sclerosing lesions frequently involves stereotactic biopsy. It usually is not possible to differentiate these lesions with certainty from cancer by mammographic features, so a larger tissue biopsy is recommended either by way of vacuum assisted biopsy or an open surgical excisional biopsy. The mammographic appearance of a radial scar or sclerosing adenosis (mass density with spiculated margins) will usually lead to an assessment that the results of a core-needle biopsy specimen showing benign disease are discordant with the radiographic findings.

Periductal Mastitis. Painful and tender masses behind the nipple-areola complex are aspirated with a 21-gauge needle attached to a 10-mL syringe. Any fluid obtained is submitted for culture using a transport medium appropriate for the detection of anaerobic organisms. In the absence of pus, women are started on a combination of metronidazole and dicloxacillin while awaiting the results of culture. Antibiotics are then continued based on sensitivity tests. Many cases respond satisfactorily to antibiotics alone, but when considerable purulent material is present, repeated ultrasound guided aspiration is performed and ultimately in a proportion of cases surgical treatment is required. Unlike puerperal abscesses, a subareolar abscess is usually unilocular and often is associated with a single duct system. Ultrasound will accurately delineate its extent. In those cases which come to surgery, the surgeon may either undertake simple drainage with a view toward formal surgery, should the problem recur, or proceed with definitive surgery. In a woman of childbearing age, simple drainage is preferred, but if there is an anaerobic infection, recurrent infection frequently develops. Recurrent abscess with fistula is a difficult problem. Treatment of periductal fistula was initially recommended to be opening up of the fistulous track and allowing it to granulate.[40] This approach may still be used especially if the fistula is recurrent after previous attempts at fistulectomy. However, nowadays the preferred initial surgical treatment is by fistulectomy and primary closure with antibiotic coverage.[41] Excision of all the major ducts is an alternative option depending on the circumstances (Table 17-5). When a localized periareolar abscess recurs at the previous site and a fistula is present, the preferred operation is fistulectomy, which has minimal complications and a high degree of success. However, when subareolar sepsis is diffuse rather than localized to one segment or when more than one fistula is present, total duct excision is the most expeditious approach. The first circumstance is seen in young women with squamous metaplasia of a single duct, whereas the latter circumstance is seen in older women with multiple ectatic ducts. Age is not always a reliable guide, however, and fistula excision is the preferred initial procedure for localized sepsis irrespective of age. Antibiotic therapy is useful for recurrent infection after fistula excision, and a 2- to 4-week course is recommended before total duct excision.

Table 17-5

Treatment of recurrent subareolar sepsis

SUITABLE FOR FISTULECTOMY	SUITABLE FOR TOTAL DUCT EXCISION
Small abscess localized to one segment	Large abscess affecting >50% of the areolar circumference
Recurrence involving the same segment	Recurrence involving a different segment
Mild or no nipple inversion	Marked nipple inversion
Patient unconcerned about nipple inversion	Patient requests correction of nipple inversion
Younger patient	Older patient
No discharge from other ducts	Purulent discharge from other ducts
No prior fistulectomy	Recurrence after fistulectomy

Nipple Inversion. More women request correction of congenital nipple inversion than request correction for the nipple inversion that occurs secondary to duct ectasia. Although the results are usually satisfactory, women seeking correction for cosmetic reasons should always be made aware of the surgical complications of altered nipple sensation, nipple necrosis, and postoperative fibrosis with nipple retraction. Because nipple inversion is a result of shortening of the subareolar ducts, a complete division of these ducts is necessary for permanent correction of the disorder.

RISK FACTORS FOR BREAST CANCER

Hormonal and Nonhormonal Risk Factors

Increased exposure to estrogen is associated with an increased risk for developing breast cancer, whereas reducing exposure is thought to be protective.[42-48] Correspondingly, factors that increase the number of menstrual cycles, such as early menarche, nulliparity, and late menopause, are associated with increased risk. Moderate levels of exercise and a longer lactation period, factors that decrease the total number of menstrual cycles, are protective. The terminal differentiation of breast epithelium associated with a full-term pregnancy is also protective, so older age at first live birth is associated with an increased risk of breast cancer. Finally, there is an association between obesity and increased breast cancer risk. Because the major source of estrogen in postmenopausal women is the conversion of androstenedione to estrone by adipose tissue, obesity is associated with a long-term increase in estrogen exposure.

Nonhormonal risk factors include radiation exposure. Young women who receive mantle radiation therapy for Hodgkin's lymphoma have a breast cancer risk that is 75 times greater than that of age-matched control subjects. Survivors of the atomic bomb blasts in Japan during World War II have a very high incidence of breast cancer, likely because of somatic mutations induced by the radiation exposure. In both circumstances, radiation exposure during adolescence, a period of active breast development, magnifies the deleterious effect. Studies also suggest that the risk of breast cancer increases as the amount of alcohol a woman consumes increases.[49] Alcohol consumption is known to increase serum levels of estradiol. Finally, evidence suggests that long-term consumption of foods with a high fat content contributes to an increased risk of breast cancer by increasing serum estrogen levels.

Risk Assessment Models

The average lifetime risk of breast cancer for newborn U.S. females is 12%.[50,51] The longer a woman lives without cancer,

the lower her risk of developing breast cancer. Thus, a woman aged 50 years has an 11% lifetime risk of developing breast cancer, and a woman aged 70 years has a 7% lifetime risk of developing breast cancer. Because risk factors for breast cancer interact, evaluating the risk conferred by combinations of risk factors is difficult. There are several risk assessment models available to predict the risk of breast cancer. From the Breast Cancer Detection Demonstration Project, a mammography screening program conducted in the 1970s, Gail et al developed the model most frequently used in the United States, which incorporates age, age at menarche, age at first live birth, the number of breast biopsy specimens, any history of atypical hyperplasia, and number of first-degree relatives with breast cancer.[52] It predicts the cumulative risk of breast cancer according to decade of life. To calculate breast cancer risk using the Gail model, a woman's risk factors are translated into an overall risk score by multiplying her relative risks from several categories (Table 17-6). This risk score is then compared to an adjusted population risk of breast cancer to determine a woman's individual or absolute risk. The output is a five-year risk and a lifetime risk of developing breast cancer. A software program incorporating the Gail model is available from the National Cancer Institute at *http://bcra.nci.nih.gov/brc*. This model was recently modified to more accurately assess risk in African American women.[52,53] The Gail model is the most widely used model in the United States. Gail and colleagues have also described a revised model that includes body weight and mammographic density but excludes age at menarche.[54]

5▶

Claus et al, using data from the Cancer and Steroid Hormone Study, a case-control study of breast cancer, developed the other frequently used risk assessment model, which is based on assumptions about the prevalence of high-penetrance breast cancer susceptibility genes.[55] Compared with the Gail model, the Claus model incorporates more information about family history but excludes other risk factors. The Claus model provides individual estimates of breast cancer risk according to decade of life based on presence of first- and second-degree relatives with breast cancer and their age at diagnosis. Risk factors that are less consistently associated with breast cancer (diet, use of oral contraceptives, lactation) or are rare in the general population (radiation exposure) are not included in either the Gail or Claus risk assessment model. Other models have been proposed that account for mammographic breast density in assessing breast cancer risk.[54,56]

Neither the Gail model nor the Claus model accounts for the risk associated with mutations in the breast cancer susceptibility genes *BRCA1* and *BRCA2* (*described in detail below*). The BRCAPRO model is a Mendelian model that calculates the probability that an individual is a carrier of a mutation in one of the breast cancer susceptibility genes based on their family history of breast and ovarian cancer.[57] The probability that an individual will develop breast or ovarian cancer is derived from this mutation probability based on age-specific incidence curves for both mutation carriers and noncarriers.[58] Use of the BRCAPRO model in the clinic is challenging since it requires input of all family history information regarding breast and ovarian cancer. The Tyrer-Cuzick model attempts to utilize both family history information and individual risk information. It uses the family history to calculate the probability that an individual carries a mutation in one of the breast cancer susceptibility genes and then the risk is adjusted based on personal risk factors, including age at menarche, parity, age at first live birth, age at menopause, history of atypical hyperplasia or LCIS, height and body mass index.[59] Once a risk model has been utilized to assess breast cancer risk, this must be communicated to the individual and put into context with competing risk and medical comorbidities. This information can then be used to discuss options that are available to the individual for managing risk.

Table 17-6

Relative risk estimates for the Gail model

VARIABLE	RELATIVE RISK
Age at menarche (years)	
≥14	1.00
12–13	1.10
<12	1.21
Number of biopsy specimens/history of benign breast disease, age <50 y	
0	1.00
1	1.70
≥2	2.88
Number of biopsy specimens/history of benign breast disease, age ≥50 y	
0	1.02
1	1.27
≥2	1.62
Age at first live birth (years)	
<20 y	
Number of first-degree relatives with history of breast cancer	
0	1.00
1	2.61
≥2	6.80
20–24 y	
Number of first-degree relatives with history of breast cancer	
0	1.24
1	2.68

Risk Management

Several important medical decisions may be affected by a woman's underlying risk of developing breast cancer.[60-68] These decisions include when to use postmenopausal hormone replacement therapy, at what age to begin mammography screening or incorporate magnetic resonance imaging (MRI) screening, when

to use tamoxifen to prevent breast cancer, and when to perform prophylactic mastectomy to prevent breast cancer. Postmenopausal hormone replacement therapy was widely prescribed in the 1980s and 1990s because of its effectiveness in controlling the symptoms of estrogen deficiency; namely, vasomotor symptoms such as hot flashes, night sweats and their associated sleep deprivation, osteoporosis, and cognitive changes. Furthermore, these hormone supplements were thought to reduce coronary artery disease as well. Use of combined estrogen and progesterone became standard for women who had not undergone hysterectomy, because unopposed estrogen increases the risk of uterine cancer. Concerns of prolonging a woman's lifetime exposure to estrogen, coupled with conflicting data regarding the impact of these hormones on cardiovascular health, motivated the implementation of large-scale phase III clinical trials to definitively evaluate the risks vs. benefits of postmenopausal hormone replacement therapy. The Women's Health Initiative was therefore designed by the National Institutes of Health as a series of clinical trials to study the effects of diet, nutritional supplements, and hormones on the risk of cancer, cardiovascular disease, and bone health in postmenopausal women. Findings from primary studies of postmenopausal hormone replacement therapy were released in 2002, demonstrating conclusively that breast cancer risk is threefold to fourfold higher after >4 years of use and there is no significant reduction in coronary artery or cerebrovascular risks. The Collaborative Group on Hormonal Factors in Breast Cancer combined and re-analyzed data from a number of studies totaling 52,705 women with breast cancer and 108,411 women without breast cancer. They found an increased risk of breast cancer with ever use of estrogen replacement therapy. They also reported increased risk among current users but not past users and risk increased with increasing duration of use of hormone replacement therapy.[69] Cheblowski et al also reported from the WHI study that estrogen + progesterone increased the incidence of breast cancer.[70] This was confirmed by the Million Women study which also showed that the increased risk was substantially greater for the combined estrogen + progesterone replacement therapy than other types of hormone replacement therapy.[71]

Breast Cancer Screening. Routine use of screening mammography in women ≥50 years of age has been reported to reduce mortality from breast cancer by 25%.[72] This reduction comes at an acceptable economic cost. More recently, there has been debate over the potential harms associated with breast screening.[73] As a result the United Kingdom recently established an independent expert panel to review the published literature and estimate the benefits and harms associated with screening women >50 years in its national screening program.[74] The expert panel estimated that an invitation to breast screening delivers about a 20% reduction in breast cancer mortality while at the same time the panel estimated that in women invited to screening, about 11% of the cancers diagnosed in their lifetime constitute over-diagnosis. Despite the overdiagnosis, the panel concluded that breast screening confers significant benefit and should continue. The use of screening mammography in women <50 years of age is more controversial for several reasons: (a) breast density is greater and screening mammography is less likely to detect early breast cancer (i.e., reduced sensitivity); (b) screening mammography results in more false-positive test findings (i.e., reduced specificity), which results in unnecessary biopsy specimens; and (c) younger women are less likely to have breast cancer (i.e., lower incidence), so fewer young women will benefit from screening.[75,76] In the United States, on a population basis, however, the benefits of screening mammography in women between the ages of 40 and 49 years is still felt to outweigh the risks; although targeting mammography to women at higher risk of breast cancer improves the balance of risks and benefits and is the approach some health care systems have taken. In one study of women aged 40 to 49 years, an abnormal mammography finding was three times more likely to be cancer in a woman with a family history of breast cancer than in a woman without such a history. Furthermore, as noted previously in the section *Risk Assessment Models*, mounting data regarding mammographic breast density demonstrate an independent correlation with breast cancer risk. Incorporation of breast density measurements into breast cancer risk assessment models appears to be a promising strategy for increasing the accuracy of these tools. Unfortunately, widespread application of these modified models is hampered by inconsistencies in the reporting of mammographic density. Ultrasonography can also be used for breast cancer screening in women with dense breasts but there is no data available that the additional cancers detected with this modality reduce mortality from breast cancer.

Current recommendations by the United States Preventive Services Task Force are that women undergo biennial mammographic screening between the ages of 50 and 74 years.[77] The American Cancer Society (ACS) continues to recommend annual mammography for women beginning at age 40 years to continue as long as she is in good health. In addition, a clinical breast examination by a health professional is recommended annually. The use of MRI for breast cancer screening is recommended by the ACS for women with a 20% to 25% or greater lifetime risk using risk assessment tools based mainly on family history, BRCA mutation carriers, those individuals who have a family member with a BRCA mutation who have not been tested themselves, individuals who received radiation to the chest between the ages of 10 to 30 years, and those individuals with a history of Li-Fraumeni syndrome, Cowden syndrome, or Bannayan-Riley-Ruvalcaba syndrome or those who have a first-degree relative with one of these syndromes. MRI is an extremely sensitive screening tool that is not limited by the density of the breast tissue as mammography is, however, its specificity is moderate leading to more false-positive events and the increased need for biopsy.

Chemoprevention. Tamoxifen, a selective estrogen receptor modulator, was the first drug shown to reduce the incidence of breast cancer in healthy women. There have been 4 prospective studies published evaluating tamoxifen vs. placebo for reducing the incidence of invasive breast cancer for women at increased risk. The largest trial was the Breast Cancer Prevention Trial (NSABP P-01) which randomly assigned >13,000 women with a 5-year Gail relative risk of breast cancer of 1.66% or higher or LCIS to receive tamoxifen or placebo. After a mean follow-up period of 4 years, the incidence of breast cancer was reduced by 49% in the group receiving tamoxifen.[60] The decrease was evident only in ER-positive breast cancers with no significant change in ER-negative tumors. The Royal Marsden Hospital Tamoxifen Chemoprevention Trial[78], the Italian Tamoxifen Prevention Trial[79], and the International Breast Cancer Intervention Study I (IBIS-I) trial all[80] showed a reduction in ER-positive breast cancers with the use of tamoxifen compared with placebo. There was no effect on mortality; however, the trials were not powered to assess either breast cancer mortality or all-cause mortality events. The adverse events were similar in all

4 randomized trials including an increased risk of endometrial cancer, thromboembolic events, cataract formation, and vasomotor disturbances in individuals receiving tamoxifen.

Tamoxifen therapy currently is recommended only for women who have a Gail relative risk of 1.66% or higher, who are aged 35 to 59, women over the age of 60 or women with a diagnosis of LCIS or atypical ductal or lobular hyperplasia. In addition, deep vein thrombosis occurs 1.6 times as often, pulmonary emboli 3.0 times as often, and endometrial cancer 2.5 times as often in women taking tamoxifen. The increased risk for endometrial cancer is restricted to early stage cancers in postmenopausal women. Cataract surgery is required almost twice as often among women taking tamoxifen. Gail et al subsequently developed a model that accounts for underlying risk of breast cancer as well as comorbidities to determine the net risk-benefit ratio of tamoxifen use for chemoprevention.[81]

The NSABP completed a second chemoprevention trial, designed to compare tamoxifen and raloxifene for breast cancer risk reduction in high-risk postmenopausal women. Raloxifene, another selective estrogen receptor modulator, was selected for the experimental arm in this follow-up prevention trial because its use in managing postmenopausal osteoporosis suggested that it might be even more effective at breast cancer risk reduction, but without the adverse effects of tamoxifen on the uterus. The P-2 trial, the Study of Tamoxifen and Raloxifene (known as the *STAR trial*), randomly assigned 19,747 postmenopausal women at high-risk for breast cancer to receive either tamoxifen or raloxifene. The initial report of the P-2 trial showed the two agents were nearly identical in their ability to reduce breast cancer risk, but raloxifene was associated with a more favorable adverse event profile.[82] An updated analysis revealed that raloxifene maintained 76% of the efficacy of tamoxifen in prevention of invasive breast cancer with a more favorable side effect profile. The risk of developing endometrial cancer was significantly higher with tamoxifen use at longer follow-up.[83] Although tamoxifen has been shown to reduce the incidence of LCIS and DCIS, raloxifene did not have an effect on the frequency of these diagnoses.

Aromatase inhibitors (AIs) have been shown to be more effective than tamoxifen in reducing the incidence of contralateral breast cancers in postmenopausal women receiving AIs for adjuvant treatment of invasive breast cancer. The MAP.3 trial was the first study to evaluate an AI as a chemopreventive agent in postmenopausal women at high risk for breast cancer. The trial randomized 4,560 women to exemestane 25 mg daily vs. placebo for five years. After a median follow-up of 35 months, exemestane was shown to reduce invasive breast cancer incidence by 65%. Side effect profiles demonstrated more grade 2 or higher arthritis and hot flashes in patients taking exemestane.[84] The IBIS II trial has recruited 6,000 patients randomized to the non-steroidal aromatase inhibitor, anastrozole, vs. placebo with a further randomization to bisphosphonate or not based on bone density.[85] The trial also had an initial sub-study which looked at the effect of the aromatase inhibitor on cognitive function and reported no adverse effects.[86] The American Society of Clinical Oncology recently updated recommendations for chemoprevention in women at increased risk of breast cancer as did the U.S. Preventive Services Task Force. Both groups recommend offering tamoxifen to women at increased risk for breast cancer or raloxifene to postmenopausal women who are noted to be at increased risk.[87,88] The discussion with an individual patient should include risk assessment and potential risks and benefits with each agent.

Risk-reducing Surgery. A retrospective study of women at high risk for breast cancer found that prophylactic mastectomy reduced their risk by >90%.[62] However, the effects of prophylactic mastectomy on the long-term quality of life are poorly quantified. A study involving women who were carriers of a breast cancer susceptibility gene (BRCA) mutation found that the benefit of prophylactic mastectomy differed substantially according to the breast cancer risk conferred by the mutations. For women with an estimated lifetime risk of 40%, prophylactic mastectomy added almost 3 years of life, whereas for women with an estimated lifetime risk of 85%, prophylactic mastectomy added >5 years of life.[66] Domchek et al evaluated a cohort of BRCA1/2 mutation carriers who were followed prospectively and reported on outcomes with risk-reducing surgery.[89] They found that risk-reducing mastectomy was highly effective at preventing breast cancer in both BRCA1 and 2 mutation carriers. Risk-reducing salpingo-oophorectomy was highly effective at reducing the incidence of ovarian cancer and breast cancer in BRCA mutation carriers and was associated with a reduction in breast cancer-specific mortality, ovarian cancer-specific mortality, and all-cause mortality. While studies of bilateral prophylactic or risk-reducing mastectomy have reported dramatic reductions in breast cancer incidence among those without known BRCA mutations, there is little data to support a survival benefit. Another consideration is that while most patients are satisfied with their decision to pursue risk-reducing surgery, some are dissatisfied with the cosmetic outcomes mostly due to reconstructive issues.

BRCA Mutations

BRCA1. Up to 5% of breast cancers are caused by inheritance of germline mutations such as *BRCA1* and *BRCA2*, which are inherited in an autosomal dominant fashion with varying degrees of penetrance (Table 17-7).[90-96] *BRCA1* is located on chromosome arm 17q, spans a genomic region of approximately 100 kilobases (kb) of DNA, and contains 22 coding exons for 1863 amino acids. Both *BRCA1* and *BRCA2* function as tumor-suppressor genes, and for each gene, loss of both alleles is required for the initiation of cancer. Data accumulated since the isolation of the *BRCA1* gene suggest a role in transcription,

Table 17-7

Incidence of sporadic, familial, and hereditary breast cancer

Sporadic breast cancer	65%–75%
Familial breast cancer	20%–30%
Hereditary breast cancer	5%–10%
BRCA1[a]	45%
BRCA2	35%
p53[a] (Li-Fraumeni syndrome)	1%
STK11/LKB1[a] (Peutz-Jeghers syndrome)	<1%
PTEN[a] (Cowden disease)	<1%
MSH2/MLH1[a] (Muir-Torre syndrome)	<1%
ATM[a] (Ataxia-telangiectasia)	<1%
Unknown	20%

[a]Affected gene.
Source: Adapted from Martin.[92]

cell-cycle control, and DNA damage repair pathways. More than 500 sequence variations in *BRCA1* have been identified. It now is known that germline mutations in *BRCA1* represent a predisposing genetic factor in as many as 45% of hereditary breast cancers and in at least 80% of hereditary ovarian cancers. Female mutation carriers have been reported to have up to a 85% lifetime risk (for some families) for developing breast cancer and up to a 40% lifetime risk for developing ovarian cancer. The initial families reported had high penetrance and subsequently the average lifetime risk has been reported to lie between 60%–70%. Breast cancer susceptibility in these families appears as an autosomal dominant trait with high penetrance. Approximately 50% of children of carriers inherit the trait. In general, *BRCA1*-associated breast cancers are invasive ductal carcinomas, are poorly differentiated, are in the majority hormone receptor negative and have a triple receptor negative (immunohistochemical profile: ER-negative, PR-negative and *HER-2*-negative) or basal phenotype (based on gene expression profiling). *BRCA1*-associated breast cancers have a number of distinguishing clinical features, such as an early age of onset compared with sporadic cases; a higher prevalence of bilateral breast cancer; and the presence of associated cancers in some affected individuals, specifically ovarian cancer and possibly colon and prostate cancers.

Several founder mutations have been identified in *BRCA1*. The two most common mutations are 185delAG and 5382insC, which account for 10% of all the mutations seen in *BRCA1*. These two mutations occur at a 10-fold higher frequency in the Ashkenazi Jewish population than in non-Jewish caucasians. The carrier frequency of the 185delAG mutation in the Ashkenazi Jewish population is 1% and, along with the 5382insC mutation, accounts for almost all *BRCA1* mutations in this population. Analysis of germline mutations in Jewish and non-Jewish women with early-onset breast cancer indicates that 20% of Jewish women who develop breast cancer before age 40 years carry the 185delAG mutation. There are founder BRCA1 mutations in other populations including, among others, Dutch, Polish, Finnish, and Russian populations.[97-101]

BRCA2. *BRCA2* is located on chromosome arm 13q and spans a genomic region of approximately 70 kb of DNA. The 11.2-kb coding region contains 26 coding exons.[90-96] It encodes a protein of 3418 amino acids. The *BRCA2* gene bears no homology to any previously described gene, and the protein contains no previously defined functional domains. The biologic function of *BRCA2* is not well defined, but like *BRCA1*, it is postulated to play a role in DNA damage response pathways. *BRCA2* messenger RNA also is expressed at high levels in the late G_1 and S phases of the cell cycle. The kinetics of *BRCA2* protein regulation in the cell cycle is similar to that of *BRCA1* protein, which suggests that these genes are coregulated. The mutational spectrum of *BRCA2* is not as well established as that of *BRCA1*. To date, >250 mutations have been found. The breast cancer risk for *BRCA2* mutation carriers is close to 85%, and the lifetime ovarian cancer risk, while lower than for *BRCA1*, is still estimated to be close to 20%. Breast cancer susceptibility in *BRCA2* families is an autosomal dominant trait and has a high penetrance. Approximately 50% of children of carriers inherit the trait. Unlike male carriers of *BRCA1* mutations, men with germline mutations in *BRCA2* have an estimated breast cancer risk of 6%, which represents a 100-fold increase over the risk in the general male population. *BRCA2*-associated breast cancers are invasive ductal carcinomas, which are more likely to be well differentiated and to express hormone receptors than are *BRCA1*-associated breast cancers. *BRCA2*-associated breast cancer has a number of distinguishing clinical features, such as an early age of onset compared with sporadic cases, a higher prevalence of bilateral breast cancer, and the presence of associated cancers in some affected individuals, specifically ovarian, colon, prostate, pancreatic, gallbladder, bile duct, and stomach cancers, as well as melanoma. A number of founder mutations have been identified in *BRCA2*. The 6174delT mutation is found in Ashkenazi Jews with a prevalence of 1.2% and accounts for 60% of ovarian cancer and 30% of early-onset breast cancer patients among Ashkenazi women.[102] Another *BRCA2* founder mutation, 999del5, is observed in Icelandic and Finnish populations while more recently 3036delACAA has been observed in a number of Spanish families.[103-105]

Identification of BRCA Mutation Carriers. Identifying hereditary risk for breast cancer is a four-step process that includes: (a) obtaining a complete, multigenerational family history, (b) assessing the appropriateness of genetic testing for a particular patient, (c) counseling the patient, and (d) interpreting the results of testing.[106] Genetic testing should not be offered in isolation, but only in conjunction with patient education and counseling, including referral to a genetic counselor. Initial determinations include whether the individual is an appropriate candidate for genetic testing and whether genetic testing will be informative for personal and clinical decision making. A thorough and accurate family history is essential to this process, and the maternal and paternal sides of the family are both assessed, because 50% of the women with a *BRCA* mutation have inherited the mutation from their fathers. To help clinicians advise women about genetic testing, statistically based models that determine the probability that an individual carries a *BRCA* mutation have been developed. A method for calculating carrier probability which has been demonstrated to have acceptable performance (i.e., both in terms of calibration and discrimination) such as the Manchester scoring system and BODICEA should be used to offer referral to a specialist genetic clinic. A hereditary risk of breast cancer is considered if a family includes Ashkenazi Jewish heritage; a first-degree relative with breast cancer before age 50; a history of ovarian cancer at any age in the patient or first- or second-degree relative with ovarian cancer; breast and ovarian cancer in the same individual; two or more first- or second-degree relatives with breast cancer at any age; patient or relative with bilateral breast cancer; and male breast cancer in a relative at any age.[107] The threshold for genetic testing is lower in individuals who are members of ethnic groups in whom the mutation prevalence is increased.

BRCA Mutation Testing. Appropriate counseling for the individual being tested for a *BRCA* mutation is strongly recommended, and documentation of informed consent is required.[106,108] The test that is clinically available for analyzing *BRCA* mutations is gene sequence analysis. In a family with a history suggestive of hereditary breast cancer and no previously tested member, the most informative strategy is first to test an affected family member. This person undergoes complete sequence analysis of both the *BRCA1* and *BRCA2* genes. If a mutation is identified, relatives are usually tested only for that specific mutation. An individual of Ashkenazi Jewish ancestry is tested initially for the three specific mutations that account for hereditary breast and ovarian cancer in that population.

If results of that test are negative, it may then be appropriate to fully analyze the *BRCA1* and *BRCA2* genes.

A positive test result is one that discloses the presence of a *BRCA* mutation that interferes with translation or function of the *BRCA* protein. A woman who carries a deleterious mutation has a breast cancer risk of up to 85% (in some families) as well as a greatly increased risk of ovarian cancer. A negative test result is interpreted according to the individual's personal and family history, especially whether a mutation has been previously identified in the family, in which case the woman is generally tested only for that specific mutation. If the mutation is not present, the woman's risk of breast or ovarian cancer may be no greater than that of the general population. In addition, no *BRCA* mutation can be passed on to the woman's children. In the absence of a previously identified mutation, a negative test result in an affected individual generally indicates that a *BRCA* mutation is not responsible for the familial cancer. However, the possibility remains of an unusual abnormality in one of these genes that cannot yet be identified through clinical testing. It also is possible that the familial cancer is indeed caused by an identifiable *BRCA* mutation but that the individual tested had sporadic cancer, a situation known as *phenocopy*. This is especially possible if the individual tested developed breast cancer close to the age of onset of the general population (age 60 years or older) rather than before age 50 years, as is characteristic of *BRCA* mutation carriers. Overall, the false-negative rate for *BRCA* mutation testing is <5%. Some test results, especially when a single base-pair change (missense mutation) is identified, may be difficult to interpret. This is because single base-pair changes do not always result in a nonfunctional protein. Thus, missense mutations not located within critical functional domains, or those that cause only minimal changes in protein structure, may not be disease associated and are usually reported as indeterminate results. In communicating indeterminate results to women, care must be taken to relay the uncertain cancer risk associated with this type of mutation and to emphasize that ongoing research might clarify its meaning. In addition, testing other family members with breast cancer to determine if a genetic variant tracks with their breast cancer may provide clarification as to its significance. Indeterminate genetic variance currently accounts for 12% of the test results.

Concern has been expressed that the identification of hereditary risk for breast cancer may interfere with access to affordable health insurance. This concern refers to discrimination directed against an individual or family based solely on an apparent or perceived genetic variation from the normal human genotype. The Health Insurance Portability and Accountability Act of 1996 (HIPAA) made it illegal in the United States for group health plans to consider genetic information as a preexisting condition or to use it to deny or limit coverage. Most states also have passed laws that prevent genetic discrimination in the provision of health insurance. In addition, individuals applying for health insurance are not required to report whether relatives have undergone genetic testing for cancer risk, only whether those relatives have actually been diagnosed with cancer. Currently there is little documented evidence of genetic discrimination resulting from findings of available genetic tests.

Cancer Prevention for BRCA Mutation Carriers. Risk management strategies for *BRCA1* and *BRCA2* mutation carriers include the following:

1. Risk-reducing mastectomy and reconstruction
2. Risk-reducing salpingo-oophorectomy
3. Intensive surveillance for breast and ovarian cancer
4. Chemoprevention

Although removal of breast tissue reduces the likelihood that *BRCA1* and *BRCA2* mutation carriers will develop breast cancer, mastectomy does not remove all breast tissue and women continue to be at risk because a germline mutation is present in any remaining breast tissue. For postmenopausal *BRCA1* and *BRCA2* mutation carriers who have not had a mastectomy, it may be advisable to avoid hormone replacement therapy, because no data exist regarding the effect of the therapy on the penetrance of breast cancer susceptibility genes. Because breast cancers in *BRCA* mutation carriers have the same mammographic appearance as breast cancers in noncarriers, a screening mammogram is likely to be effective in *BRCA* mutation carriers, provided it is performed and interpreted by an experienced radiologist with a high level of suspicion. Present screening recommendations for *BRCA* mutation carriers who do not undergo risk-reducing mastectomy include clinical breast examination every 6 months and mammography every 12 months beginning at age 25 years, because the risk of breast cancer in *BRCA* mutation carriers increases after age 30 years. Recent attention has been focused on the use MRI for breast cancer screening in high-risk individuals and known *BRCA* mutation carriers. MRI appears to be more sensitive at detecting breast cancer in younger women with dense breasts.[109] However, as noted previously, MRI does lead to the detection of benign breast lesions that cannot easily be distinguished from malignancy, and these false-positive events can result in more interventions, including biopsy specimens. The current recommendations from the American Cancer Society are for annual MRI in women with a 20% to 25% or greater lifetime risk of developing breast cancer, including women with a strong family history of breast or ovarian cancer and women who were treated for Hodgkin's disease in their teens or early twenties.[110] Despite a 49% reduction in the overall incidence of breast cancer and a 69% reduction in the incidence of estrogen receptor positive tumors in high-risk women taking tamoxifen reported in the NSABP P1 trial, there is insufficient evidence to recommend the use of tamoxifen uniformly for *BRCA*1 mutation carriers.[60] Cancers arising in *BRCA1* mutation carriers are usually high grade and are most often hormone receptor negative. Approximately 66% of *BRCA1*-associated DCIS lesions are estrogen receptor negative, which suggests early acquisition of the hormone-independent phenotype. In the NSABP P1 trial there was a 62% reduction in the incidence of breast cancer in BRCA2 carriers, similar to the overall reduction seen in the P1 trial. In contrast, there was no reduction seen in breast cancer incidence in BRCA1 carriers who started tamoxifen in P1 age 35 years or older.[111] Tamoxifen appears to be more effective at preventing estrogen receptor-positive breast cancers.

The risk of ovarian cancer in *BRCA1* and *BRCA2* mutation carriers ranges from 20% to 40%, which is 10 times higher than that in the general population. Risk-reducing salpingo-oophorectomy is a reasonable prevention option in mutation carriers. In women with a documented *BRCA1* or *BRCA2* mutation, consideration for bilateral risk-reducing salpingo-ophorectomy should be between the ages of 35 and 40 years at the completion of childbearing. Removing the ovaries reduces the risk of ovarian cancer and breast cancer when performed in premenopausal *BRCA* mutation carriers. Hormone replacement therapy is discussed with the patient at the time of oophorectomy. The Cancer Genetics Studies Consortium recommends yearly transvaginal

ultrasound timed to avoid ovulation and annual measurement of serum cancer antigen 125 levels beginning at age 25 years as the best screening modalities for ovarian carcinoma in *BRCA* mutation carriers who have opted to defer prophylactic surgery.

Other hereditary syndromes associated with an increased risk of breast cancer include Cowden disease (*PTEN* mutations, in which cancers of the thyroid, GI tract, and benign skin and subcutaneous nodules are also seen), Li-Fraumeni syndrome (p53 mutations, also associated with sarcomas, lymphomas, and adrenocortical tumors), and syndromes of breast and melanoma.

EPIDEMIOLOGY AND NATURAL HISTORY OF BREAST CANCER

Epidemiology

Breast cancer is the most common site-specific cancer in women and is the leading cause of death from cancer for women aged 20 to 59 years. It accounts for 29% of all newly diagnosed cancers in females and is responsible for 14% of the cancer-related deaths in women. It is predicted that approximately 234,580 breast cancers will be diagnosed in the United States in 2013 and that 40,030 individuals will die from breast cancer.[112] Breast cancer was the leading cause of cancer-related mortality in women until 1987, when it was surpassed by lung cancer. In the 1970s, the probability that a woman in the United States would develop breast cancer at some point in her lifetime was estimated at 1 in 13; in 1980 it was 1 in 11; and in 2004 it was 1 in 8. Cancer registries in Connecticut and upper New York State document that the age-adjusted incidence of new breast cancer cases had steadily increased since the mid-1940s. The incidence in the United States, based on data from nine Surveillance, Epidemiology, and End Results (SEER) registries, has been decreasing by 23% per year since 2000. The increase had been approximately 1% per year from 1973 to 1980, and there was an additional increase in incidence of 4% between 1980 and 1987, which was characterized by frequent detection of small primary cancers. The increase in breast cancer incidence occurred primarily in women ≥55 years and paralleled a marked increase in the percentage of older women who had mammograms taken. At the same time, incidence rates for regional metastatic disease dropped and breast cancer mortality declined. From 1960 to 1963, 5-year overall survival rates for breast cancer were 63% and 46% in white and African American women, respectively, whereas the rates for 1981 to 1983 were 78% and 64%, respectively. For 2002 to 2008 rates were 92% and 78%, respectively.

There is a 10-fold variation in breast cancer incidence among different countries worldwide. Cyprus and Malta have the highest age-adjusted mortality for breast cancer (29.6 per 100,000 population), whereas Haiti has the lowest (2.0 deaths per 100,000 population). The United States has an age-adjusted mortality for breast cancer of 19.0 cases per 100,000 population. Women living in less-industrialized nations tend to have a lower incidence of breast cancer than women living in industrialized countries, although Japan is an exception. In the United States, Mormons, Seventh Day Adventists, American Indians, Alaska natives, Hispanic/Latina Americans, and Japanese and Filipino women living in Hawaii have a below-average incidence of breast cancer, whereas nuns (due to nulliparity) and Ashkenazi Jewish women have an above-average incidence.

The incidence rates of breast cancer increased in most countries through the 1990s. Since the estimates for 1990, there was an overall increase in incidence rates of approximately 0.5% annually. It was predicted that there would be approximately 1.4 million new cases in 2010. The cancer registries in China have noted annual increases in incidence of up to 3% to 4%, and in eastern Asia, increases are similar.

Recent data from the SEER program reveal declines in breast cancer incidence over the past decade, and this is widely attributed to decreased use of hormone replacement therapy as a consequence of the Women's Health Initiative reports.[113]

Breast cancer burden has well-defined variations by geography, regional lifestyle, and racial or ethnic background.[114] In general, both breast cancer incidence and mortality are relatively lower among the female populations of Asia and Africa, relatively underdeveloped nations, and nations that have not adopted the Westernized reproductive and dietary patterns. In contrast, European and North American women and women from heavily industrialized or westernized countries have a substantially higher breast cancer burden. These international patterns are mirrored in breast cancer incidence and mortality rates observed for the racially, ethnically, and culturally diverse population of the United States.[115]

Although often related, the factors that influence breast cancer incidence may differ from those that affect mortality. Incidence rates are lower among populations that are heavily weighted with women who begin childbearing at young ages and who have multiple full-term pregnancies followed by prolonged lactation. These are features that characterize many underdeveloped nations and also many eastern nations. Breast cancer mortality rates should be lower in populations that have a lower incidence, but the mortality burden will simultaneously be adversely affected by the absence of effective mammographic screening programs for early detection and diminished access to multidisciplinary cancer treatment programs. These features are likely to account for much of the disproportionate mortality risks that are seen in underdeveloped nations. Similar factors probably account for differences in breast cancer burden observed among the various racial and ethnic groups within the United States. Interestingly, breast cancer incidence and mortality rates rise among second- and third-generation Asian Americans as they adopt Western lifestyles.

Disparities in breast cancer survival among subsets of the American population are generating increased publicity because they are closely linked to disparities in socioeconomic status. Poverty rates and proportions of the population that lack health care insurance are two to three times higher among minority racial and ethnic groups such as African Americans and Hispanic/Latino Americans. These socioeconomic disadvantages create barriers to effective breast cancer screening and result in delayed breast cancer diagnosis, advanced stage distribution, inadequacies in comprehensive treatment, and ultimately increased mortality rates. Furthermore, the rapid growth in the Hispanic population is accompanied by increasing problems in health education because of linguistic barriers between physicians and recently immigrated, non-English-speaking patients. Recent studies also are documenting inequities in the treatments delivered to minority breast cancer patients, such as increased rates of failure to provide systemic therapy, use of sentinel lymph node dissection, and breast reconstruction. Some of the treatment delivery disparities are related to inadequately controlled comorbidities (such as hypertension and diabetes), which are more prevalent in minority populations. However, some studies that adjust for these factors report persistent and unexplained

unevenness in treatment recommendations. It is clear that breast cancer disparities associated with racial or ethnic background have a multifactorial cause, and improvements in outcome will require correction of many public health problems at both the patient and provider levels.

Advances in the ability to characterize breast cancer subtypes and the genetics of the disease are now provoking speculation regarding possible hereditary influences on breast cancer risk that are related to racial or ethnic ancestry.[116] These questions become particularly compelling when one looks at disparities in breast cancer burden between African Americans and Caucasians. Lifetime risk of breast cancer is lower for African Americans, yet a paradoxically increased breast cancer mortality risk also is seen. African Americans also have a younger age distribution for breast cancer; among women <45 years of age, breast cancer incidence is highest among African Americans compared to other subsets of the American population. Lastly and most provocatively, African American women of all ages have notably higher incidence rates for estrogen receptor-negative tumors. These same patterns of disease are seen in contemporary female populations of western, sub-Saharan Africa, who are likely to share ancestry with African American women as a consequence of the Colonial-era slave trade. Interestingly, male breast cancer also is seen with increased frequency among both African Americans and Africans.

Natural History

Bloom and colleagues described the natural history of breast cancer based on the records of 250 women with untreated breast cancers who were cared for on charity wards in the Middlesex Hospital, London, between 1805 and 1933. The median survival of this population was 2.7 years after initial diagnosis (Fig. 17-13).[117] The 5- and 10-year survival rates for these women were 18.0% and 3.6%, respectively. Only 0.8% survived for 15 years or longer. Autopsy data confirmed that 95% of these women died of breast cancer, whereas the remaining 5% died of other causes. Almost 75% of the women developed ulceration of the breast during the course of the disease. The longest surviving patient died in the nineteenth year after diagnosis.

Natural history of untreated breast cancer [1803–1933]: Comparison of untreated and treated cases according to histological grade of malignancy.* Br Med J. *With permission from BMJ Publishing Group, Ltd.*)

Primary Breast Cancer. More than 80% of breast cancers show productive fibrosis that involves the epithelial and stromal tissues. With growth of the cancer and invasion of the surrounding breast tissues, the accompanying desmoplastic response entraps and shortens Cooper's suspensory ligaments to produce a characteristic skin retraction. Localized edema (peaud'orange) develops when drainage of lymph fluid from the skin is disrupted. With continued growth, cancer cells invade the skin, and eventually ulceration occurs. As new areas of skin are invaded, small satellite nodules appear near the primary ulceration. The size of the primary breast cancer correlates with disease-free and overall survival, but there is a close association between cancer size and axillary lymph node involvement (Fig. 17-14). In general, up to 20% of breast cancer recurrences are local-regional, >60% are distant, and 20% are both local-regional and distant.

Axillary Lymph Node Metastases. As the size of the primary breast cancer increases, some cancer cells are shed into cellular spaces and transported via the lymphatic network of the breast to the regional lymph nodes, especially the axillary lymph nodes. Lymph nodes that contain metastatic cancer are at first ill-defined and soft but become firm or hard with continued growth of the metastatic cancer. Eventually the lymph nodes adhere to each other and form a conglomerate mass. Cancer cells may grow through the lymph node capsule and fix to contiguous structures in the axilla, including the chest wall. Typically, axillary lymph nodes are involved sequentially from the low (level I) to the central (level II) to the apical (level III) lymph node groups. Approximately 95% of the women who die of breast cancer have distant metastases, and traditionally the most important prognostic correlate of disease-free and overall survival was axillary lymph node status (see Fig. 17-14A). Women with node-negative disease had less than a 30% risk of recurrence, compared with as much as a 75% risk for women with node-positive disease.

Distant Metastases. At approximately the twentieth cell doubling, breast cancers acquire their own blood supply (neovascularization). Thereafter, cancer cells may be shed directly into the systemic venous blood to seed the pulmonary circulation via the axillary and intercostal veins or the vertebral column via Batson's plexus of veins, which courses the length of the vertebral column. These cells are scavenged by natural killer lymphocytes and macrophages. Successful implantation of metastatic foci from breast cancer predictably occurs after the primary cancer exceeds 0.5 cm in diameter, which corresponds to the twenty-seventh cell doubling. For 10 years after initial treatment, distant metastases are the most common cause of death in breast cancer patients. For this reason, conclusive results cannot be derived from breast cancer trials until at least 5 to 10 years have elapsed. Although 60% of the women who develop distant metastases will do so within 60 months of treatment, metastases may become evident as late as 20 to 30 years after treatment of the primary cancer.[118] Patients with estrogen receptor negative breast cancers are proportionately more likely to develop

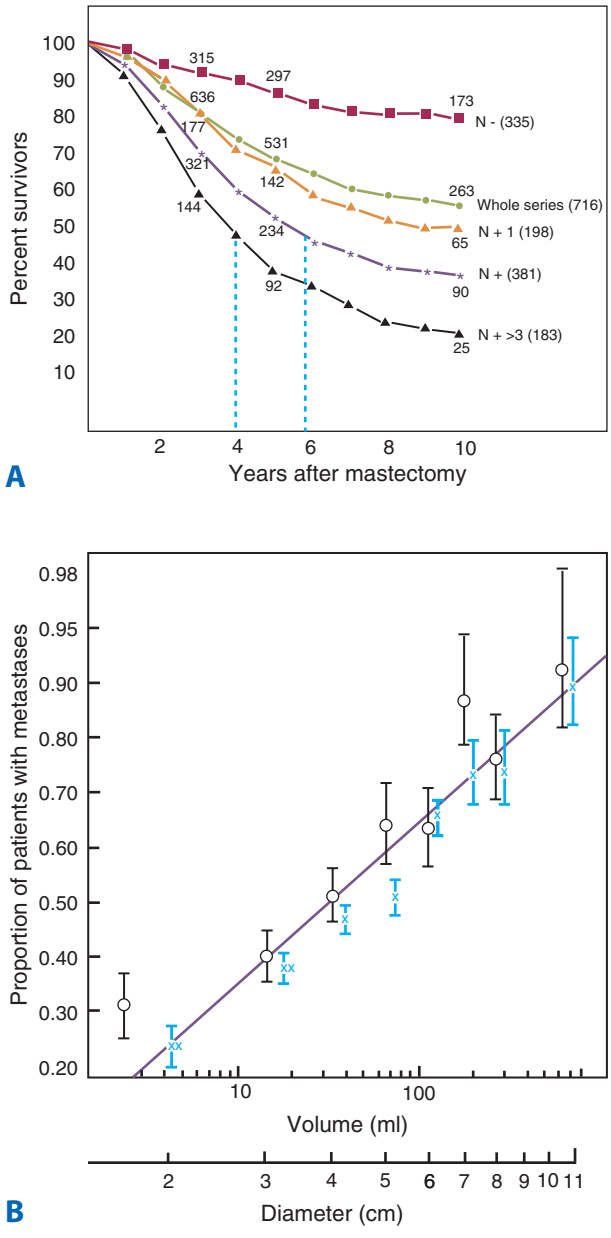

Figure 17-14. **A.** Overall survival for women with breast cancer according to axillary lymph node status. The time periods are years after radical mastectomy. recurrence in the first 3 to 5 years, whereas those with estrogen receptor positive tumors have a risk of developing recurrence which drops off more slowly beyond 5 years than is seen with ER negative tumors.[119] Recently a report showed that tumor size and nodal status remain powerful predictors of late recurrences compared to more recently developed tools such as the immunohistochemical score (IHC4) and two gene expression profile tests (Recurrence Score and PAM50).[120] Common sites of involvement, in order of frequency, are bone, lung, pleura, soft tissues, and liver. Brain metastases are less frequent overall although with the advent of adjuvant systemic therapies it has been reported that CNS disease may be seen earlier.[121,122] There are also reports of factors which are associated with the risk of developing brain metastases.[123] For example, they are more likely to be seen in patients with triple receptor negative breast cancer (ER-negative, PR-negative and HER2-negative) or patients with HER2-positive breast cancer who have received chemotherapy and HER2-directed therapies.

HISTOPATHOLOGY OF BREAST CANCER

Carcinoma In Situ

Cancer cells are in situ or invasive depending on whether or not they invade through the basement membrane.[124,125] Broders's original description of in situ breast cancer stressed the absence of invasion of cells into the surrounding stroma and their confinement within natural ductal and alveolar boundaries.[124] Because areas of invasion may be minute, the accurate diagnosis of in situ cancer necessitates the analysis of multiple microscopic sections to exclude invasion. In 1941, Foote and Stewart published a landmark description of LCIS, which distinguished it from DCIS.[125] In the late 1960s, Gallagher and Martin published their study of whole-breast sections and described a stepwise progression from benign breast tissue to in situ cancer and subsequently to invasive cancer. Before the widespread use of mammography, diagnosis of breast cancer was by physical examination. At that time, in situ cancers constituted <6% of all breast cancers, and LCIS was more frequently diagnosed than DCIS by a ratio of >2:1. However, when screening mammography became popular, a 14-fold increase in the incidence of in situ cancer (45%) was demonstrated, and DCIS was more frequently diagnosed than LCIS by a ratio of >2:1. Table 17-8 lists the clinical and pathologic characteristics of DCIS and LCIS. *Multicentricity* refers to the occurrence of a second breast cancer outside the breast quadrant of the primary cancer (or at least 4 cm away), whereas *multifocality* refers to the occurrence of a second cancer within the same breast quadrant as the primary cancer (or within 4 cm of it). Multicentricity occurs in 60% to 90% of women with LCIS, whereas the rate of multicentricity for DCIS is reported to be 40% to 80%. LCIS occurs bilaterally in 50% to 70% of cases, whereas DCIS occurs bilaterally in 10% to 20% of cases.

Lobular Carcinoma In Situ. LCIS originates from the terminal duct lobular units and develops only in the female breast. It is characterized by distention and distortion of the terminal duct lobular units by cells which are large but maintain a normal nuclear: cytoplasmic ratio. Cytoplasmic mucoid globules are a distinctive cellular feature. LCIS may be observed in breast tissues that contain microcalcifications, but the calcifications associated with LCIS typically occur in adjacent tissues. This neighborhood calcification is a feature that is unique to LCIS and contributes to its diagnosis. The frequency of LCIS in the general population cannot be reliably determined because it usually presents as an incidental finding. The average age at diagnosis is 45 years, which is approximately 15 to 25 years younger than the age at diagnosis for invasive breast cancer. LCIS has a distinct racial predilection, occurring 12 times more frequently

Table 17-8

Salient characteristics of in situ ductal (DCIS) and lobular (LCIS) carcinoma of the breast

	LCIS	DCIS
Age (years)	44–47	54–58
Incidence[a]	2%–5%	5%–10%
Clinical signs	None	Mass, pain, nipple discharge
Mammographic signs	None	Microcalcifications
Premenopausal	2/3	1/3
Incidence of synchronous invasive carcinoma	5%	2%–46%
Multicentricity	60%–90%	40%–80%
Bilaterality	50%–70%	10%–20%
Axillary metastasis	1%	1%–2%
Subsequent carcinomas:		
Incidence	25%–35%	25%–70%
Laterality	Bilateral	Ipsilateral
Interval to diagnosis	15–20 y	5–10 y
Histologic type	Ductal	Ductal

in white women than in African American women. Invasive breast cancer develops in 25% to 35% of women with LCIS. Invasive cancer may develop in either breast, regardless of which breast harbored the initial focus of LCIS, and is detected synchronously with LCIS in 5% of cases. In women with a history of LCIS, up to 65% of subsequent invasive cancers are ductal, not lobular, in origin. For these reasons, LCIS is regarded as a marker of increased risk for invasive breast cancer rather than as an anatomic precursor. Individuals should be counseled regarding their risk of developing breast cancer and appropriate risk reduction strategies, including observation with screening, chemoprevention, and risk-reducing bilateral mastectomy.

Ductal Carcinoma In Situ. Although DCIS is predominantly seen in the female breast, it accounts for 5% of male breast cancers. Published series suggest a detection frequency of 7% in all biopsy tissue specimens. The term *intraductal carcinoma* is frequently applied to DCIS, which carries a high risk for progression to an invasive cancer. Histologically, DCIS is characterized by a proliferation of the epithelium that lines the minor ducts, resulting in papillary growths within the duct lumina. Early in their development, the cancer cells do not show pleomorphism, mitoses, or atypia, which leads to difficulty in distinguishing early DCIS from benign hyperplasia. The papillary growths (papillary growth pattern) eventually coalesce and fill the duct lumina so that only scattered, rounded spaces remain between the clumps of atypical cancer cells, which show hyperchromasia and loss of polarity (cribriform growth pattern). Eventually pleomorphic cancer cells with frequent mitotic figures obliterate the lumina and distend the ducts (solid growth pattern). With continued growth, these cells outstrip their blood supply and become necrotic (comedo growth pattern). Calcium deposition occurs in the areas of necrosis and is a common feature seen on mammography. DCIS is now frequently classified based on nuclear grade and the presence of necrosis (Table 17-9). Based on multiple consensus meetings, grading of DCIS has been recommended. Although there is no universal agreement on classification, most systems endorse the use of cytologic grade and presence or absence of necrosis.[126]

The risk for invasive breast cancer is increased nearly fivefold in women with DCIS.[127] The invasive cancers are observed in the ipsilateral breast, usually in the same quadrant as the DCIS that was originally detected, which suggests that DCIS is an anatomic precursor of invasive ductal carcinoma (Fig. 17-15A and B).

Invasive Breast Carcinoma

Invasive breast cancers have been described as lobular or ductal in origin.[128-131] Early classifications used the term *lobular* to describe invasive cancers that were associated with LCIS, whereas all other invasive cancers were referred to as *ductal.* Current histologic classifications recognize special types of breast cancers (10% of total cases), which are defined by specific histologic features. To qualify as a special-type cancer, at least 90% of the cancer must contain the defining histologic features. About 80% of invasive breast cancers are described as

Table 17-9

Classification of breast ductal carcinoma in situ (DCIS)

	DETERMINING CHARACTERISTICS		
HISTOLOGIC SUBTYPE	NUCLEAR GRADE	NECROSIS	DCIS GRADE
Comedo	High	Extensive	High
Intermediate[a]	Intermediate	Focal or absent	Intermediate
Noncomedo[b]	Low	Absent	Low

[a]Often a mixture of noncomedo patterns.
[b]Solid, cribriform, papillary, or focal micropapillary.

invasive ductal carcinoma of no special type (NST). These cancers generally have a worse prognosis than special-type cancers. Foote and Stewart originally proposed the following classification for invasive breast cancer[125]:

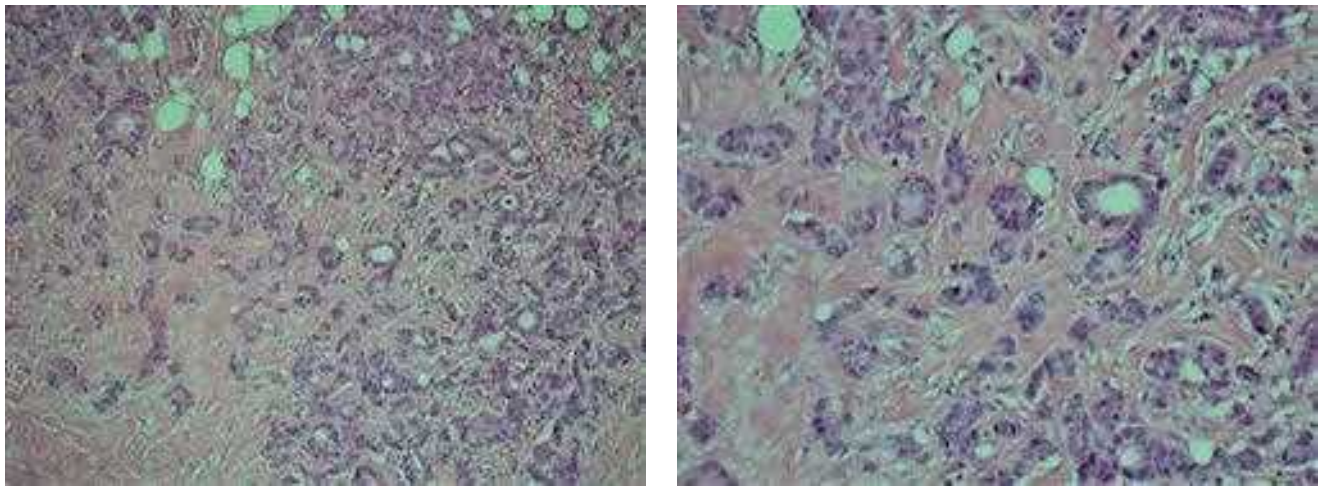
1. Paget's disease of the nipple
2. Invasive ductal carcinoma—Adenocarcinoma with productive fibrosis (scirrhous, simplex, NST), 80%
3. Medullary carcinoma, 4%
4. Mucinous (colloid) carcinoma, 2%
5. Papillary carcinoma, 2%
6. Tubular carcinoma, 2%
7. Invasive lobular carcinoma, 10%
8. Rare cancers (adenoid cystic, squamous cell, apocrine)

Paget's disease of the nipple was described in 1874. It frequently presents as a chronic, eczematous eruption of the nipple, which may be subtle but may progress to an ulcerated, weeping lesion. Paget's disease usually is associated with extensive DCIS and may be associated with an invasive cancer. A palpable mass may or may not be present. A nipple biopsy specimen will show a population of cells that are identical to the underlying DCIS cells (pagetoid features or pagetoid change). Pathognomonic of this cancer is the presence of large, pale, vacuolated cells (Paget cells) in the rete pegs of the epithelium. Paget's disease may be confused with superficial spreading melanoma. Differentiation from pagetoid intraepithelial melanoma is based on the presence of S-100 antigen immunostaining in melanoma and carcinoembryonic antigen immunostaining in Paget's disease. Surgical therapy for Paget's disease may involve lumpectomy or mastectomy, depending on the extent of involvement of the nipple-areolar complex and the presence of DCIS or invasive cancer in the underlying breast parenchyma.

Invasive ductal carcinoma of the breast with productive fibrosis (scirrhous, simplex, NST) accounts for 80% of breast cancers and presents with macroscopic or microscopic axillary lymph node metastases in up to 25% of screen-detected cases and up to 60% of symptomatic cases. This cancer occurs most frequently in perimenopausal or postmenopausal women in the fifth to sixth decades of life as a solitary, firm mass. It has poorly defined margins and its cut surfaces show a central stellate configuration with chalky white or yellow streaks extending into surrounding breast tissues. The cancer cells often are arranged in small clusters, and there is a broad spectrum of histologic types with variable cellular and nuclear grades (Fig. 17-16A and B). In a large patient series from the SEER database, 75% of ductal cancers showed estrogen receptor expression.[132]

Medullary carcinoma is a special-type breast cancer; it accounts for 4% of all invasive breast cancers and is a frequent phenotype of *BRCA1* hereditary breast cancer. Grossly, the cancer is soft and hemorrhagic. A rapid increase in size may occur secondary to necrosis and hemorrhage. On physical examination, it is bulky and often positioned deep within the breast. Bilaterality is reported in 20% of cases. Medullary carcinoma is characterized microscopically by: (a) a dense lymphoreticular infiltrate composed predominantly of lymphocytes and plasma cells; (b) large pleomorphic nuclei that are poorly differentiated and show active mitosis; and (c) a sheet-like growth pattern with minimal or absent ductal or alveolar differentiation. Approximately 50% of these cancers are associated with DCIS, which characteristically is present at the periphery of the cancer, and <10% demonstrate hormone receptors. In rare circumstances, mesenchymal metaplasia or anaplasia is noted. Because of the intense lymphocyte response associated with the cancer, benign or hyperplastic enlargement of the lymph nodes of the axilla may contribute to erroneous clinical staging. Women with this cancer have a better 5-year survival rate than those with NST or invasive lobular carcinoma.

Mucinous carcinoma (colloid carcinoma), another special-type breast cancer, accounts for 2% of all invasive breast cancers and typically presents in the elderly population as a bulky tumor. This cancer is defined by extracellular pools of mucin, which surround aggregates of low-grade cancer cells. The cut surface of this cancer is glistening and gelatinous in quality. Fibrosis is variable, and when abundant it imparts a firm consistency to the cancer. Over 90% of mucinous carcinomas display hormone receptors.[132] Lymph node metastases occur in 33%



A **B**

Figure 17-16. Invasive ductal carcinoma with productive fibrosis (scirrhous, simplex, no special type) **A.** 100x and **B.** 200x. of cases, and 5- and 10-year survival rates are 73% and 59%, respectively. Because of the mucinous component, cancer cells may not be evident in all microscopic sections, and analysis of multiple sections is essential to confirm the diagnosis of a mucinous carcinoma.

Papillary carcinoma is a special-type cancer of the breast that accounts for 2% of all invasive breast cancers. It generally presents in the seventh decade of life and occurs in a disproportionate number of nonwhite women. Typically, papillary carcinomas are small and rarely attain a size of 3 cm in diameter. These cancers are defined by papillae with fibrovascular stalks and multilayered epithelium. In a large series from the SEER database 87% of papillary cancers have been reported to express estrogen receptor.[132] McDivitt and colleagues noted that these tumors showed a low frequency of axillary lymph node metastases and had 5- and 10-year survival rates similar to those for mucinous and tubular carcinoma.[133]

Tubular carcinoma is another special-type breast cancer and accounts for 2% of all invasive breast cancers. It is reported in as many as 20% of women whose cancers are diagnosed by mammographic screening and usually is diagnosed in the perimenopausal or early menopausal periods. Under low-power magnification, a haphazard array of small, randomly arranged tubular elements is seen. In a large SEER database 94% of tubular cancers were reported to express estrogen receptor.[132] Approximately 10% of women with tubular carcinoma or with invasive cribriform carcinoma, a special-type cancer closely related to tubular carcinoma, will develop axillary lymph node metastases. However, the presence of metastatic disease in one or two axillary lymph nodes does not adversely affect survival. Distant metastases are rare in tubular carcinoma and invasive cribriform carcinoma. Long-term survival approaches 100%.

Invasive lobular carcinoma accounts for 10% of breast cancers. The histopathologic features of this cancer include small cells with rounded nuclei, inconspicuous nucleoli, and scant cytoplasm (Fig. 17-17). Special stains may confirm the presence of intracytoplasmic mucin, which may displace the nucleus (signet-ring cell carcinoma). At presentation, invasive

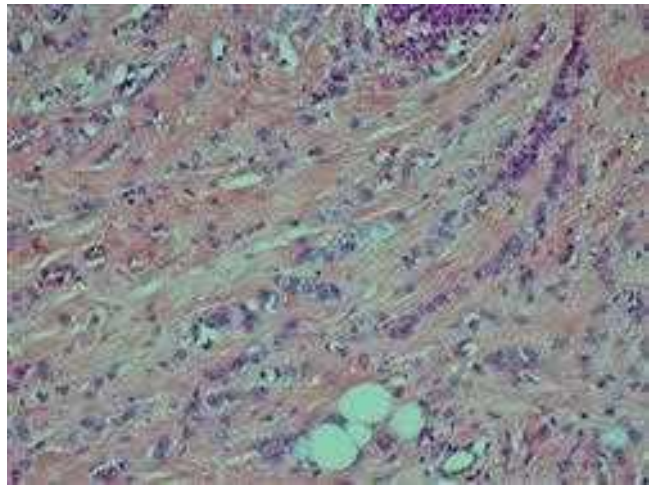

Figure 17-17. Lobular carcinoma (100×). Uniform, relatively small lobular carcinoma cells are seen arranged in a single-file orientation ("Indian file"). (Used with permission of Dr. Sindhu Menon, Consultant Histopathologist & Dr. Rahul Deb, Consultant Histopathologist and Lead Breast Pathologist, Royal Derby Hospital, Derby, UK.)

lobular carcinoma varies from clinically inapparent carcinomas to those that replace the entire breast with a poorly defined mass. It is frequently multifocal, multicentric, and bilateral. Because of its insidious growth pattern and subtle mammographic features, invasive lobular carcinoma may be difficult to detect. Over 90% of lobular cancers express estrogen receptor.[132]

DIAGNOSIS OF BREAST CANCER

In~30% of cases, the woman discovers a lump in her breast. Other less frequent presenting signs and symptoms of breast cancer include: (a) breast enlargement or asymmetry; (b) nipple changes, retraction, or discharge; (c) ulceration or erythema of the

skin of the breast; (d) an axillary mass; and (e) musculoskeletal discomfort. However, up to 50% of women presenting with breast complaints have no physical signs of breast pathology. Breast pain usually is associated with benign disease.

Misdiagnosed breast cancer accounts for the greatest number of malpractice claims for errors in diagnosis and for the largest number of paid claims. Litigation often involves younger women, whose physical examination and mammogram may be misleading. If a young woman (≤45 years) presents with a palpable breast mass and equivocal mammographic findings, ultrasound examination and biopsy are used to avoid a delay in diagnosis.

Examination

Inspection. **The** surgeon inspects the woman's breast with her arms by her side (Fig. 17-18A), with her arms straight up in the air (Fig. 17-18B), and with her hands on her hips (with and without pectoral muscle contraction).[134,135] Symmetry, size, and shape of the breast are recorded, as well as any evidence of edema (peaud'orange), nipple or skin retraction, or erythema. With the arms extended forward and in a sitting position, the woman leans forward to accentuate any skin retraction.

Palpation. **As** part of the physical examination, the breast is carefully palpated. With the patient in the supine position (see Fig. 17-18C) the surgeon gently palpates the breasts, making certain to examine all quadrants of the breast from the sternum laterally to the latissimus dorsi muscle and from the clavicle inferiorly to the upper rectus sheath. The surgeon performs the examination with the palmar aspects of the fingers, avoiding a grasping or pinching motion. The breast may be cupped or molded in the surgeon's hands to check for retraction. A systematic search for lymphadenopathy then is performed. Figure 17-18D shows the position of the patient for examination of the axilla. By supporting the upper arm and elbow, the surgeon stabilizes the shoulder girdle. Using gentle palpation, the surgeon assesses all three levels of possible axillary lymphadenopathy. Careful palpation

of supraclavicular and parasternal sites also is performed. A diagram of the chest and contiguous lymph node sites is useful for recording location, size, consistency, shape, mobility, fixation, and other characteristics of any palpable breast mass or lymphadenopathy (Fig. 17-19).

Imaging Techniques

Mammography. Mammography has been used in North America since the 1960s, and the techniques used continue to be modified and improved to enhance image quality.[136-139] Conventional mammography delivers a radiation dose of 0.1 cGy per study. By comparison, chest radiography delivers 25% of this dose. However, there is no increased breast cancer risk associated with the radiation dose delivered with screening mammography. Screening mammography is used to detect unexpected breast cancer in asymptomatic women. In this regard, it supplements history taking and physical examination. With screening mammography, two views of the breast are obtained, the craniocaudal (CC) view (Fig. 17-20A and B) and the mediolateral oblique (MLO) view (Fig. 17-20 C and D). The MLO view images the greatest volume of breast tissue, including the upper outer quadrant and the axillary tail of Spence. Compared with the MLO view, the CC view provides better visualization of the medial aspect of the breast and permits greater breast compression. Diagnostic mammography is used to evaluate women with abnormal findings such as a breast mass or nipple discharge. In addition to the MLO and CC views, a diagnostic examination may use views that better define the nature of any abnormalities, such as the 90-degree lateral and spot compression views. The 90-degree lateral view is used along with the CC view to triangulate the exact location of an abnormality. Spot compression may be done in any projection by using a small compression device, which is placed directly over a mammographic abnormality that is obscured by overlying tissues (Fig. 17-21C). The compression device minimizes motion artifact, improves definition, separates overlying tissues, and decreases the radiation dose needed to penetrate the breast. Magnification techniques (×1.5) often are combined with spot compression to better resolve

calcifications and the margins of masses. Mammography also is used to guide interventional procedures, including needle localization and needle biopsy.

Specific mammographic features that suggest a diagnosis of breast cancer include a solid mass with or without stellate features, asymmetric thickening of breast tissues, and clustered microcalcifications. The presence of fine, stippled calcium in and around a suspicious lesion is suggestive of breast cancer and occurs in as many as 50% of nonpalpable cancers. These microcalcifications are an especially important sign of cancer in younger women, in whom it may be the only mammographic abnormality. The clinical impetus for screening mammography

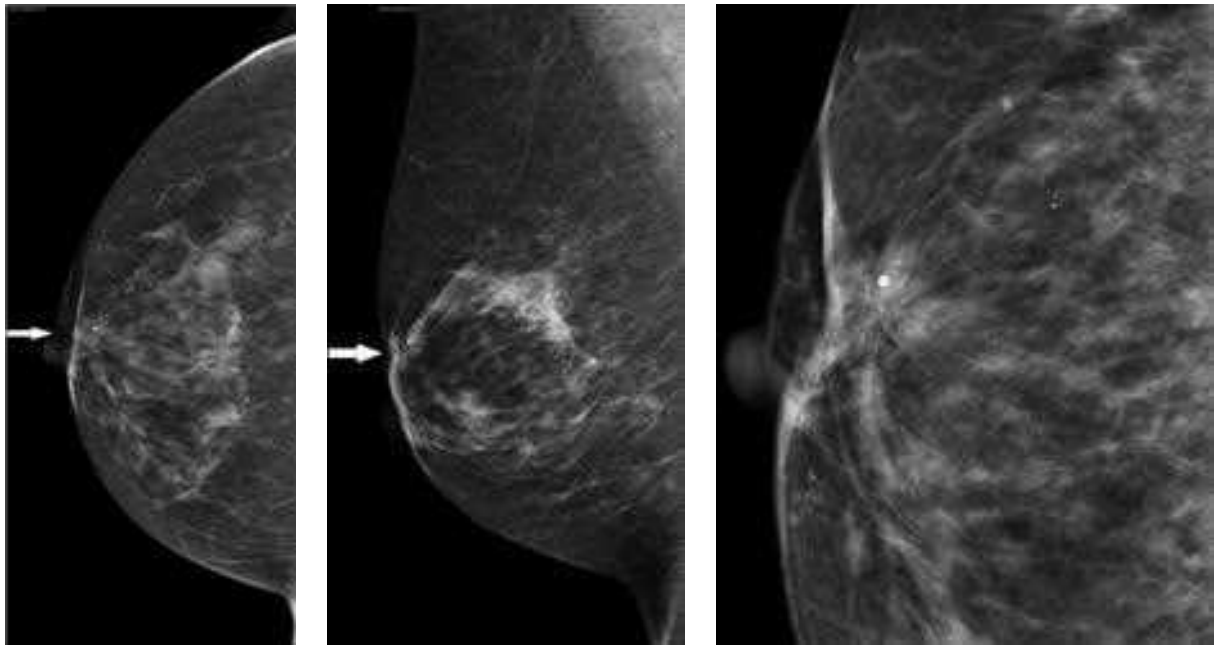

Figure 17-21. Mammogram revealing a small, spiculated mass in the right breast **A.** A small, spiculated mass is seen in the right breast with skin tethering (CC view). **B.** Mass seen on oblique view of the right breast. **C.** Spot compression mammography view of the cancer seen in **A** and **B**. came from the Health Insurance Plan study and the Breast Cancer Detection Demonstration Project, which demonstrated a 33% reduction in mortality for women after[72] screening mammography. Mammography was more accurate than clinical examination for the detection of early breast cancers, providing a true-positive rate of 90%. Only 20% of women with nonpalpable cancers had axillary lymph node metastases, compared with 50% of women with palpable cancers.[140] Current guidelines of the National Comprehensive Cancer Network suggest that normal-risk women ≥20 years of age should have a breast examination at least every 3 years. Starting at age 40 years, breast examinations should be performed yearly and a yearly mammogram should be taken. The benefits from screening mammography in women ≥50 years of age has been noted above to be between 20% and 25% reduction in breast cancer mortality.[72,74] With the increased discussion about the potential harms associated with breast screening the United Kingdom recently established an independent expert panel to review the published literature and estimate the benefits and harms associated with its national screening program for women >50 years. The expert panel estimated that in women invited to screening, about 11% of the cancers diagnosed in their lifetime constitute over-diagnosis. Despite the over-diagnosis the panel concluded that breast screening programs confer significant benefit and should continue. The use of screening mammography in women <50 years of age is more controversial again for reasons noted above: (a) reduced sensitivity; (b) reduced specificity; and (c) lower incidence of breast cancer. For the combination of these three reasons targeting mammography screening to women <50 years at higher risk of breast cancer improves the balance of risks and benefits and is the approach some health care systems have taken. There are now a number of risk assessment models—as described earlier in that section—which can be used to estimate a younger woman's risk of developing breast cancer to help assess the risks and benefits of regular screening.

Screen film mammography has replaced xeromammography because it requires a lower dose of radiation and provides similar image quality. Digital mammography was developed to allow the observer to manipulate the degree of contrast in the image. This is especially useful in women with dense breasts and women <50 years of age. Recently, investigators directly compared digital vs. screen film mammography in a prospective (DMIST) trial enrolling over 42,000 women.[141] They found that digital and screen film mammography had similar accuracy; however, digital mammography was more accurate in women <50 years of age, women with mammographically dense breasts, and premenopausal or perimenopausal women. The use of digital breast tomosynthesis with 3D images has been introduced as an alternative to standard 2D mammography imaging that is limited by superimposition of breast parenchyma and breast density. The STORM trial reported that in 7,292 women screened, 3D mammography had a higher cancer detection rate and fewer false-positive recalls than the standard 2D imaging.[142] Randomized controlled trials are planned to further study tomosynthesis and its role in breast cancer screening.

Ductography. The primary indication for ductography is nipple discharge, particularly when the fluid contains blood. Radiopaque contrast media is injected into one or more of the major ducts and mammography is performed. A duct is gently enlarged with a dilator and then a small, blunt cannula is inserted under sterile conditions into the nipple ampulla. With the patient in a supine position, 0.1 to 0.2 mL of dilute contrast media is injected and CC and MLO mammographic views

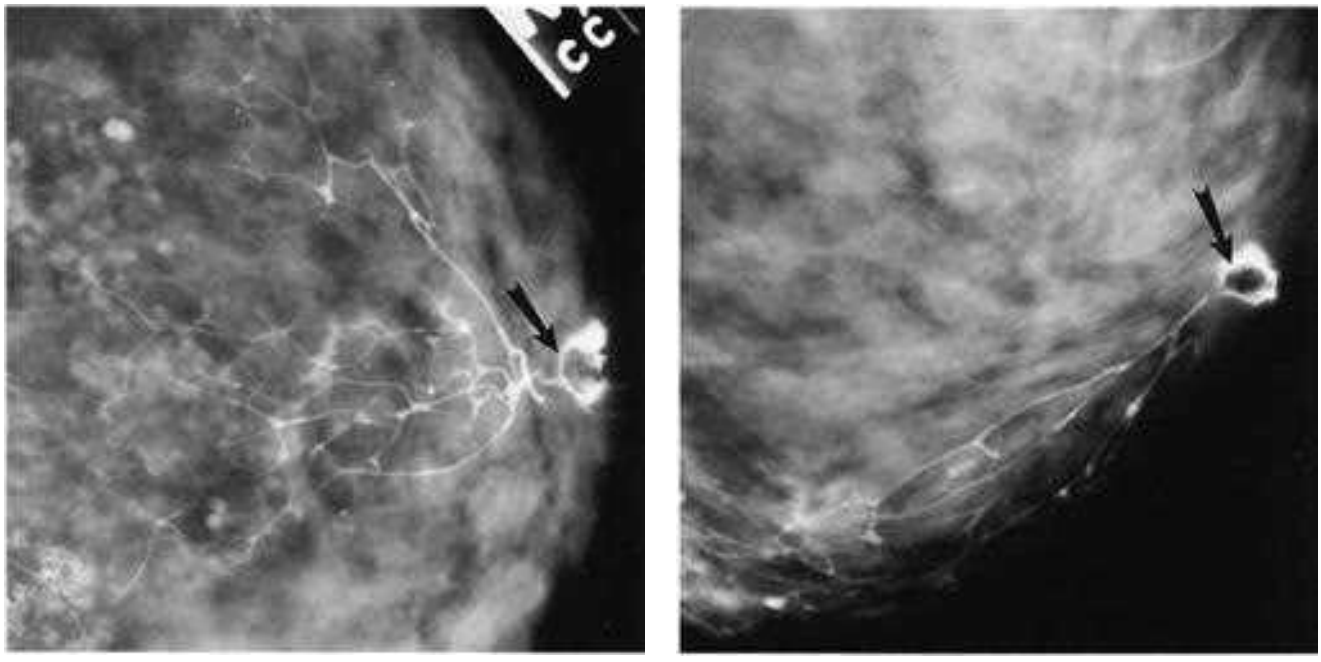

Figure 17-22. Ductogram. Craniocaudal (**A**) and mediolateral oblique (**B**) mammographic views demonstrate a mass (*arrows*) posterior to the nipple and outlined by contrast, which also fills the proximal ductal structures. (Photos used with permission of B. Steinbach.)

are obtained without compression. Intraductal papillomas are seen as small filling defects surrounded by contrast media (Fig. 17-22). Cancers may appear as irregular masses or as multiple intraluminal filling defects.

Ultrasonography. Second only to mammography in frequency of use for breast imaging, ultrasonography is an important method of resolving equivocal mammographic findings, defining cystic masses, and demonstrating the echogenic qualities of specific solid abnormalities. On ultrasound examination, breast cysts are well circumscribed, with smooth margins and an echo-free center (Fig. 17-23). Benign breast masses usually show smooth contours, round or oval shapes, weak internal echoes, and well-defined anterior and posterior margins (Fig 17-24). Breast cancer characteristically has irregular walls (Fig. 17-25) but may have smooth margins with acoustic enhancement. Ultrasonography is used to guide fine-needle aspiration biopsy, core-needle biopsy, and needle localization of breast lesions. Its findings are highly reproducible and it has a high patient acceptance rate, but it does not reliably detect lesions that are ≤1 cm in diameter. Ultrasonography can also be utilized to image the regional lymph nodes in patients with breast cancer (Fig. 17-26). The sensitivity of examination for the status of axillary nodes ranges from 35% to 82% and specificity ranges from 73% to 97%. The features of a lymph node involved with cancer include cortical thickening, change in shape of the node to more circular appearance, size larger than 10 mm, absence of a fatty hilum and hypoechoic internal echoes.[143]

Magnetic Resonance Imaging. In the process of evaluating magnetic resonance imaging (MRI) as a means of characterizing mammographic abnormalities, additional breast lesions have been detected. However, in the circumstance of negative findings on both mammography and physical examination, the probability of a breast cancer being diagnosed by MRI is extremely low. There is current interest in the use of MRI to screen the breasts of high-risk women and of women with a newly diagnosed breast cancer. In the first case, women who have a strong family history of breast cancer or who carry known genetic mutations require screening at an early age, because mammographic evaluation is limited due to the increased breast density in younger women. In the second case, an MRI study of the contralateral breast in women with a known breast cancer has shown a contralateral breast cancer in 5.7% of these women (Fig. 17-27). MRI can also detect additional tumors in the index breast (multifocal or multicentric disease) that may be missed on routine breast imaging and this may alter surgical decision making (Fig. 17-28). In fact, MRI has been advocated by some for routine use in surgical treatment planning based on the fact that additional disease can be identified with this advanced imaging modality and the extent of disease may be more accurately assessed. A randomized trial performed in the United Kingdom (COMICE trial) which enrolled 1,623 women did not show a decrease in rates of reoperation in those women randomized to undergo MRI in addition to mammography and ultrasonography (19%) compared to those undergoing standard breast imaging without MRI (19%).[144] Houssami and colleagues performed a meta-analysis including 2 randomized trials and 7 comparative cohort studies to examine the effect of preoperative MRI compared to standard preoperative evaluation on surgical outcomes.[145] They reported that the use of MRI was associated with increased mastectomy rates. This is problematic since there is no evidence that the additional disease detected by MRI is of clinical or biologic significance, particularly in light of the low local-regional failure rates currently reported in patients undergoing breast conserving surgery who receive whole breast irradiation and systemic therapies.

The use of dedicated breast coils is mandatory in the MRI imaging of the breast. A BIRADS lexicon is assigned to each examination and an abnormality noted on MRI that is not seen

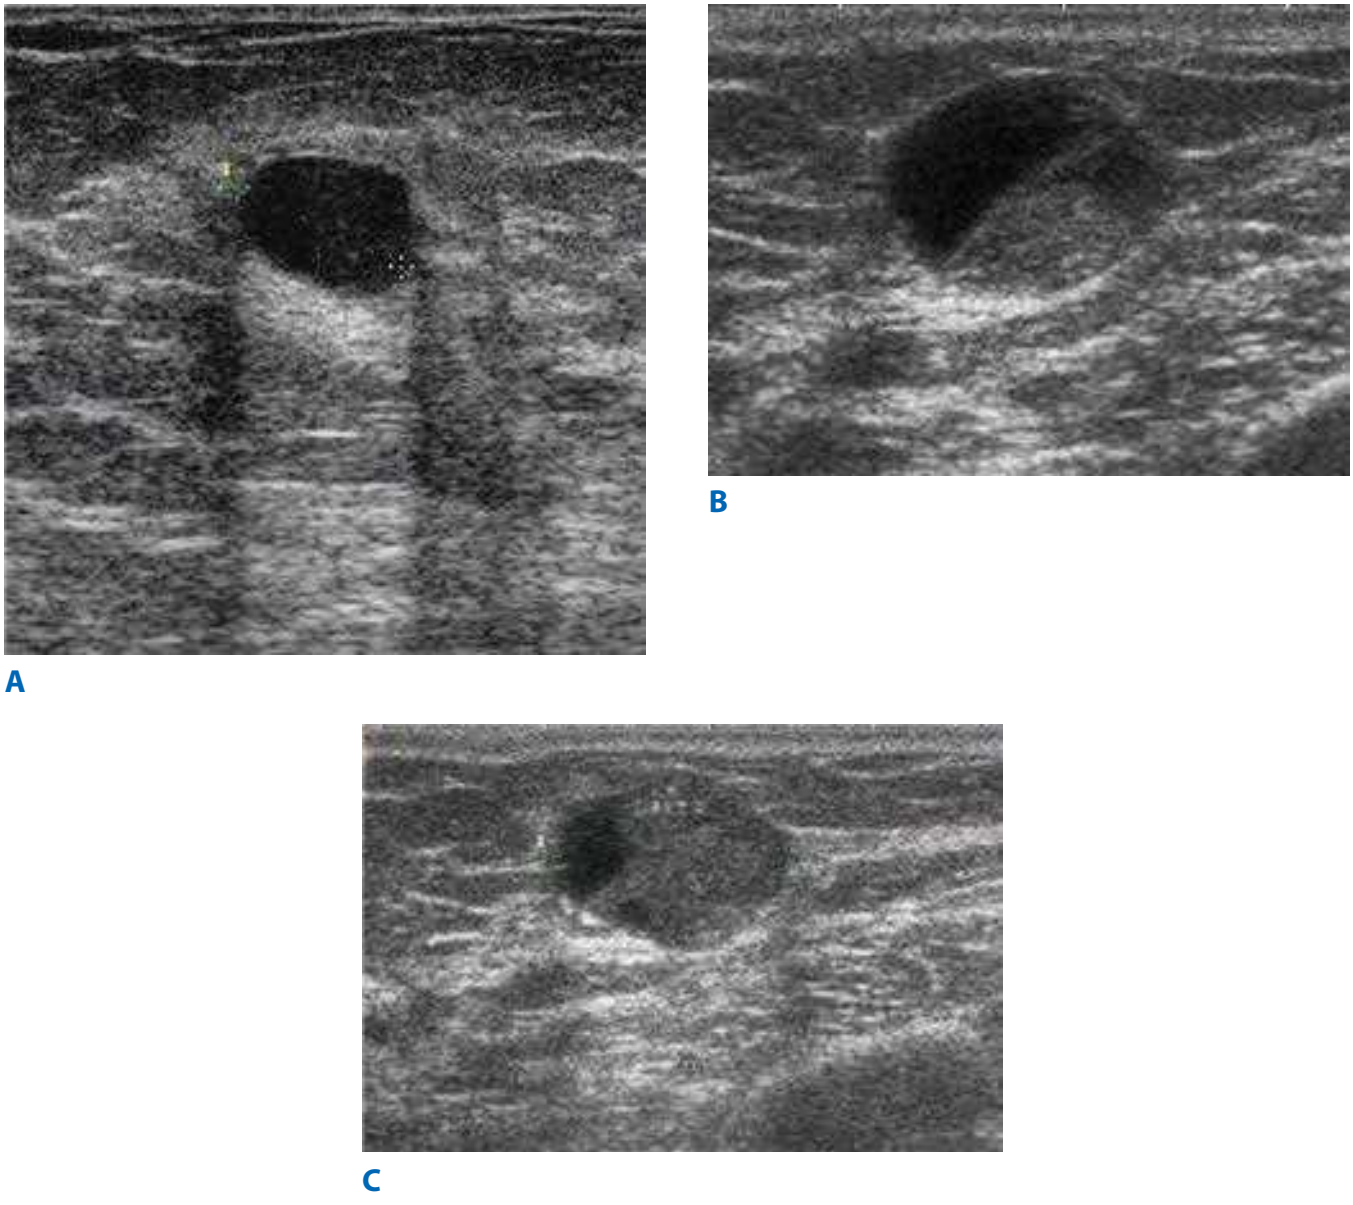

Figure 17-23. Breast cyst. **A.** Simple cyst. Ultrasound image of the mass shows it to be anechoic with a well-defined back wall, characteristic of a cyst. **B.** Complex solid and cystic mass. on mammography requires a focused ultrasound examination for further assessment. If the abnormality is not seen on corresponding mammogram or ultrasound then MRI guided biopsy is necessary. Some clinical scenarios where MRI may be useful include the evaluation of a patient who presents with nodal metastasis from breast cancer without an identifiable primary tumor; to assess response to therapy in the setting of neoadjuvant systemic treatment; to select patients for partial breast irradiation techniques; and evaluation of the treated breast for tumor recurrence.

Breast Biopsy

Nonpalpable Lesions. Image-guided breast biopsy specimens are frequently required to diagnose nonpalpable lesions.[146] Ultrasound localization techniques are used when a mass is present, whereas stereotactic techniques are used when no mass is present (microcalcifications or architectural distortion only). The combination of diagnostic mammography, ultrasound or stereotactic localization, and fine-needle aspiration (FNA) biopsy achieves almost 100% accuracy in the preoperative diagnosis of breast cancer. However, although FNA biopsy permits cytologic evaluation, core-needle permits the analysis of breast tissue architecture and allows the pathologist to determine whether invasive cancer is present. This permits the surgeon and patient to discuss the specific management of a breast cancer before therapy begins. Core-needle biopsy is preferred over open biopsy for nonpalpable breast lesions because a single surgical procedure can be planned based on the results of the core biopsy. The advantages of core-needle biopsy include a low complication rate, minimal scarring, and a lower cost compared with excisional breast biopsy.

7▶

Palpable Lesions. FNA or core biopsy of a palpable breast mass can usually be performed in an outpatient setting.[147] A 1.5-in, 22-gauge needle attached to a 10-mL syringe or a 14 gauge core biopsy needle is used. For FNA, use of a syringe holder

enables the surgeon performing the FNA biopsy to control the syringe and needle with one hand while positioning the breast mass with the opposite hand. After the needle is placed in the mass, suction is applied while the needle is moved back and forth within the mass. Once cellular material is seen at the hub of the needle, the suction is released and the needle is withdrawn. The cellular material is then expressed onto microscope slides. Both air-dried and 95% ethanol–fixed microscopic sections are prepared for analysis. When a breast mass is clinically and mammographically suspicious, the sensitivity and specificity of FNA biopsy approaches 100%. Core-needle biopsy of palpable breast masses is performed using a 14-gauge needle, such as the Tru-Cut needle. Automated devices also are available. Vacuum assisted core biopsy devices (with 8–10 gauge needles) are commonly utilized with image guidance where between 4 and 12 samples can be acquired at different positions within a mass, area of architectural distortion or microcalcifications. If the target lesion was microcalcifications, the specimen should be radiographed to confirm appropriate sampling. A radiopaque marker should be placed at the site of the biopsy to mark the area for future intervention. In some cases the entire lesion is removed with the biopsy technique and clip placement allows for accurate targeting of the site for surgical resection. Tissue specimens are placed in formalin and then processed to paraffin blocks. Although the false-negative rate for core-needle biopsy specimens is very low, a tissue specimen that does not show breast cancer cannot conclusively rule out that diagnosis because a sampling error may have occurred. The clinical, radiographic, and pathologic findings should be in concordance. If the biopsy findings do not concur with the clinical and radiographic findings, the multi-disciplinary team (including clinician, radiologist, and pathologist) should review the findings and decide whether or not to recommend an image-guided or open biopsy to be certain that the target lesion has been adequately sampled for diagnosis.

BREAST CANCER STAGING AND BIOMARKERS

Breast Cancer Staging

The clinical stage of breast cancer is determined primarily through physical examination of the skin, breast tissue, and regional lymph nodes (axillary, supraclavicular, and internal mammary).[148] However, clinical determination of axillary lymph node metastases has an accuracy of only 33%. Ultrasound (US) is more sensitive than physical examination alone in determining axillary lymph node involvement during preliminary staging of breast carcinoma. Fine-needle aspiration (FNA) or core biopsy of sonographically indeterminate or suspicious lymph nodes can provide a more definitive diagnosis than US alone.[143,149] Pathologic stage combines the findings from pathologic examination of the resected primary breast cancer and axillary or other regional lymph nodes. Fisher and colleagues found that accurate predictions regarding the occurrence of distant metastases were possible after resection and pathologic analysis of 10 or more level I and II axillary lymph nodes.[150] A frequently used staging system is the TNM (tumor, nodes, and metastasis) system. The American Joint Committee on Cancer (AJCC) has modified the TNM system for breast cancer (Tables 17-10 and 17-11).[151]Koscielny and colleagues demonstrated that tumor size correlates with the presence of axillary lymph node metastases (see Fig. 17-14B). Others have shown an association between tumor size, axillary lymph node metastases, and disease-free survival. One of the most important predictors of 10- and 20-year survival rates in breast cancer is the number of axillary lymph nodes involved with metastatic disease. Routine biopsy of internal mammary lymph nodes is not generally performed; however, it has been reported that in the context of a 'triple node' biopsy approach either the internal mammary node or a low axillary node when positive alone carried the same prognostic weight. When both nodes were positive the prognosis declined to the level associated with apical node positivity. A double node biopsy of the low axillary node and either the apical or the internal mammary node gave the same maximum prognostic information as a triple node biopsy.[152] With the advent of sentinel lymph node dissection and the use of preoperative lymphoscintigraphy for localization of the sentinel nodes, surgeons have again begun to biopsy the internal mammary nodes but in a more targeted manner. The 7th edition of the AJCC staging system does allow for staging based on findings from the internal mammary sentinel nodes.[151] Drainage to the internal mammary nodes is more frequent with central and medial quadrant cancers. Clinical or pathologic evidence of metastatic spread to supraclavicular lymph nodes is no longer considered stage IV disease, but routine scalene or supraclavicular lymph node biopsy is not indicated.

Biomarkers

Breast cancer biomarkers are of several types. Risk factor biomarkers are those associated with increased cancer risk.[153-157] These include familial clustering and inherited germline abnormalities, proliferative breast disease with atypia, and mammographic densities. Exposure biomarkers are a subset of

Table 17-10

TNM staging system for breast cancer

Primary tumor (T)

The T classification of the primary tumor is the same regardless of whether it is based on clinical or pathologic criteria, or both. Size should be measured to the nearest millimeter. If the tumor size is slightly less than or greater than a cutoff for a given T classification, it is recommended that the size be rounded to the millimeter reading that is closest to the cutoff. For example, a reported size of 1.1 mm is reported as 1 mm, or a size of 2.01 cm is reported as 2.0 cm. Designation should be made with the subscript "c" or "p" modifier to indicate whether the T classification was determined by clinical (physical examination or radiologic) or pathologic measurements, respectively. In general, pathologic determination should take precedence over clinical determination of T size.

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Tis (DCIS)	Ductal carcinoma in situ
Tis (LCIS)	Lobular carcinoma in situ
Tis (Paget's)	Paget's disease of the nipple NOT associated with invasive carcinoma and/or carcinoma in situ (DCIS and/or LCIS) in the underlying breast parenchyma. Carcinomas in the breast parenchyma associated with Paget's disease are categorized based on the size and characteristics of the parenchymal disease, although the presence of Paget's disease should still be noted
T1	Tumor ≤20 mm in greatest dimension
T1mi	Tumor ≤1 mm in greatest dimension
T1a	Tumor >1 mm but ≤5 mm in greatest dimension
T1b	Tumor >5 mm but ≤10 mm in greatest dimension
T1c	Tumor >10 mm but ≤20 mm in greatest dimension
T2	Tumor >20 mm but ≤5 cm in greatest dimension
T3	Tumor >50 mm in greatest dimension
T4	Tumor of any size with direct extension to the chest wall and/or to the skin (ulceration or skin nodules)*
T4a	Extension to chest wall, not including only pectoralis muscle adherence/invasion
T4b	Ulceration and/or ipsilateral satellite nodules and/or edema (including peaud'orange) of the skin, which do not meet the criteria for inflammatory carcinoma
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma**
	*Note: Invasion of the dermis alone does not qualify as T4
	**Note: Inflammatory carcinoma is restricted to cases with typical skin changes involving a third or more of the skin of the breast. While the histologic presence of invasive carcinoma invading dermal lymphatics is supportive of the diagnosis, it is not required, nor is dermal lymphatic invasion without typical clinical findings sufficient for a diagnosis of inflammatory breast cancer.

Regional lymph nodes—Clinical (N)

NX	Regional lymph nodes cannot be assessed (e.g., previously removed)
N0	No regional lymph node metastases
N1	Metastases to movable ipsilateral level I, II axillary lymph node(s)
N2	Metastases in ipsilateral level I, II axillary lymph nodes that are clinically fixed or matted; or in clinically detected* ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastases
N2a	Metastases in ipsilateral level I, II axillary lymph nodes fixed to one another (matted) or to other structures
N2b	Metastases only in clinically detected* ipsilateral internal mammary nodes and in the absence of clinically evident level I, II axillary lymph node metastases
N3	Metastasis in ipsilateral infraclavicular (level III axillary) lymph node(s) with or without level I, II axillary lymph node involvement; or in clinically detected* ipsilateral internal mammary lymph node(s) with clinically evident level I, II axillary lymph node metastases; or metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N3a	Metastasis in ipsilateral infraclavicular lymph node(s)
N3b	Metastasis in ipsilateral internal mammary lymph nodes(s) and axillary lymph node(s)
N3c	Metastasis in ipsilateral supraclavicular lymph node(s)
	*Notes: "Clinically detected" is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination and having characteristics highly suspicious for malignancy or a presumed pathologic macrometastasis based on fine needle aspiration biopsy with cytologic examination. Confirmation of clinically detected metastatic disease by fine needle aspiration without excision biopsy is designated with an (f) suffix, e.g., cN3a(f). Excisional biopsy of a lymph node or biopsy of a sentinel node, in the absence of assignment of a pT, is classified as a clinical N, e.g., cN1. Information regarding the confirmation of the nodal status will be designated in site-specific factors as clinical, fine needle aspiration, core biopsy, or sentinel lymph node biopsy. Pathologic classification (pN) is used for excision or sentinel lymph node biopsy only in conjunction with a pathologic T assignment.

Table 17-10

TNM staging system for breast cancer (continued)

Regional lymph nodes—Pathologic (pN)	
pNX	Regional lymph nodes cannot be assessed (e.g., previously removed, or not removed for pathologic study)
pN0[b]	No regional lymph node metastasis identified histologically Note: Isolated tumor cell clusters (ITC) are defined as small clusters of cells not greater than 0.2 mm, or single tumor cells, or a cluster of fewer than 200 cells in a single histologic cross-section. ITCs may be detected by routine histology or by immunohistochemical (IHC) methods. Nodes containing only ITCs are excluded from the total positive node count for purposes of N classification but should be included in the total number of nodes evaluated.
pN0(i–)	No regional lymph node metastasis histologically, negative IHC
pN0(i+)	Malignant cells in regional lymph node(s) no greater than 0.2 mm (detected by H&E or IHC including ITC)
pN0(mol–)	No regional lymph node metastasis histologically, negative molecular findings [reverse-transcriptase polymerase chain reaction (RT-PCR)]
pN0(mol+)	Positive molecular findings (RT-PCR)**, but no regional lymph node metastases detected by histology or IHC
pN1	Micrometastases; or metastases in 1-3 axillary lymph nodes; and/or in internal mammary nodes with metastases detected by sentinel lymph node biopsy but not clinically detected***
pN1mi	Micrometastases (greater than 0.2 mm and/or more than 200 cells, but none greater than 2.0 mm)
pN1a	Metastases in 1-3 axillary lymph nodes, at least one metastasis greater than 2.0 mm
pN1b	Metastases in internal mammary nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected***
pN1c	Metastases in 1-3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected
pN2	Metastases in 4-9 axillary lymph nodes; or in clinically apparent*** internal mammary lymph nodes in the absence of axillary lymph node metastases
pN2a	Metastases in 4-9 axillary lymph nodes (at least one tumor deposit greater than 2.0 mm)
pN2b	Metastases in clinically detected*** internal mammary lymph nodes in the absence of axillary lymph node metastases
pN3	Metastases in 10 or more axillary lymph nodes; or in infraclavicular (level III axillary) lymph nodes; or in clinically detected **** ipsilateral internal mammary lymph nodes in the presence of one or more positive level I, II axillary lymph nodes; or in more than three axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected***; or in ipsilateral supraclavicular lymph nodes
pN3a	Metastases in 10 or more axillary lymph nodes (at least one tumor deposit greater than 2.0 mm); or metastases to the infraclavicular (level III axillary lymph) nodes
pN3b	Metastases in clinically detected**** ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes; or in more than three axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected***
pN3c	Metastasis in ipsilateral supraclavicular lymph nodes * Classification is based on axillary lymph node dissection with or without sentinel lymph node biopsy. Classification based solely on sentinel lymph node biopsy without subsequent axillary lymph node dissection is designated (sn) for "sentinel node," e.g., pN0(sn). ** RT-PCR: reverse transcriptase/polymerase chain reaction. *** "Not clinically detected" is defined as not detected by imaging studies (excluding lymphoscintigraphy) or not detected by clinical examination. **** "Clinically detected" is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination and having characteristics highly suspicious for malignancy or a presumed pathologic macrometastasis based on fine needle aspiration biopsy with cytologic examination.
Distant metastasis (M)	
M0	No clinical or radiographic evidence of distant metastases
cM0(i+)	No clinical or radiographic evidence of distant metastases, but deposits of molecularly or microscopically detected tumor cells in circulating blood, bone marrow, or other nonregional nodal tissue that are no larger than 0.2 mm in a patient without symptoms or signs of metastases
M1	Distant detectable metastases as determined by classic clinical and radiographic means and/or histologically proven larger than 0.2 mm

TNM stage groupings

STAGE 0	TIS	N0	M0
Stage IA	T1[a]	N0	M0
Stage IB	T0	N1mi	M0
	T1[a]	N1mi	M0
Stage IIA	T0	N1[b]	M0
	T1[a]	N1[b]	M0
	T2	N0	M0
Stage IIB	T2	N1	M0
	T3	N0	M0
Stage IIIA	T0	N2	M0
	T1[a]	N2	M0
	T2	N2	M0
	T3	N1	M0
	T3	N2	M0
Stage IIIB	T4	N0	M0
	T4	N1	M0
	T4	N2	M0
Stage IIIC	Any T	N3	M0
Stage IV	Any T	Any N	M1

[a]T1 includes T1mi
[b]T0 and T1 tumors with nodal micrometastases only are excluded from Stage IIA and are classified Stage IB
–M0 includes M0(i+).
–The designation pM0 is not valid; any M0 should be clinical.
–If a patient presents with M1 prior to neoadjuvant systemic therapy, the stage is considered Stage IV and remains Stage IV regardless of response to neoadjuvant therapy.
–Stage designation may be changed if postsurgical imaging studies reveal the presence of distant metastases, provided that the studies are carried out within 4 months of diagnosis in the absence of disease progression and provided that the patient has not received neoadjuvant therapy.
–Postneoadjuvant therapy is designated with "yc" or "yp" prefix.
Of note, no stage group is assigned if there is a complete pathologic response (CR) to neoadjuvant therapy, e.g., ypT0ypN0cM0.

risk factors that include measures of carcinogen exposure such as DNA adducts. Surrogate endpoint biomarkers are biologic alterations in tissue that occur between cancer initiation and development. These biomarkers are used as endpoints in short-term chemoprevention trials and include histologic changes, indices of proliferation, and genetic alterations leading to cancer. Prognostic biomarkers provide information regarding cancer outcome irrespective of therapy, whereas predictive biomarkers provide information regarding response to therapy.[158] Candidate prognostic and predictive biomarkers and biologic targets for breast cancer include (a) the steroid hormone receptor pathway; (b) growth factors and growth factor receptors such as human epidermal growth factor receptor 2 (HER-2)/*neu*, epidermal growth factor receptor (EGFR), transforming growth factor, platelet-derived growth factor, and the insulin-like growth factor family; (c) indices of proliferation such as proliferating cell nuclear antigen (PCNA) and Ki-67; (d) indices of angiogenesis such as vascular endothelial growth factor (VEGF) and the angiogenesis index; (e) the mammalian target of rapamycin (mTOR) signaling pathway; (f) tumor-suppressor genes such as p53; (g) the cell cycle, cyclins, and cyclin-dependent kinases; (h) the proteasome; (i) the COX-2 enzyme; (j) the peroxisome proliferator-activated receptors (PPARs); and (k) indices of apoptosis and apoptosis modulators such as bcl-2 and the bax:bcl-2 ratio.

Steroid Hormone Receptor Pathway. Hormones play an important role in the development and progression of breast cancer. Estrogens, estrogen metabolites, and other steroid hormones such as progesterone all have been shown to have an effect. Breast cancer risk is related to estrogen exposure over time. In postmenopausal women, hormone replacement therapy consisting of estrogen plus progesterone increases the risk of breast cancer by 26% compared to placebo.[70] Patients with hormone receptor-positive tumors survive two to three times longer after a diagnosis of metastatic disease than do patients with hormone receptor-negative tumors. Patients with tumors negative for both estrogen receptors and progesterone receptors are not considered candidates for hormonal therapy. Tumors positive for estrogen or progesterone receptors have a higher response rate to endocrine therapy than tumors that do not express estrogen or progesterone receptors. Tumors positive for both receptors have a response rate of >50%, tumors negative for both receptors have a response rate of <10%, and tumors positive for one receptor but not the other have an intermediate response rate of 33%. The determination of estrogen and progesterone receptor status used to require biochemical evaluation of fresh tumor tissue. Today, however, estrogen and progesterone receptor status can be measured in archived tissue using immunohistochemical techniques. Hormone receptor status also can be measured in specimens obtained with fine-needle aspiration biopsy or core-needle biopsy, and this can help guide treatment planning. Testing for estrogen and progesterone receptors should be performed on all primary invasive breast cancer specimens. The tumor hormone receptor status should be ascertained for both premenopausal and postmenopausal patients to identify patients who are most likely to benefit from endocrine therapy.

Growth Factor Receptors and Growth Factors. Overexpression of EGFR in breast cancer correlates with estrogen receptor–negative status and with p53 overexpression.[159-161] Similarly, increased immunohistochemical membrane staining for the *HER-2/neu* growth factor receptor in breast cancer is associated with mutated p53, Ki-67 overexpression, and estrogen receptor–negative status. *HER-2/neu* is a member of the EGFR family of growth factor receptors in which ligand binding results in receptor homodimerization and tyrosine phosphorylation by tyrosine kinase domains within the receptor. Tyrosine phosphorylation is followed by signal transduction, which results in changes in cell behavior. An important property of this family of receptors is that ligand binding to one receptor type also may result in heterodimerization between two different receptor types that are coexpressed; this leads to transphosphorylation and transactivation of both receptors in the complex (transmodulation). In this context, the lack of a specific ligand for the HER-2/*neu*

receptor suggests that *HER-2/neu* may function solely as a coreceptor, modulating signaling by other EGFR family members. *HER-2/neu* is both an important prognostic factor and a predictive factor in breast cancer.[162] When overexpressed in breast cancer, *HER-2/neu* promotes enhanced growth and proliferation, and increases invasive and metastatic capabilities. Clinical studies have shown that patients with *HER-2/neu*–overexpressing breast cancer have poorly differentiated tumors with high proliferation rates, positive lymph nodes, decreased hormone receptor expression, and an increased risk of recurrence and death due to breast cancer.[162-166] Routine testing of the primary tumor specimen for *HER-2/neu* expression should be performed on all invasive breast cancers. This can be done with immunohistochemical analysis to evaluate for overexpression of the cell-surface receptor at the protein level or by using fluorescence in situ hybridization to evaluate for gene amplification. Patients whose tumors overexpress HER-2/*neu* are candidates for anti–*HER-2/neu* therapy. Trastuzumab (Herceptin) is a recombinant humanized monoclonal antibody directed against *HER-2/neu*. Randomized clinical trials have demonstrated that single-agent trastuzumab therapy is an active and well-tolerated option for first-line treatment of women with *HER-2/neu*–overexpressing metastatic breast cancer. More recently, adjuvant trials demonstrated that trastuzumab also was highly effective in the treatment of women with early-stage breast cancer when used in combination with chemotherapy. Patients who received trastuzumab in combination with chemotherapy had between a 40%–50% reduction in the risk of breast cancer recurrence and approximately a third reduction in breast cancer mortality compared with those who received chemotherapy alone.[167-170]

Indices of Proliferation. PCNA is a nuclear protein associated with a DNA polymerase whose expression increases in phase G_1 of the cell cycle, reaches its maximum at the G_1/S interface, and then decreases through G_2.[171-174] Immunohistochemical staining for PCNA outlines the proliferating compartments in breast tissue. Good correlation is noted between PCNA expression and (a) cell-cycle distributions seen on flow cytometry based on DNA content, and (b) uptake of bromodeoxyuridine and the proliferation-associated Ki-67 antigen. Individual proliferation markers are associated with slightly different phases of the cell cycle and are not equivalent. PCNA and Ki-67 expression are positively correlated with p53 overexpression, high S-phase fraction, aneuploidy, high mitotic index, and high histologic grade in human breast cancer specimens, and are negatively correlated with estrogen receptor content. Ki67 was included with three other widely measured breast cancer markers (ER, PR, and HER2) into a panel of four immunohistochemical makers (IHC4) which together provided similar prognostic information to that in the Genomic Health 21 Gene Recurrence Score.[175] While there has been significant interest in using Ki67 as a biomarker, and while the IHC4 panel would be much less costly than the 21 Gene Recurrence Score there remain issues regarding reproducibility across laboratories.

Indices of Angiogenesis. Angiogenesis is necessary for the growth and invasiveness of breast cancer and promotes cancer progression through several different mechanisms, including delivery of oxygen and nutrients and the secretion of growth-promoting cytokines by endothelial cells.[176,177] VEGF induces its effect by binding to transmembrane tyrosine kinase receptors. Overexpression of VEGF in invasive breast cancer is correlated with increased microvessel density and recurrence in node-negative breast cancer. An angiogenesis index has been developed in which microvessel density (CD31 expression) is combined with expression of thrombospondin (a negative modulator of angiogenesis) and p53 expression. Both VEGF expression and the angiogenesis index may have prognostic and predictive significance in breast cancer. Antiangiogenesis breast cancer therapy is now being studied in human trials. Bevacizumab (a monoclonal antibody to VEGF) was approved by the U.S. Food and Drug Administration (FDA) for use in metastatic breast cancer in combination with paclitaxel chemotherapy. This approval was based on results from a phase III trial by the Eastern Cooperative Oncology Group. The group's E2100 trial showed that when bevacizumab was added to paclitaxel chemotherapy, median progression-free survival increased to 11.3 months from the 5.8 months seen in patients who received paclitaxel alone.[178] The results were not reproduced in other trials and the indication for the drug was revoked by the FDA in 2011.

Indices of Apoptosis. Alterations in programmed cell death (apoptosis), which may be triggered by p53-dependent or p53-independent factors, may be important prognostic and predictive biomarkers in breast cancer.[179-181] Bcl-2 family proteins appear to regulate a step in the evolutionarily conserved pathway for apoptosis, with some members functioning as inhibitors of apoptosis and others as promoters of apoptosis. *Bcl-2* is the only oncogene that acts by inhibiting apoptosis rather than by directly increasing cellular proliferation. The death-signal protein bax is induced by genotoxic stress and growth factor deprivation in the presence of wild-type (normal) p53 and/or AP-1/fos. The bax:bcl-2 ratio and the resulting formation of either bax-baxhomodimers, which stimulate apoptosis, or bax–bcl-2 heterodimers, which inhibit apoptosis, represent an intracellular regulatory mechanism with prognostic and predictive implications. In breast cancer, overexpression of bcl-2 and a decrease in the bax:bcl-2 ratio correlate with high histologic grade, the presence of axillary lymph node metastases, and reduced disease-free and overall survival rates. Similarly, decreased bax expression correlates with axillary lymph node metastases, a poor response to chemotherapy, and decreased overall survival.

The remaining biomarkers and biologic targets listed earlier are still in preclinical and clinical trials evaluating their importance in breast cancer for both prognostic and predictive purposes.

Coexpression of Biomarkers. Selection of optimal therapy for breast cancer requires both an accurate assessment of prognosis and an accurate prediction of response to therapy. The breast cancer markers that are most important in determining therapy are estrogen receptor, progesterone receptor, and *HER-2/neu*. Clinicians evaluate clinical and pathologic staging and the expression of estrogen receptor, progesterone receptor, and *HER-2/neu* in the primary tumor to assess prognosis and assign therapy. Adjuvant! Online (*http://www.adjuvantonline.com*) is one of a number of programs available to clinicians that incorporates clinical and pathologic factors for an individual patient and calculates risk of recurrence and death due to breast cancer and then provides an assessment of the reduction in risk of recurrence that would be expected with the use of combination chemotherapy, endocrine therapy, or both of these. Adjuvant! Online was developed using information from the SEER database, the EBCTCG overview analyses, and results from other individual published trials.[182] The website is updated and modified as new information becomes available. Clinicopathologic factors are used to separate breast cancer patients into broad

Table 17-12

Traditional prognostic and predictive factors for invasive breast cancer

TUMOR FACTORS	HOST FACTORS
Nodal status	Age
Tumor size	Menopausal status

prognostic groups, and treatment decisions are made on this basis (Table 17-12). Other indices and programs which are validated and used include the Nottingham Prognostic Index, and PREDICT.[183-185] When an approach, which combines prognostic factors is used, up to 70% of early breast cancer patients receive adjuvant chemotherapy that is either unnecessary or ineffective. As described earlier, a wide variety of biomarkers have been shown to individually predict prognosis and response to therapy, but they do not improve the accuracy of either the assessment of prognosis or the prediction of response to therapy.

As knowledge regarding cellular, biochemical, and molecular biomarkers for breast cancer increases, prognostic indices are being developed that combine the predictive power of several individual biomarkers with the relevant clinicopathologic factors.

Most recently, technologic advances have led to the ability to measure the expression of multiple genes in a tumor sample simultaneously. This gene expression profiling can provide information about tumor behavior that can be used in determining prognosis and therapy.[186] These high-throughput analyses require bioinformatics support that can categorize and analyze the immense amount of data that are generated. This allows for a detailed stratification of breast cancer patients for assessment of prognosis and for prediction of response to therapy. The Onco*type* DX is a 21-gene assay that has been validated in newly diagnosed patients with node-negative, estrogen receptor–positive breast cancer.[187] A recurrence score is generated, and those patients with high recurrence scores are found to benefit the most from chemotherapy, whereas those with low recurrence scores benefit most from endocrine therapy and may not require chemotherapy. The 21-gene recurrence score assay has been validated to quantify the risk of recurrence in patients with ER-positive, node-negative breast cancer and also predicts the potential for chemotherapy benefit. Recent data have demonstrated that knowledge of the recurrence score alters treatment recommendations by oncologists and patients likewise change their decision to undergo treatment based on results of the recurrence score.[188] A recently completed clinical trial, the Trial Assessing Individualized Options for Treatment for breast cancer (TAILORx), randomly assigned patients with an intermediate recurrence score to endocrine therapy alone or to chemotherapy followed by endocrine therapy. When these trial results mature we will learn whether this intermediate risk group of patients with hormone receptor positive disease benefit from the addition of chemotherapy. The MammaPrint test was approved by the FDA for use in patients with newly diagnosed, node-negative breast cancer. The MammaPrint test is based on a 70-gene profile, and although fresh tissue was initially required to perform the assay, it has recently been adapted for use in paraffin-embedded tissue samples. The MINDACT (**M**icroarray**I**n-**N**ode negative and 1-3 positive lymph node **D**isease may **A**void **C**hemo**T**herapy) trial is a phase III randomized trial comparing MammaPrint to Adjuvant! Online for selecting node negative and node-positive (1-3 nodes) breast cancer patients for adjuvant chemotherapy. This trial has completed enrollment with 6,700 patients and will provide important information regarding the use of molecular over standard clinic-pathologic predictors in clinical practice.

OVERVIEW OF BREAST CANCER THERAPY

Before diagnostic biopsy, the surgeon must consider the possibility that a suspicious mass or mammographic finding may be a breast cancer. Once a diagnosis of breast cancer is made, the type of therapy offered to a breast cancer patient is determined by the stage of the disease, the biologic subtype and the general health status of the individual. Laboratory tests and imaging studies are performed based on the initial stage as presented in Table 17-13. Before therapy is initiated, the patient and the surgeon must share a clear perspective on the planned

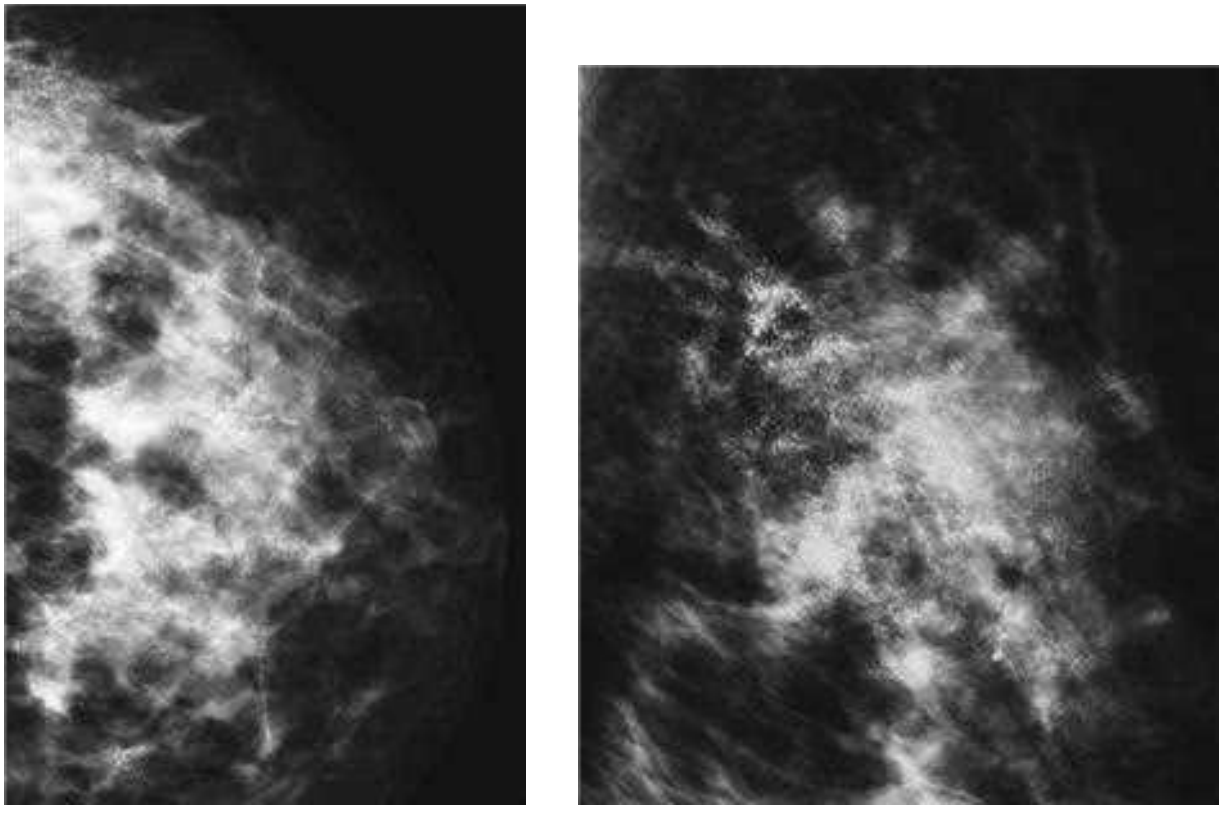
course of treatment. Before initiating local therapy, the surgeon should determine the clinical stage, histologic characteristics, and appropriate biomarker levels. 8▶

In Situ Breast Cancer (Stage 0)

Both LCIS and DCIS may be difficult to distinguish from atypical hyperplasia or from cancers with early invasion.[60,189-194] Expert pathologic review is required in all cases. Bilateral mammography is performed to determine the extent of the in situ cancer and to exclude a second cancer. Because LCIS is considered a marker for increased risk rather than an inevitable precursor of invasive disease, the current treatment options for LCIS include observation, chemoprevention, and bilateral total mastectomy. The goal of treatment is to prevent or detect at an early stage the invasive cancer that subsequently develops in 25% to 35% of these women. There is no benefit to excising LCIS, because the disease diffusely involves both breasts in many cases and the risk of developing invasive cancer is equal for both breasts. The use of tamoxifen as a risk reduction strategy should be considered in women with a diagnosis of LCIS.

Women with DCIS and evidence of extensive disease (>4 cm of disease or disease in more than one quadrant) usually require mastectomy (Fig. 17-29). For women with limited disease, lumpectomy and radiation therapy are generally recommended. For nonpalpable DCIS, needle localization or other image-guided techniques are used to guide the surgical resection. Specimen mammography is performed to ensure that all visible evidence of cancer is excised. Adjuvant tamoxifen therapy is considered for DCIS patients with ER-positive disease. The gold standard against which breast conservation therapy for DCIS is evaluated is mastectomy. Women treated with mastectomy have local recurrence and mortality rates of <2%. There is no randomized trial comparing mastectomy vs. breast conserving surgery and none of the randomised trials of breast conserving surgery with or without radiotherapy for DCIS were powered to show a difference in mortality. Women treated with lumpectomy and adjuvant radiation therapy have a local recurrence rate that is increased compared to mastectomy. About 45% of these recurrences will be invasive cancer when radiation therapy is not used. The B-17 trial was conducted by the NSABP to assess the need for radiation in patients treated with breast conserving surgery for DCIS.[195] Patients were randomly assigned to lumpectomy with radiation or lumpectomy alone and after a mean follow-up time of 90 months, rates of both ipsilateral noninvasive and invasive recurrences were significantly lower in patients who received radiation. However in the B-17 trial the margins were not prospectively assessed and it is estimated that up to half the patients may have had tumor at the margin of resection. The benefit of the addition of radiation over breast-conserving surgery alone for DCIS has also been demonstrated in several other randomized trials where margins were prospectively assessed including the European Organization for Research and Treatment of Cancer (EORTC) protocol 10853; the United Kingdom, Australia, New Zealand DCIS Trial; and the Swedish Trial.[189,196-198]

Despite the data from randomized trials showing a benefit in all patient subgroups with the addition of radiation in DCIS there has been an interest in trying to define a subset where radiation could be avoided in order to minimize the cost and inconvenience



A B

Figure 17-29. Extensive DCIS seen on mammography. **A.** Extensive calcifications are seen throughout the breast on this CC view. **B.** Magnification view of calcifications. Due to the extent of the disease the patient is not a good candidate for breast conserving surgery. associated with radiation. In addition, there have been several studies published where patients were treated with excision alone and never developed invasive breast cancer even at 25 years of follow-up. Silverstein and colleagues have been proponents of avoiding radiation therapy in selected patients with DCIS who have widely negative margins after surgery.[193] They reported that when greater than 10 mm margins were achieved, there was no additional benefit from radiation therapy. When margins were between 1- to 10-mm there was a relative risk of local recurrence of 1.49, compared to 2.54 for those with margins less than 1 mm. These data suggested that appropriately selected patients with DCIS might not require postoperative radiation therapy.

The Eastern Cooperative Oncology Group (ECOG) initiated a prospective registry trial (ECOG 5194) to identify those patients who could safely undergo breast conserving surgery without radiation.[199] Eligible patients were those with low or intermediate grade DCIS measuring 2.5 cm or less who had negative margins of at least 3 mm and those with high grade DCIS who had tumors measuring 1 cm or less with a negative margin of at least 3 mm. At a median follow-up of 6.2 years, patients with low or intermediate grade DCIS had an in-breast recurrence rate of 6.1% while those with high grade DCIS had a recurrence rate of 15.3%. Approximately 4% of patients developed a contralateral breast cancer during follow-up in both the low/intermediate and high grade groups. This study identified an acceptable recurrence rate for those patients with low or intermediate grade DCIS treated with excision alone with a margin of at least 3 mm. In contrast, patients with high grade DCIS had an unacceptably high local recurrence rate.

The Radiation Therapy Oncology Group (RTOG) initiated the 9804 trial for patients with "good risk" DCIS and randomized them to lumpectomy vs. lumpectomy with whole breast irradiation. Eligible patients were those with unicentric, low or intermediate grade DCIS measuring 2.5 cm or less with a margin of 3 mm or greater. The trial was closed early due to slow accrual, however the results for 585 patients were recently reported with a median follow-up of 6.46 years.[200] The local recurrence rate at 5 years was 0.4% for patients randomized to receive radiation and 3.2% for those who did not receive radiation. This study has only been reported in abstract form and continued follow-up for enrolled patients is planned.

Solin et al utilized samples from the ECOG 5194 trial to develop a quantitative multigene RT-PCR assay for predicting recurrence risk in patients with DCIS treated with surgery alone.[201] They were able to define low, intermediate and high risk groups using a DCIS Score. The DCIS Score was able to quantify the risk of recurrence in the breast for both DCIS and invasive events. This tool will need to be evaluated in additional studies but appears to be a promising tool for clinical use. When selecting therapy for patients with DCIS, one must consider clinical and pathologic factors, including tumor size, grade, mammographic appearance, and patient preference. There is no single correct surgical treatment and many patients will require extensive counseling in order to make a decision regarding surgical therapy. The role of axillary staging in patients with DCIS is limited. One consideration is for patients undergoing mastectomy. Since most lesions are currently diagnosed with needle core biopsy, there is about a 20% incidence of invasive breast cancer on final pathologic assessment of the primary tumor.

Since it is not feasible to perform sentinel node dissection after mastectomy, most surgeons will recommend the use of sentinel node dissection at the time of mastectomy for DCIS.

Results from the NSABP B-24 trial reported a significant reduction in local recurrence after 5 years of tamoxifen in women with ER-positive DCIS. Based on this some guidelines have advocated that all patients (women with ER-positive DCIS without contraindications to tamoxifen therapy) should be offered tamoxifen following surgery and radiation therapy for a duration of 5 years. The B-24 trial revealed a significant reduction in recurrence with adjuvant tamoxifen therapy for patients with DCIS, however the results were not initially assessed based on ER status.[202] There were 1,804 women with DCIS randomized to lumpectomy and radiation with or without tamoxifen. The rate of breast cancer events was significantly lower in those who received tamoxifen at a median follow-up of 74 months (8.2% vs. 13.4%, $P = 0.0009$). Subsequently, Allred and colleagues evaluated 41% of patients with DCIS in the NSABP B-24 trial to determine the effect of tamoxifen based on ER status measured in the primary tumor.[203] They found that 76% of women had DCIS that was ER-positive and these women had a greater reduction in ipsilateral breast tumor recurrence with tamoxifen than did patients with ER-negative DCIS (11% vs. 5.2%, $P<0.001$). However it should be noted that 15% of patients in B-24 had tumor at the resection margins for whom tamoxifen could be viewed as treating what by current standard would be viewed as inadequate local excision of the primary tumor. Five years of tamoxifen is not uniformly prescribed across the world as adjuvant therapy following breast conserving surgery and radiation therapy for DCIS.

Early Invasive Breast Cancer (Stage I, IIA, or IIB)

There have been six prospective randomized trials comparing breast conserving surgery to mastectomy in early stage breast cancer and all have shown equivalent survival rates regardless of the surgical treatment type. One caveat however is that the majority of studies had a restriction of tumor size; most were either 2 cm or 2.5 cm while the NSABP B-06 trial was 4 cm and the NCI trial was up to 5 cm. NSABP B-06, which is the largest of all the breast conservation trials, compared total mastectomy to lumpectomy with or without radiation therapy in the treatment of women with stage I and II breast cancer.[11,204-210] After 5- and 8-year follow-up periods, the disease-free (DFS), distant disease-free, and overall survival (OS) rates for lumpectomy with or without radiation therapy were similar to those observed after total mastectomy. However, the incidence of ipsilateral breast cancer recurrence was higher in the group not receiving radiation therapy. These findings supported the use of lumpectomy and radiation therapy in the treatment of stage I and II breast cancer and this has since become the preferred method of treatment for women with early stage breast cancer who have unifocal disease and who are not known BRCA mutation carriers. Reanalysis of the B-06 study results was undertaken after 20 years of follow-up and confirmed that there was no difference in disease-free survival rates after total mastectomy or after lumpectomy with or without adjuvant radiation therapy. The in-breast recurrence rate was substantially higher in the lumpectomy alone group (39.2%) compared with the lumpectomy plus adjuvant radiation therapy group (14.3%) confirming the importance of radiation therapy in the management of patients with invasive disease. However it should be noted that there were several criteria in the B-06 study. There was a specific lymphadenopathy exclusion criteria. Secondly, all patients randomized to breast conserving surgery had a frozen section and if the margins were involved they were converted to mastectomy

but were included in the analysis as having had a breast conserving operation (on the basis of intention to treat). Finally, in the breast conserving group recurrences in the treated breast were considered as a 'non event'.

Data from all of the randomized trials where breast conservation was performed with or without radiation therapy have been examined by the EBCTCG.[12] At 15 years of follow-up, the absolute reduction in mortality with the use of radiation therapy after lumpectomy was 5.1% in node-negative patients and 7.1% in node-positive patients. These data support the concept that the addition of radiation not only improves local control but also has an impact on survival. Similar to DCIS, clinicians have sought to identify subgroups of patients who may not benefit from the addition of radiation therapy, particularly older patients who may have a shorter life expectancy due to medical comorbidities. Two randomized trials have shown that in selected patients with small, low-grade tumors, lumpectomy alone without radiation therapy may be appropriate.[211,212] The Cancer and Leukemia Group B (CALGB) C9343 trial enrolled women over the age of 70 with T1N0 breast cancer and randomized them to lumpectomy with or without radiation therapy. All patients received adjuvant tamoxifen. Although there were fewer local recurrences with radiation (1% vs. 4%, $P<0.001$), there were no differences in DFS and OS. A trial similar to CALGB C9343 was conducted in Canada where they enrolled women 50 years and older and randomized them to lumpectomy with or without radiation. Mean age was 68 years, and 80% of women had ER-positive tumors. Again, local recurrence rates were lower in women who received radiation (0.6% vs. 7.7%, $P<0.001$), however, at a median follow-up of 5.6 years, there were no differences in DFS or OS. These studies suggest that radiation can be avoided in early-stage breast cancer patients over the age of 70 when they are diagnosed with T1, N0, ER-positive breast cancer.

Accelerated partial breast irradiation (APBI) is also an option for carefully selected patients with DCIS and early-stage breast cancer. Since the majority of recurrences after breast conservation occur in or adjacent to the tumor bed there has been interest in limiting the radiation to the area of the primary tumor bed with a margin of normal tissue. APBI is delivered in an abbreviated fashion (twice daily for 5 days) and at a lower total dose compared with the standard course of 5 to 6 weeks of radiation (50 Gray with or without a boost) in the case of whole breast irradiation. Proponents have suggested that this shortened course of treatment may increase the feasibility of breast conservation for some women and may improve radiation therapy compliance. The RTOG 04-13/NSABP B-39 trial is a randomized comparison of whole breast irradiation to APBI in women with early stage breast cancer. The trial recently completed accrual and it will likely be several years before data are mature to report outcomes between the two radiation treatment strategies. TARGIT is another study which randomized 3,451 patients in 33 centers over 10 countries to intraoperative breast irradiation (IORT) or external beam radiotherapy (EBRT). The preliminary results were reported in 2012—with a median follow-up of 2.4 years use of IORT had a recurrence rate of 3.3% vs. 1.3% with EBRT, a 2% increased recurrence risk. [213]

The American Society for Radiation Oncology (ASTRO) developed guidelines for the use of APBI outside of clinical trials based on data reported from published studies.[214] The ASTRO guidelines describe patients "suitable" for APBI to include women 60 years of age or older with a unifocal, T1, ER-positive tumor with no lymphovascular invasion, and margins of at least 2 mm. They describe a group where there is uncertainty about the appropriateness of APBI ("cautionary" group) to include patients with invasive lobular histology, a tumor size of 2.1 cm to 3 cm, ER-negative disease, focal lymphovascular invasion, or margins less than 2 mm. Finally, a group felt to be "unsuitable" for APBI includes those with T3 or T4 disease, ER-negative disease, multifocality, multicentricity, extensive LVI, or positive margins.

Currently, mastectomy with axillary staging and breast conserving surgery with axillary staging and radiation therapy are considered equivalent treatments for patients with stage I and II breast cancer. Breast conservation is considered for all patients because of the important cosmetic advantages and equivalent survival outcomes, however, this approach is not advised in women who are known BRCA mutation carriers due to the high lifetime risk for development of additional breast cancers. Relative contraindications to breast conservation therapy include (a) prior radiation therapy to the breast or chest wall, (b) persistently positive surgical margins after reexcision, (c) multicentric disease, and (d) scleroderma or lupus erythematosus.

For most patients with early-stage disease, reconstruction can be performed immediately at the time of mastectomy. Immediate reconstruction allows for skin-sparing, thus optimizing cosmetic outcomes. Skin-sparing mastectomy with immediate reconstruction has been popularized over the past decade as reports of low local-regional failure rates have been reported and reconstructive techniques have advanced. There is a growing interest in the use of nipple-areolar sparing mastectomy although few reports on the long-term safety of this approach are available at this time. Patients who are planned for postmastectomy radiation therapy are not ideal candidates for nipple-sparing mastectomy because of the effects of radiation on the preserved nipple. In addition to providing optimal cosmesis from preservation of the skin and/or the nipple-areolar complex, immediate reconstruction allows patients to wake up with a breast mound which provides some psychological benefit for the patient. Immediate reconstruction is also more economical as both the extirpative and reconstructive surgery are combined in one operation.

Immediate reconstruction can be performed using implants or autologous tissue; tissue flaps commonly used include the transverse rectus abdominis myocutaneous flap, deep inferior epigastric perforator flap, and latissimus dorsi flap (with or without an implant). If postmastectomy radiation therapy is needed, a tissue expander can be placed at the time of mastectomy to save the shape of the breast and reduce the amount of skin replacement needed at the time of definitive reconstruction. The expander can be deflated at the initiation of radiation therapy to allow for irradiation of the chest wall and regional nodal basins. Removal of the tissue expander and definitive reconstruction, usually with autologous tissue, can proceed 6 months to 1 year after completion of radiation therapy.

Axillary lymph node status has traditionally been an important determinant in staging and prognosis for women with early stage breast cancer. Historically, axillary lymph node dissection (ALND) was utilized for axillary staging and regional control by removing involved lymph nodes. Randomized trials evaluating immediate ALND over ALND performed in a delayed fashion once clinically palpable axillary disease became evident have not shown any detriment in survival.[9,215] With increased mammographic screening and detection of

smaller, node-negative breast cancers, it became clear that routine use of ALND for axillary staging was not necessary in up to 75% percent of women with operable breast cancer presenting with a negative axilla at the time of screening. Lymphatic mapping and sentinel lymph node (SLN) dissection were initially developed for assessment of patients with clinically node-negative melanoma. Given the changing landscape of newly diagnosed breast cancer patients with a clinically node-negative axilla, surgeons quickly began to explore the utility of SLN dissection as a replacement for ALND in axillary staging.

In the early 1990s, David Krag at the University of Vermont began performing SLN dissection with injection of a radioisotope in the primary tumor site and localizing the SLN node with a handheld gamma probe.[216] He was able to identify a SLN in 18 of 22 patients examined and the SLN was positive in all 7 patients with positive lymph nodes. Giuliano and colleagues initiated a pilot study in 1991 to examine the use of SLN dissection using blue dye in patients with clinically negative nodes. They reported successful identification of a SLN in 114 (65.5%) of 174 patients and in 109 (95.6%), the SLN accurately predicted the status of the axillary nodes.[217,218] These studies along with initial work by Doug Reintgen and Charles Cox at the Moffitt Cancer Center and Umberto Veronesi and his colleagues at the European Institute of Oncology in Milan led the way toward validation of the technique in large single institution and multicenter studies.

Following validation of the technique of SLN dissection for staging of the axilla by multiple centers, randomized trials were initiated in order to determine if SLN dissection could replace ALND in the contemporary management of breast cancer patients. The ALMANAC trial randomized 1,031 patients with primary operable breast cancer to SLN dissection vs. standard axillary surgery. The incidence of lymphedema and sensory loss for the SLN group was significantly lower than with the standard axillary treatment. At 12 months, drain usage, length of hospital stay, and time to resumption of normal day-to-day activities after surgery were also statistically significantly lower in the SLN group.[219]

The NSABP B-32 trial compared clinically node negative patients undergoing SLN dissection followed by ALND with patients undergoing SLN dissection with ALND only if a SLN was positive for metastatic disease.[220] A total of 5,611 patients were randomized with a SLN identification rate of 97%, and a false-negative rate of 9.7%. A total of 26% of these clinically node-negative patients had a positive SLN. Over 60% of patients with positive SLNs had no additional positive lymph nodes within the ALND specimen. The B-32 trial and other randomized trials demonstrated no difference in DFS, OS, and local-regional recurrence rates between patients with negative SLNs who had SLN dissection alone compared with those who underwent ALND.[221,222] Most important, patients who had SLN dissection alone were found to have decreased morbidity (arm swelling and range of motion) and improved quality of life vs. patients who underwent ALND.[222,223]

The American College of Surgeons Oncology Group (ACOSOG) initiated the Z0010 and Z0011 trials in order to evaluate the incidence and prognostic significance of occult metastases identified in the bone marrow and SLNs (Z0010) of early-stage clinically node-negative patients and to evaluate the utility of ALND in patients with clinical T1-2, N0 breast cancer with 1 or 2 positive SLNs for patients treated with breast conserving surgery and whole breast irradiation (WBI) .[224,225]

The Z0010 study enrolled 5,539 patients with clinical T1-2 breast cancer planned for breast conserving surgery and WBI.[224] There were 24% of patients who proved to have positive SLNs based on standard pathologic assessment and of the negative SLNs subjected to immunohistochemical staining for cytokeratin, 10.5% proved to have occult metastasis. Of the patients who had bone marrow aspiration, 3.0% had immunohistochemically detected tumor cells in the bone marrow. Although the presence of disease in the bone marrow identified a population at high risk for recurrence, neither immunohistochemical detection of disease in the SLNs or the bone marrow was statistically significant on multivariable analysis with clinicopathologic and treatment factors included. The investigators concluded that routine use of immunohistochemistry to detect occult disease in SLNs is not warranted.

The Z0011 trial was a companion study to Z0010 and was designed to study the role of completion ALND on survival in women with positive SLNs. Patients were not eligible if they received neoadjuvant chemotherapy or neoadjuvant hormonal therapy or if their treatment plan included mastectomy, lumpectomy without radiation, or lumpectomy with APBI. WBI was to be administered using standard tangential fields without specific treatment of the axilla or additional fields targeting other nodal basins. Patients with 1 or 2 positive SLNs were randomized to completion ALND or no further surgery. Adjuvant systemic therapy recommendations were left to the treating clinicians. After median follow-up of 6.3 years, there was no difference between patients randomized to ALND and those randomized to no further surgery (SLN only) in terms of OS (91.9% and 92.5%, respectively; P=0.25) or DFS (82.2% and 83.8%, respectively; P=0.14).

The morbidity of SLN dissection alone vs. SLN dissection with completion ALND has been reported by the ACOSOG investigators.[226,227] Immediate effects of SLN dissection in the Z0010 trial included wound infection in 1%, axillary seroma in 7.1%, and axillary hematoma in 1.4%.[226] At 6 months following surgery, axillary paresthesias were noted in 8.6% of patients, decreased range of motion in the upper extremity was reported in 3.8%, and 6.9% of patients had a change in the arm circumference of >2 cm on the ipsilateral side, which was reported as lymphedema. Younger patients were more likely to report paresthesias, whereas increasing age and body mass index were more predictive of lymphedema. When adverse surgical effects were examined in the Z0011 trial, patients undergoing SLN dissection with ALND had more wound infections, seromas, and paresthesias than those women undergoing SLN dissection alone. Lymphedema at one year after surgery was reported by 13% in the SLN plus ALND group but only 2% in the SLN dissection alone group. Arm circumference measurements were greater at one year in patients undergoing SLN dissection plus ALND, but the difference between study groups was not statistically significant.[227] This supports the results published from the ALMANAC trial.

Prior to the publication of ACOSOG Z0011, completion ALND was standard of care for patients with positive SLNs. Since the reporting of ACOSOG Z0011, the National Comprehensive Cancer Network (NCCN) guidelines now state that there was no OS difference for patients with 1 or 2 positive SLNs treated with breast conserving surgery who underwent completion ALND vs. those who had no further axillary surgery. In addition, the American Society of Breast Surgeons issued a consensus statement supporting omission of ALND for patients who meet Z0011 criteria.[228] The results of ACOSOG Z0011

9▶

have revolutionized management of the axilla and changed practice such that selected patients with axillary metastasis can now avoid ALND if they have clinical and pathologic features similar to those patients enrolled on Z0011. However, there have been some concerns raised about the Z0011 study which include the fact that the study only recruited about half of the intended patients and that there was no standardization of whether or not patients received irradiation to the low axilla when the radiation oncologist irradiated the breast. These issues have thus far limited the uptake of the results of Z0011 by some centers.

The International Breast Cancer Study Group (IBCSG) 23-01 trial was similar in design to Z0011 but enrolled only patients with micrometastases in the SLNs. Patients with SLN micrometastases were randomized to ALND vs. no further surgery. Unlike Z0011, the 23-01 trial did not exclude patients treated with mastectomy. Approximately 9% of patients randomized to each study arm underwent mastectomy. The investigators published the primary and secondary endpoints of the trial showing no differences in OS or local-regional recurrence between the study arms.[229] However, as with the Z0011 trial, some concerns have been raised regarding the 23-01 study. For example, in the statistics on the primary endpoint, local recurrence included contralateral breast cancer and other tumor types as events. No hypothesis was presented as to why the difference in axillary surgery should impact on either of these events. Including these events therefore reduced the power of the study to show a statistical difference between treatment arms. There is also concern that the study appears underpowered to show a meaningful difference in overall survival.

Most pathology laboratories perform a more detailed analysis of the SLN than is routinely done for axillary nodes recovered from a level I and II dissection. This can include examining thin sections of the node with step sectioning at multiple levels through the paraffin blocks or performing immunohistochemical staining of the SLN for cytokeratin or a combination of these techniques. The results of ACOSOG Z0010 and NSABP B-32 showed no clinically meaningful difference in survival based on detection of occult metastases in the SLNs using immunohistochemical staining and do not support the routine use in SLN processing. The type of intraoperative assessment of SLNs also varies for different clinicians and pathology laboratories. Some centers prefer to use touch preparation cytologic analysis of the SLNs, whereas others use frozen-section analysis, and the sensitivity and specificity of these assays vary considerably. The GeneSearch Breast Lymph Node Assay is a real-time reverse-transcriptase polymerase chain reaction assay that detects breast tumor cell metastasis in lymph nodes through the identification of the gene expression markers mammaglobin and cytokeratin 19. These markers are present in higher levels in breast tissue and not in nodal tissue (cell type-specific messenger RNA). The GeneSearch assay generates expression data for genes of interest, which are then evaluated against predetermined criteria to provide a qualitative (positive/negative) result. The assay is designed to detect foci that correspond to metastases which are seen with examination by standard hematoxylin and eosin staining and measure >0.2 mm. The GeneSearch assay results have been compared with permanent-section histologic analysis and frozen-section analysis of sentinel nodes in a prospective trial, and the assay was recently approved by the FDA for the intraoperative assessment of sentinel nodes.[230] When a positive node is identified intraoperatively by touch preparation, frozen-section analysis, or GeneSearch assay, the surgeon can proceed with immediate ALND. With the findings of ACOSOG Z0011 that there is not a survival benefit to the use of ALND in selected patients, many surgeons have abandoned the intraoperative evaluation of SLNs. There are a number of nomograms and predictive models designed to determine which patients with a positive SLN are at risk for harboring additional positive non-SLNs in the axilla. These tools can be helpful in determining the likelihood of additional disease in the axilla and may be used clinically to counsel patients.[231]

In patients who present with axillary lymphadenopathy that is confirmed to be metastatic disease on FNA or core biopsy, SLN dissection is not necessary and patients can proceed directly to ALND or be considered for preoperative systemic therapy (see section on Neoadjuvant [Preoperative] Chemotherapy under Non-Surgical Breast Cancer Therapies). Initially there was controversy about the suitability of SLN dissection in women with larger primary tumors (T3) and those treated with neoadjuvant chemotherapy. The American Society of Clinical Oncology has included SLN dissection is its guidelines as appropriate for axillary staging in these patients.[232] If a SLN cannot be identified, then ALND is generally performed for appropriate staging. However, this is not universally accepted and there are as yet no randomized studies which have assessed how a patient with a locally advanced cancer at presentation should be treated if their SLN dissection reveals no metastases or micrometastases after neoadjuvant therapy.

Adjuvant chemotherapy for patients with early-stage invasive breast cancer is considered for patients with node-positive cancers, patients with cancers that are >1 cm, and patients with node-negative cancers of >0.5 cm when adverse prognostic features are present. Adverse prognostic factors include blood vessel or lymph vessel invasion, high nuclear grade, high histologic grade, *HER*-2/*neu* overexpression or amplification, and negative hormone receptor status. Adjuvant endocrine therapy is considered for women with hormone receptor-positive cancers, and use of an aromatase inhibitor is recommended if the patient is postmenopausal. There remains some debate as to whether patients should have 5 years of an aromatase inhibitor or two years of tamoxifen followed by 3 years of an aromatase inhibitor (the so called, 'switch' regime); the majority of clinicians appear to favor 5 years of an aromatase inhibitor, especially with increasing risk of recurrence. *HER*-2/*neu* status is determined for all patients with newly diagnosed invasive breast cancer and when positive, should be used to guide systemic therapy recommendations. Trastuzumab is the only *HER*-2/*neu*–targeted agent that is currently approved for use in the adjuvant setting. The FDA approved trastuzumab in November 2006 for use as part of a treatment regimen containing doxorubicin, cyclophosphamide, and paclitaxel for treatment of *HER*-2/*neu*–positive, node-positive breast cancer.[167,168] Subsequently, the BCIRG 006 study reported that giving trastuzumab concurrently with docetaxel and carboplatin appeared as effective as giving trastuzumab following an anthracycline containing regimen.[169,170]

Advanced Local-Regional Breast Cancer (Stage IIIA or IIIB)

Women with stage IIIA and IIIB breast cancer have advanced local-regional breast cancer but have no clinically detected distant metastases (Fig. 17-30).[233] In an effort to provide optimal local-regional disease-free survival as well as distant disease-free survival for these women, surgery is integrated with radiation therapy and chemotherapy (Fig. 17-31). However, it should

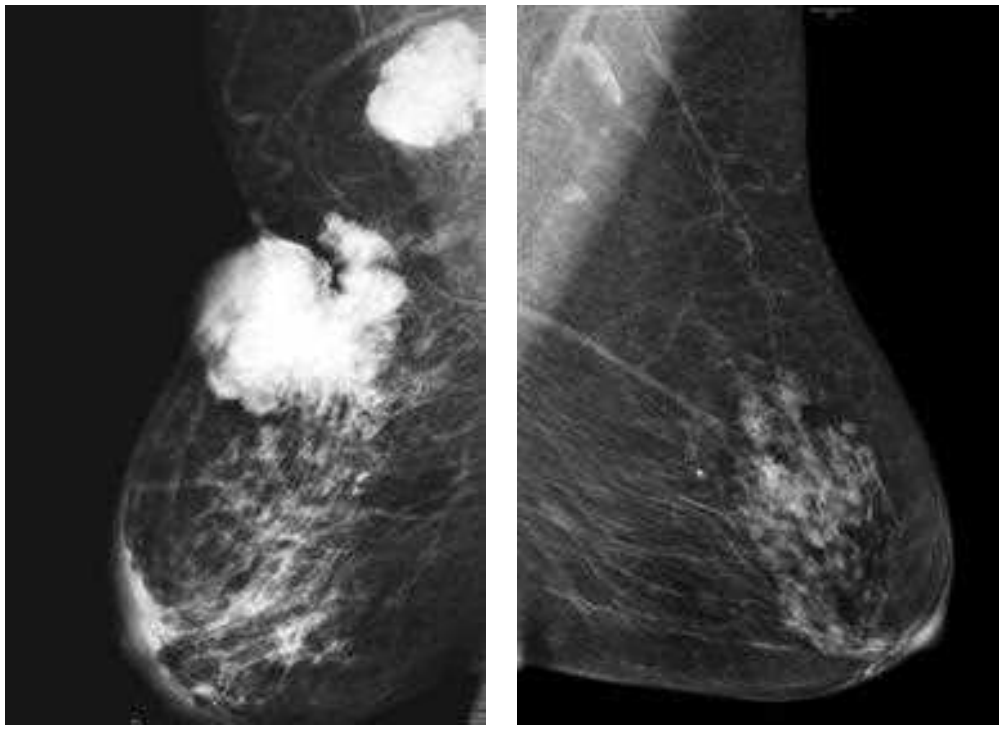

Figure 17-30. Locally advanced breast cancer. **A.** Mammography of the right breast reveals a large tumor with enlarged axillary lymph nodes. **B.** Imaging of the left breast is normal. (Photos used with permission of Dr. Anne Turnbull, Consultant Radiologist/Director of Breast Screening, Royal Derby Hospital, Derby, UK.)

be noted that most of these patients will already have distant metastasis which is often highlighted by radiological evidence when bone scans, PET &/or CT scans are performed. Even when they are negative, elevated serum tumor markers may be another indicator that distant spread has already occurred. The paradigm therefore which is appropriate for small screen detected cancers where cure can be expected in >90% of patients, often by local treatment alone is not the same clinical scenario as with locally advanced disease. Indeed, a previous randomized study of neoadjuvant therapy followed by modified radical mastectomy, post-operative radiotherapy and endocrine therapy vs. primary endocrine therapy followed by sequential therapy on progression of disease showed no difference in either overall survival or uncontrolled local disease at death.[234]

Preoperative (also known as neoadjuvant) chemotherapy should be considered in the initial management of patients with locally advanced stage III breast cancer, especially those with estrogen receptor negative tumors. For selected clinically indolent,

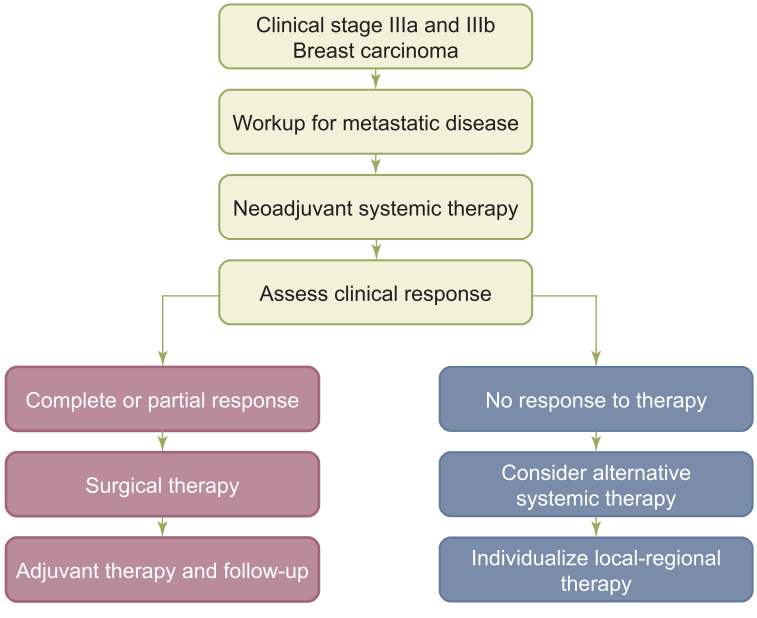

Figure 17-31. Treatment pathways for stage IIIA and stage IIIB breast cancer.

estrogen receptor positive, locally advanced tumors, primary endocrine therapy may be considered, especially if the patient has other co-morbid conditions. A series of 195 patients with ER-positive locally advanced breast cancer treated by endocrine therapy—median age 69 years, median tumor size 6 cm, median follow-up 61 months—reported a five year overall survival of 76%, a breast cancer specific survival of 86%, and a metastasis free survival of 77%. The median time to an alternative treatment was 48 months.[235] Given that this was a 20-year series, the number of such patients is small but should be considered when the clinician is discussing treatment options. Surgical therapy for women with stage III disease is usually a modified radical mastectomy, followed by adjuvant radiation therapy. Chemotherapy is used to maximize distant disease-free survival, whereas radiation therapy is used to maximize local-regional control and disease-free survival. In selected patients with stage IIIA cancer, preoperative chemotherapy can reduce the size of the primary cancer and permit breast-conserving surgery. Investigators from the MD Anderson Cancer Center reported that low local-regional failure rates could be achieved in selected patients with stage III disease treated with preoperative chemotherapy followed by breast-conserving surgery and radiation.[236] The 5-year actuarial ipsilateral breast tumor recurrence-free survival rates in this study were 95%. They noted that the ipsilateral breast tumor recurrence rates increased when patients had clinical N2 or N3 disease, >2 cm of residual disease in the breast at surgery, a pattern of multifocal residual disease in the breast at surgery, and lymphovascular space invasion in the primary tumor. This study demonstrates that breast-conserving surgery can be used for appropriately selected patients with locally advanced breast cancer who achieve a good response with preoperative chemotherapy. However, the Oxford overview of all randomized studies of neoadjuvant therapy (vs. adjuvant therapy) reported a hazard ratio of 1.5 (i.e., 50% increase) in local recurrence rates. A meta-analysis reported a hazard ratio of 1.3.[237] These findings are important in view of the previous findings that the avoidance of recurrence in a conserved breast avoids about one breast cancer death over the next 15 years for every four such recurrences avoided.[12] Furthermore, the German Breast Cancer Group recently reported their local recurrence rate in 5,535 patients in seven studies. With a median of 46 months (range 1–127) follow-up the local recurrence rates ranged from 7.6% to 19.5% for T1-T4 tumors and from 6.4%–17.9% for N0-N3 tumors treated with neoadjuvant therapy.[238] Therefore, this is an important issue which needs to be addressed in future locally advanced and neoadjuvant studies. For patients with stage IIIA disease who experience minimal response to chemotherapy and for patients with stage IIIB breast cancer, preoperative chemotherapy can decrease the local-regional cancer burden enough to permit subsequent modified radical mastectomy to establish local-regional control. In both stage IIIA and IIIB disease, surgery is followed by adjuvant radiation therapy. However there is a small percentage of patients who experience progression of disease during neoadjuvant therapy and therefore the surgeon should review patients with the oncologist at regular points during the neoadjuvant regimen.

Internal Mammary Lymph Nodes

Metastatic disease to internal mammary lymph nodes may be occult, may be evident on chest radiograph or CT scan, or may present as a painless parasternal mass with or without skin involvement. There is no consensus regarding the need for internal mammary lymph node radiation therapy in women who are at increased risk for occult involvement (cancers involving the medial aspect of the breast, axillary lymph node involvement) but who show no signs of internal mammary lymph node involvement. Systemic chemotherapy and radiation therapy are indicated in the treatment of grossly involved internal mammary lymph nodes.

Distant Metastases (Stage IV)

Treatment for stage IV breast cancer is not curative but may prolong survival and enhance a woman's quality of life.[239] Endocrine therapies that are associated with minimal toxicity are preferred to cytotoxic chemotherapy in estrogen receptor positive disease. Appropriate candidates for initial endocrine therapy include women with hormone receptor-positive cancers who do not have immediately life threatening disease (or 'visceral crisis'). This includes not only women with bone or soft tissue metastases but also women with limited visceral metastases. Symptoms per se (e.g., breathlessness) are not in themselves an indication for chemotherapy. For example, breathlessness due to a pleural effusion can be treated with percutaneous drainage and if the breathlessness is relieved the patient should be commenced on endocrine therapy whereas if the breathlessness is due to lymphangitic spread then chemotherapy would be the treatment of choice. The same approach should be taken to other symptoms such as pain. Systemic chemotherapy is indicated for women with hormone receptor-negative cancers, 'visceral crisis', and hormone-refractory metastases. Women with stage IV breast cancer may develop anatomically localized problems that will benefit from individualized surgical or radiation treatment, such as brain metastases, pleural effusion, pericardial effusion, biliary obstruction, ureteral obstruction, impending or existing pathologic fracture of a long bone, spinal cord compression, and painful bone or soft tissue metastases. Bisphosphonates, which may be given in addition to chemotherapy or endocrine therapy, should be considered in women with bone metastases. Whether to perform surgical resection of the local-regional disease in women with stage IV breast cancer has been debated after several reports have suggested that women who undergo resection of the primary tumor have improved survival over those who do not. Khan and associates used the National Cancer Data Base to identify patterns of treatment in women with metastatic breast cancer and found that those who had surgical resection with negative margins had a better prognosis than those women who did not have surgical therapy.[240] Gnerlich et al reported similar findings using the SEER database, and there have been several reports subsequent to this study from single institutions that have confirmed these findings.[241] Some have suggested that the finding of improved survival is due to selection bias and that local therapy should be reserved for palliation of symptoms. A randomized trial is currently underway through ECOG to address this question. In the meantime, surgical management of patients with stage IV disease should be addressed by obtaining multidisciplinary input and by considering the treatment goals of each individual patient and the patient's treating physicians.

Local-Regional Recurrence

Women with local-regional recurrence of breast cancer may be separated into two groups: those who have had mastectomy and those who have had lumpectomy. Women treated previously with mastectomy undergo surgical resection of the local-regional recurrence and appropriate reconstruction.

Chemotherapy and antiestrogen therapy are considered, and adjuvant radiation therapy is given if the chest wall has not previously received radiation therapy or if the radiation oncologist feels that given the time from previous treatment there is scope for further radiation therapy, particularly if this is palliative. Women treated previously with a breast conservation procedure undergo a mastectomy and appropriate reconstruction. Chemotherapy and antiestrogen therapy are considered.

Breast Cancer Prognosis

Survival rates for women diagnosed with breast cancer in the United States can be obtained from the SEER Program of the National Cancer Institute. Data have been collected since 1973 and is updated at regular intervals. The overall 5-year relative survival for breast cancer patients from the time period of 2003–2009 from 18 SEER geographic areas was 89.2%. The 5-year relative survival by race was reported to be 90.4% for white women and 78.7% for black women. The 5-year survival rate for patients with localized disease (61% of patients) is 98.6%; for patients with regional disease (32% of patients), 84.4%; and for patients with distant metastatic disease (5% of patients), 24.3%. Breast cancer survival has significantly increased over the past two decades due to improvements in screening and local and systemic therapies. Data from the American College of Surgeons National Cancer Data Base can also be accessed and reports survival based on stage of disease at presentation using the AJCC staging system.

SURGICAL TECHNIQUES IN BREAST CANCER THERAPY

Excisional Biopsy with Needle Localization

Excisional biopsy implies complete removal of a breast lesion with a margin of normal-appearing breast tissue. In the past, surgeons would obtain prior consent from the patient allowing mastectomy if the initial biopsy results confirmed cancer. Today it is important to consider the options for local therapy (lumpectomy vs. mastectomy with or without reconstruction) and the need for nodal assessment with SLN dissection. Needle core biopsy is the preferred diagnostic method and excisional biopsy should be reserved for those cases where the needle biopsy results are discordant with the imaging findings or clinical examination (Fig. 17-32). In general circumareolar incisions can be used to access lesions which are subareolar or within a short distance of the nipple-areolar complex. Elsewhere in the breast, incisions should be placed which are in the lines of tension in the skin that are generally concentric with the nipple-areola complex. In the lower half of the breast, the use of radial incisions typically provides the best outcome. When the tumor is quite distant from the central breast, the biopsy incision can be excised separately from the primary mastectomy incision, should a mastectomy be required. Radial incisions in the upper half of the breast are not recommended because of possible scar contracture resulting in displacement of the ipsilateral nipple-areola complex. Similarly, curvilinear incisions in the lower half of the breast may displace the nipple-areolar complex downward.

After excision of a suspicious breast lesion, the specimen should be x-rayed to confirm the lesion has been excised with appropriate margins. The biopsy tissue specimen is orientated for the pathologist using sutures, clips, or dyes. Additional margins (superior, inferior, medial, lateral, superficial, and deep) may be taken from the surgical bed if the specimen x-ray shows the lesion is close to one or more margins. Some surgeons also take additional shavings from the margins as one approach to confirm complete excision of the suspicious lesion. Electrocautery or absorbable ligatures are used to achieve wound hemostasis. Cosmesis may be facilitated by approximation of the surgical defect using 3-0 absorbable sutures. A running subcuticular closure of the skin using 4-0 or 5-0 absorbable monofilament sutures is performed. Wound drainage is usually not required.

Excisional biopsy with needle localization requires a preoperative visit to the mammography suite for placement of a

localization wire or a radiolabeled seed that can be detected intraoperatively with a handheld probe. The lesion can also be targeted by sonography in the imaging suite or in the operating room. The lesion to be excised is accurately localized by mammography, and the tip of a thin wire hook is positioned close to the lesion (Fig. 17-33). Using the wire hook as a guide, the surgeon subsequently excises the suspicious breast lesion while removing a margin of normal-appearing breast tissue. Before the patient leaves the operating room, specimen radiography is performed to confirm complete excision of the suspicious lesion (Fig. 17-34).

Sentinel Lymph Node Dissection

Sentinel lymph node (SLN) dissection is primarily used to assess the regional lymph nodes in women with early breast cancers who are clinically node negative by physical examination and imaging studies.[242-250] This method also is accurate in women with larger tumors (T3 N0), but nearly 75% of these women will prove to have axillary lymph node metastases on histologic examination and wherever possible it is better to identify them preoperatively as this will allow a definitive procedure for known axillary disease. SLN dissection has also been reported to be accurate for staging of the axilla after chemotherapy in women with clinically node-negative disease at initial presentation.[251,252] Tan et al in a review and meta-analysis of 449 cases of SLN biopsy in clinically lymph node negative disease reported a sensitivity of 93% giving a false negative rate of 7% with a negative predictive value of 94% and an overall accuracy of 95%.[253] Clinical situations where SLN dissection is not recommended include patients with inflammatory breast cancers, those with palpable axillary lymphadenopathy and biopsy proven metastasis, DCIS without mastectomy, or prior axillary surgery. Although limited data are available, SLN dissection appears to be safe in pregnancy when performed with radioisotope alone.

9▶

Evidence from large prospective studies suggests that the combination of intraoperative gamma probe detection of radioactive colloid and intraoperative visualization of blue dye (isosulfan blue dye or methylene blue) is more accurate for identification of SLNs than the use of either agent alone. Some surgeons use preoperative lymphoscintigraphy, although it is not required for identification of the SLNs. On the day before surgery, or the day of surgery, the radioactive colloid is injected either in the breast parenchyma around the primary tumor or prior biopsy site, into the subareolar region, or subdermally in proximity to the primary tumor site. With a 25-gauge needle, 0.5 mCi of 0.2-μm technetium 99m–labeled sulfur colloid is injected for same-day surgery or a higher dose of 2.5 mCi of technetium-labeled sulfur colloid is administered when the isotope is to be injected on the day before surgery. Subdermal injections are given in proximity to the cancer site or in the subareolar location. Later, in the operating room, 3 to 5 mL of blue dye is injected either in the breast parenchyma or in the subareolar location. It is not recommended that the blue dye be used in a subdermal injection because this can result in tattooing of the skin (isosulfan blue dye) or skin necrosis (methylene blue). For nonpalpable cancers, the injection of the technetium-labeled sulfur colloid solution can be guided by ultrasound or by mammographic guidance. It is helpful for the radiologist to mark the skin overlying the breast cancer at the time of needle localization using an indelible marker. In women who have undergone previous excisional biopsy, the injections are made in the breast parenchyma around the biopsy cavity but not into the cavity itself. Women are told preoperatively that the isosulfan blue dye injection will cause a change in the color of their urine and that there is a very small risk of allergic reaction to

the dye (1 in 10,000). Anaphylactic reactions have been documented and some groups administer a regimen of antihistamine, steroids, and a histamine H-2 receptor antagonist preoperatively as a prophylactic regimen to prevent allergic reactions. The use of radioactive colloid is safe, and radiation exposure is very low. Sentinel node dissection can be performed in pregnancy with the radioactive colloid without the use of blue dye.

A hand-held gamma counter is used to transcutaneously identify the location of the SLN. This can help to guide placement of the incision. A 3- to 4-cm incision is made in line with that used for an axillary dissection, which is a curved transverse incision in the lower axilla just below the hairline. After dissecting through the subcutaneous tissue, the surgeon dissects through the axillary fascia, being mindful to identify blue lymphatic channels. Following these channels can lead directly to the SLN and limit the amount of dissection through the axillary tissues. The gamma probe is used to facilitate the dissection and to pinpoint the location of the SLN. As the dissection continues, the signal from the probe increases in intensity as the SLN is approached. The SLN also is identified by visualization of blue dye in the afferent lymph vessel and in the lymph node itself. Before the SLN is removed, a 10-second in vivo radioactivity count is obtained. After removal of the SLN, a 10-second ex vivo radioactive count is obtained, and the node is then sent to the pathology laboratory for either permanent- or frozen-section analysis. The lowest false-negative rates for SLN dissection have been obtained when all blue lymph nodes and all lymph nodes with counts >10% of the 10-second ex vivo count of the SLN are harvested ("10% rule"). Based on this, the gamma counter is used before closing the axillary wound to measure residual radioactivity in the surgical bed. A search is made for additional SLNs if the counts remain high. This procedure is repeated until residual radioactivity in the surgical bed is less than 10% of the 10-second ex vivo count of the most radioactive SLN and all blue nodes have been removed. Studies have demonstrated that 98% of all positive SLNs will be recovered with the removal of four SLNs, therefore it is not necessary to remove greater than four SLNs for accurate staging of the axilla.

Results from the NSABP B-32 trial showed that the false-negative rate for SLN dissection is influenced by tumor location, type of diagnostic biopsy, and number of SLNs removed at surgery.[220] The authors reported that tumors located in the lateral breast were more likely to have a false-negative SLN. This may be explained by difficulty in discriminating the hot spot in the axilla when the radioisotope has been injected at the primary tumor site in the lateral breast. Those patients who had undergone an excisional biopsy before the SLN procedure were significantly more likely to have a false-negative SLN. This report further confirms that surgeons should use needle biopsy for diagnosis whenever possible and reserve excisional biopsy for the rare situations in which needle biopsy findings are nondiagnostic or discordant. Finally, removal of a larger number of SLNs at surgery appears to reduce the false-negative rate. In B-32, the false-negative rate was reduced from 17.7% to 10% when two SLNs were recovered and to 6.9% when three SLNs were removed. Yi and associates reported that the number of SLNs that need to be removed for accurate staging is influenced by individual patient and primary tumor factors.[254]

In the B-32 trial, SLNs were identified outside the level I and II axillary nodes in 1.4% of cases. This was significantly influenced by the site of radioisotope injection. When a subareolar or periareolar injection site was used, there were no instances

of SLNs identified outside the level I or II axilla, compared with a rate of 20% when a peritumoral injection was used. This supports the overall concept that the SLN is the first site of drainage from the lymphatic vessels of the primary tumor. Although many patients will have similar drainage patterns from injections given at the primary tumor site and at the subareolar plexus, some patients will have extra-axillary drainage, either alone or in combination with axillary node drainage, and this is best assessed with a peritumoral injection of the radioisotope. Kong et al reported that internal mammary node drainage on preoperative lymphoscintigraphy was associated with worse distant disease-free survival in early-stage breast cancer patients.[255]

Breast Conservation

Breast conservation involves resection of the primary breast cancer with a margin of normal-appearing breast tissue, adjuvant radiation therapy, and assessment of regional lymph node status.[256,257] Resection of the primary breast cancer is alternatively called *segmental mastectomy, lumpectomy, partial mastectomy, wide local excision,* and *tylectomy.* For many women with stage I or II breast cancer, breast-conserving therapy (BCT) is preferable to total mastectomy because BCT produces survival rates equivalent to those after total mastectomy while preserving the breast.[258] Six prospective randomized trials have shown that overall and disease-free survival rates are similar with BCT and mastectomy, however three of the studies showed higher local-regional failure rates in patients undergoing BCT. In two of these studies, there were no clear criteria for histologically negative margins.[12,256-258] Data from the EBCTCG meta-analysis revealed that the addition of radiation reduces recurrence by half and improves survival at year 15 by about a sixth.[259] When all of this information is taken together, BCT is considered to be oncologically equivalent to mastectomy.

In addition to being equivalent to mastectomy in terms of oncologic safety, BCT appears to offer advantages over mastectomy with regard to quality of life and aesthetic outcomes. BCT allows for preservation of breast shape and skin as well as preservation of sensation, and provides an overall psychologic advantage associated with breast preservation.

Breast conservation surgery is currently the standard treatment for women with stage 0, I, or II invasive breast cancer. Women with DCIS require only resection of the primary cancer and adjuvant radiation therapy without assessment of regional lymph nodes. When a lumpectomy is performed, a curvilinear incision lying concentric to the nipple-areola complex is made in the skin overlying the breast cancer when the tumor is in the upper aspect of the breast. Radial incisions are preferred when the tumor is in the lower aspect of the breast. Skin excision is not necessary unless there is direct involvement of the overlying skin by the primary tumor. The breast cancer is removed with an envelope of normal-appearing breast tissue that is adequate to achieve a cancer-free margin. Significant controversy exists on the appropriate margin width for BCT.[260] Specimen x-ray should routinely be performed to confirm the lesion has been excised and that there appears to be an appropriate margin. Specimen orientation is performed by the surgeon. Additional margins from the surgical bed are taken as needed to provide a histologically negative margin. Requests for determination of ER, PR, and HER-2 status are conveyed to the pathologist.

It is the surgeon's responsibility to ensure complete removal of cancer in the breast. Ensuring surgical margins that are free of breast cancer will minimize the chances of local recurrence and will enhance cure rates. Local recurrence of breast cancer after conservation surgery is determined primarily by the adequacy of surgical margins. Cancer size and the extent of skin excision are not significant factors in this regard. It is the practice of many North American and European surgeons to undertake re-excision when residual cancer within 2 mm of a surgical margin is determined by histopathologic examination. If clear margins are not obtainable with re-excision, mastectomy is required. SLN is performed before removal of the primary breast tumor. When indicated, intraoperative assessment of the sentinel node can proceed while the segmental mastectomy is being performed.

The use of oncoplastic surgery can be entertained at the time of segmental mastectomy or at a later time to improve the overall aesthetic outcome. The use of oncoplastic techniques range from a simple re-shaping of breast tissue to local tissue rearrangement to the use of pedicled flaps or breast reduction techniques. The overall goal is to achieve the best possible aesthetic result. In determining which patients are candidates for oncoplastic breast surgery, several factors should be considered, including the extent of the resection of breast tissue necessary to achieve negative margins, the location of the primary tumor within the breast, and the size of the patient's breast and body habitus. Oncoplastic techniques are of prime consideration when: (a) a significant area of breast skin will need to be resected with the specimen to achieve negative margins; (b) a large volume of breast parenchyma will be resected resulting in a significant defect; (c) the tumor is located between the nipple and the inframammary fold, an area often associated with unfavorable cosmetic outcomes; or (d) excision of the tumor and closure of the breast may result in malpositioning of the nipple.

Mastectomy and Axillary Dissection

A skin-sparing mastectomy removes all breast tissue, the nipple-areola complex, and scars from any prior biopsy procedures.[261,262] There is a recurrence rate of less than 6% to 8%, comparable to the long-term recurrence rates reported with standard mastectomy, when skin-sparing mastectomy is used for patients with Tis to T3 cancers. A total (simple) mastectomy without skin sparing removes all breast tissue, the nipple-areola complex, and skin. An extended simple mastectomy removes all breast tissue, the nipple-areola complex, skin, and the level I axillary lymph nodes. A modified radical ('Patey') mastectomy removes all breast tissue, the nipple-areola complex, skin, and the levels I, II and III axillary lymph nodes: the pectoralis minor which was divided and removed by Patey may be simply divided, giving improved access to level III nodes, and then left in-situ or occasionally the axillary clearance can be performed without dividing pectoralis minor. The Halsted radical mastectomy removes all breast tissue and skin, the nipple-areola complex, the pectoralis major and pectoralis minor muscles, and the level I, II, and III axillary lymph nodes. The use of systemic chemotherapy and hormonal therapy as well as adjuvant radiation therapy for breast cancer have nearly eliminated the need for the radical mastectomy.

Nipple-areolar sparing mastectomy has been popularized over the last decade especially for risk-reducing mastectomy in high risk women. For those patients with a cancer diagnosis, many consider the following factors for eligibility: tumor located more than 2–3 cm from the border of the areola, smaller breast size, minimal ptosis, no prior breast surgeries with

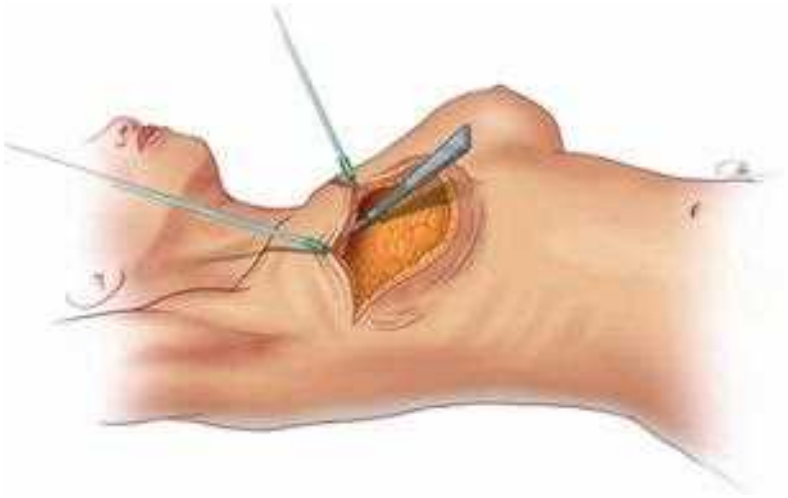

Figure 17-35. Modified radical mastectomy: elevation of skin flaps. Skin flaps are 7 to 8 mm in thickness, inclusive of the skin and telasubcutanea. (Visual Art: © 2012. The University of Texas MD Anderson Cancer Center.)

periareolar incisions, body mass index less than 40 kg/m^2, no active tobacco use, no prior breast irradiation, and no evidence of collagen vascular disease.

For a variety of biologic, economic, and psychosocial reasons, some women desire mastectomy rather than breast conservation. Women who are less concerned about cosmesis may view mastectomy as the most expeditious and desirable therapeutic option because it avoids the cost and inconvenience of radiation therapy. Some women whose primary breast cancers cannot be excised with a reasonable cosmetic result or those who have extensive microcalcifications are best treated with mastectomy. Similarly women with large cancers that occupy the subareolar and central portions of the breast and women with multicentric primary cancers also undergo mastectomy.

Modified Radical Mastectomy

A modified radical mastectomy preserves the pectoralis major muscle with removal of level I, II, and III (apical) axillary lymph nodes.[261] The operation was first described by David Patey, a surgeon at St Bartholomew's Hospital London, who reported a series of cases where he had removed the pectoralis minor muscle allowing complete dissection of the level III axillary lymph nodes while preserving the pectoralis major and the lateral pectoral nerve. A modified radical mastectomy permits preservation of the medial (anterior thoracic) pectoral nerve, which courses in the lateral neurovascular bundle of the axilla and usually penetrates the pectoralis minor to supply the lateral border of the pectoralis major. Anatomic boundaries of the modified radical mastectomy are the anterior margin of the latissimus dorsi muscle laterally, the midline of the sternum medially, the subclavius muscle superiorly, and the caudal extension of the breast 2 to 3 cm inferior to the inframammary fold inferiorly. Skin-flap thickness varies with body habitus but ideally is 7 to 8 mm inclusive of skin and telasubcutanea (Fig. 17-35). Once the skin flaps are fully developed, the fascia of the pectoralis major muscle and the overlying breast tissue are elevated off the underlying musculature, which allows for the complete removal of the breast (Fig. 17-36).

Subsequently, an axillary lymph node dissection is performed. The most lateral extent of the axillary vein is identified and the areolar tissue of the lateral axillary space is elevated as the vein is cleared on its anterior and inferior surfaces. The areolar tissues at the junction of the axillary vein and the anterior edge of the latissimus dorsi muscle, which include the lateral and subscapular lymph node groups (level I), are cleared. Care is taken to preserve the thoracodorsal neurovascular bundle.

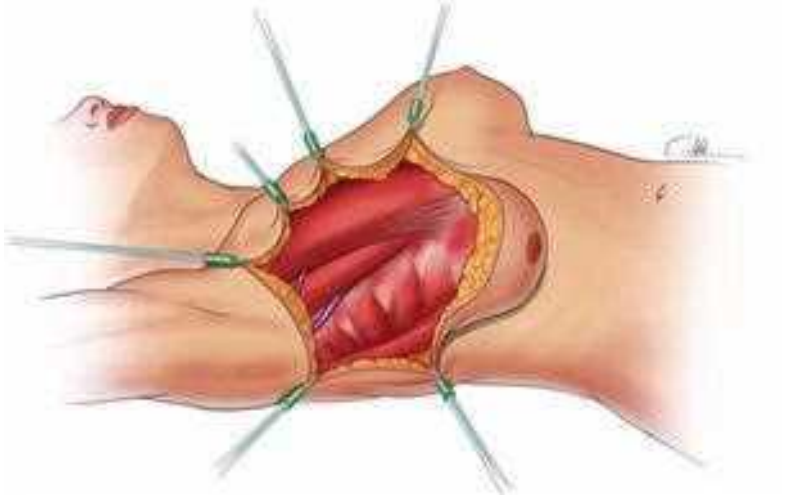

Figure 17-36. Modified radical mastectomy after resection of breast tissue. The pectoralis major muscle is cleared of its fascia as the overlying breast is elevated. The latissimus dorsi muscle is the lateral boundary of the dissection. (Visual Art: © 2012.The University of Texas MD Anderson Cancer Center.)

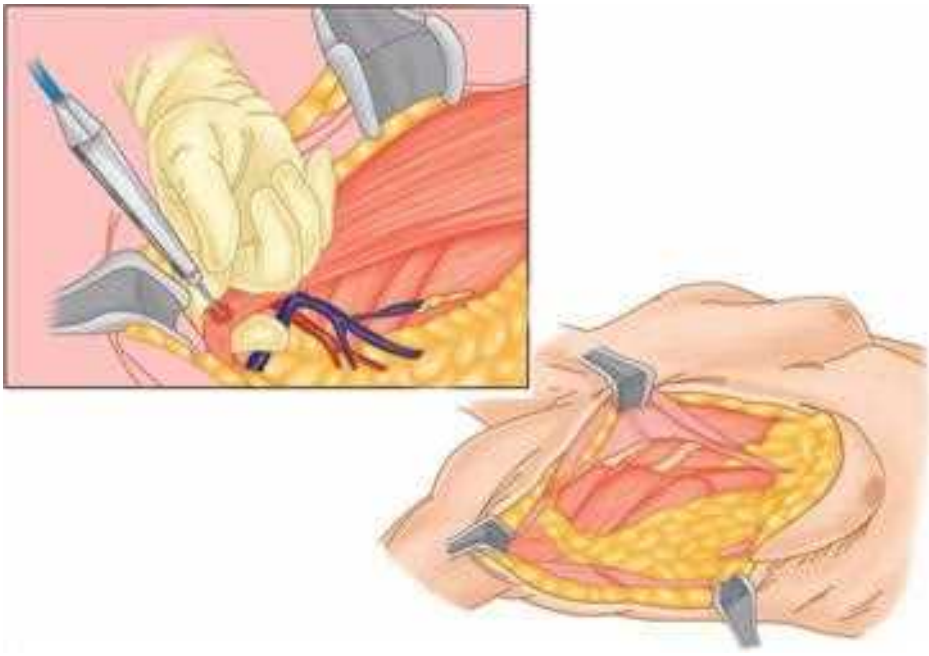

Figure 17-37. Modified radical mastectomy (Patey): axillary lymph node dissection. The dissection proceeds from lateral to medial, with complete visualization of the anterior and inferior aspects of the axillary vein. Loose areolar tissue at the junction of the axillary vein and the anterior margin of the latissimus dorsi muscle is swept inferomedially inclusive of the lateral (axillary) lymph node group (level I). Care is taken to preserve the thoracodorsal artery, vein, and nerve in the deep axillary space. The lateral lymph node group is resected in continuity with the subscapular lymph node group (level I) and the external mammary lymph node group (level I). Dissection anterior to the axillary vein allows removal of the central lymph node group (level II) and the apical (subclavicular) lymph node group (level III). The superomedial limit of this dissection is the clavipectoral fascia (Halsted's ligament). *Inset* depicts division of the insertion of the pectoralis minor muscle at the coracoid process. The surgeon's finger shields the underlying brachial plexus. (*Reproduced with permission from Bland KI, et al. Modified radical mastectomy and total (simple) mastectomy. In: Bland KI, Copeland EMI, eds.* The Breast: Comprehensive Management of Benign and Malignant Diseases. *Philadelphia: Saunders, 2009. Copyright Elsevier.*)

The dissection then continues medially with clearance of the central axillary lymph node group (level II). The long thoracic nerve of Bell is identified and preserved as it travels in the investing fascia of the serratus anterior muscle. Every effort is made to preserve this nerve, because permanent disability with a winged scapula and shoulder weakness will follow denervation of the serratus anterior muscle. Patey divided the pectoralis minor and removed it to allow access right up to the apex of the axilla. The pectoralis minor muscle is usually divided at the tendinous portion near its insertion onto the coracoid process (Fig. 17-37 *inset*), which allows dissection of the axillary vein medially to the costoclavicular (Halsted's) ligament. Finally, the breast and axillary contents are removed from the surgical bed and are sent for pathologic assessment. In Patey's modified radical mastectomy he removed the pectoralis minor muscle. Many surgeons now divide only the tendon of the pectoralis minor muscle at its insertion onto the coracoid process while leaving the rest of the muscle intact, which still provides good access to the apex of the axilla.

Seromas beneath the skin flaps or in the axilla represent the most frequent complication of mastectomy and axillary lymph node dissection, reportedly occurring in as many as 30% of cases. The use of closed-system suction drainage reduces the incidence of this complication. Catheters are retained in the wound until drainage diminishes to <30 mL per day. Wound infections occur infrequently after a mastectomy and the majority are a result of skin-flap necrosis. Cultures of specimens taken from the infected wound for aerobic and anaerobic organisms, débridement, and antibiotic therapy are effective management. Moderate or severe hemorrhage in the postoperative period is rare and is best managed with early wound exploration for control of hemorrhage and re-establishment of closed-system suction drainage. The incidence of functionally significant lymphedema after a modified radical mastectomy is approximately 20% but can be as high as 50% to 60% when postoperative radiation is employed. Extensive axillary lymph node dissection, the delivery of radiation therapy, the presence of pathologic lymph nodes, and obesity are predisposing factors. Patients should be referred to physical therapy at the earliest signs of lymphedema to prevent progression to the later stages. The use of individually fitted compressive sleeves and complex decongestive therapy may be necessary.

Reconstruction of the Breast and Chest Wall

The goals of reconstructive surgery after a mastectomy for breast cancer are wound closure and breast reconstruction, which is either immediate or delayed.[263] In most cases, wound closure after mastectomy is accomplished with simple approximation of the wound edges. However, if a more radical removal of skin and subcutaneous tissue is necessary, a pedicled myocutaneous flap from the latissimus dorsi muscle is generally the best approach for wound coverage. A skin graft provides functional coverage that will tolerate adjuvant radiation therapy; however, this is not preferred, because poor graft adherence may delay delivery of radiation therapy. Breast reconstruction after risk-reducing mastectomy or after mastectomy for early-stage breast cancer may be performed at the same time as the mastectomy. This allows for a skin-sparing mastectomy to be performed,

which offers the best overall cosmetic outcomes. Reconstruction can proceed with an expander/implant reconstruction or with autologous tissue such as a pedicled myocutaneous flap or a free flap using microvascular techniques. In patients with locally advanced breast cancer, reconstruction is often delayed until after completion of adjuvant radiation therapy to ensure that local-regional control of disease is obtained. The expected use of postmastectomy radiotherapy should also be considered as a reason for delayed reconstruction as radiotherapy to a reconstructed breast has been reported to result in inferior cosmetic outcomes. Consideration can be made for placement of a tissue expander to allow for skin-sparing but this should be discussed with the radiation oncologist and other members of the treatment team. If chest wall coverage is needed to replace a large skin or soft tissue defect, many different types of myocutaneous flaps are employed, but the latissimus dorsi and the rectus abdominis myocutaneous flaps are most frequently used. The latissimus dorsi myocutaneous flap consists of a skin paddle based on the underlying latissimus dorsi muscle, which is supplied by the thoracodorsal artery with contributions from the posterior intercostal arteries. A transverse rectus abdominis myocutaneous (TRAM) flap consists of a skin paddle based on the underlying rectus abdominis muscle, which is supplied by vessels from the deep inferior epigastric artery. The free TRAM flap uses microvascular anastomoses to establish blood supply to the flap. When the bony chest wall is involved with cancer, resection of a portion of the bony chest wall is indicated. If only one or two ribs are resected and soft tissue coverage is provided, reconstruction of the bony defect is usually not necessary, because scar tissue will stabilize the chest wall. If more than two ribs are sacrificed, it is advisable to stabilize the chest wall with prosthetic material, which is then covered with soft tissue by using a latissimus dorsi or TRAM flap.

NONSURGICAL BREAST CANCER THERAPIES

Radiation Therapy

Radiation therapy is used for all stages of breast cancer depending on whether the patient is undergoing BCT or mastectomy.[264-270] Adjuvant radiation for patients with DCIS and early-stage breast cancer are described above. Those women treated with mastectomy who have cancer at the surgical margins are at sufficiently high risk for local recurrence to warrant the use of adjuvant radiation therapy to the chest wall postoperatively. Women with metastatic disease involving four or more axillary lymph nodes and premenopausal women with metastatic disease involving one to three lymph nodes also are at increased risk for recurrence and are candidates for the use of chest wall and supraclavicular lymph node radiation therapy. In advanced local-regional breast cancer (stage IIIA or IIIB), women are at high risk for recurrent disease after surgical therapy, and adjuvant radiation therapy is used to reduce the risk of recurrence. Current recommendations for stages IIIA and IIIB breast cancer are: (a) adjuvant radiation therapy to the breast and supraclavicular lymph nodes after neoadjuvant chemotherapy and segmental mastectomy with or without axillary lymph node dissection, (b) adjuvant radiation therapy to the chest wall and supraclavicular lymph nodes after neoadjuvant chemotherapy and mastectomy with or without axillary lymph node dissection, and (c) adjuvant radiation therapy to the chest wall and supraclavicular lymph nodes after segmental mastectomy or mastectomy with axillary lymph node dissection and adjuvant chemotherapy.

The use of partial breast irradiation (APBI) for patients treated with breast-conserving surgery is also described above. APBI can be delivered via brachytherapy, external beam radiation therapy using three-dimensional conformal radiation, or intensity-modulated radiation therapy. Although initial results are promising in highly selected low-risk populations, APBI should be used in the clinical setting only as part of a prospective trial.

Chemotherapy Adjuvant

Chemotherapy. The Early Breast Cancer Trialists' Collaborative Group overview analysis of adjuvant chemotherapy demonstrated reductions in the odds of recurrence and of death in women ≤70 years of age with stage I, IIA, or IIB breast cancer.[118,271-275] For those ≥70 years of age, the lack of definitive clinical trial data regarding adjuvant chemotherapy prevented definitive recommendations. Adjuvant chemotherapy is of minimal benefit to women with negative nodes and cancers ≤0.5 cm in size and is not recommended. Women with negative nodes and cancers 0.6 to 1.0 cm are divided into those with a low risk of recurrence and those with unfavorable prognostic features that portend a higher risk of recurrence and a need for adjuvant chemotherapy. Adverse prognostic factors include blood vessel or lymph vessel invasion, high nuclear grade, high histologic grade, *HER*-2/*neu* overexpression, and negative hormone receptor status. Adjuvant chemotherapy is recommended by the NCCN guidelines for women with these unfavorable prognostic features. Table 17-14 lists the frequently used chemotherapy regimens for breast cancer.

For women with hormone receptor-negative cancers that are >1 cm in size, adjuvant chemotherapy is appropriate. However, women with node-negative hormone receptor–positive cancers and T1 tumors are candidates for antiestrogen therapy with or without chemotherapy. Assessment of overall risk using known prognostic factors or additional testing such as the 21-gene recurrence score assay can help to guide decision making regarding chemotherapy in patients with node-negative ER-positive breast cancer. For special-type cancers (tubular, mucinous, medullary, etc), which are usually strongly estrogen receptor positive, adjuvant antiestrogen therapy should be advised for cancers >1 cm. For women with node-positive tumors or with a special-type cancer that is >3 cm, the use of chemotherapy is appropriate: those with hormone receptor-positive tumors should receive antiestrogen therapy.

For stage IIIA breast cancer preoperative chemotherapy with an anthracycline-containing or taxane-containing regimen followed by either a modified radical mastectomy or segmental mastectomy with axillary dissection followed by adjuvant radiation therapy should be considered, especially for estrogen receptor negative disease. While the same regimen may be considered for estrogen receptor positive disease it is known that these tumors respond less well to chemotherapy with <10% pCR rate overall and <3% pCR rate for lobular cancers. Other options such as neoadjuvant endocrine therapy followed by local-regional treatment or in a minority of cases primary endocrine therapy may be considered depending on other tumor characteristics and the patient's co-morbid conditions and preference.

Neoadjuvant (Preoperative) Chemotherapy. **In** the early 1970s, the National Cancer Institute in Milan, Italy, initiated

Table 17-14

Adjuvant chemotherapy regimens for breast cancer

HER-2/*neu* NEGATIVE (NON–TRASTUZUMAB-CONTAINING REGIMENS)	HER-2/*neu* POSITIVE (TRASTUZUMAB-CONTAINING REGIMENS)
FAC/CAF	AC → T + concurrent trastuzumab (T = paclitaxel)
FEC/CEF	Docetaxel + trastuzumab → FEC
AC or EC	TCH (docetaxel, carboplatin, trastuzumab)
TAC (T = docetaxel)	Chemotherapy followed by trastuzumab sequentially
A → CMF	AC → docetaxel + trastuzumab
E → CMF	
CMF	
AC × 4	
A → T → C (T = paclitaxel)	
FEC → T (T = docetaxel)	
TC (T = docetaxel)

two prospective randomized multimodality clinical trials for women with T3 or T4 breast cancer.[276] The best results were achieved when surgery was interposed between chemotherapy courses, with 82% local-regional control and 25% having a 5-year disease-free survival. The NSABP B-18 trial evaluated the role of neoadjuvant chemotherapy in women with operable stage II and III breast cancer.[188] Women entered into this study were randomly assigned to receive either surgery followed by chemotherapy or neoadjuvant chemotherapy followed by surgery. There was no difference in the 5-year disease-free survival rates for the two groups, but after neoadjuvant chemotherapy there was an increase in the number of lumpectomies performed and a decreased incidence of node positivity. It was suggested that neoadjuvant chemotherapy be considered for the initial management of breast cancers judged too large for initial lumpectomy.

Several prospective clinical trials have evaluated the neoadjuvant approach and two meta-analyses have been performed each showing that neoadjuvant vs. adjuvant chemotherapy are equivalent in terms of OS.[237,277] These analyses also evaluated local-regional recurrence (LRR) and found that there was an increase in LRR rates for patients receiving neoadjuvant chemotherapy when radiation therapy was used alone without surgery after completion of chemotherapy. Mittendorf and colleagues evaluated a contemporary series of almost 3000 patients treated with breast conserving surgery and radiation therapy who received either neoadjuvant or adjuvant chemotherapy for breast cancer.[278] They found that the risk of LRR was driven by biologic factors and disease stage and was not impacted by the timing of chemotherapy delivery. These data highlight the importance of the multidisciplinary management of patients with breast cancer in achieving the best outcomes.

10▶

The use of neoadjuvant chemotherapy offers the opportunity to observe the response of the intact primary tumor and any regional nodal metastases to a specific chemotherapy regimen.[279] For patients whose tumors remain stable in size or even progress with the initial neoadjuvant chemotherapy regimen, a new regimen may be considered that uses another class of agents, although there is no randomized data confirming this will improve outcome.

After treatment with neoadjuvant chemotherapy, patients are assessed for clinical and pathologic response to the regimen. Patients whose tumors achieve a pathologic complete response to neoadjuvant chemotherapy have been shown to have statistically improved survival outcomes to those of patients whose tumors demonstrate only a partial response, remain stable, or progress on treatment. Patients who experience progression of disease during neoadjuvant chemotherapy have the poorest survival.[280,281] This means that while patients who achieve a pCR will have a better outlook based on their response to neoadjuvant chemotherapy. Equally other patients will have a poorer outlook compared to when they started neoadjuvant therapy based on the non-response to treatment. The FDA is now proposing to use the neoadjuvant platform and pathologic response rates as a mechanism of accelerated approval for new agents although the short term endpoints (i.e., pCR) have not yet been shown to correlate with long-term outcomes (i.e., disease free survival and overall survival).

Current NCCN recommendations for treatment of operable advanced local-regional breast cancer are neoadjuvant chemotherapy with an anthracycline-containing or taxane-containing regimen or both, followed by mastectomy or lumpectomy with axillary lymph node dissection if necessary, followed by adjuvant radiation therapy. For patients with HER-2-positive breast cancer, trastuzumab can be combined with chemotherapy in the preoperative setting to increase pathologic complete response rates. For inoperable stage IIIA and for stage IIIB breast cancer, neoadjuvant chemotherapy is used to decrease the local-regional cancer burden. This may then permit subsequent modified radical or radical mastectomy, which is followed by adjuvant radiation therapy.

Nodal Evaluation in Patients Receiving Neoadjuvant Chemotherapy The management of the axilla after neoadjuvant chemotherapy has not been specifically addressed in randomized trials. Standard practice has been to perform an axillary lymph node dissection after chemotherapy or to perform a sentinel lymph node dissection before chemotherapy for nodal staging before chemotherapy is initiated. A number of small single-institution studies, one multicenter study, and a recent meta-analysis have explored the use of SLN dissection at the completion of chemotherapy. The published results from these studies have demonstrated the feasibility of SLN dissection in breast cancer patients after neoadjuvant chemotherapy. Review of 14 studies with 818 patients showed a false negative rate of 11% with an overall accuracy of 94%.[251,252,282] Although the issue has not been specifically addressed in the published trials, the presence of suspected or documented axillary metastases at initial presentation generally is considered a contraindication to SLN

dissection after neoadjuvant chemotherapy, and these patients usually undergo axillary lymph node dissection after completion of chemotherapy.

Neoadjuvant Endocrine Therapy. There is little randomized data on neoadjuvant endocrine therapy and virtually none which reports local recurrence rates. Neoadjuvant endocrine therapy has not been based on randomized controlled trials. It has most commonly been used in elderly women who were deemed poor candidates for surgery or cytotoxic chemotherapy. As clinicians have gained experience with neoadjuvant treatment strategies, it is now clear from examination of predictors of complete pathologic response that ER-positive tumors do not shrink in response to chemotherapy as readily as ER-negative tumors.[283] Indeed the pCR rate in estrogen receptor negative tumors is approximately three times that of estrogen receptor positive tumors. Fisher et al examined the results of the NSABP B-14 and B-20 trials and found that, as age increased, women obtained less benefit from chemotherapy. They recommended that factors[194] including tumor estrogen receptor concentration, nuclear grade, histologic grade, tumor type, and markers of proliferation should be considered in these patients before choosing between the use of chemotherapy and hormonal therapy. If in fact the tumor is estrogen receptor rich, these patients may benefit more from endocrine therapy in the neoadjuvant setting than they might if they received standard chemotherapy. Neoadjuvant endocrine therapy has been shown to shrink tumors, enabling breast-conserving surgery in women with hormone receptor-positive disease who otherwise would have to be treated with mastectomy although long-term recurrence rates have not been reported.[284]

With the use of neoadjuvant chemotherapy or endocrine therapy, observation of the response of the intact tumor and/or nodal metastases to a specific regimen could ultimately help to define which patients will benefit from specific therapies in the adjuvant setting. In adjuvant trials the primary endpoint is typically survival, whereas in neoadjuvant trials the endpoints have more often been clinical or pathologic response rates. However, with the reported increase in local recurrence and the link between local recurrence and survival by the Early Breast Cancer Trialists' Collaborative Group, surgeons need to become more focused on local recurrence as a primary endpoint of neoadjuvant therapies. There are a number of clinical trials underway comparing neoadjuvant chemotherapy and endocrine therapy regimens with pretreatment and posttreatment biopsy samples obtained from the primary tumors in all of the participants. These samples are being subjected to intensive genomic and proteomic analyses that may help to define a more personalized or individualized approach to breast cancer treatment in the future.

Antiestrogen Therapy

Tamoxifen. Within the cytosol of breast cancer cells are specific proteins (receptors) that bind and transfer steroid moieties into the cell nucleus to exert specific hormonal effects.[274,285-289] The most widely studied hormone receptors are the estrogen receptor and progesterone receptor. Hormone receptors are detectable in >90% of well-differentiated ductal and lobular invasive cancers. Although the receptor status may remain the same between the primary cancer and metastatic disease in the same patient in the vast majority of cases, there are instances where the status is changed in the metastatic focus and therefore biopsy of newly diagnosed metastatic disease should be considered for assessment of hormone receptor and HER-2 status.

After binding to estrogen receptors in the cytosol, tamoxifen blocks the uptake of estrogen by breast tissue. Clinical responses to antiestrogen are evident in >60% of women with hormone receptor-positive breast cancers but in <10% of women with hormone receptor-negative breast cancers. A meta-analysis by the Early Breast Cancer Trialists' Collaborative Group showed that adjuvant therapy with tamoxifen for 5 years reduced breast cancer mortality by about a third through the first 15 years of follow-up.[290] This mortality benefit continues to be statistically significant in the second and third 5-year periods (i.e., years 5–9 and 10–15) when the patients are no longer receiving endocrine treatment—the so called 'carry-over effect'. The analysis also showed a 39% reduction in the risk of cancer in the contralateral breast. The antiestrogens do have defined toxicity, including bone pain, hot flashes, nausea, vomiting, and fluid retention. Thrombotic events occur in <3% of treated women. Cataract surgery is more frequently performed in patients receiving tamoxifen. A long-term risk of tamoxifen use is endometrial cancer. Tamoxifen therapy usually is discontinued after 5 years although recent data from randomized trials suggest a survival benefit for 10 years of tamoxifen therapy over 5 years. However, somewhat surprisingly the benefit is not seen in the second five years (i.e., years 5–9) while the patients are on treatment but only from years 10–15. In high risk patients who have received 5 years of adjuvant tamoxifen extended adjuvant therapy with at least 3 years of an aromatase inhibitor has been shown to provide a significant benefit in terms of disease outcome.[291]

Tamoxifen therapy is also considered for women with DCIS that is found to be estrogen receptor positive on immunohistochemical studies. The goals of such therapy are to decrease the risk of an ipsilateral recurrence after breast conservation therapy for DCIS and to decrease the risk of a primary invasive breast cancer or a contralateral breast cancer event. This approach has not been universally accepted.

Aromatase inhibitors. In postmenopausal women, aromatase inhibitors are now considered first-line therapy in the adjuvant setting or as a secondary agent after 1 to 2 years of adjuvant tamoxifen therapy. The nonsteroidal third generation aromatase inhibitors, anastrozole and letrozole, have both been shown to result in significantly fewer local and distant recurrences.[292,293] While neither trial on its own has shown a significant survival advantage, an overview of all the studies of adjuvant aromatase inhibitors has reported a survival advantage to the use of aromatase inhibitors The HR is about 0.80 for 5 years of an aromatase inhibitor vs. 5 years of tamoxifen and this is irrespective of absolute risk. This has led some to suggest a switch policy—2 years of tamoxifen followed by 3 years of an aromatase inhibitor—for low risk patients where the absolute benefits may be small and the cost of an aromatase inhibitor may be significant for some individuals. As aromatase inhibitors come off patent, the cost issue should decrease and even for small benefits the additional cost of an aromatase inhibitor should become cost-effective. Whether 10 years of an aromatase inhibitor will be better than 5 years is currently the subject of a randomised trial by the NSABP (B-42). For patients who have completed 5 years of adjuvant endocrine therapy and are 6–20 years from presentation, the question of whether reintroducing endocrine therapy

might decrease long term recurrence rates is being addressed by the later study which randomizes patients to 5 years of letrozole or placebo.

The aromatase inhibitors are less likely than tamoxifen to cause endometrial cancer but do lead to changes in bone mineral density that may result in osteoporosis and an increased rate of fractures in postmenopausal women. The risk of osteoporosis can be averted by treatment with bisphosphonates. Joint pains are a side effect which affects a significant number of patients.

Node-negative and node-positive breast cancer patients whose tumors express hormone receptors should be considered for endocrine therapy in the adjuvant setting. Women with hormone receptor-positive cancers achieve significant reduction in risk of recurrence and mortality due to breast cancer through the use of endocrine therapies. For women with stage IV breast cancer, a third generation non-steroidal aromatase inhibitor is the preferred initial therapy. For postmenopausal women with prior aromatase inhibitor exposure, recommended second-line endocrine therapies include the pure anti-estrogen fulvestrant (at the 500-mg dose) or tamoxifen followed by progestins, high-dose estrogen, and androgens. For postmenopausal patients who received tamoxifen as prior endocrine therapy, subsequent endocrine therapies would be an aromatase inhibitor or fulvestrant (500 mg) followed by progestins, high dose estrogens, and androgens. In premenopausal patients with stage IV breast cancer either tamoxifen or oophorectomy (medical, surgical, or radioablative) could be used alone with the other then being added in on progression. An overview of four randomized trials suggested combining oophorectomy and tamoxifen would be the initial treatment options. If a tumor progresses while a premenopausal patient is on ovarian ablation plus tamoxifen then the tamoxifen can be stopped and an aromatase inhibitor added to the ovarian ablation. Subsequent therapies if the patient's tumor is still deemed to be potentially hormone responsive can include ovarian ablation plus fulvestrant, ovarian ablation plus exemestane, and then progestins followed by high dose estrogens. Women whose tumors respond to an endocrine therapy with either shrinkage of their breast cancer (objective response) or long-term stabilization of disease (stable disease) are together consider to represent 'clinical benefit' and should receive additional endocrine therapy at the time of progression since their chances of a further response remain high.[294-296] Patients whose tumors progress de-novo on an endocrine agent have a low rate of clinical benefit (<20%) to subsequent endocrine therapy; the choice of endocrine or chemotherapy should be considered based on the disease site and extent as well as the patient's general condition and treatment preference.[294]

Ablative Endocrine Therapy

In the past, oophorectomy, adrenalectomy, and/or hypophysectomy were the primary endocrine modalities used to treat metastatic breast cancer, but today they are rarely used. Oophorectomy was used in premenopausal breast cancer patients. In contrast, pharmacologic doses of exogenous estrogens were given to postmenopausal women with similar recurrences. For both groups, the response rates were nearly 30%. Adrenalectomy and hypophysectomy were effective in individuals who had previously responded to either oophorectomy or exogenous estrogen therapy, and the response to these additional procedures was nearly 30%. Aminoglutethimide blocks enzymatic conversion of cholesterol to γ-5-pregnenolone and inhibits the conversion of androstenedione to estrogen in peripheral tissues. Dose-dependent and transient side effects include ataxia, dizziness, and lethargy. After treatment with this agent (medical adrenalectomy), adrenal suppression necessitates glucocorticoid therapy. Neither permanent adrenal insufficiency nor acute crises have been observed. Because the adrenal glands are the major site for production of endogenous estrogens after menopause, treatment with aminoglutethimide has been compared prospectively with surgical adrenalectomy and hypophysectomy in postmenopausal women and is equally efficacious.

Anti–HER-2/*neu* Therapy

The determination of tumor HER-2/*neu* expression or gene amplification for all newly diagnosed patients with breast cancer is now recommended.[297-300] It is used to assist in the selection of adjuvant chemotherapy in both node-negative and node-positive patients. Patients with HER-2-positive disease appear to have better outcomes with anthracycline-based adjuvant chemotherapy regimens. Patients with HER-2-positive tumors benefit if trastuzumab is added to paclitaxel chemotherapy. Cardiotoxicity may develop if trastuzumab is delivered concurrently with anthracycline-based chemotherapy.

Trastuzumab was initially approved for the treatment of HER-2/*neu*–positive breast cancer in patients with metastatic disease. Once efficacy was demonstrated for patients with metastatic disease, the NSABP and the North Central Cancer Treatment Group conducted phase III trials evaluating the impact of adjuvant trastuzumab therapy in patients with early-stage breast cancer. After approval from the FDA, these groups amended their adjuvant trastuzumab trials (B-31 and N9831, respectively), to provide for a joint efficacy analysis. The first joint interim efficacy analysis demonstrated an improvement in 3-year disease-free survival from 75% in the control arm to 87% in the trastuzumab arm (hazard ratio = 0.48, $P<.0001$). There was an accompanying 33% reduction in mortality in the patients who received trastuzumab (hazard ratio = 0.67, $P = 0.015$). The magnitude of reduction in hazard for disease-free survival events crossed prespecified early reporting boundaries, so the data-monitoring committees for both groups recommended that randomized accrual to the trials be ended, and the results were subsequently published.[167]

Buzdar and colleagues reported the results of a randomized neoadjuvant trial of trastuzumab in combination with sequential paclitaxel followed by FEC-75 (5-fluorouracil, epirubicin, cyclophosphamide) vs. the same chemotherapy regimen without trastuzumab in 42 women with early-stage operable breast cancer. The pathologic complete response rates in this trial increased from 25 to 66.7% when chemotherapy was given concurrently with trastuzumab. None of the patients receiving the concurrent trastuzumab and FEC regimen developed symptoms of congestive heart failure. However, given the small sample size in this report, the 95% confidence interval for developing heart failure was 0% to 14.8%.[301] A subsequent report which included additional patients treated with concurrent chemotherapy and trastuzumab further confirmed the high pathologic complete response rates and continued to show that cardiac function was preserved.[302] This regimen was tested in a phase III multicenter trial (ACOSOG Z1041) which recently completed accrual.

Several new agents have been approved for the treatment of women with metastatic *HER*-2-positive breast cancers. Lapatinib is a dual tyrosine kinase inhibitor that targets both *HER*-2

and EGFR. It was approved for use with capecitabine in patients with *HER*-2-positive metastatic disease. Ado-trastuzumab (previously known as TDM1) was approved for patients who have previously received trastuzumab and a taxane either separately or in combination. Ado-trastuzumab binds to the HER-2 receptor and releases a cytotoxic agent into the cell that leads to apoptosis. The FDA has also approved pertuzumab, which also targets the HER-2 receptor, in combination with trastuzumab and docetaxel for treatment of metastatic HER-2-positive breast cancer. There is significant interest in dual targeting of HER-2 and multiple trials are ongoing in the metastatic and neoadjvuant settings.

SPECIAL CLINICAL SITUATIONS

Nipple Discharge

Unilateral Nipple Discharge Nipple discharge is a finding that can be seen in a number of clinical situations. It may be suggestive of cancer if it is spontaneous, unilateral, localized to a single duct, present in women ≥40 years of age, bloody, or associated with a mass. A trigger point on the breast may be present so that pressure around the nipple-areolar complex induces discharge from a single duct. In this circumstance, mammography and ultrasound are indicated for further evaluation. A ductogram also can be useful and is performed by cannulating a single discharging duct with a small nylon catheter or needle and injecting 1.0 mL of water-soluble contrast solution. Nipple discharge associated with a cancer may be clear, bloody, or serous. Testing for the presence of hemoglobin is helpful, but hemoglobin may also be detected when nipple discharge is secondary to an intraductal papilloma or duct ectasia. Definitive diagnosis depends on excisional biopsy of the offending duct and any associated mass lesion. A 3.0 lacrimal duct probe can be used to identify the duct that requires excision. Another approach is to inject methylene blue dye within the duct after ductography. The nipple must be sealed with collodion or a similar material so that the blue dye does not discharge through the nipple but remains within the distended duct facilitating its localization. Needle localization biopsy is performed when there is an associated mass that lies >2.0 to 3.0 cm from the nipple.

Bilateral Nipple Discharge Nipple discharge is suggestive of a benign condition if it is bilateral and multiductal in origin, occurs in women ≤39 years of age, or is milky or blue-green. Prolactin-secreting pituitary adenomas are responsible for bilateral nipple discharge in <2% of cases. If serum prolactin levels are repeatedly elevated, plain radiographs of the sellaturcica are indicated and thin section CT scan is required. Optical nerve compression, visual field loss, and infertility are associated with large pituitary adenomas.

Axillary Lymph Node Metastases in the Setting of an Unknown Primary Cancer

A woman who presents with an axillary lymph node metastasis that is consistent with a breast cancer metastasis has a 90% probability of harboring an occult breast cancer.[303] However, axillary lymphadenopathy is the initial presenting sign in only 1% of breast cancer patients. Fine-needle aspiration biopsy or core-needle biopsy can be used to establish the diagnosis when an enlarged axillary lymph node is identified. When metastatic cancer is found, immunohistochemical analysis may classify the cancer as epithelial, melanocytic, or lymphoid in origin. The presence of hormone receptors (estrogen or progesterone receptors) suggests metastasis from a breast cancer but is not diagnostic. The search for a primary cancer includes careful examination of the thyroid, breast, and pelvis, including the rectum. The breast should be examined with diagnostic mammography, ultrasonography, and MRI to evaluate for an occult primary lesion. Further radiologic and laboratory studies should include chest radiography and liver function studies. Additional imaging of the chest, abdomen, and skeleton may be indicated if the extent of nodal involvement is consistent with stage III breast cancer. Suspicious findings on mammography, ultrasonography, or MRI necessitate breast biopsy. When a breast cancer is found, treatment consists of an axillary lymph node dissection with a mastectomy or preservation of the breast followed by whole-breast radiation therapy. Chemotherapy and endocrine therapy should be considered.

Breast Cancer During Pregnancy

Breast cancer occurs in 1 of every 3000 pregnant women, and axillary lymph node metastases are present in up to 75% of these women.[304] The average age of the pregnant woman with breast cancer is 34 years. Fewer than 25% of the breast nodules developing during pregnancy and lactation will be cancerous. Ultrasonography and needle biopsy specimens are used in the diagnosis of these nodules. Mammography is rarely indicated because of its decreased sensitivity during pregnancy and lactation; however, the fetus can be shielded if mammography is needed. Approximately 30% of the benign conditions encountered will be unique to pregnancy and lactation (galactoceles, lobular hyperplasia, lactating adenoma, and mastitis or abscess). Once a breast cancer is diagnosed, complete blood count, chest radiography (with shielding of the abdomen), and liver function studies are performed.

Because of the potential deleterious effects of radiation therapy on the fetus, radiation cannot be considered until the fetus is delivered. A modified radical mastectomy can be performed during the first and second trimesters of pregnancy, even though there is an increased risk of spontaneous abortion after first-trimester anesthesia. During the third trimester, lumpectomy with axillary node dissection can be considered if adjuvant radiation therapy is deferred until after delivery. Lactation is suppressed. Chemotherapy administered during the first trimester carries a risk of spontaneous abortion and a 12% risk of birth defects. There is no evidence of teratogenicity resulting from administration of chemotherapeutic agents in the second and third trimesters. For this reason, many clinicians now consider the optimal strategy to be delivery of chemotherapy in the second and third trimesters as a neoadjuvant approach, which allows local therapy decisions to be made after the delivery of the baby. Pregnant women with breast cancer often present at a later stage of disease because breast tissue changes that occur in the hormone-rich environment of pregnancy obscure early cancers. However, pregnant women with breast cancer have a prognosis, stage by stage, that is similar to that of nonpregnant women with breast cancer.

Male Breast Cancer

Fewer than 1% of all breast cancers occur in men.[305,306] The incidence appears to be highest among North Americans and the British, in whom breast cancer constitutes as much as 1.5% of

all male cancers. Jewish and African American males have the highest incidence. Male breast cancer is preceded by gynecomastia in 20% of men. It is associated with radiation exposure, estrogen therapy, testicular feminizing syndromes, and Klinefelter's syndrome (XXY). Breast cancer is rarely seen in young males and has a peak incidence in the sixth decade of life. A firm, nontender mass in the male breast requires investigation. Skin or chest wall fixation is particularly worrisome.

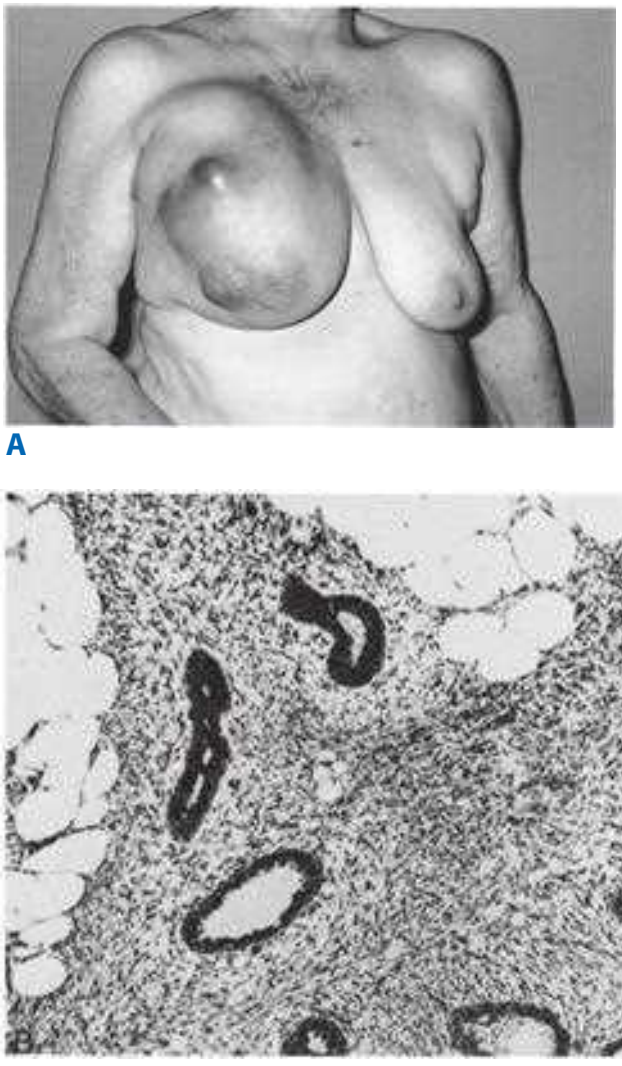
DCIS makes up <15% of male breast cancer, whereas infiltrating ductal carcinoma makes up >85%. Special-type cancers, including infiltrating lobular carcinoma, have occasionally been reported. Male breast cancer is staged in the same way as female breast cancer, and stage by stage, men with breast cancer have the same survival rate as women. Overall, men do worse because of the more advanced stage of their cancer (stage II, III or IV) at the time of diagnosis. The treatment of male breast cancer is surgical, with the most common procedure being a modified radical mastectomy. SLN dissection has been shown to be feasible and accurate for nodal assessment in men presenting with a clinically node-negative axilla. Adjuvant radiation therapy is appropriate in cases in which there is a high risk for local-regional recurrence. Approximately 80% of male breast cancers are hormone receptor positive, and adjuvant tamoxifen is considered. Systemic chemotherapy is considered for men with hormone receptor-negative cancers and for men with large primary tumors, multiple positive nodes, and locally advanced disease.

Phyllodes Tumors

The nomenclature, presentation, and diagnosis of phyllodes tumors (including cystosarcoma phyllodes) have posed many problems for surgeons.[307] These tumors are classified as benign, borderline, or malignant. Borderline tumors have a greater potential for local recurrence.

Mammographic evidence of calcifications and morphologic evidence of necrosis do not distinguish between benign, borderline, and malignant phyllodes tumors. Consequently, it is difficult to differentiate benign phyllodes tumors from the malignant variant and from fibroadenomas. Phyllodes tumors are usually sharply demarcated from the surrounding breast tissue, which is compressed and distorted. Connective tissue composes the bulk of these tumors, which have mixed gelatinous, solid, and cystic areas. Cystic areas represent sites of infarction and necrosis. These gross alterations give the gross cut tumor surface its classical leaf-like (phyllodes) appearance. The stroma of a phyllodes tumor generally has greater cellular activity than that of a fibroadenoma. After microdissection to harvest clusters of stromal cells from fibroadenomas and from phyllodes tumors, molecular biology techniques have shown the stromal cells of fibroadenomas to be either polyclonal or monoclonal (derived from a single progenitor cell), whereas those of phyllodes tumors are always monoclonal.

Most malignant phyllodes tumors (Fig. 17-38) contain liposarcomatous or rhabdomyosarcomatous elements rather than fibrosarcomatous elements. Evaluation of the number of mitoses and the presence or absence of invasive foci at the tumor margins may help to identify a malignant tumor. Small phyllodes tumors are excised with a margin of normal-appearing breast tissue. When the diagnosis of a phyllodes tumor with suspicious malignant elements is made, reexcision of the biopsy specimen site to ensure complete excision of the tumor with a 1-cm margin of normal-appearing breast tissue is indicated.



A

B

Figure 17-38. A. Malignant phyllodes tumor (cystosarcoma-phyllodes). **B.** Histologic features of a malignant phyllodes tumor (hematoxylin and eosin stain, ×100).

Large phyllodes tumors may require mastectomy. Axillary dissection is not recommended because axillary lymph node metastases rarely occur.

Inflammatory Breast Carcinoma

Inflammatory breast carcinoma (stage IIIB) accounts for <3% of breast cancers. This cancer is characterized by the skin changes of brawny induration, erythema with a raised edge, and edema (peaud'orange).[308] Permeation of the dermal lymph vessels by cancer cells is seen in skin biopsy specimens. There may be an associated breast mass (Fig. 17-39). The clinical differentiation of inflammatory breast cancer may be extremely difficult, especially when a locally advanced scirrhous carcinoma invades dermal lymph vessels in the skin to produce peaud'orange and lymphangitis (Table 17-15). Inflammatory breast cancer also may be mistaken for a bacterial infection of the breast. More than 75% of women who have inflammatory breast cancer present with palpable axillary lymphadenopathy, and distant metastases also are frequently present. A positron emission

Figure 17-39. Inflammatory breast carcinoma. Stage IIIB cancer of the breast with erythema, skin edema (peaud'orange), nipple retraction, and satellite skin nodules.

tomography (PET)-computed tomography (CT) scan should be considered at the time of diagnosis to rule out concurrent metastatic disease. A report of the SEER program described distant metastases at diagnosis in 25% of white women with inflammatory breast carcinoma.

Table 17-15

Inflammatory vs. noninflammatory breast cancer

INFLAMMATORY	NONINFLAMMATORY
Dermal lymph vessel invasion is present with or without inflammatory changes.	Inflammatory changes are present without dermal lymph vessel invasion.
Cancer is not sharply delineated.	Cancer is better delineated.
Erythema and edema frequently involve >33% of the skin over the breast.	Erythema is usually confined to the lesion, and edema is less extensive.
Lymph node involvement is present in >75% of cases.	Lymph nodes are involved in approximately 50% of the cases.
Distant metastases are present in 25% of cases.	Distant metastases are less common at presentation.
Distant metastases are more common at initial presentation.

Surgery alone and surgery with adjuvant radiation therapy have produced disappointing results in women with inflammatory breast cancer. However, neoadjuvant chemotherapy with ananthracycline-containing regimen may affect dramatic regressions in up to 75% of cases. Tumor should be assessed for *HER-2* and hormone receptors with treatment dictated based on receptor status. Modified radical mastectomy is performed after demonstrated response to systemic therapy to remove residual cancer from the chest wall and axilla. Adjuvant chemotherapy may be indicated depending on final pathologic assessment of the breast and regional nodes. Finally, the chest wall and the supraclavicular, internal mammary, and axillary lymph node basins receive adjuvant radiation therapy. This multimodal approach results in 5-year survival rates that approach 30%. Patients with inflammatory breast cancer should be encouraged to participate in clinical trials.

Rare Breast Cancers

Squamous Cell (Epidermoid) Carcinoma. Squamous cell (epidermoid) carcinoma is a rare cancer that arises from metaplasia within the duct system and generally is devoid of distinctive clinical or radiographic characteristics.[309] Regional metastases occur in 25% of patients, whereas distant metastases are rare.

Adenoid Cystic Carcinoma. Adenoid cystic carcinoma is very rare, accounting for <0.1% of all breast cancers. It is typically indistinguishable from adenoid cystic carcinoma arising in salivary tissues. These cancers are generally 1 to 3 cm in diameter at presentation and are well circumscribed. Axillary lymph node metastases are rare, but deaths from pulmonary metastases have been reported.

Apocrine Carcinomas. Apocrine carcinomas are well-differentiated cancers that have rounded vesicular nuclei and prominent nucleoli. There is a very low mitotic rate and little variation in cellular features. However, apocrine carcinomas may display an aggressive growth pattern.

Sarcomas. Sarcomas of the breast are histologically similar to soft tissue sarcomas at other anatomic sites. This diverse group includes fibrosarcoma, malignant fibrous histiocytoma, liposarcoma, leiomyosarcoma, malignant schwannoma, rhabdomyosarcoma, osteogenic sarcoma, and chondrosarcoma. The clinical presentation is typically that of a large, painless breast mass with rapid growth. Diagnosis is by core-needle biopsy or by open incisional biopsy. Sarcomas are graded based on cellularity, degree of differentiation, nuclear atypia, and mitotic activity. Primary treatment is wide local excision, which may necessitate mastectomy. Axillary dissection is not indicated unless there is biopsy proven lymph node involvement. Angiosarcomas are classified as de novo, as postradiation, or as arising in association with postmastectomy lymphedema. In 1948, Stewart and Treves described lymphangiosarcoma of the upper extremity in women with ipsilateral lymphedema after radical mastectomy.[310] *Angiosarcoma* is now the preferred name. The average interval between modified radical or radical mastectomy and the development of an angiosarcoma is 7 to 10 years. Sixty percent of women developing this cancer have a history of adjuvant radiation therapy. Forequarter amputation may be necessary to palliate the ulcerative complications and advanced lymphedema.

Lymphomas. Primary lymphomas of the breast are rare, and there are two distinct clinicopathologic variants. One type occurs in women ≤39 years of age, is frequently bilateral, and

has the histologic features of Burkitt's lymphoma. The second type is seen in women ≥40 years of age and is usually of the B-cell type. Breast involvement by Hodgkin's lymphoma has been reported. An occult breast lymphoma may be diagnosed after detection of palpable axillary lymphadenopathy. Treatment depends on the stage of disease. Lumpectomy or mastectomy may be required. Axillary dissection for staging and for clearance of palpable disease is appropriate. Recurrent or progressive local-regional disease is best managed by chemotherapy and radiation therapy. The prognosis is favorable, with 5- and 10-year survival rates of 74% and 51%, respectively.

chapter 18

Disorders of the Head and Neck

Richard O. Wein, Rakesh K. Chandra,
C. René Leemans, and Randal S. Weber

A COMPLEX REGION

The head and neck constitute a complex anatomic region where different pathologies may affect an individual's ability to see, smell, hear, speak, obtain nutrition and hydration, or breathe. The use of a multidisciplinary approach to many of the disorders in this region is essential in an attempt to achieve the best functional results with care. This chapter reviews many of the common diagnoses encountered in the field of otolaryngology–head and neck surgery—and aims to provide an overview that clinicians can use as a foundation for understanding of this region. As is the case with every field of surgery, care for patients with disorders of the head and neck is constantly changing as issues of quality of life and the economics of medicine continue to evolve.

BENIGN CONDITIONS OF THE HEAD AND NECK

Ear Infections

Infections may involve the external, middle, and/or internal ear. In each of these scenarios, the infection may follow an acute or chronic course and may be associated with both otologic and intracranial complications. *Otitis externa* typically refers to infection of the skin of the external auditory canal.[1] Acute otitis externa is commonly known as *swimmer's ear*, because moisture that persists within the canal after swimming often initiates the process and leads to skin maceration and itching. Typically, the patient subsequently traumatizes the canal skin by scratching (i.e., with a cotton swab or fingernail), thus eroding the normally protective skin/cerumen barrier. Because the environment within the external ear canal is already dark, warm, and humid, it then becomes susceptible to rapid microbial proliferation and tissue cellulitis. The most common organism responsible is *Pseudomonas aeruginosa*, although other bacteria and fungi may also be implicated. Symptoms and signs of otitis externa include itching during the initial phases and pain with swelling of the canal soft tissues as the infection progresses. Infected, desquamated debris accumulates within the canal. In the chronic inflammatory stage of the infection, the pain subsides, but profound itching occurs for prolonged periods with gradual thickening of the external canal skin. Standard treatment requires removal of debris under otomicroscopy and application of appropriate topical antimicrobials, such as neomycin/polymyxin or quinolone-containing eardrops, which often include topical steroid such as hydrocortisone or dexamethasone to nonspecifically decrease pain and swelling. Nonantibiotic antimicrobial preparations, such as 2% acetic acid, may also have a role, particularly for mixed bacterial/fungal infections. For this reason, the patient should also be instructed to keep the ear dry. Systemic antibiotics are reserved for those with severe infections, diabetics, and immunosuppressed patients.

Diabetic, elderly, and immunodeficient patients are susceptible to a condition called *malignant otitis externa*, a fulminant necrotizing infection of the otologic soft tissues combined with osteomyelitis of the temporal bone. In addition to the previously mentioned findings, cranial neuropathies may be observed. The classic physical finding is granulation tissue along the floor of the external auditory canal (EAC). Symptoms include persistent otalgia for longer than 1 month and purulent otorrhea for several weeks. These patients require aggressive medical therapy; including IV antibiotics covering *Pseudomonas*.[2] Other gram-negative bacteria and fungi are occasionally implicated, necessitating culture-directed therapy in those cases. Patients who do not respond to medical management require surgical debridement. This condition may progress to involvement of the adjacent skull base and soft tissues, meningitis, brain abscess, and death.

In its acute phase, otitis media typically implies a bacterial infection of the middle ear. This diagnosis accounts for 25% of

Key Points

1. Patients with obstructive sleep apnea require evaluation to determine the specific anatomic site(s) of involvement. Long-term cardiovascular problems are a significant concern in these patients.
2. Repair of traumatic soft tissue injuries requires precise re-alignment of anatomic landmarks such as the grey line and vermilion border.
3. The key principle in the surgical repair of facial fractures is immobilization, which may require plates, screws, wires, and/or intermaxillary fixation.
4. Concurrent abuse of tobacco and alcohol are synergistic in increasing the risk of developing head and neck cancer
5. Monomodality therapy (surgery or radiation) is used for early stage (I/II) head and neck cancer, whereas combination surgery and chemoradiation is utilized with advanced stage (III/IV) malignancies.
6. Infectious conditions of the head and neck may present with life-threatening sequelae such as loss of airway or intracranial extension.
7. Disorders of the head and neck can cause significant cosmetic and functional impairment. The practitioner must be empathetic to the effect of these morbidities on quality of life.
8. Hoarseness, odynophagia, referred otalgia, nonhealing oral ulceration and/or cervical lymphadenopathy present for >2 weeks duration require consideration for subspecialty consultation for evaluation.

pediatric antibiotic prescriptions and is the most common bacterial infection of childhood. Most cases occur before 2 years of age and are secondary to immaturity of the Eustachian tube. Contributing factors include upper respiratory viral infection and day-care attendance, as well as craniofacial conditions affecting Eustachian tube function, such as cleft palate. It is also possible that social factors such as day-care attendance and the inappropriate prescribing of antibiotics have led to antibiotic resistance.

Classification of the infection as acute is based upon the duration of the process being less than 3 weeks. In this phase, otalgia and fever are the most common symptoms and physical exam reveals a bulging, opaque tympanic membrane (Fig. 18-1). The most common organisms responsible are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. If the process lasts 3 to 8 weeks, it is deemed subacute. Chronic otitis media, lasting more than 8 weeks, usually results from an unresolved acute otitis media. About 20% of patients demonstrate a persistent middle ear effusion 8 weeks after resolution of the acute phase. Rather than a purely infectious process, however, it represents chronic inflammation and hypersecretion by the middle ear mucosa associated with Eustachiantube dysfunction, viruses, allergy, ciliary dysfunction, and other factors. The bacteriology is variable, but often includes those found in acute otitis media and may be polymicrobial. The exact role of bacteria in the pathophysiology is controversial. The patient experiences otalgia, ear fullness, and conductive hearing loss. Physical examination reveals a retracted tympanic membrane that may exhibit an opaque character or an air-fluid level. Bubbles may be seen behind the retracted membrane.

Treatment for uncomplicated otitis media is oral antibiotic therapy. However, penicillin resistance of the commonly implicated organisms is rising such that almost 100% of *Moraxella*, 50% to 70% of *Haemophilus*, and up to 40% of pneumococcal strains are resistant.[3] Beta-lactamase-resistant combinations, cephalosporins, and macrolides are often required, although amoxicillin and sulfas are still considered first-line drugs. Chronic otitis media is frequently treated with myringotomy and tube placement (Fig. 18-2). This is indicated for frequent acute episodes, chronic effusions persisting beyond 3 months, and those associated with significant conductive hearing loss. The purpose of this procedure is to remove the effusion and provide a route for middle ear ventilation. Tympanic membrane perforation during acute otitis media frequently results in resolution of severe pain and provides for drainage of purulent

Figure 18-1. Acute otitis media.

Figure 18-2. Myringotomy and tube.

fluid and middle ear ventilation. These perforations will heal spontaneously after the infection has resolved in the majority of cases. Chronic otitis media, however, may be associated with nonhealing tympanic membrane perforations. Patients may have persistent otorrhea, which is treated with topical drops. Preparations containing aminoglycoside are avoided, because this class of drugs is toxic to the inner ear. Solutions containing alcohol or acetic acid may be irritative or caustic to the middle ear, and are also avoided in the setting of a perforation.

Nonhealing perforation requires surgical closure (tympanoplasty) after medical treatment of any residual acute infection. Chronic inflammation may also be associated with erosion of the ossicular chain, which can be reconstructed with various prostheses or autologous ossicular replacement techniques. Cholesteatoma is an epidermoid cyst of the middle ear and/or mastoid, which causes bone destruction secondary to its expansile nature and through enzymatic destruction. Cholesteatoma develops as a consequence of Eustachian tube dysfunction and chronic otitis media secondary to retraction of squamous elements of the tympanic membrane into the middle ear space. Squamous epithelium may also migrate into the middle ear via a perforation. Chronic mastoiditis that fails medical management or is associated with cholesteatoma is treated by mastoidectomy.

Complications of otitis media may be grouped into two categories: intratemporal (otologic) and intracranial.[4] Fortunately, complications are rare in the antibiotic era, but mounting antibiotic resistance necessitates an increased awareness of these conditions. Intratemporal complications include acute coalescent mastoiditis, petrositis, facial nerve paralysis, and labyrinthitis. In acute coalescing mastoiditis, destruction of the bony lamellae by an acute purulent process results in severe pain, fever, and swelling behind the ear. The mastoid air cells coalesce into one common space filled with pus. Mastoid infection may also spread to the petrous apex, causing retro-orbital pain and sixth-nerve palsy. These diagnoses are confirmed by computed tomographic (CT) scan.

Facial nerve paralysis may also occur secondary to an acute inflammatory process in the middle ear or mastoid.[5] Intratemporal complications are managed by myringotomy tube placement in addition to appropriate IV antibiotics. In acute coalescent mastoiditis, and petrositis, mastoidectomy is also performed as necessary to drain purulent foci. Labyrinthitis refers to inflammation of the inner ear. Most cases are idiopathic or are secondary to viral infections of the endolymphatic space. The patient experiences vertigo with sensorineural hearing loss and symptoms may smolder over several weeks. Labyrinthitis associated with middle ear infection may be serous or suppurative. In the former case, bacterial products and/or inflammatory mediators transudate into the inner ear via the round window membrane, establishing an inflammatory process therein. Total recovery is eventually possible after the middle ear is adequately treated. Suppurative labyrinthitis, however, is a much more toxic condition in which the acute purulent bacterial infection extends into the inner ear and causes marked destruction of the sensory hair cells and neurons of the eighth-nerve ganglion. This condition may hallmark impending meningitis and must be treated rapidly. The goal of management of inner ear infection, which occurs secondary to middle ear infection, is to "sterilize" the middle ear space with antibiotics and the placement of a myringotomy tube.

Meningitis is the most common intracranial complication. Otologic meningitis in children is most commonly associated with a *H. influenzae* type B infection. Other intracranial complications include epidural abscess, subdural abscess, brain abscess, otitic hydrocephalus (pseudotumor), and sigmoid sinus thrombophlebitis. In these cases, the otogenic source must be urgently treated with antibiotics and myringotomy tube placement. Mastoidectomy and neurosurgical consultation may be necessary.

Bell's palsy, or idiopathic facial paralysis, may be considered within the spectrum of otologic disease given the facial nerve's course through the temporal bone. This entity is the most common etiology of facial nerve paralysis and is clinically distinct from that occurring as a complication of otitis media in that the otologic exam is normal. Historically, Bell's palsy was synonymous with "idiopathic" facial paralysis. It is now accepted, however, that the majority of these cases represent a viral neuropathy caused by herpes simplex. Treatment includes oral steroids plus antiviral therapy (i.e., valacyclovir). Complete recovery is the norm, but does not occur universally, and selected cases may benefit from surgical decompression of the nerve within its bony canal. Electrophysiologic testing has been used to identify those patients in whom surgery might be indicated.[6] The procedure involves decompression of the nerve via exposure in the mastoid and middle cranial fossa. Varicella zoster virus may also cause facial nerve paralysis when the virus reactivates from dormancy in the nerve. This condition, known as *Ramsay Hunt syndrome*, is characterized by severe otalgia followed by the eruption of vesicles of the external ear. Treatment is similar to Bell's palsy, but full recovery is only seen in approximately two-thirds of cases.

Traumatic facial nerve injuries may occur secondary to accidental trauma or surgical injury. Iatrogenic facial nerve trauma most often occurs during mastoidectomy.[7] When the facial nerve is injured during an operative procedure, it is explored. Injury to >50% of the neural diameter of the facial nerve is addressed either with primary re-anastomosis or reconstructed with the use a nerve graft. Complete recovery of nerve function is uncommon in these cases.

Sinus Inflammatory Disease

Sinusitis is a clinical diagnosis based on patient signs and symptoms.[8] The Task Force on Rhinosinusitis (sponsored by the American Academy of Otolaryngology–Head and Neck Surgery) has established criteria to define "a history consistent with sinusitis." To establish the diagnosis a patient must exhibit at least two major factors or one major and two minor factors. The classification of sinusitis as acute vs. subacute or chronic is primarily based on the time course over which those criteria have been met. If signs and symptoms are present for at least 7 to 10 days, but for less than 4 weeks, the process is designated acute sinusitis. Subacute sinusitis is present for 4 to 12 weeks and chronic sinusitis is diagnosed when the patient has had signs and symptoms for at least 12 weeks. In addition, the diagnosis of chronic sinusitis requires some objective demonstration of mucosal inflammatory disease. This may be accomplished by endoscopic or radiologic examination (i.e., CT scan).

Acute sinusitis typically follows a viral upper respiratory infection whereby sinonasal mucosal inflammation results in closure of the sinus ostium. This results in stasis of secretions, tissue hypoxia, and ciliary dysfunction. These conditions promote bacterial proliferation and acute inflammation. The mainstay of treatment is the use of antibiotics that are empirically directed toward the three most common organisms *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. As with otitis media, antibiotic

resistance is a mounting concern. Nosocomial acute sinusitis frequently involves *Pseudomonas* or *S. aureus*, both of which may also exhibit significant antibiotic resistance. Other treatments include topical and systemic decongestants, nasal saline spray, topical nasal steroids, and oral steroids in selected cases. In the acute setting, surgery is reserved for complications or pending complications, which may include extension to the eye (orbital cellulitis or abscess) or the intracranial space (meningitis, intracranial abscess). It should also be noted that, strictly speaking, a viral upper respiratory infection (common cold) is a form of acute sinusitis. The working definition outlined previously, however, attempts to exclude these cases by requiring that symptoms be present for at least 7 to 10 days, by which time the common cold should be in a resolution phase. Use of this working definition strives to avoid unnecessary antibiotic prescriptions and further promotion of resistance.

Chronic sinusitis represents a heterogeneous group of patients with multifactorial etiologies contributing to ostial obstruction, ciliary dysfunction, and inflammation. Components of genetic predisposition, allergy, anatomic obstruction, bacteria, fungi, and environmental factors play various roles, depending on the individual patient.[8] Diagnosis is suspected with clinical signs and symptoms persisting for at least 12 weeks. Chronic sinusitis may also be associated with the presence of nasal polyps, particularly when there is heavy eosinophilic inflammation. Mucosal inflammation in nonpolypoid chronic sinusitis is predominantly mediated by neutrophils, or is mixed in nature.

Nasal endoscopy is a critical element of the diagnosis of chronic sinusitis. Anatomic abnormalities, such as septal deviation, nasal polyps, and purulence may be observed (Fig. 18-3 and 18-4). The finding of purulence or polypoid change by nasal endoscopy is supportive of the diagnosis of chronic sinusitis, if symptoms persist for at least 12 weeks. In this setting, purulence may represent an acute exacerbation of chronic sinusitis. Pus found on endoscopic exam may be cultured, and subsequent antibiotic therapy can be directed accordingly. Further, the spectrum of bacteria found in chronic sinusitis is highly variable and includes higher prevalence of polymicrobial infections and antibiotic-resistant organisms. Overall, *S. aureus*, coagulase-negative staphylococci, gram-negative bacilli, and streptococci are isolated, in addition to the typical pathogens of acute sinusitis. Thus, the increased prevalence of community acquired methicillin resistant *S. aureus* is a mounting concern.[9]

Figure 18-4. Endoscopic image of a nasal polyp.

The diagnosis of chronic sinusitis can be confirmed by CT scan, which demonstrates mucosal thickening and/or sinus opacification. It should be underscored, however, that CT scan is not the positive gold standard because many asymptomatic patients will demonstrate findings on a sinus CT scan, and many patients with presumed sinusitis will have negative findings. CT scan has excellent negative predictive value when performed in the setting of active symptoms. Thus, if a patient complains of sinusitis-like symptoms but has no specific physical (endoscopic) findings, and the scan is negative, other diagnoses (e.g., allergies, migraines, tension headaches) should be sought. This has led to the utility of point-of-care CT (POC-CT) scan that can be performed in the physician's office. POC-CT utilizes cone beam technology[10], which acquires the equivalent of >100 axial slices in approximately 1 minute at an effective resolution of 0.3 mm or less. The equipment occupies a room of 8' × 10' and can thus be accommodated in almost any office setting (Fig. 18-5). Perhaps most important, the radiation dosing for

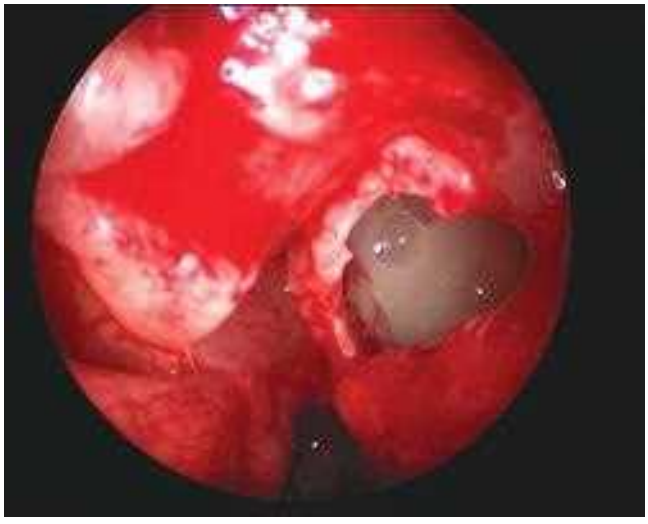

Figure 18-3. Endoscopic view of purulence within a surgically opened maxillary sinus cavity.

Figure 18-5. POC-CT system. All components can be fit within an 8' × 10' room in an outpatient office setting.

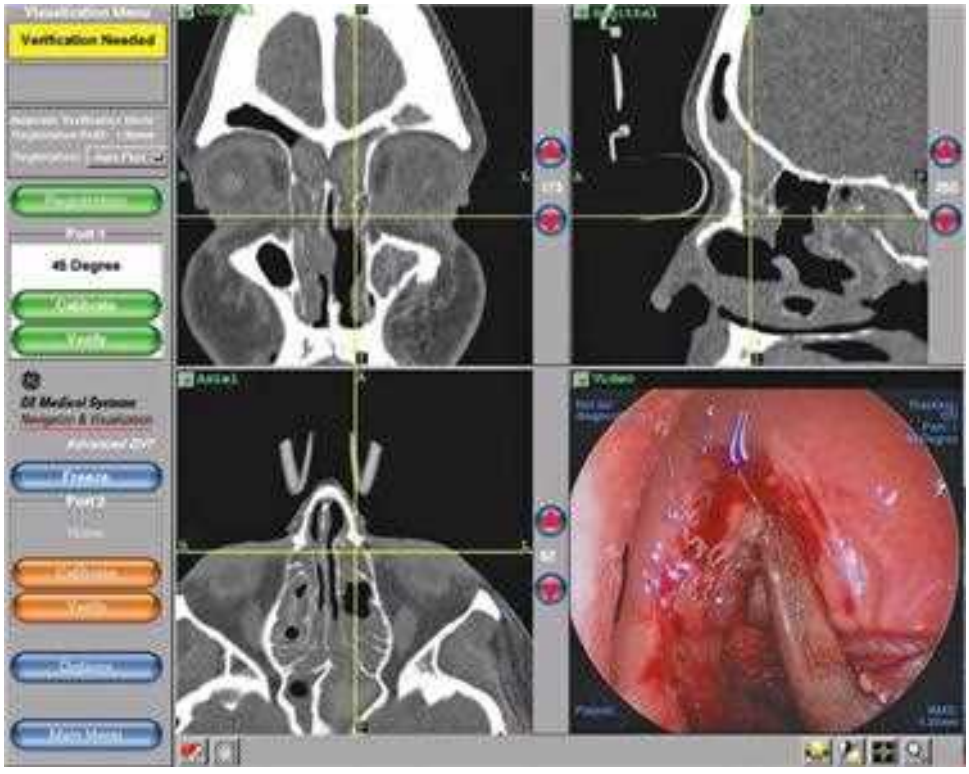

Figure 18-6. Triplanar imaging revealing proximity to critical structures such as the orbital wall and skull base. This can be used for diagnosis of sinus opacification as well as stereotactic intraoperative navigation, where endoscope view (lower right) can be radiologically correlated with location in the 3 cardinal planes. This case reflects classic allergic fungal sinusitis where the opacified sinuses are filled with heterogeneous whitish material on CT images. Polyps in the ethmoid cavity are seen on the endoscope image.

even the most sophisticated protocol is 0.17 mSv, which is <10% the dose of a conventional head CT and equivalent to approximately 20 days of background radiation. One theoretical shortcoming of this technology is that it does not permit soft tissue imaging. This is seldom a concern in sinonasal evaluation, as this is typically undertaken in bone windows. The acquired data are immediately formatted into triplanar (axial, sagittal, coronal) reconstructions and is also compatible with devices used for intraoperative stereotactic navigation, which can be used to confirm relationships between the disease process, medial orbital wall, and skull base during surgery (Fig. 18-6 and 18-7). Variations of this and other technologies have also been adapted for intraoperative use to ensure completeness of resection and to update anatomic relationships for further intraoperative stereotaxis.Notably, imaging of the temporal bone for evaluation of middle ear structures can be performed via POC-CT as well.

Medical management of chronic sinusitis includes a prolonged course of oral antibiotics for 3 to 6 weeks, nasal and/or oral steroids, and nasal irrigations with saline or antibiotic solutions.[8] Underlying allergic disease may be managed with antihistamines and possible allergy immunotherapy. Although the role of these treatments in resolving chronic sinusitis remains questionable, they may be considered in patients with comorbid allergic rhinitis or as part of empirical management before consideration of surgery. The use of oral steroids may also be selected empirically, particularly in patients with comorbid chronic airway inflammatory diseases such as nasal polyps, allergic rhinitis, or asthma. The decision to use oral steroids must be individualized with consideration of the risks and side effects of these medications. As yet, there is no consensus regarding what constitutes a "maximum" course of medical therapy that should be attempted before consideration of surgery for chronic sinusitis. It should be noted that unless there is suspicion of neoplasm or pending complication of sinusitis, the decision to proceed with surgery is highly individualized. This is because surgery for uncomplicated chronic sinusitis is elective, and patients who "fail" medical management will exhibit significant variability in symptoms, physical signs, and CT findings. More aggressive medical and surgical management may be necessary in patients with comorbid chronic inflammatory disease of the airways such as allergic rhinitis, nasal polyposis, and asthma. Surgery is typically preformed endoscopically where the goals are to remove polyps, enlarge the natural sinus ostia (see Fig. 18-3), and to remove chronically infected bone to promote both ventilation and drainage of the sinus cavities. Inspissated mucin or pus is drained and cultured. Eventual resolution of the chronic inflammatory process can be attained with a combination of meticulous surgery and directed medical therapy, although the patient must understand that surgery may not alter the underlying immunologic pathophysiology. In cases where resection of inflammatory tissue and polyps are not required, recent trends have also included use of angioplasty-type balloons to dilate sinus ostia. The exact role for this technology is unclear, but appears to have promise in outpatient office management of patients with focal or limited obstructive pathology.

The role of fungi in sinusitis is an area of active investigation. Fungal sinusitis may take on both noninvasive and invasive forms. The noninvasive forms include intracavitary fungal ball and allergic fungal sinusitis, both of which occur in immunocompetent patients. A fungal ball is typically seen in individuals with chronic (or recurrent acute) symptoms that are often

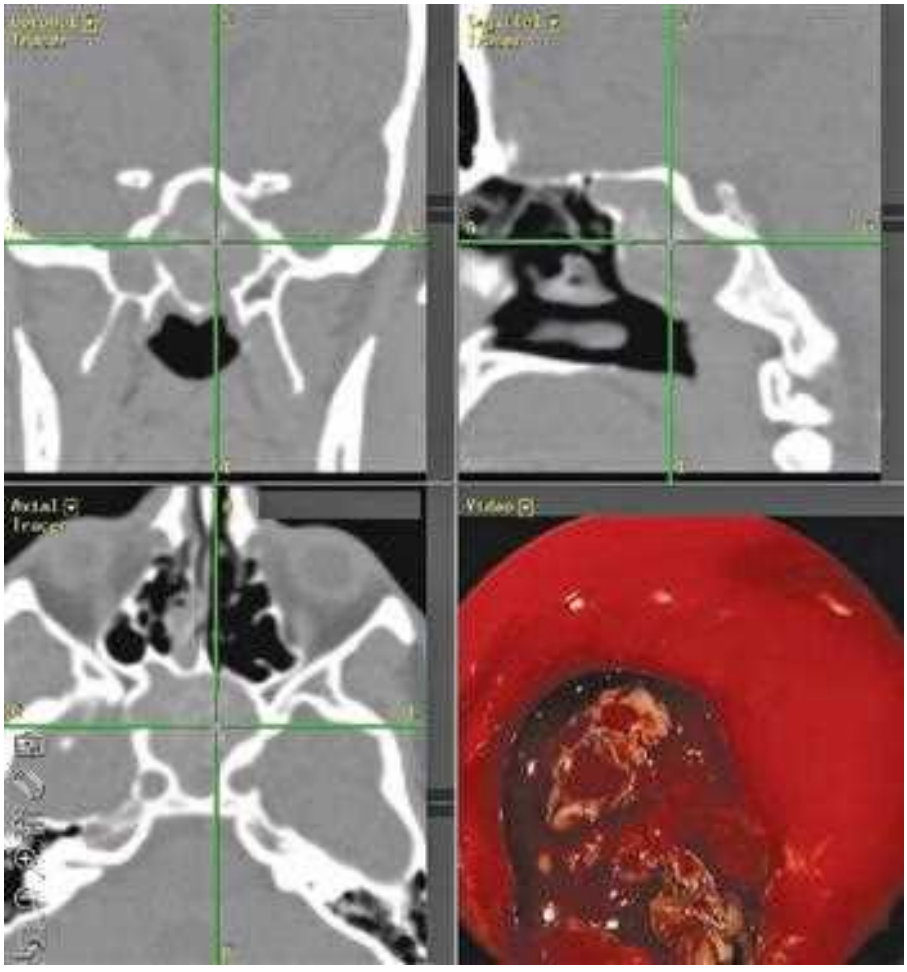

Figure 18-7. Sphenoid sinus fungal ball. The sinus has been opened revealing cheesy material during this intraoperative endoscopic view (lower right). The crosshairs stereotactically confirm location within the sphenoid sinus radiologically in the cardinal planes.

subtle and limited to a single sinus. Patients may complain about the perception of a foul odor and occasionally report expelling crusty debris upon nose blowing. Fungus balls represent a significant proportion of isolated sphenoid sinus pathology (Fig. 18-7). The most common scenario, however, is surgery to remove the debris and re-establish sinus ventilation, which is almost always curative.

Classic allergic fungal sinusitis is thought to involve direct stimulation of eosinophils by a subset of helper T cells (T_H2) primed by fungal antigens. Patients often present with chronic sinusitis that has been especially refractory to medical management. CT scan has characteristic features, and endoscopic evaluation reveals florid polyposis and inspissated mucin containing fungal debris and products of eosinophil breakdown. The implicated organisms are usually those of the Dematiaceae family, but *Aspergillus* species are also seen.[11] Treatment includes systemic steroids, surgery, and nasal irrigations. Oral antifungal therapy is sometimes indicated as well.

Immunocompetent patients may occasionally develop an indolent form of invasive fungal sinusitis, but more commonly, invasive fungal sinusitis affects immunocompromised patients, diabetics, or the elderly.[11] Fungal invasion of the microvasculature causes ischemic necrosis and black eschar of the sinonasal mucosa. *Aspergillus* and fungi of the Mucoraceae family are often implicated with the latter more common in diabetic patients. Treatment requires aggressive surgical debridement and IV antifungals, but the prognosis is dismal.[12]

Pharyngeal and Adenotonsillar Disease

The pharyngeal mucosa contains significant concentrations of lymphoid tissue, predisposing this area to reactive inflammatory changes. Lymphoid tissue of various pharyngeal subsites forms the so-called *Waldeyer's ring*, consisting of the palatine tonsils ("the tonsils"), lingual tonsil (lymphoid tissue accumulation within the tongue base), and adenoid. The mucosa of the posterior and lateral pharyngeal walls is also rich with lymphoid cells. Infection, immune-mediated inflammatory disease, or local stressors, such as radiation or acid reflux, may initiate lymphoid reactivity and associated symptoms. Chronic or recurrent adenotonsillitis and adenotonsillar hypertrophy are the most common disorders affecting these structures.

In the vast majority of cases, infectious pharyngitis is viral rather than bacterial in origin. Most cases resolve without complication from supportive care and possibly antibiotics. Patients with tonsillitis typically present with sore throat, dysphagia, and fever. The mucosa is inflamed. Tonsillar exudates and cervical adenitis may be seen, especially when the etiology is bacterial. If adenoiditis is present, symptoms may be similar to those of sinusitis. Objective evaluation of the adenoid requires endoscopy and/or radiographic imaging (lateral neck soft-tissue X-ray). Tonsillitis and adenoiditis may follow acute, recurrent acute, and chronic temporal patterns.

It should be noted, however, that clinical diagnosis often is inaccurate for determining whether the process is bacterially induced. When the patient also has hoarseness, rhinorrhea,

cough, and no evidence of exudates or adenitis, an upper respiratory viral infection can be presumed. When a bacterial cause is suspected antibiotics should be initiated to cover the usual organisms: group A beta-hemolytic streptococci (*Streptococcus pyogenes*), *S. pneumoniae*, and group C and G streptococci.[13] *H. influenzae* and anaerobes also have been implicated. It is particularly important to identify group A beta-hemolytic streptococci in pediatric patients to initiate timely antibiotic therapy, given the risk of rheumatic fever, which may occur in up to 3% of cases if antibiotics are not used. Historically, if bacterial pharyngitis was suspected in a child, oropharyngeal swab with culture was performed to identify group A beta-hemolytic streptococci. Currently, rapid antigen assays are available with sensitivity and specificity of approximately 85% and 90%, respectively. Some experts advocate culture only when these are negative. Unnecessary antibiotic therapy for patients who are unlikely to have a bacterial etiology should be avoided, given the already mounting antibiotic resistance problem. When suspicion for a bacterial process is high, or with positive culture/antigen assay results, treatment may include penicillin, cephalosporin, or macrolide antibiotics in penicillin-allergic patients.

Complications of *S. pyogenes* pharyngitis may be systemic, including rheumatic fever, poststreptococcal glomerulonephritis, and scarlet fever. The incidence of glomerulonephritis is not influenced by antibiotic therapy. Scarlet fever results from production of erythrogenic toxins by streptococci. This causes a punctate rash, first appearing on the trunk and then spreading distally, sparing the palms and soles. The so-called *strawberry tongue* also is seen. Locoregional complications include peritonsillar abscess and, rarely, deep-neck space abscess. Peritonsillar abscess is typically drained with transoral technique under local anesthesia, as is the authors' practice, but some suggest that needle aspiration without incision is sufficient.[13] Deep neck space abscess, which more commonly is odontogenic in origin, usually requires operative incision and drainage via a transcervical approach.

Candida albicans is the most common fungal organism to cause pharyngitis. This organism is a normal component of the oral flora, but under conditions of immunosuppression, broad-spectrum antibacterial therapy, poor oral hygiene, or vitamin deficiency, it may become pathogenic. Whitish-cheesy or creamy mucosal patches are observed with underlying erythema. Diagnosis is easily established by Gram's stain of this material, revealing budding yeast and pseudohyphae. Oral (-azole) and topical (nystatin) antifungals are usually effective, and immunosuppressed patients may require prophylactic therapy.

Atypical cases of pharyngitis may be caused by *Corynebacterium diphtheriae*, *Bordetella pertussis* (whooping cough), *Neisseria gonorrhoeae*, and secondary syphilis. Diphtheria and pertussis are fortunately rare in developed countries as a result of pediatric vaccination. Atypical viral causes include herpes simplex virus, Epstein-Barr virus (EBV), cytomegalovirus, and HIV are associated with pharyngitis. Systemic EBV infection represents clinical mononucleosis, although syphilis, cytomegalovirus, and HIV are known to cause mononucleosis-like syndromes. These conditions, particularly EBV, may exhibit an exudative pharyngotonsillitis that may be confused with a bacterial etiology. Progression of the clinical picture reveals lymphadenopathy, splenomegaly, and hepatitis. Diagnosis is established based on the detection of heterophile antibodies or atypical lymphocytes in the peripheral blood. Occasionally, pharyngeal biopsy specimen or cervical lymph node biopsy specimen is required to establish the diagnosis.

Noninfectious causes of pharyngitis must also be considered. These include mucositis from chemoradiation therapy, which may be associated with fungal superinfection. Pharyngitis may also be seen in immune-mediated conditions such as erythema multiforme, bullous pemphigoid, and pemphigus vulgaris. In addition, reflux is being increasingly identified as a cause of both laryngitis and pharyngitis, particularly when the symptoms are chronic. A 24-hour pH probe is the gold standard diagnostic test, and treatment is usually successful with lifestyle modification, although proton pump inhibitors are often prescribed.[14]

Obstructive adenotonsillar hypertrophy may present with nasal obstruction, rhinorrhea, voice changes, dysphagia, and sleep-disordered breathing or OSA depending on the particular foci of lymphoid tissue involved.

Tonsillectomy and adenoidectomy are indicated for chronic or recurrent acute infection and for obstructive hypertrophy.[15] The American Academy of Otolaryngology–Head and Neck Surgery Clinical Indicators Compendium suggests tonsillectomy after three or more infections per year despite adequate medical therapy. Tonsillectomy has also been advocated in children who miss 2 or more weeks of school annually secondary to recurrent tonsil infection. Multiple techniques have been described, including electrocautery, sharp dissection, laser, and radiofrequency ablation. There is no consensus as to the best method. In cases of chronic or recurrent infection, surgery is considered only after failure of medical therapy. Patients with recurrent peritonsillar abscess should undergo tonsillectomy when the acute inflammatory changes have resolved. Selected cases, however, require tonsillectomy in the acute setting for the management of severe inflammation, systemic toxicity, or impending airway compromise. Adenoidectomy, in conjunction with myringotomy and tube placement, may be beneficial for children with chronic or recurrent otitis media.[16] This is because the adenoid appears to function as a bacterial reservoir that seeds the middle ear via the Eustachian tube. Adenoidectomy is also the first line of surgical management for children with chronic sinusitis. In addition to acting as a bacterial reservoir, an obstructive adenoid impairs mucociliary clearance from the sinonasal tract into the pharynx.

The primary complications of tonsillectomy include perioperative bleeding, airway obstruction, death, and readmission for dehydration secondary to postoperative dysphagia.[17] Complications of adenoidectomy also include hemorrhage, as well as nasopharyngeal stenosis. In both procedures, there is risk of velopharyngeal insufficiency. In the latter condition, nasal regurgitation of liquids and hypernasal speech are experienced. Patients with significant airway obstruction secondary to adenotonsillar hypertrophy are also at risk for postobstructive pulmonary edema syndrome, once the obstruction is relieved by adenotonsillectomy. Overall, bleeding is the most prevalent risk and may require a return trip to the operating room for control. With the exception of bleeding, which is observed in 3% to 5% of patients, most of these complications are rare or self-limiting. It deserves special notation that adenotonsillectomy in a child with Down syndrome requires attention to the cervical spine. Patients with this syndrome may exhibit atlantoaxial instability, resulting in cervical spine injury if the neck is extended for the procedure. Baseline radiographs, with appropriate orthopedic or neurosurgical consultation, are indicated preoperatively.

Sleep disorders represent a continuum from simple snoring to upper airway resistance syndrome to obstructive sleep apnea (OSA).[18] Upper airway resistance syndrome and OSA are associated with snoring, excessive daytime somnolence, fatigue, and frequent sleep arousals. In OSA, polysomnogram demonstrates at least 10 episodes of apnea or hypopnea per hour of sleep. The average number of apneas and hypopneas per hour can be used to calculate a respiratory disturbance index, which, along with oxygen saturation, can be used to grade the severity of OSA. These episodes occur as a result of collapse of the pharyngeal soft tissues during sleep. In adults, it should be noted that in addition to tonsil size, factors such as tongue size and body mass index (especially >35 kg/m^2) are significant predictors of OSA. Other anatomic findings associated with OSA include obese neck, retrognathia, low hyoid bone, and enlarged soft palate. Surgery should be considered after failure of more conservative measures, such as weight loss, elimination of alcohol use, use of oral appliances to open the airway during sleep, and continuous positive airway pressure (CPAP). Recent trends have also included the use of oral appliances to prevent base of tongue retro-prolapsed and subsequent narrowing of the pharyngeal airway during sleep. Oral appliances are useful to avert simple snoring and mild OSA, but their role in more advanced cases is unclear. It is well accepted that CPAP is much more efficacious than an oral appliance, while the latter is associated with improved patient compliance. Those failing conservative therapies may elect a surgical procedure should be tailored to the particular patient's pattern of obstruction. In children, surgical management typically involves tonsillectomy and/or adenoidectomy, because the disorder is usually caused, at least in part, by hypertrophy or collapse of these structures. In any individual patient, the anatomy must be carefully evaluated to determine whether the site of airway collapse is in the retropalatal region, retrolingual area, or both. In adults, uvulopalatoplasty is frequently performed to alleviate soft-palate collapse and is the most common operation performed for sleep-disordered breathing. The goal of this procedure is to remove redundant tissue from the uvula and soft palate, along with obstructive tonsillar tissue. This can be accomplished with cold steel, laser, and/or cautery. Adults with significant nasal obstruction may benefit from adenoidectomy, septoplasty, reduction in size of the inferior turbinates, and possibly external nasal surgery. Patients with a significant component of retrolingual obstruction may be candidates for tongue base reduction, tongue base advancement, or hyoid suspension. Additionally, a variety of maxillomandibular advancement procedures also have been described to enlarge the anterior-posterior dimension of the retrolingual airway. Patients with moderate to severe sleep apnea frequently manifest involvement of the tongue base. However, management of this subgroup may be difficult, as procedures addressing the retrolingual airway can involve difficult recovery, significant morbidity, and limited success. These patients often continue to require continuous positive airway pressure despite performance of multilevel surgical procedures. Patients with severe OSA (respiratory disturbance index >40, lowest nocturnal oxygen saturation <70%) and unfavorable anatomy or comorbid cardiopulmonary disease may require tracheotomy,[19] which is the only surgical "cure" for OSA. Tracheotomy should be offered in patients with evidence of right heart failure (cor pulmonale), which is a potential sequela of severe OSA or undertreated cases of moderate OSA.

1▶

On the opposite end of the spectrum, many patients present with snoring but fail to exhibit OSA according to polysomnographic criteria. These "social snorers" may pursue elective procedures that stiffen the uvula and soft palate. This may be accomplished by the application of radiofrequency energy or cautery to induce submucosal scar, or by palatal implants. Elective uvulopharyngoplasty may also be a consideration in this population.

Benign Conditions of the Larynx

Disorders of voice may affect a wide array of patients with respect to age, gender, and socioeconomic status. The principal symptom of these disorders, at least when a mass lesion is present, is hoarseness. Other vocal manifestations include hypophonia or aphonia, breathiness, and pitch breaks. Benign laryngeal disorders may also be associated with airway obstruction, dysphagia, and reflux.[20] Smoking may also be a risk factor for benign disease, but this element of the history should raise the index of suspicion for malignancy.

Recurrent respiratory papillomatosis (RRP) reflects involvement of human papillomavirus (HPV) within the mucosal epithelium of the upper aerodigestive tract. The larynx is the most frequently involved site, and subtypes 6 and 11 are the most often implicated. The disorder typically presents in early childhood, secondary to viral acquisition during vaginal delivery. Many cases resolve after puberty, but the disorder may progress into adulthood. Adult-onset RRP typically occurs in the third or fourth decade of life, is usually less severe, and is more likely to involve extralaryngeal sites of the upper aerodigestive tract. With laryngeal involvement, RRP is most likely to present with hoarseness, although airway compromise may be observed. The diagnosis can be established with office endoscopy. Currently, there is no "cure" for RRP. Treatment involves operative microlaryngoscopy with excision or laser ablation, and the natural history is eventual recurrence. Therefore, surgery has an ongoing role for palliation of the disease. Multiple procedures are typically required over the patient's lifetime. Several medical therapies, including intralesional cidofovir injection and oral indole-3-carbinol, are being investigated to determine their abilities to retard recurrence. Additionally, the advent of HPV vaccines has suggested a role for this therapy in prevention of RRP.[21]

Laryngeal granulomas typically occur in the posterior larynx on the arytenoid mucosa (Fig. 18-8). These lesions are

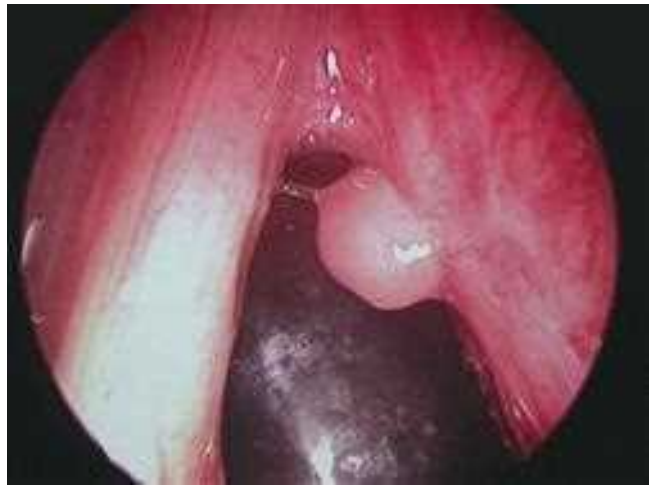

Figure 18-8. Laryngeal granuloma.

typically secondary to multiple factors,[22] including reflux, voice abuse, chronic throat clearing, endotracheal intubation, and vocal fold paralysis. Effective management requires identification of the underlying cause(s). Patients report pain (often with swallowing) more commonly than vocal changes. In addition to fiber-optic laryngoscopy, work-up may include voice analysis, laryngeal electromyography (EMG), and pH probe testing.[23] Treatment is individualized, depending on the contributing factors identified. First-line modalities that may be used include voice rest, voice retraining therapy, and anti-reflux therapy. The management of vocal cord paresis/paralysis is discussed later in this section. It is notable that the majority of cases demonstrate a component of reflux and when maximal medical therapy has failed, fundoplication may be indicated. The role of surgical excision is somewhat controversial, because it does not address the underlying etiology and is frequently associated with recurrence. Nonetheless, excision is indicated when carcinoma is suspected or when the patient has airway obstruction. Surgery may also be indicated in selected cases when a granuloma has matured into a fibroepithelial polyp, or when the patient (e.g., a performing artist) requires prompt removal for voice restoration. Surgical excision is optimally performed under jet ventilation so as to avoid endotracheal intubation. During surgery, it is important to preserve the arytenoid perichondrium to promote epithelialization postoperatively.

Edema in the superficial lamina propria of the vocal cord is known as *polypoid corditis*, *polypoid laryngitis*, *polypoid degeneration of the vocal cord*, or *Reinke's edema*. The superficial lamina propria just underlies the vibratory epithelial surface. Edema is thought to arise from injury to the capillaries that exist in this layer, with subsequent extravasation of fluid. Patients report progressive development of a rough, low-pitched voice. Females more commonly present for medical attention because the lowered vocal frequency is more evident, given the higher fundamental frequency of the female voice. The etiology is also multifactorial and may involve smoking, laryngopharyngeal reflux, hypothyroidism, and vocal hyperfunction. Most of these patients are heavy smokers and findings are typically bilateral.[24]

Focal, unilateral hemorrhagic vocal cord polyps are more common in men. These occur secondary to capillary rupture within the mucosa by shearing forces during voice abuse. Use of anticoagulant or antiplatelet drugs may be a risk factor. As with laryngeal granulomas, treatment of polypoid corditis and vocal cord polyps requires addressing the underlying factors. Conservative management includes absolute discontinuance of smoking, reflux management, and voice therapy. Notably, topical and systemic steroids are ineffective for these conditions. For polypoid corditis, elective surgery may be performed under microlaryngoscopy to evacuate the gelatinous matrix within the superficial lamina propria and trim excess mucosa. Focal polyps may be excised superficially under microlaryngoscopy. Surgery, particularly for polypoid corditis, will be less effective in patients who continue to smoke, although it should be noted that because of their heavy smoking history, surgery might be necessary to rule out occult malignancy. Surgery for polypoid corditis and hemorrhagic polyps may be accomplished either with cold steel or by using the carbon dioxide (CO_2) laser. Postoperative voice therapy is usually indicated.

Vocal cord cysts may occur under the laryngeal mucosa, particularly in regions containing mucous-secreting glands, such as the supraglottic larynx. Occasionally, they derive from minor salivary glands, and congenital cysts may persist as remnants of the branchial arch. Cysts may present in a variety of ways depending on the size and site of origin (Fig. 18-9). Cysts of the vocal cord may be difficult to distinguish from vocal polyps, and video stroboscopic laryngoscopy may be necessary to help establish the diagnosis. Cysts observed in children can be quite large, thus compromising the airway. Lesions of the true vocal cord usually present with hoarseness. Treatment again depends on the size and site of the cyst. Large cysts of the supraglottic larynx are treated by marsupialization with cold steel or a CO_2 laser. Those of the vocal cord itself require careful microsurgical technique for complete removal of the cyst while preserving the overlying mucosa.

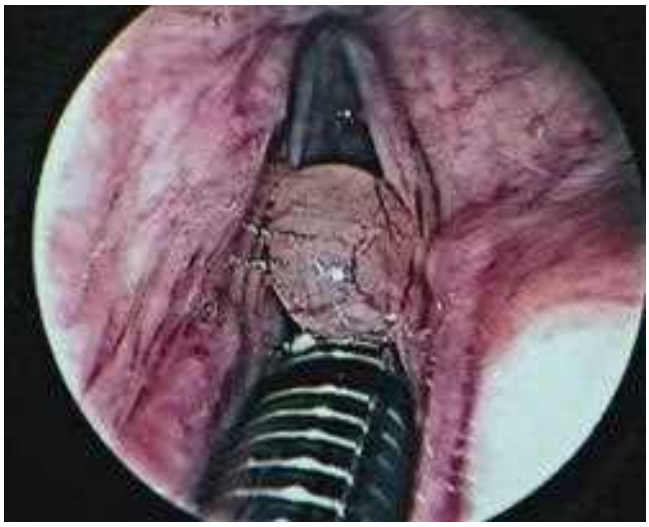

Figure 18-9. Large cyst of vocal cord.

Leukoplakia of the vocal fold represents a white patch (which cannot be wiped off) on the mucosal surface, usually on the superior surface of the true vocal cord. Rather than a diagnosis per se, the term *leukoplakia* describes a finding on laryngoscopic examination. The significance of this finding is that it may represent squamous hyperplasia, dysplasia, and/or carcinoma. Lesions exhibiting hyperplasia have a 1% to 3% risk of progression to malignancy. In contrast, that risk is 10% to 30% for those demonstrating dysplasia. Furthermore, leukoplakia may be observed in association with inflammatory and reactive pathologies, including polyps, nodules, cysts, granulomas, and papillomas. The wide, differential diagnosis for leukoplakia necessitates sound clinical judgment when selecting lesions that require operative direct laryngoscopy with biopsy specimen for histopathologic analysis. Features of ulceration and erythroplasia are particularly suggestive of possible malignancy. A history of smoking and alcohol abuse should also prompt a malignancy work-up. In the absence of suspected malignancy, conservative measures are used for 1 month. These include reduction of caffeine and alcohol, which are dehydrating and promote laryngopharyngeal reflux, proper hydration, and elimination of vocal abuse behaviors. Antireflux therapy, including proton pump inhibitors, may be prescribed. Investigational therapies, including retinoids, also have been attempted. Any lesions that progress, persist, or recur should be considered for excisional biopsy specimen.

Unilateral vocal cord paralysis is typically iatrogenic in origin,[25] following surgery to the thyroid, parathyroid, carotid, or cardiothoracic structures. Vocal cord paralysis may also be secondary to malignant processes in the lungs, thoracic cavity, skull base, or neck. In the pediatric population up to one fourth of cases may be neurologic in origin, with Arnold-Chiari malformation being the most common. Overall, the left vocal cord is more commonly involved secondary to the longer course of the recurrent laryngeal nerve (RLN) on that side, which extends into the thoracic cavity. When anterior approaches to the cervical spine are performed, however, the right RLN is at an increased risk, because it courses more laterally to the tracheoesophageal complex. Neurotoxic medications, trauma, intubation injury, and atypical infections are less common causes of vocal cord paralysis. The cause remains idiopathic in up to 20% of adults and 35% of children. These cases should prompt an imaging work-up to examine the course of the vagal/RLN in question: from the skull base to the aortic arch on the left, and from skull base to the subclavian on the right.

"Idiopathic" left true vocal cord paralysis may be a presenting sign of malignancy involving the lung, thyroid, or esophagus. Adults typically present with hoarseness and the voice may be breathy if the contralateral vocal cord has not compensated to close the glottic valve. If the proximal vagus nerve or the superior laryngeal nerve is involved, the patient may demonstrate aspiration secondary to diminished supraglottic sensation. Stridor, weak cry, and respiratory distress are seen in children, but adults typically do not exhibit signs of airway compromise unless paralysis is bilateral. Flexible fiber-optic laryngoscopy usually confirms the diagnosis, but laryngeal EMG may be necessary to distinguish vocal cord paralysis from mechanical fixation secondary to scar tissue or cricoarytenoid joint fixation. The position of the paralyzed fold depends on the residual innervation, pattern of reinnervation, and the degrees of atrophy and fibrosis of the laryngeal musculature. In bilateral vocal cord paralysis, the cords are often paralyzed in a paramedian position, creating airway compromise that necessitates tracheotomy. Once an airway is secure, vocal cord lateralization or arytenoidectomy may be performed electively to provide an adequate airway. Treatment of unilateral vocal cord paralysis includes speech therapy, which promotes glottic closure to optimize the voice and prevent aspiration. Some patients do well with this modality alone.

Surgical treatment to augment or medialize the paralyzed vocal fold is performed to provide a surface against which the contralateral normal fold may make contact. Injection laryngoplasty may be performed under office or operative laryngoscopy with a variety of autologous (fat, collagen) or alloplastic (hydroxyapatite, hyaluronic acid, micronized cadaveric human collagen) compounds. Teflon injection is of historical significance only secondary to the incidence of severe foreign body inflammatory reactions. Injection of the vocal fold increases its bulk to optimize closure with the contralateral normal fold. This technique also is useful for vocal cord atrophy, which may occur with aging. Laryngeal framework surgery involves the implantation of cartilage, hydroxyapatite, Gore-Tex, or silicone under the musculomembranous fold via an external approach through a window in the thyroid cartilage (Fig. 18-10).[26] This may be combined with procedures to adduct the vocal process of the arytenoids. Laryngeal reinnervation (with the ansa cervicalis to the RLN transfer) and pacing have also been attempted with various success.

Figure 18-10. Cross-section of the larynx demonstrating the principle of medialization laryngoplasty. An implant is used to push the paralyzed vocal cord toward the midline.

Vascular Lesions

Vascular lesions can be broadly classified into two groups: hemangiomas and vascular malformations.[27] Hemangiomas are the most common vascular lesions present in infancy and childhood. These lesions are present at birth in up to 30% of cases, but usually become apparent in the first few weeks of life. The lesions proliferate in size over the first year before beginning involution, which subsequently occurs over the next 2 to 12 years. While 40% of cases will resolve completely, the remainder will require intervention. Once the proliferative phase has ended, the lesion should be observed every 3 months for involution, and surgery should be considered for those that have not significantly involuted by 3 to 4 years of age. Surgical treatment of proliferating hemangiomas is reserved for lesions associated with severe functional or cosmetic problems, such as those involving the nasal tip or periorbital region. Treatment is performed with either the flashlamp-pumped pulsed-dye laser (FPDL), the potassium titanyl phosphate (KTP) laser, or the neodymium yttrium-aluminum garnet (Nd:YAG) laser, repeated every 4 to 6 weeks until the lesion disappears. Systemic steroids may be used to halt rapidly proliferating lesions until the child reaches 12 to 18 months, after which growth should stabilize or involution begin. Subcutaneous interferon-α-2a may also be used for this purpose. This treatment, however, is associated with neurologic side effects and should be used with caution.[27,28] There have also been recent trends of using propranolol to inhibit hemangioma growth, and this practice is gaining popularity in complicated cases.

Vascular malformations, in contrast, are almost always present at birth and slowly enlarge without proliferation.[29] These may arise from capillaries, venules, veins, arteriovenous channels, and/or lymphatics. Capillary malformations usually involve the midline neck or forehead, and may fade with age. Venular malformations are also known as *port-wine stains*. These lesions often follow facial dermatomes and usually thicken with age. Venous malformations are composed of ectatic veins within the lips, tongue, or buccal area. These may present as purple masses or subcutaneous/submucosal nodules. Arteriovenous malformations are rare malformations of arteriovenous channels that failed to regress during development.

Lymphatic malformations or lymphangiomas of the head and neck usually involve the cervical area, in which case they are more commonly macrocystic and well demarcated. Those arising above the hyoid bone tend to be microcystic and have an infiltrative quality. Lymphangiomas may become secondarily infected and may rapidly enlarge, causing airway compromise. These lesions may also be associated with feeding difficulties and failure to thrive.

Capillary hemangiomas and superficial port-wine stains are effectively treated by FPDL. The KTP or Nd:YAG laser is used for deeper port-wine stains. Venous malformations may be treated with laser, sclerotherapy, and/or surgical excision, depending on the depth, size, and location. Superficial lesions are treated with the Nd:YAG laser, which has deeper penetration than either the FPDL or KTP laser. Deeper venous malformations may benefit from Nd:YAG therapy of the superficial component followed by meticulous surgical excision of the deeper component. Sclerotherapy should be undertaken with extreme caution in the head and neck, because the valveless quality of the veins in this region introduces significant risk of cavernous sinus thrombosis. Arteriovenous malformations require formal surgical resection with negative margins. Preoperative angiographic embolization is frequently used to facilitate surgery. Microvascular reconstruction may be necessary, depending on the extent of the resection required. Surgical excision is also required for lymphatic malformations, although superficial lesions are sometimes treatable with the CO_2 laser. This often is difficult for microcystic cases given the infiltrative nature. Sclerotherapy with OK-432 is effective in macrocystic lymphangiomas, and multiple other sclerosing agents, including bleomycin, have been explored.[30]

TRAUMA OF THE HEAD AND NECK

Management of head and neck soft-tissue trauma follows general surgical principles, with several salient features. In the acute setting, patients should be managed with head-of-bed elevation to decrease tissue edema. Most lacerations without significant tissue loss can be closed primarily, which is preferred where possible. Head and neck soft tissues have the benefit of a robust blood supply. Thus, nearly devitalized soft tissues often survive, such that any tissue debridement should be very conservative. Closure of trapdoor lacerations requires conservative undermining of surrounding tissue and good approximation of subdermal levels prior to epidermal closure. A pressure dressing is also applied. These measures are employed to avoid a pincushion deformity (Fig. 18-11). Typically, when repairing facial lacerations, subdermal layers are approximated with an absorbable 3-0 or 4-0 suture such as, Vicryl or polydioxanone, and the skin is closed using 5-0 or 6-0 monofilament nylon or Prolene. Sutures are removed after 4 to 5 days, but may be removed earlier in thin-skinned areas. Systemic antibiotics are reserved for through-and-through mucosal lacerations, contaminated wounds, bite injuries, and when delayed closure is performed (>72 hours). The chosen antibiotic should cover *S. aureus*. After skin injuries, the patient is instructed to avoid sunlight, because this can cause pigmentary abnormalities in the abrasion or scar line, which matures over a 6- to 12-month period.

Wound closure must be understood in the context of the cosmetic and functional anatomic landmarks of the head and neck. Management of injuries to the eyelid requires identification of the orbicularis oculi, which is closed in a separate layer. The gray line (conjunctival margin; Fig. 18-12) must

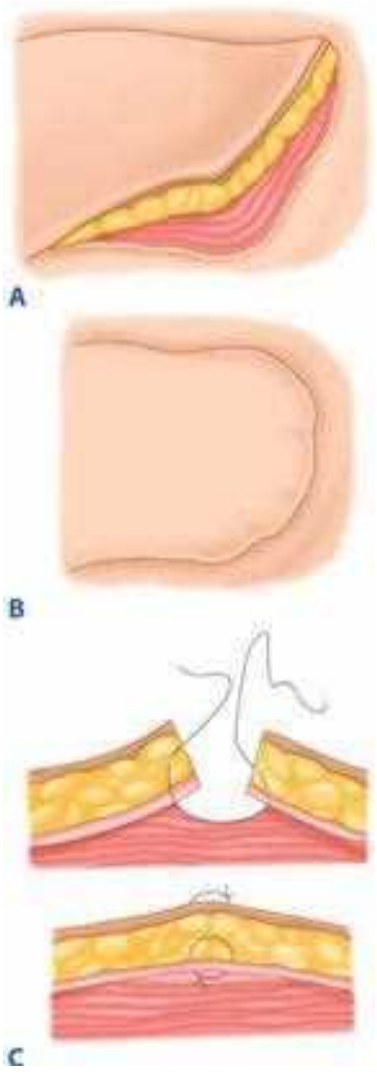

Figure 18-11. Trap door laceration (A) healed with a "pin cushion" deformity (B) soft-tissue layers must be meticulously approximated (C) to avoid this complication.

Figure 18-12. Alignment of the gray line is the key step in the repair of eyelid lacerations.

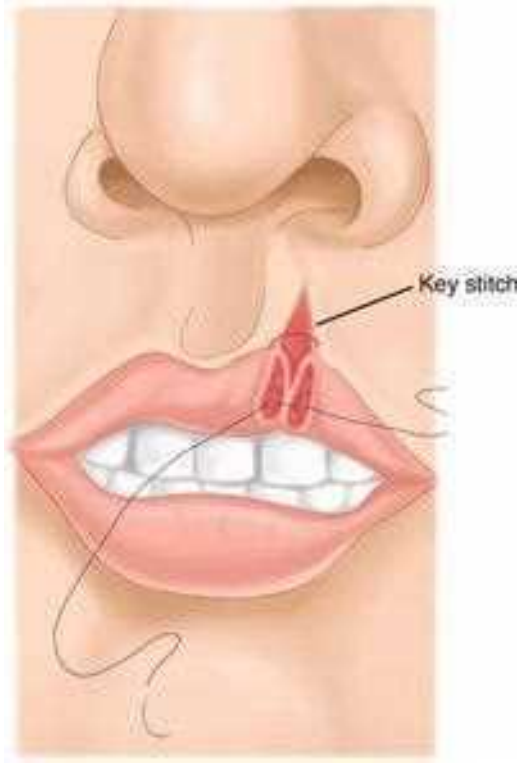

Figure 18-13. Approximation of the vermilion border is the key step in the repair of lip lacerations.

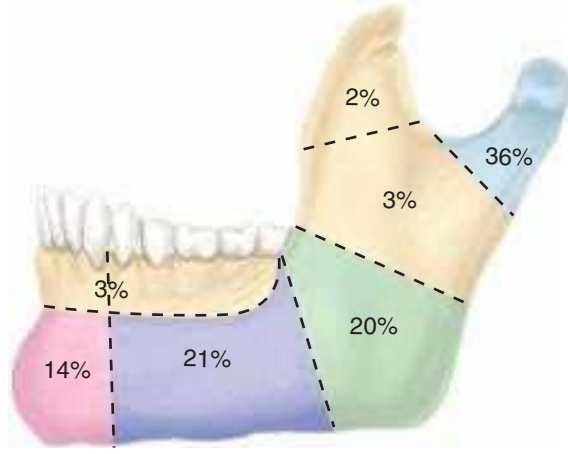

Figure 18-14. Sites of common mandible fractures.

be carefully approximated to avoid lid notching or height mismatch. Management of lip injuries follows the same principle.

2▶ The orbicularis oris must be closed, and the vermilion border carefully approximated (Fig. 18-13). Injuries involving one-fourth the width of the eyelid or one third the width of the lip may be closed primarily; otherwise, flap or grafting procedures may be required. With laceration of the auricle, key structures such as the helical rim and antihelix must be carefully aligned. These injuries must be repaired so that the cartilage is covered. The principles of auricular repair are predicated on the fact that the cartilage has no intrinsic blood supply and is thus susceptible to ischemic necrosis following trauma. The suture should be passed through the perichondrium, while placement through the cartilage itself should be avoided.

Auricular hematomas should be drained promptly, with placement of a bolster as a pressure dressing. A pressure dressing is frequently advocated after closure of an ear laceration. It also deserves note that the surgeon must avoid the temptation to perform aggressive debridement after injuries to the eyelid or auricle. Given the rich vascular supply to the face and neck, many soft-tissue components that appear devitalized will indeed survive.

Most traumatic facial nerve injuries are secondary to temporal bone trauma, which is discussed later in this section. Soft-tissue injuries occurring in the midface may involve distal facial nerve branches. Those injured anterior to a vertical line dropped from the lateral cantus do not require repair secondary to collateral innervation in the anterior midface. Posterior to this line, the nerve should be repaired, primarily if possible, using 8-0 to 10-0 monofilament suture to approximate the epineurium under microscopic visualization. If neural segments are missing, cable grafting is performed using either the greater auricular (provides 7 to 8 cm) or sural nerve (up to 30 cm) as a donor. Injuries to the buccal branch should alert the examiner to a possible parotid duct injury. This structure lies along an imaginary line drawn from the tragus to the midline upper lip, running along with the buccal branch of the facial nerve. The duct should be repaired over a 22-gauge stent or marsupialized into the oral cavity.

Facial bone fractures most commonly involve the mandible. Fractures most often involve the angle, body, or condyle, and in most cases, two or more sites are almost always involved (Fig. 18-14). Fractures are described as either favorable or unfavorable, depending on whether or not the masticatory musculature tends to pull the fracture into reduction or distraction. Vertically favorable fractures are brought into reduction by the masseter, while horizontally favorable fractures are brought into reduction by the pterygoid musculature. The fracture is usually evaluated by radiographic exam using a Panorex, but specialized plain film views, and occasionally CT scan, are necessary in selected cases. Classical management of mandible fractures dictated closed reduction and a 4- to 6-week period of intermaxillary fixation (IMF) with arch bars applied via circumdental wiring. Comminuted, displaced, or unfavorable fractures underwent open reduction and wire fixation in addition to IMF. Currently, arch bars and IMF are performed to establish occlusion. The fracture is then exposed and reduced, using transoral approaches where possible.

Transcervical approaches are required to address fractures of the ramus or posterior body, with careful attention given to preserving the marginal mandibular branch of the facial nerve. Rigid fixation is then accomplished by the application of plates

3▶ and screws. Selected fractures, such as those of the body, benefit from dynamic compression plating, which applies pressure toward the fracture line. With rigid fixation, IMF is required to establish occlusion, and may not be necessary for a full 6 postoperative weeks. This is preferable because IMF is associated with gingival and dental disease, as well as with significant weight loss and malnutrition, during the fixation period. New techniques have included the 4-point fixation technique, where the maxilla and mandible are held in occlusion by wires attached to intraoral cortical bone screws, with two screws above and below the occlusal line anteriorly. In edentulous patients, determining the baseline occlusion is of less

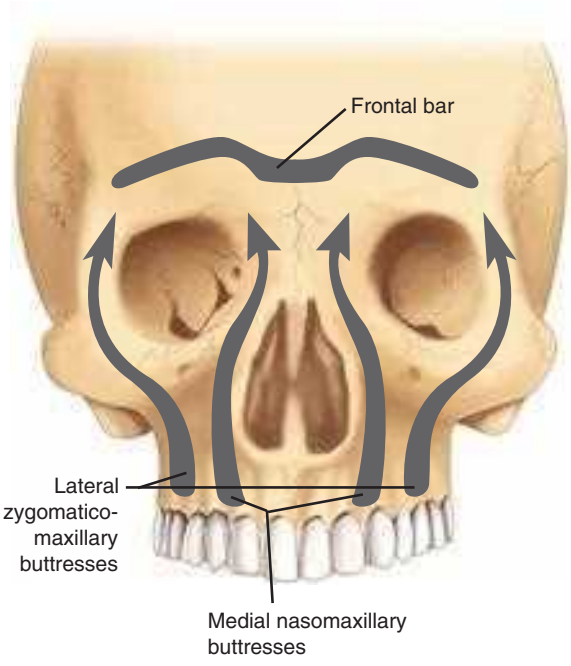

Figure 18-15. Major buttresses of the midface.

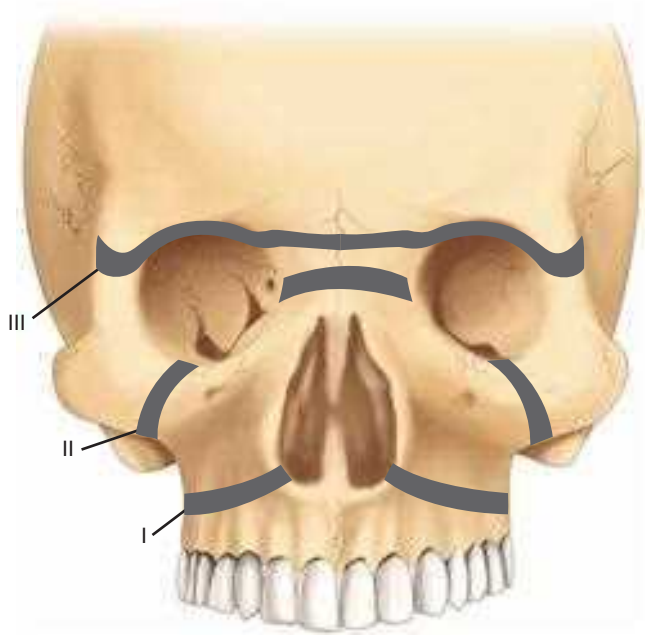

Figure 18-16. Classic Le Fort fracture patterns.

significance because dentures may be refashioned once healing is complete. If IMF is required to aid in immobilization of the fracture in an edentulous patient, interosseous wiring and/or the fabrication of custom-made splints is required.

Midface fractures are classically described in three patterns: Le Fort I, II, and III. A full understanding of midface structure is first necessary (Fig. 18-15). Three vertical buttresses support the midface: the nasofrontal-maxillary, the frontozygomaticomaxillary, and pterygomaxillary.[31] The five horizontal buttresses include the frontal bone, nasal bones, upper alveolus, zygomatic arches, and the infraorbital region. Classical signs of midface fractures in general include subconjunctival hemorrhage; malocclusion; midface numbness or hypesthesia (maxillary division of the trigeminal nerve); facial ecchymoses/hematoma; ocular signs/symptoms; and mobility of the maxillary complex.

Le Fort I fractures occur transversely across the alveolus, above the level of the teeth apices. In a pure Le Fort I fracture, the palatal vault is mobile while the nasal pyramid and orbital rims are stable. The Le Fort II fracture extends through the nasofrontal buttress, medial wall of the orbit, across the infraorbital rim, and through the zygomaticomaxillary articulation. The nasal dorsum, palate, and medial part of the infraorbital rim are mobile. The Le Fort III fracture is also known as *craniofacial disjunction*. The frontozygomaticomaxillary, frontomaxillary, and frontonasal suture lines are disrupted. The entire face is mobile from the cranium. It is convenient to conceptualize complex midface fractures according to these patterns (Fig. 18-16); however, in reality, fractures reflect a combination of these three types. Also, the fracture pattern may vary between the left and right sides of the midface. Lateral blows to the cheek may be associated with isolated zygoma fractures. The zygoma is typically displaced inferiorly and medially with disruption of the suture lines between the temporal, frontal, and maxillary bones and the zygoma. Disruption of the latter articulation may be associated with depression into the maxillary sinus and blood in the sinus cavity. Fractures of the midface and/or zygoma may be associated with an orbital blowout, whereas the orbital floor is disrupted and orbital soft tissues subsequently herniate into the maxillary sinus (Fig. 18-17). The mechanism of orbital blowout may involve propagation of adjacent fracture lines or may be the result of a sudden increase in intraorbital pressure during the injury. This may be associated with enophthalmos or entrapment of the inferior oblique muscle. The latter results in diplopia upon upward gaze. Entrapment is confirmed by forced duction testing, where, under topical or general anesthesia, the muscular attachment of the inferior oblique is grasped with forceps and manipulated to determine passive ocular mobility. Fractures of the midface, zygoma, and orbital floor are best evaluated using CT scan, and repair requires a combination of transoral and external approaches to achieve at least two points of fixation for each fractured segment.[32] Significant areas of bone loss can be reconstructed with commercially available hydroxyapatite

Figure 18-17. Coronal computed tomography demonstrating an orbital blowout fracture with herniation of orbital contents into the maxillary sinus.

bone cements, an osteoconductive calcium-phosphate matrix. Blowout fractures demonstrating significant entrapment or enophthalmos are treated by orbital exploration and reinforcement of the floor with mesh or bone grafting.

Temporal bone fractures occur in approximately one fifth of skull fractures. As with fractures of the mandible and midface, blunt trauma (from motor vehicle accident or assault) usually is implicated. Unfortunately, the incidence of temporal bone fracture from gunshot wounds to the head is rising. Fractures are divided into two patterns (Fig. 18-18), longitudinal and transverse, based on the clinical picture and CT imaging. In practice, most fractures are oblique. By classical descriptions, longitudinal fractures constitute 80% and are associated with lateral skull trauma. Signs and symptoms include conductive hearing loss, ossicular injury, bloody otorrhea, and labyrinthine concussion. The facial nerve is injured in approximately 20% of cases. In contrast, the transverse pattern constitute only 20% of temporal bone fractures and occurs secondary to fronto-occipital trauma. The facial nerve is injured in 50% of cases. These injuries frequently involve the otic capsule to cause sensorineural hearing loss and loss of vestibular function. Hemotympanum may be observed. A cerebrospinal fluid (CSF) leak must be suspected in temporal bone trauma. This resolves with conservative measures in most cases. The most significant consideration in the management of temporal bone injuries is the status of the facial nerve. Delayed or partial paralysis will almost always resolve with conservative management. However, immediate paralysis that does not recover within 1 week should be considered for nerve decompression. Electroneurography and EMG have been used to help determine which patients with delayed-onset complete paralysis will benefit from surgical decompression. The finding of >90% degeneration more than 72 hours after the onset of complete paralysis is considered an indication for surgery.[33] Multiple approaches have been described for facial nerve decompression, some of which require the sacrifice of hearing. These patients may have severe intracranial or vascular injuries such that the decision to operate must also be made in the context of the patient's overall medical stability. It is of paramount importance to protect the eye in patients with facial nerve paralysis of any etiology, because absence of an intact blink reflex will predispose to corneal drying and abrasion. This requires the placement of artificial tears throughout the day with lubricant ointment, eye taping, and/or a humidity chamber at night.[34,35]

TUMORS OF THE HEAD AND NECK

When a discussion of neoplasms of the head and neck is initiated, the conversation frequently focuses on squamous cell carcinoma. This is because the majority of malignancies of this region are represented by this pathology. The diagnosis and treatment of lesions spanning from the lips and oral cavity to the larynx and hypopharynx requires a similar methodic approach.

The selection of treatment protocols varies for each site within the upper aerodigestive tract. The importance of multidisciplinary management cannot be underestimated. Presentation of cases before a tumor board allowing review of a patient's history, physical examination findings, imaging, and prior pathology specimens allows for confirmation of the patient's status. Additionally, it should encourage discussion from multiple points of view concerning the most appropriate treatment options available. Participation in the discussion with representatives of radiation oncology, medical oncology, surgical oncology, oral maxillofacial surgery/dental medicine, along with radiologists and pathologists specializing in upper aerodigestive tract disorders benefits not only the patient but also represents an excellent teaching opportunity for all disciplines.

The development of organ preservation protocol and the evolution of free tissue reconstructive techniques are some of the most significant advances made within the field during the last two decades. The future of the treatment of head and neck cancer lies within the field of molecular biology. As more is understood about the genetics of cancer, tailoring treatment options to a particular tumor mutation has the capacity to maximize survival while achieving the highest quality of life.

Etiology and Epidemiology

It should come as no surprise that abuse of tobacco and alcohol are the most common preventable risk factors associated with the development of head and neck cancers. This relationship is synergistic rather than additive. Smoking confers a 1.9-fold increased risk to males and a threefold increased risk to females for developing a head and neck carcinoma, compared to nonsmokers. The risk increases as the number of years smoking and number of cigarettes smoked per day increases. Alcohol alone confers a 1.7-fold increased risk to males drinking one to two drinks per day, compared to nondrinkers. This increased risk rises to > threefold for heavy drinkers. Individuals who both smoke (two packs per day) and drink (four units of alcohol

4▶

per day) had a 35-fold increased risk for the development of a carcinoma compared to controls.[36] Users of smokeless tobacco have a four times increased risk of oral cavity carcinoma compared to nonusers.

Tobacco is the leading preventable cause of death in the United States and is responsible for one of every five deaths.[37]Approximately one fourth of U.S. adults habitually use tobacco products, with recent trends demonstrating an increase in the use of tobacco products by women. The evidence supporting the need for head and neck cancer patients to pursue smoking cessation after treatment is compelling. In a study by Moore, 40% of patients who continued to smoke after definitive treatment for an oral cavity malignancy went on to recur or develop a second head and neck malignancy.[38] For patients who stopped smoking after treatment, only 6% went on to develop a recurrence. Induction of specific p53 mutations within upper aerodigestive tract tumors has been noted in patients with histories of tobacco and alcohol use.[39,40]

When smokers who develop head and neck squamous cell carcinomas are compared to nonsmokers, differences between the two populations emerge. Koch and associates[41] noted that nonsmokers were represented by a disproportionate number of women and were more frequently at the extremes of age (<30 or >85 years of age). Tumors from nonsmokers presented more frequently in the oral cavity, specifically within the oral tongue, buccal mucosa, and alveolar ridge. Smokers presented more frequently with tumors of the larynx, hypopharynx, and floor of mouth. Former smokers, defined as those individuals who had quit >10 years prior, demonstrated a profile more consistent with nonsmokers.

In India and Southeast Asia, the product of the areca catechu tree, known as a betel nut, is chewed in a habitual manner and acts as a mild stimulant similar to that of coffee. The nut is chewed in combination with lime and cured tobacco as a mixture known as a quid. The long-term use of the betel nut quid can be destructive to oral mucosa and dentition and is highly carcinogenic.[42] Another habit associated with oral malignancy is that of reverse smoking, where the lighted portion of the tobacco product is within the mouth during inhalation. The risk of hard palate carcinoma is 47 times greater in reverse smokers compared to nonsmokers.

HPV is an epitheliotropic virus that has been detected to various degrees within samples of oral cavity squamous cell carcinoma. Infection alone is not considered sufficient for malignant conversion; however, results of multiple studies suggest a role of HPV in a subset of head and neck squamous cell carcinoma. Multiple reports reflect that up to 40% to 60% of current diagnoses of tonsillar carcinoma demonstrate evidence of HPV types 16 or 18.

Environmental ultraviolet light exposure has been associated with the development of lip cancer. The projection of the lower lip, as it relates to this solar exposure, has been used to explain why the majority of squamous cell carcinomas arise along the vermilion border of the lower lip. In addition, pipe smoking also has been associated with the development of lip carcinoma. Factors such as mechanical irritation, thermal injury, and chemical exposure have been described as an explanation for this finding.

Other entities associated with oral malignancy include Plummer-Vinson syndrome (achlorhydria, iron-deficiency anemia, mucosal atrophy of mouth, pharynx, and esophagus), chronic infection with syphilis, and immunocompromised status (30-fold increase with renal transplant).

Although evidence linking HIV infection to squamous cell carcinoma of the head and neck is lacking, several AIDS-defining malignancies, including Kaposi's sarcoma, and non-Hodgkin's lymphoma may require the care of an otolaryngologist.

Anatomy and Histopathology

The upper aerodigestive tract is divided into several distinct sites that include the oral cavity, pharynx, larynx, and nasal cavity/paranasal sinuses. Within these sites are individual subsites with specific anatomic relationships that affect diagnosis, tumor spread, and selection of treatment options. The spread of a tumor from one site to another is determined by the course of the nerves, blood vessels, lymphatic pathways, and fascial planes. The fascial planes serve as barriers to the direct invasion of tumor and facilitate the pattern of spread to regional lymph nodes.

The oral cavity extends from the vermilion border of the lip to the hard-palate/soft-palate junction superiorly, to circumvallate papillae inferiorly, and to the anterior tonsillar pillars laterally (Fig. 18-19). It is divided into seven subsites: lips, alveolar ridges, oral tongue, retromolar trigone, floor of mouth, buccal mucosa, and hard palate. Advanced oral cavity lesions may present with mandibular and/or maxillary involvement requiring special consideration at the time of resection and reconstruction. Regional metastatic spread of lesions of the oral cavity is to the lymphatics of the submandibular and the upper jugular region (e.g., levels I, II, and III).

The pharynx is divided into three regions: nasopharynx, oropharynx, and hypopharynx. The nasopharynx extends from the posterior nasal septum and choana to the skull base and includes the fossa of Rosenmüller and torus tubarius of the Eustachian tubes laterally. The inferior margin of the nasopharynx is the superior surface of the soft palate. The adenoids, typically involuted in adults, are located with the posterior aspect of this site. Given the midline location of the nasopharynx, bilateral regional metastatic spread is common in these lesions. Lymphadenopathy of the posterior triangle (level V) of the neck should provoke consideration for a nasopharyngeal primary.

The major sites within the oropharynx are the tonsillar region, base of tongue, soft palate, and posterolateral pharyngeal walls. Regional lymphatic drainage for oropharyngeal lesions

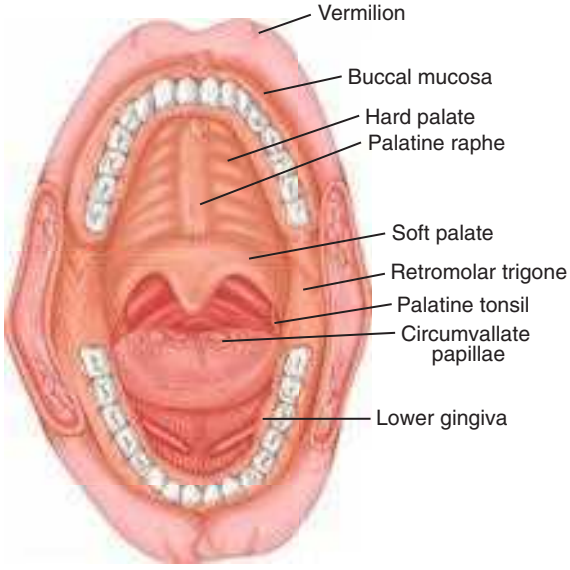

Figure 18-19. Oral cavity landmarks.

frequently occurs to the upper and lower cervical lymphatics (e.g., levels II, III, IV). Retropharyngeal metastatic lymphatic spread may occur with oropharyngeal lesions.

The hypopharynx extends from the vallecula to the lower border of the cricoid posterior and lateral to the larynx. The subsites of this region include the pyriform fossa, the postcricoid space, and posterior pharyngeal wall. Regional lymphatic spread is frequently bilateral and to the mid- and lower cervical lymph nodes (e.g., levels III, IV).

The larynx is divided into three regions: the supraglottis, glottis, and subglottis. The supraglottic larynx includes the epiglottis, false vocal cords, medial surface of the aryepiglottic folds, and the roof of the laryngeal ventricles. The glottis includes the true vocal cords, anterior and posterior commissure, and the floor of the laryngeal ventricle. The subglottis extends from below the true vocal cords to the cephalic border of the cricoid within the airway. The supraglottis has a rich lymphatic network, which accounts for the high rate of bilateral spread of metastatic disease that is not typically seen with the glottis. Glottic and subglottic lesions, in addition to potential spread to the cervical chain lymph nodes, may also spread to the paralaryngeal and paratracheal lymphatics and require attention to prevent lower central neck recurrence.

Carcinogenesis

Development of a tumor represents the loss of cellular signaling mechanisms involved in the regulation of growth. Following malignant transformation, the processes of replication (mitosis), programmed cell death (apoptosis), and the interaction of a cell with its surrounding environment are altered. Advances in molecular biology have allowed for the identification of many of the mutations associated with this transformation.

Overexpression of mutant p53 is associated with carcinogenesis at multiple sites within the body. Point mutations in p53 have been reported in up to 45% of head and neck carcinomas. Koch et al noted that p53 mutation is a key event in the malignant transformation of >50% of head and neck squamous cell carcinomas in smokers.[41]

Carcinogenesis has long been explained as a two-hit process, involving DNA damage and the progression of mutated cells through the cell cycle. These two events also are known as *initiation* and *promotion*. It has been proposed that approximately 6 to 10 independent genetic mutations are required for the development of a malignancy. Overexpression of mitogenic receptors, loss of tumor-suppressor proteins, expression of oncogene-derived proteins that inhibit apoptosis, and overexpression of proteins that drive the cell cycle can allow for unregulated cell growth.

Genetic mutations may occur as a result of environmental exposure (e.g., radiation or carcinogen exposure), viral infection, or spontaneous mutation (deletions, translocations, frame shifts). Common genetic alterations, such as loss of heterozygosity at 3p, 4q, and 11q13, and the overall number of chromosomal microsatellite losses are found more frequently in the tumors of smokers than in the tumors of nonsmokers.[41]

Second Primary Tumors in the Head and Neck

Patients diagnosed with a head and neck cancer are predisposed to the development of a second tumor within the aerodigestive tract. The overall rate of second primary tumors is approximately 14%. A second primary tumor detected within 6 months of the diagnosis of the initial primary lesion is defined as a synchronous neoplasm. The prevalence of synchronous tumors is approximately 3% to 4%. The detection of a second primary lesion more than 6 months after the initial diagnosis is referred to as metachronous tumor. About 80% of second primaries are metachronous and at least half of these lesions develop within 2 years of the diagnosis of the original primary. The incidence and site of the second primary tumor vary and depend on the site and the inciting factors associated with the initial primary tumor. The importance of advocating smoking cessation and addressing alcoholism in these patients cannot be overemphasized.

Patients with a primary malignancy of the oral cavity or pharynx are most likely to develop a second lesion within the cervical esophagus, whereas patients with a carcinoma of the larynx are at risk for developing a neoplasm in the lung. As such, the presentation of a new-onset dysphagia, unexplained weight loss, or chronic cough/hemoptysis must be assessed thoroughly in patients with a history of prior treatment for a head and neck cancer.

A staging examination is recommended at the initial evaluation of all patients with primary cancers of the upper aerodigestive tract. This may involve a direct laryngoscopy, rigid/flexible esophagoscopy, and rigid/flexible bronchoscopy also known as *"panendoscopy."* Some surgeons argue against the use of bronchoscopy because of the low yield of the examination in asymptomatic patients with a normal chest X-ray. Additionally, barium swallow has been used instead of esophagoscopy as a preoperative evaluation.

Staging

Staging for upper aerodigestive tract malignancies is defined by the American Joint Committee on Cancer and follows the TNM (primary tumor, regional nodal metastases, distant metastasis) staging format[43]. The T staging criteria for each site varies depending upon the relevant anatomy (e.g., vocal cord immobility is seen with T3 lesions). Table 18-1 demonstrates TNM staging for oral cavity lesions. The N classification system is uniform for all head and neck sites except for the nasopharynx.

Upper Aerodigestive Tract

Lip. The lips represent a transition from external skin to internal mucous membrane that occurs at the vermilion border. The underlying musculature of the orbicularis oris creates a circumferential ring that allows the mouth to have a sphincter-like function. Cancer of the lip is most commonly seen in white men from the ages of 50 to 70 years, but can be seen in younger patients, particularly those with fair complexions. Risk factors include prolonged exposure to sunlight, fair complexion, immunosuppression, and tobacco use.

The majority of lip malignancies are diagnosed on the lower lip (88%–98%), followed by the upper lip (2%–7%) and oral commissure (1%). The histology of lip cancers is predominantly squamous cell carcinoma; however, other tumors, such as keratoacanthoma, verrucous carcinoma, basal cell carcinoma, malignant melanoma, minor salivary gland malignancies, and tumors of mesenchymal origin (e.g., malignant fibrous histiocytoma, leiomyosarcoma, and rhabdomyosarcoma), may also present in this location. Basal cell carcinoma presents more frequently on the upper lip than lower.

Clinical findings in lip cancer include an ulcerated lesion on the vermilion or cutaneous surface. Careful palpation is important in determining the actual size and extent of these lesions.

Table 18-1

TNM staging for oral cavity carcinoma

Primary Tumor			
TX	Unable to assess primary tumor		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ		
T1	Tumor is < 2 cm in greatest dimension		
T2	Tumor > 2 cm and < 4 cm in greatest dimension		
T3	Tumor > 4 cm in greatest dimension		
T4 (lip)	Primary tumor invading cortical bone, inferior alveolar nerve, floor of mouth, or skin of face (e.g., nose or chin)		
T4a (oral)	Tumor invades adjacent structures (e.g., cortical bone, into deep tongue musculature, maxillary sinus) or skin of face		
T4b (oral)	Tumor invades masticator space, pterygoid plates, or skull base and/or encases the internal carotid artery		
Regional lymphadenopathy			
NX	Unable to assess regional lymph nodes		
N0	No evidence of regional metastasis		
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension		
N2a	Metastasis in single ipsilateral lymph node, >3 cm and < 6 cm		
N2b	Metastasis in multiple ipsilateral lymph nodes, all nodes < 6 cm		
N2c	Metastasis in bilateral or contralateral lymph nodes, all nodes < 6 cm		
N3	Metastasis in a lymph node > 6 cm in greatest dimension		
Distant metastases			
MX	Unable to assess for distant metastases		
M0	No distant metastases		
M1	Distant metastases		
TMN Staging			
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
	T1-3	N1	M0
Stage IVa	T4a	N0	M0
	T4a	N1	M0
	T1-4a	N2	M0
Stage IVb	Any T	N3	M0
	T4b	Any N	M0
Stage IVc	Any T	Any N	M1

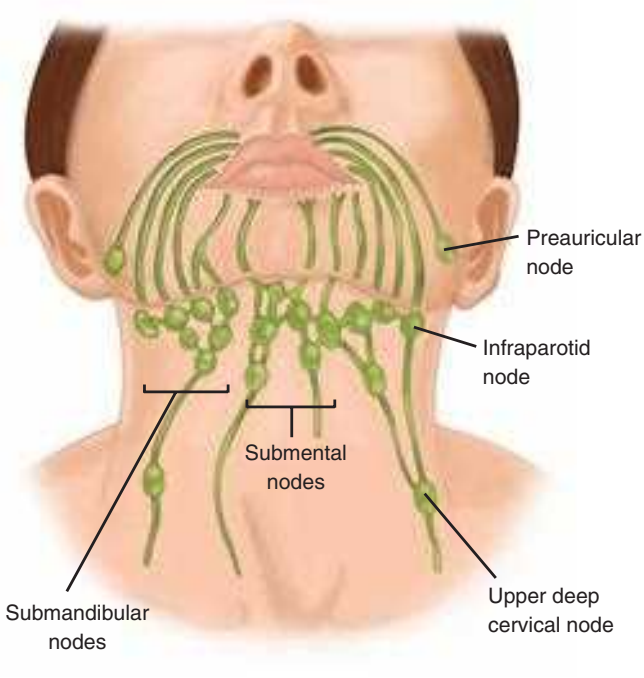

Figure 18-20. Lymphatics of the lip.

Figure 18-21. Wedge resection of lower lip squamous cell carcinoma.

The presence of paresthesia in the area adjacent to the lesion may indicate mental nerve involvement.

Characteristics of lip primaries that negatively affect prognosis include perineural invasion, involvement of the underlying maxilla/mandible, presentation on the upper lip or commissure, regional lymphatic metastasis, and age younger than 40 years at onset. Lip cancer results in fewer than 200 patient deaths annually and is stage dependent. Early diagnosis coupled with adequate treatment results in a high likelihood of disease control.

The selection of treatment for any given lip cancer is determined by the overall health of the patient, size of the primary lesion, and the presence of regional metastases. Small primary lesions may be treated with surgery or radiation with equal success and acceptable cosmetic results. However, surgical excision with histologic confirmation of tumor-free margins is the preferred treatment modality. Lymph node metastasis occurs in fewer than 10% of patients with lip cancer (Fig. 18-20). The primary echelon of nodes at risk is in the submandibular and submental regions. In the presence of clinically evident neck metastasis, neck dissection is indicated. The overall 5-year cure rate of lip cancer approximates 90% and drops to 50% in the presence of neck metastases. Postoperative radiation is administered to the primary site and neck for patients with close or positive margins, lymph node metastases, when tumor thickness is >4mm or in the setting of perineural invasion.[44]

The reconstruction of lip defects after tumor excision requires innovative techniques to provide oral competence, maintenance of dynamic function, and acceptable cosmesis. The typical lip length is 6 to 7 cm. This simple fact is important because the reconstructive algorithms available to the head and neck surgeon are based on the proportion of lip resected. Realignment of the vermilion border during the reconstruction and preservation of the oral commissure (when possible) are important principles in attempting to attain an acceptable cosmetic result. Resection with primary closure is possible with a defect of up to one third of the lip (Fig. 18-21). When the resection includes one third to one half of the lip, rectangular excisions can be closed using Burow's triangles in combination with advancement flaps and releasing incisions in the mental crease.[45] Rotational transposition of tissue from the upper lip can repair other medium-size defects. For larger defects of up to 75%, the Karapandzic flap uses a sensate, neuromuscular flap that includes the remaining orbicularis oris muscle, conserving its blood supply from branches of the labial artery (Fig. 18-22). The lip-switch (Abbe-Estlander) flap or a stair-step advancement technique can be used to repair defects of either the upper or lower lip. Microstomia is a potential complication with these types of lip reconstruction. For very large defects, Webster or Bernard types of repair using lateral nasolabial flaps with buccal advancement have also been described.[46]

Oral Cavity. As previously mentioned in *Anatomy and Histopathology*, the oral cavity is composed of several sites with different anatomic relationships. The majority of tumors in the oral cavity are squamous cell carcinomas (>90%). Each site is briefly reviewed with emphasis placed on anatomy, diagnosis, and treatment options.

Oral Tongue. The oral tongue is a muscular structure with overlying nonkeratinizing squamous epithelium. The posterior limit of the oral tongue is the circumvallate papillae, whereas its ventral portion is contiguous with the anterior floor of mouth. The tongue is composed of four intrinsic and four extrinsic muscles separated at the midline by the median fibrous septum.

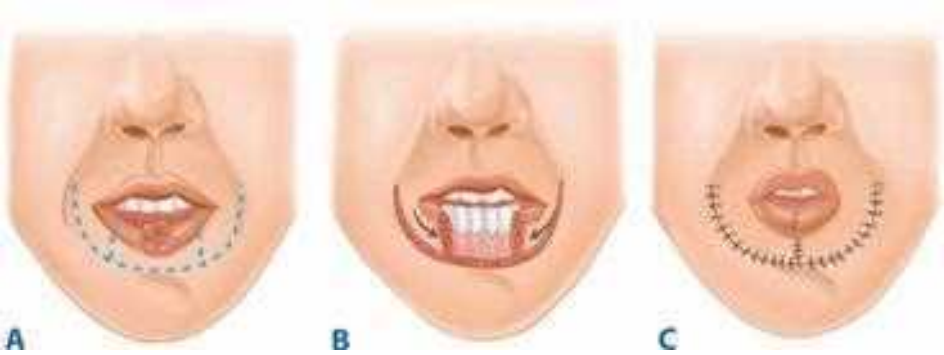

Figure 18-22. A-C. Karapandzic labiaplasty for lower lip carcinoma.

Tumors of the tongue begin in the stratified epithelium of the surface and eventually invade into the deeper muscular structures. The tumors may present as ulcerations or as exophytic masses (Fig. 18-23).[47] The regional lymphatics of the oral cavity are to the submandibular space and the upper cervical lymph nodes (Fig. 18-24). The lingual nerve and the hypoglossal nerve may be directly invaded by locally extensive tumors (Fig. 18-25). Involvement can result in ipsilateral paresthesias and deviation of the tongue on protrusion with fasciculations and eventual atrophy. Tumors on the tongue may occur on any surface, but are most commonly seen on the lateral and ventral surfaces.[48] Primary tumors of the mesenchymal components of the tongue include leiomyomas, leiomyosarcomas, rhabdomyosarcomas, and neurofibromas.

Surgical treatment of small (T1–T2) primary tumors is wide local excision with either primary closure or healing by secondary intention. The CO_2 laser may be used for excision

Figure 18-23. Oral tongue squamous cell carcinoma.

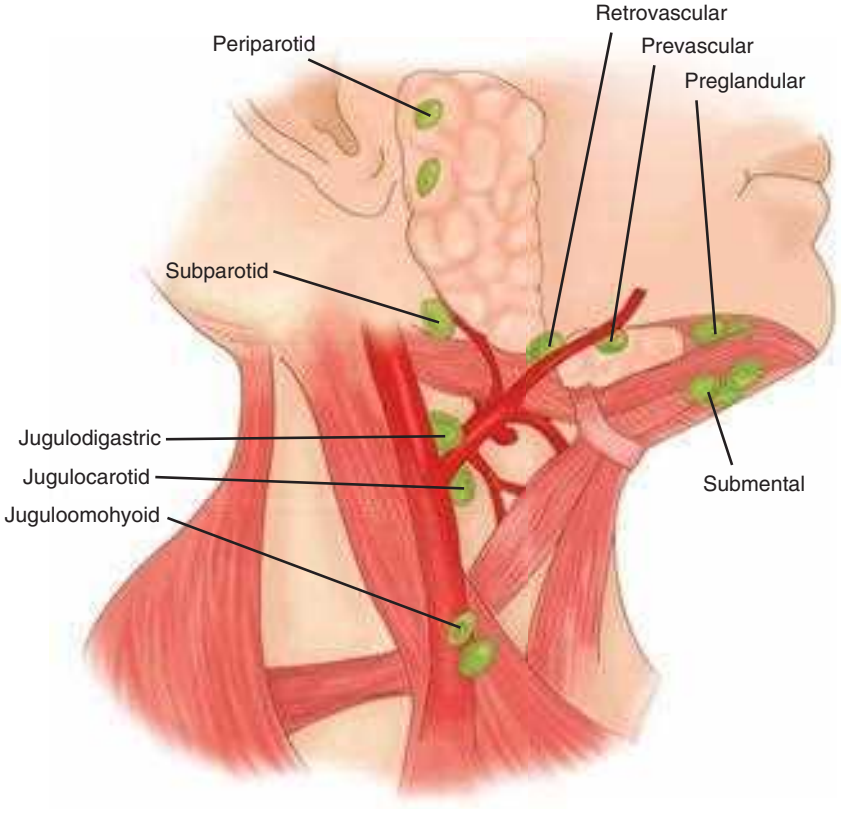

Figure 18-24. Primary lymphatics for regional spread of oral cavity malignancies.

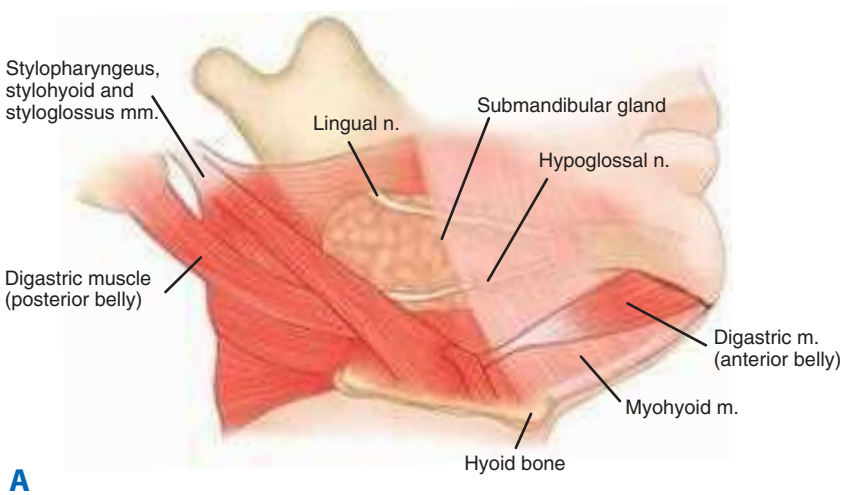
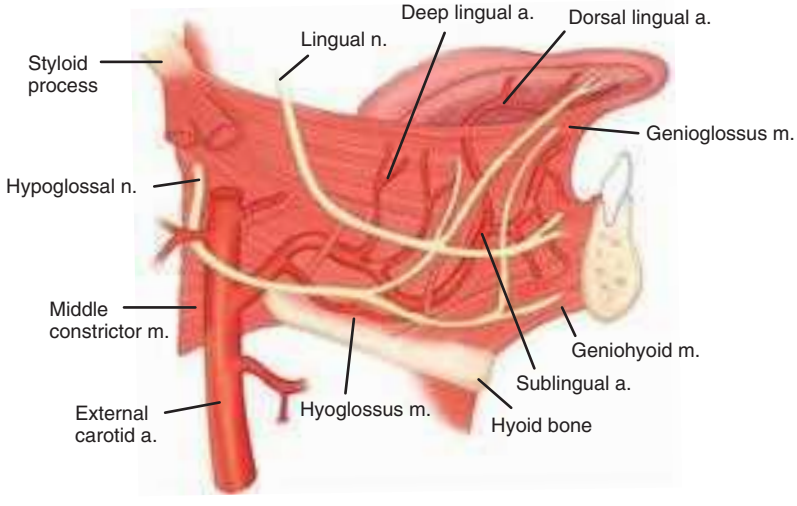


A



B

Figure 18-25. A and B. Anatomy of the floor of mouth and submandibular space. a. = artery; m. = muscle; n. = nerve.

of early tongue cancers or for ablation of premalignant lesions. A partial glossectomy, which removes a significant portion of the lateral oral tongue, still permits reasonably effective postoperative function. Resection of larger tumors of the tongue that invade deeply can result in significant functional impairment. If lingual contact with the palate, lip, and teeth is decreased, it will result in impaired articulation. The use of soft, pliable fasciocutaneous free flaps can provide intraoral bulk and preservation of tongue mobility. Prosthetic augmentation can allow for contact between the remaining tongue tissue and the palate, improving a patient's ability to speak and swallow. Treatment of the regional lymphatics is typically performed with the same modality used to address the primary site. When the primary site is addressed surgically, modified radical neck dissection (MRND) or selective neck dissection (SND) is performed. Depth of invasion of the primary tumor can direct the need for elective lymph node dissection with early stage lesions.[49]

Floor of Mouth. The floor of mouth is a mucosal covered semilunar area that extends from the anterior tonsillar pillar posteriorly to the frenulum anteriorly, and from the inner surface of the mandible to the ventral surface of the oral tongue. The ostia of the submaxillary and sublingual glands are contained in the anterior floor of mouth. The muscular floor of mouth is composed of the sling-like genioglossus, mylohyoid, and hyoglossus muscles, which serve as a barrier to spread of disease. Invasion into these muscles can result in decreased tongue mobility and poor articulation. Another pathway for spread of tumor is along the salivary ducts, which can result in direct extension into the sublingual space.

Anterior or lateral extension to the mandibular periosteum is of primary importance in the preoperative assessment for these lesions. Imaging studies of the mandible, including CT scan, magnetic resonance imaging (MRI), and Panorex radiography, are helpful for ascertaining bone invasion. A careful clinical evaluation, which includes bimanual palpation to assess adherence or fixation to adjacent bone, is also essential (Fig. 18-26). The absence of fixation of the lesion to the inner mandibular cortex indicates that a mandible-sparing procedure is feasible.[50] Deep invasion into the intrinsic musculature of the tongue causes fixation and mandates a partial glossectomy in conjunction with resection of the floor of mouth. Lesions in the anterior floor of mouth may invade the sublingual gland or submandibular duct and require resection of either of these structures in continuity with the primary lesion. Direct extension of tumors into or through the sublingual space and into the submaxillary space may necessitate the need for removal of the primary tumor with the neck dissection specimen in continuity.

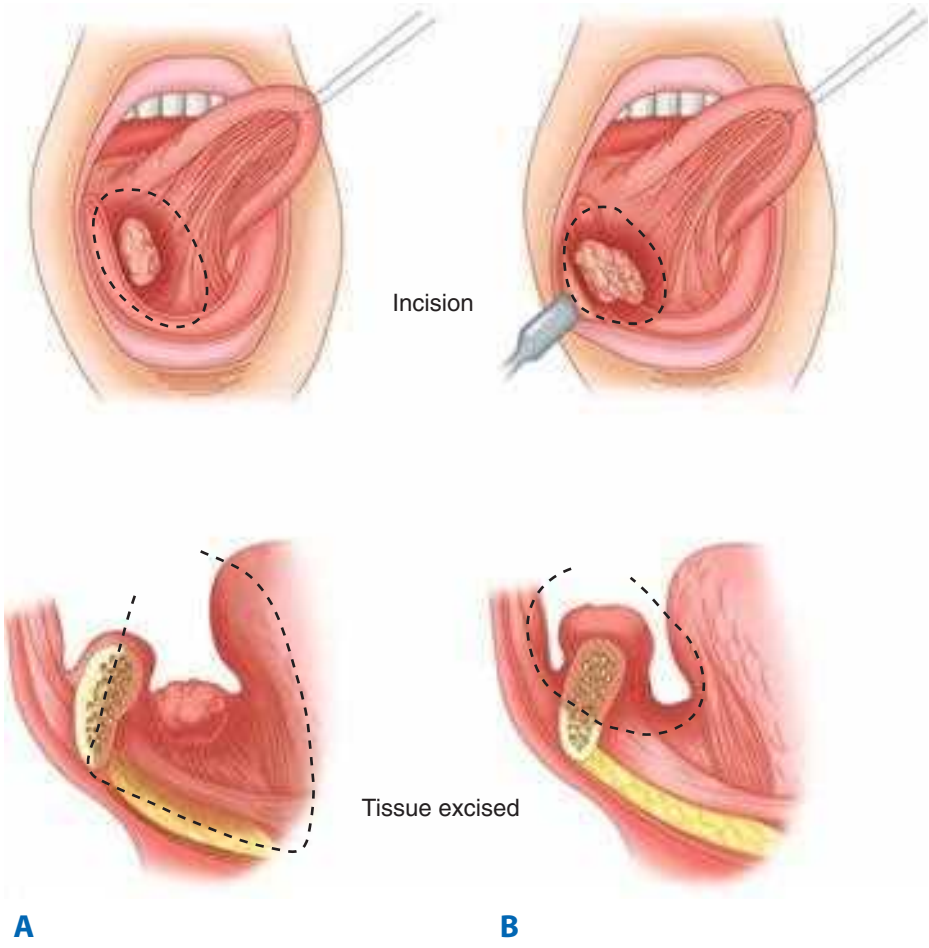


Figure 18-26. A and B. Differences in the transoral resection of a floor of mouth and alveolar ridge lesion.

The resection of large tumors of the floor of mouth may require a lip-splitting incision (Fig. 18-27) and immediate reconstruction. The goals are to obtain watertight closure to avoid a salivary fistula and to avoid tongue tethering to maximize mobility. For small mucosal lesions, wide local excision can be followed by placement of a split-thickness skin graft over the muscular bed. Larger defects that require marginal or segmental mandibulectomy require complex reconstruction with a fasciocutaneous or a vascularized osseous free flap.

Figure 18-27. Composite resection specimen of a T4 floor of mouth squamous cell carcinoma.

Alveolus/Gingiva. The alveolar mucosa overlies the bone of the mandible and maxilla. It extends from the gingivobuccal sulcus to the mucosa of the floor of mouth and hard palate. The posterior limits are the pterygopalatine arch and the ascending portion of the ramus of the mandible. Because of the tight attachment of the alveolar mucosa to the mandibular and maxillary periosteum, treatment of lesions of the alveolar mucosa frequently requires resection of the underlying bone.

Marginal resection of the mandible can be performed for tumors of the alveolar surface that present with minimal bone invasion. Although access for such a procedure can be performed by using an anterior mandibulotomy (Fig. 18-28), use of transoral and pull-through procedures is preferred if a coronal or sagittal marginal mandibulotomy is performed. For more extensive tumors that invade into the medullary cavity, segmental mandibulectomy is necessary. Preoperative radiographic evaluation of the mandible plays an important role in determining the type of bone resection required. For radiographic evaluation of the mandible, Panorex views demonstrate gross cortical invasion. MRI is the best modality for demonstrating invasion of the medullary cavity of the mandible. Sectional CT scanning with bone settings is the optimum modality for imaging subtle cortical invasion. Gross bony invasion involvement at the mandibular symphysis negatively impacts locoregional control.[51]

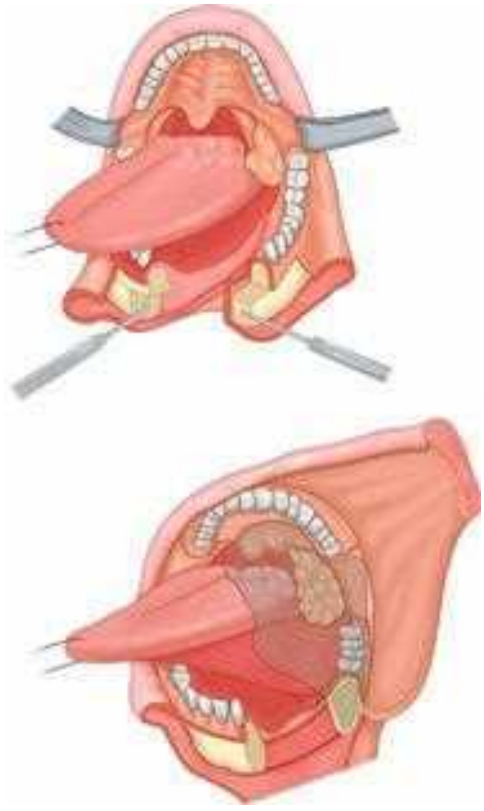

Figure 18-28. Anterior mandibulotomy with mandibular swing to approach a posterior lesion.

Retromolar Trigone. The retromolar trigone is represented by tissue posterior to the posterior inferior alveolar ridge and ascends over the inner surface of the ramus of the mandible. Similar to alveolar lesions, early involvement of the mandible is common because of the lack of intervening soft tissue in the region. The clinical presentation of trismus represents involvement of the muscles of mastication and may indicate spread to the skull base. Tumors of the region may extend posteriorly into the oropharyngeal anatomy or laterally to invade the mandible. As a result, resection of retromolar trigone tumors usually requires a marginal or segmental mandibulectomy with a soft-tissue and/or osseous reconstruction to maximize a patient's postoperative ability for speech and swallowing. Ipsilateral neck dissection is performed because of the risk of metastasis to the regional lymphatics. Huang and associates demonstrated a 5-year, disease-free survival rate for T1 lesions of 76%, which declined to 54% for T4 disease. Patients with N0 disease had a 5-year survival rate of 69%.[52]

Buccal Mucosa. The buccal mucosa includes all of the mucosal lining from the inner surface of the lips to the line of attachment of mucosa of the alveolar ridges and pterygomandibular raphe. The etiologies of malignancies in the buccal area include lichen planus, chronic dental trauma, and the habitual use of tobacco and alcohol. Tumors in this area have a propensity to spread locally and to metastasize to regional lymphatics. Local intraoral spread may necessitate resection of the alveolar ridge of the mandible or maxilla. Lymphatic drainage is to the facial and the submandibular nodes (level I). Small lesions can be excised surgically, but more advanced tumors require combined surgery and postoperative radiation.[53] Deep invasion into the cheek may require through-and-through resection. Reconstruction aimed at providing both an internal and external lining may be accomplished with a folded fasciocutaneous free flap or a combination of pedicled and free tissue techniques.

Palate. The hard palate is defined as the semilunar area between the upper alveolar ridge and the mucous membrane covering the palatine process of the maxillary palatine bones. It extends from the inner surface of the superior alveolar ridge to the posterior edge of the palatine bone. Most squamous cell carcinomas of the hard palate are caused by habitual tobacco and alcohol use. Chronic irritation from ill-fitting dentures also may play a causal role. Inflammatory lesions arising on the palate may mimic malignancy and can be differentiated by biopsy specimen. Necrotizing sialometaplasia appears on the palate as a butterflyshaped ulcer that clinically appears similar to a neoplasm. Treatment is symptomatic and biopsy specimen confirms its benign nature. Torus palatini are bony outgrowths of the midline palate and do not specifically require surgical treatment unless symptomatic.

Squamous cell carcinoma and minor salivary gland tumors are the most common malignancies of the palate.[54] The latter include adenoid cystic carcinoma, mucoepidermoid carcinoma, adenocarcinoma, and polymorphous low-grade adenocarcinoma. Mucosal melanoma may occur on the palate and presents as a nonulcerated, pigmented plaque. Kaposi's sarcoma of the palate is the most common intraoral site for this tumor. Tumors may present as either an ulcerative, exophytic, or submucosal mass. Minor salivary gland tumors tend to arise at the junction of the hard and soft palate. Direct infiltration of bone leads to extension into the floor of the nasal cavity and/or maxillary sinus. Squamous cell carcinoma of the hard palate is treated surgically. Adjuvant radiation is indicated for advanced staged tumors. Because the periosteum of the palate can act as a barrier to spread of tumor, mucosal excision may be adequate for very superficial lesions. Involvement of the periosteum requires removal of a portion of the bony palate. Partial palatectomy of infrastructure maxillectomy may be required for larger lesions involving the palate or maxillary antrum. Malignancies may extend along the greater palatine nerve making biopsy specimen important for identifying neurotropic spread. Through-and-through defects of the palate require a dental prosthesis for rehabilitation of swallowing and speech.

Oropharynx. The oropharynx extends from the soft palate to the superior surface of the hyoid bone (or floor of the vallecula) and includes the base of tongue, the inferior surface of the soft palate and uvula, the anterior and posterior tonsillar pillars, the glossotonsillar sulci, tonsils, and the lateral and posterior pharyngeal walls. Laterally, the borders of this region are the pharyngeal constrictors and the medial aspect of the mandible. Direct extension of tumors from the oropharynx into these lateral tissues may involve spread into the parapharyngeal space. The ascending ramus of the mandible can be involved when tumors invade the medial pterygoid muscle.

As was true of the oral cavity, the histology of the majority of tumors in this region is squamous cell carcinoma. Although less common, minor salivary gland tumors may present as submucosal masses in the tongue base and soft palate. Additionally, the tonsils and tongue base may be the presenting site for a lymphoma noted clinically as asymmetrical enlargement.

Oropharyngeal cancer may present as an ulcerative lesion or an exophytic mass. Tumor fetor from necrosis is common.

A muffled or "hot potato" voice is seen with large tongue base tumors. Dysphagia and weight loss are common symptoms. Referred otalgia, mediated by the tympanic branches of cranial nerve (CN) IX and CN X, is a common complaint. Trismus may indicate advanced disease and usually results from involvement of the pterygoid musculature. The incidence of regional metastases from cancers of the oropharynx is high. Consequently, ipsilateral or bilateral nontender cervical lymphadenopathy is a common presenting sign.

The incidence of oropharyngeal squamous cell carcinoma has increased significantly over the last three decades. The etiology for this rise has been attributed to the HPV-16 related development of malignancy. HPV infection can induce the production of two viral oncoproteins, E6 and E7, which inactivate tumor suppressors p53 and Rb leading to tumor promotion. In a prospective clinical trial of patients enrolled in the Eastern Cooperative Group (ECOG) trial 2399, Fakhry et al reported on the survival benefit seen in oropharyngeal cancer patients that were HPV-positive. Patients were treated with sequential chemoradiation for advanced stage disease. HPV positivity was found in 57% of all oropharyngeal cancers in the study. HPV-positive cancers demonstrated a higher response rate to induction chemotherapy (82% vs. 55%) and improved 2-year survival (95% vs. 62%). Compared to patients with HPV-negative tumors, HPV-positive cancers presented in younger male patients and were associated with a history of higher lifetime number of sexual partners and oral sex.[55] HPV-associated oropharyngeal carcinoma is considered to represents a distinct clinicopathologic entity different from the traditional squamous cell carcinoma of the head and neck associated with the long-term use of tobacco and alcohol (Table 18-2). Surprisingly, the rate of distant metastasis is similar in HPV-positive and HPV-negative patients indicating survival benefits are likely from improved locoregional control with treatment. Clinical trials are currently being performed to assess if therapy can be deintensified in the HPV patient population while obtaining the same locoregional and overall survival seen with standard treatment options.

Imaging studies are important for adequate staging and should assess for extension to the larynx, parapharyngeal space, pterygoid musculature, mandible, and nasopharynx. Lymph node metastasis from oropharyngeal cancer most commonly occurs in the subdigastric area of level II. Metastases also are found in levels III, IV, and V, in addition to the retropharyngeal and parapharyngeal lymph nodes. Approximately 50% of patients have metastases at the time of presentation and bilateral metastases are common from tumors arising in the tongue base and soft palate.

Table 18-2

Head and neck squamous cell carcinoma patterns of presentation

VARIABLE	HPV-POSITIVE	HPV-NEGATIVE
Typical age	40 – 60 years	over 60 years of age
Primary site	tongue base, tonsil	entire UADT
Prognosis with ASD	favorable	poor
Risk factors	oral sex, number of partners	habitual tobacco and alcohol use
Incidence	increasing	stable, decreasing

(UADT – upper aerodigestive tract, ASD -advanced stage disease)

The treatment goals for patients with oropharyngeal cancer include maximizing survival and preserving function. Management of squamous cell cancers of this region includes surgery alone, primary radiation alone, surgery with postoperative radiation, and combined chemotherapy with radiation therapy.[56] Tumors of the oropharynx tend to be radiosensitive.[57] Patients with early stage lesions may be candidates for monomodality radiation alone. Adequate treatment of the neck is important with oropharyngeal squamous cancer because of the high risk of regional metastasis. Concomitant chemoradiation is commonly utilized in patients with advanced stage (III, IV) oropharyngeal carcinoma.[58] This approach has been effectively demonstrated to preserve function and is associated with survivorship comparable to surgery with postoperative radiation.

5▶

In an effort to resect tumors of the oropharynx in a minimally invasive fashion, that might otherwise require a lip-splitting mandibulotomy approach with dissection through the floor of mouth, the transoral robotic surgical approach utilizing the da Vinci Surgical System has been utilized with favorable results. Dean et al reported on the use of robot-assisted primary and salvage surgery for 36 patients with T1 and T2 tumors of the oropharynx compared to traditional open salvage resection. Patients that underwent robot-assisted surgery had shorter lengths of stay and were less likely to be gastrostomy tube or tracheostomy dependent at 6 months.[59] Of patients undergoing primary transoral robotic surgery to tonsillar carcinoma, 93% still required some form of postoperative adjuvant therapy.[60] Advocates of the technique believe that initial surgical management of the oropharynx, a site typically treated with primary radiation or chemoradiation therapy, allows for a better long-term functional result with the potential for decreasing the intensity of adjuvant therapy to radiation alone as opposed to postoperative chemoradiation. Clinical trials and experience with the technique and continue evolve with the focus of use directed at early-stage oropharyngeal carcinomas.

Extensive oropharyngeal cancers may require surgical resection and postoperative radiotherapy. Lesions that involve the mandible require composite resections, such as the classic jaw-neck resection or "commando" procedure. Surgical management of the tongue base may require total glossectomy for extensive lesions crossing the anatomic midline. The potential need for synchronous performance of total laryngectomy at the time of tongue base resection should be explained to the patient. Preservation of the larynx after total glossectomy is associated with a significant risk of postoperative dysphagia and aspiration.[61]

Swallowing rehabilitation in patients with oropharyngeal carcinoma is an important aspect of posttreatment care. For soft palate defects, palatal obturators may assist in providing a seal between the nasopharynx and the posterior pharyngeal wall. Nasal regurgitation of air and liquids can be decreased with use. Close cooperation between the head and neck surgeon and the maxillofacial prosthodontist is essential to provide patients with the optimum prosthetic rehabilitation. Preoperative planning can result in the creation of a defect that better tolerates obturation. For patients with postglossectomy defects, palatal augmentation prostheses can provide bulk extending inferiorly from

the palate. The prosthesis decreases the volume of the oral cavity and allows the remaining tongue or soft tissue to articulate with the palate. It also facilitates posterior projection of the food bolus during the oral and pharyngeal phases of swallowing.

Hypopharynx and Cervical Esophagus. The hypopharynx extends from the vallecula to the lower border of the cricoid cartilage and includes the pyriform sinuses, the lateral and posterior pharyngeal walls, and the postcricoid region (Fig. 18-29). Squamous cancers of the hypopharynx frequently present at an advanced stage. Clinical findings are similar to those of lower oropharyngeal lesions and include a neck mass, muffled or hoarse voice, referred otalgia, dysphagia, and weight loss. A common symptom is dysphagia, starting with solids and progressing to liquids, leaving patients malnourished at the time of presentation. Invasion of the larynx by direct extension can result in vocal cord paralysis and may lead to airway compromise.

Routine office examination should include flexible fiberoptic laryngoscopy to properly assess the extent of tumor. During examination, the patient should be instructed to perform a Valsalva maneuver, which will result in passive opening of the pyriform sinuses and postcricoid regions, providing improved visualization. Decreased laryngeal mobility or fixation may indicate invasion of the prevertebral fascia and unresectability. Barium swallow can provide information regarding postcricoid and upper esophageal extension, potential multifocality within the esophagus, and document the presence of aspiration. CT and/or MRI imaging should be obtained through the neck and upper chest to assess for invasion of the laryngeal framework and to identify for regional metastases, with special attention given to the paratracheal and upper mediastinal lymph nodes (Fig. 18-30). Bilateral metastatic adenopathy in the paratracheal chain is common and the majority of patients present with nodal disease at the time of diagnosis.

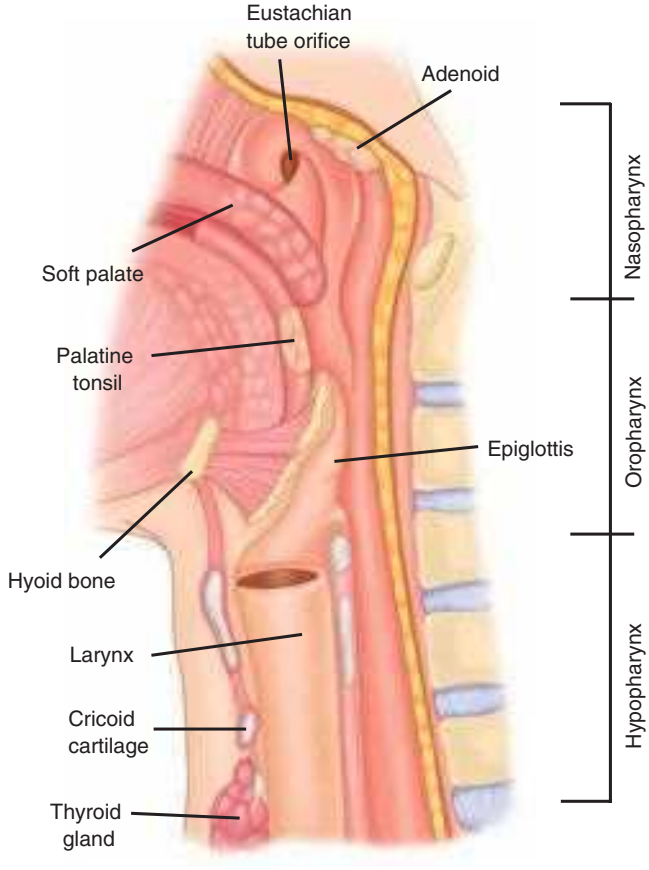

Figure 18-29. Relationship of nasopharynx, oropharynx, and hypopharynx.

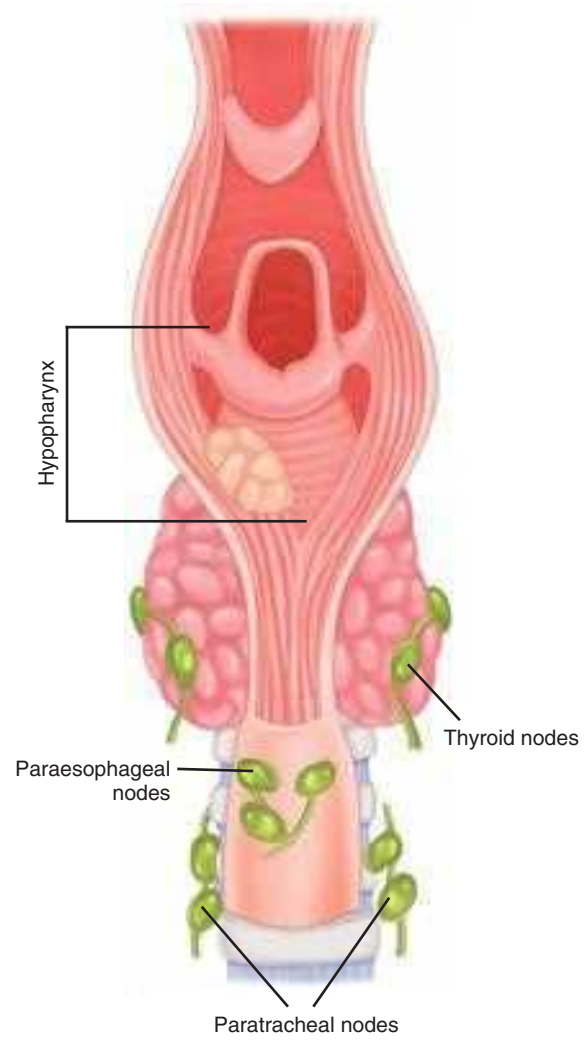

Figure 18-30. View of the hypopharynx demonstrating the potential pathways of spread of tumor and pertinent anatomy.

Tumors of the hypopharynx and cervical esophagus are associated with poorer survival rates than are other sites in the head and neck because of advanced stage and lymph node metastasis at presentation. Surgery with postoperative radiation therapy improves locoregional control compared to single-modality therapy in the treatment of advanced stage tumors.[62] Definitive radiation therapy may be effective for limited T1 tumors, whereas concomitant chemoradiation is generally used for T2 and T3 tumors.[63] Surgical salvage after radiation failure has a success rate of less than 50% and can be associated with significant wound-healing complications.

Larynx-preserving surgical procedures for tumors of the hypopharynx are possible for only a limited number of lesions. Tumors of the medial pyriform wall or pharyngo-epiglottic fold may be resected with partial laryngopharyngectomy. In this circumstance, the tumor must not involve the apex of the pyriform sinus, vocal cord mobility must be unimpaired, and the patient

must have adequate pulmonary reserve. Given the increased risk for postoperative aspiration associated with various forms of partial laryngectomy, a history significant for pulmonary disease is a contraindication for performing the procedures. Because the majority of patients with tumors of the hypopharynx present with large lesions with significant submucosal spread, total laryngectomy often is required to achieve negative resection margins. Resection of the primary tumor and surrounding pharyngeal tissue is performed en bloc. Bilateral neck dissection is frequently indicated given the elevated risk of nodal metastases found with these lesions.

When laryngopharyngectomy is performed for hypopharyngeal tumors the surgical defect is repaired by primary closure when possible. Generally, 4 cm or more of pharyngeal mucosa is necessary for primary closure to provide an adequate lumen for swallowing and to minimize the risk of stricture formation. Larger surgical defects require closure with the aid of pedicled myocutaneous flaps or microvascular reconstruction with radial forearm or jejunal free flap. When total laryngopharyngoesophagectomy is necessary, gastric pull-up is performed.

Cervical esophageal cancer may be managed surgically or by concomitant chemoradiation. Preservation of the larynx is possible if the cricopharyngeus muscle demonstrates limited involvement. Unfortunately, this is not often the case and many patients with cervical esophageal cancer require laryngectomy. Total esophagectomy is performed because of the tendency for multiple primary tumors and skip lesions seen with esophageal cancers.

Despite aggressive treatment strategies, the 5-year survival rate for cervical esophageal cancer is less than 20%. Given the presence of paratracheal lymphatic spread, surgical treatment for tumors of this area must include paratracheal lymph node dissection, in addition to treatment of the lateral cervical lymphatics.

Larynx. Laryngeal carcinoma is a diagnosis typically entertained in individuals with prominent smoking histories and the complaint of a change in vocal quality (Fig. 18-31). The borders of the larynx span from the epiglottis superiorly to the cricoid

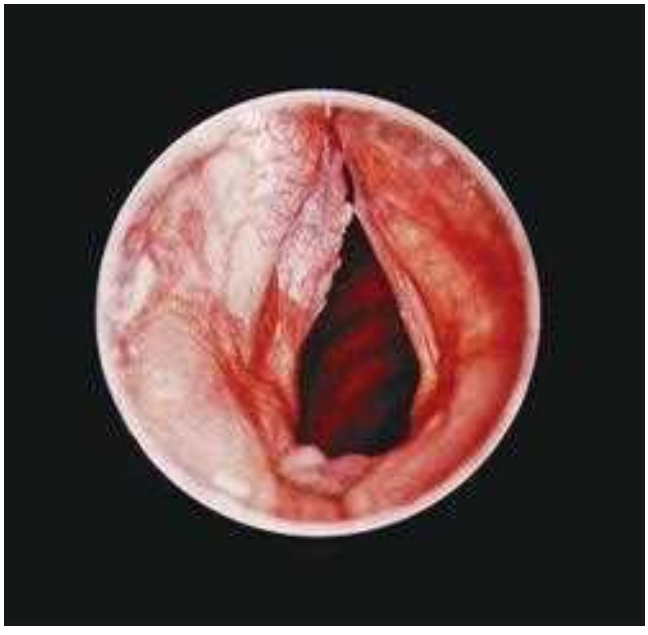

Figure 18-31. Endoscopic view of a laryngeal squamous carcinoma.

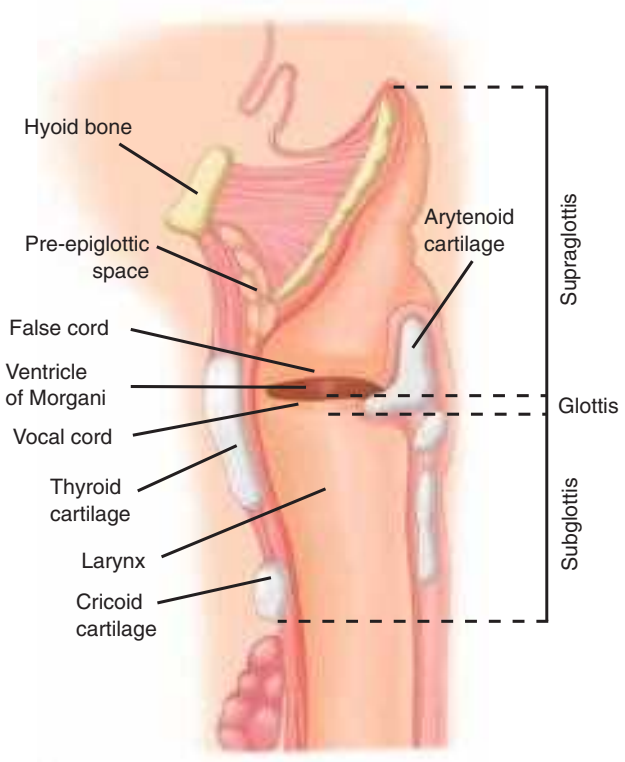

Figure 18-32. Sagittal view of the larynx with the divisions of the supraglottis, glottis, and subglottis demonstrated.

cartilage inferiorly. The lateral limits of the larynx are the aryepiglottic folds. The larynx is composed of three regions: the supraglottis, the glottis, and the subglottic (Fig. 18-32).

The supraglottic includes the epiglottis, aryepiglottic folds, arytenoids, and ventricular bands (false vocal folds). The inferior boundary of the supraglottic is a horizontal plane passing through the lateral margin of the ventricle. The glottis is composed of the true vocal cords (superior and inferior surfaces) and includes the anterior and posterior commissures. The subglottic extends from the inferior surface of the glottis to the lower margin of the cricoid cartilage. The soft-tissue compartments of the larynx are separated by fibroelastic membranes, which can act as barriers to the spread of cancer. These membranes thicken medially to form the false vocal fold and the vocal ligament (the true vocal cord).

The supraglottic larynx contains pseudostratified, ciliated respiratory epithelium that covers the false vocal cords. The epiglottis and the vocal cords are lined by stratified, nonkeratinizing squamous epithelium. The subglottic mucosa is pseudostratified, ciliated respiratory epithelium. Minor salivary glands are also found in the supraglottic and subglottic. Tumor types that arise in the larynx are primarily squamous cell carcinoma but also include tumors of neuroendocrine origin, squamous papillomas, granular cell tumors, and tumors of salivary origin. Several histologic variants of squamous cell carcinoma exist and include verrucous, basaloid squamous cell, adenosquamous, and spindle cell carcinoma. Tumors of the laryngeal framework include synovial sarcoma, chondroma, and chondrosarcoma.

The normal functions of the larynx are airway patency, protection of the tracheobronchial tree during swallowing, and phonation. Patients with tumors of the supraglottic larynx may present with symptoms of chronic sore throat, dysphonia

("hot potato" voice), dysphagia, or a neck mass secondary to regional metastasis. Supraglottic tumors may cause vocal cord fixation by inferior extension in the paraglottic space or direct invasion of the cricoarytenoid joint. Anterior extension of tumors arising on the laryngeal surface of the epiglottis into the preepiglottic space produces a muffled quality to the voice. Referred otalgia or odynophagia is encountered with advanced supraglottic cancers. Bulky tumors of the supraglottic may result in airway compromise. In contrast to most supraglottic lesions, hoarseness is an early symptom in patients with tumors of the glottis.[64] Airway obstruction from a glottic tumor is usually a late symptom and is the result of tumor bulk or impaired vocal cord mobility. Decreased vocal cord mobility may be caused by direct muscle invasion or involvement of the RLN. Fixation of the vocal cord indicates invasion into the vocalis muscle, paraglottic space, or cricoarytenoid joint. Superficial tumors that are bulky may appear to cause cord fixation through mass effect. Subglottic cancers are relatively uncommon and typically present with vocal cord paralysis (usually unilateral) and/or airway compromise.

The staging classification for squamous cell cancers of the larynx includes assessment of vocal cord mobility as well as local tumor extension. Accurate clinical staging of laryngeal tumors requires flexible fiber-optic endoscopy in the office and direct microlaryngoscopy under general anesthesia. Direct laryngoscopy, used to assess the extent of local spread, may be combined with esophagoscopy or bronchoscopy to adequately stage the primary tumor and to exclude the presence of a synchronous lesion. Key areas to note for tumor extension in supraglottic tumors are the vallecula, base of tongue, ventricle, arytenoid, and anterior commissure. For glottic cancers, it is important to determine extension to the false cords, anterior commissure, arytenoid, and subglottic.

Radiographic imaging by CT and/or MRI provides important staging information and is crucial for identifying cartilage erosion or invasion and extension into the preepiglottic or paraglottic spaces. High quality, thin-section images through the larynx should be obtained in patients with laryngeal tumors and used with clinical assessment to arrive at a final disease pretreatment staging. Lymph node metastasis may be defined more readily with the use of imaging studies.

Lymphatic drainage of the larynx is distinct for each subsite. Two major groups of laryngeal lymphatic pathways exist: those that drain areas superior to the ventricle, and those that drain areas inferior to it. Supraglottic drainage routes pierce the thyrohyoid membrane with the superior laryngeal artery, vein, and nerve, and drain mainly to the subdigastric and superior jugular nodes.[64]Those from the glottic and subglottic areas exit via the cricothyroid ligament and end in the prelaryngeal node (the delphian node), the paratracheal lymph nodes, and the deep cervical nodes along the inferior thyroid artery. Limited glottic cancers typically do not spread to regional lymphatics (1%–4%). However, there is a high incidence of lymphatic spread from supraglottic (30%–50%) and subglottic cancers (40%).

When considering treatment for laryngeal tumors, it is useful to categorize them as a continuum from early tumors (those with a small area of involvement resulting in minimal functional impairment) to advanced tumors (those with significant airway compromise and local extension). For example, severe dysplasia and carcinoma in situ often can be treated successfully with CO_2 laser resection or conservative surgical approaches. In contrast, more advanced tumors may require partial laryngectomy (Fig. 18-33) or even total laryngectomy (Fig. 18-34).[65] Further complicating the

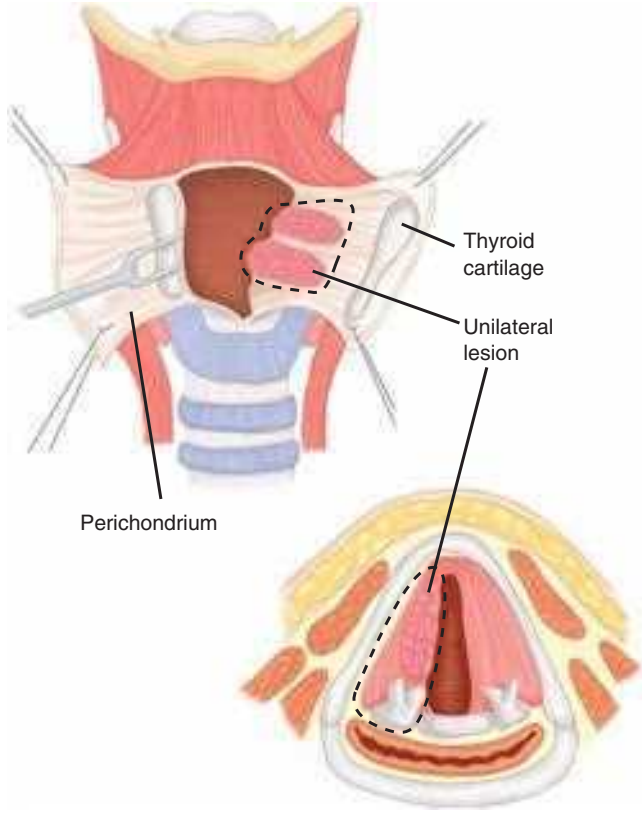

Figure 18-33. Example of the resection of a vertical partial laryngectomy for an early stage glottic carcinoma.

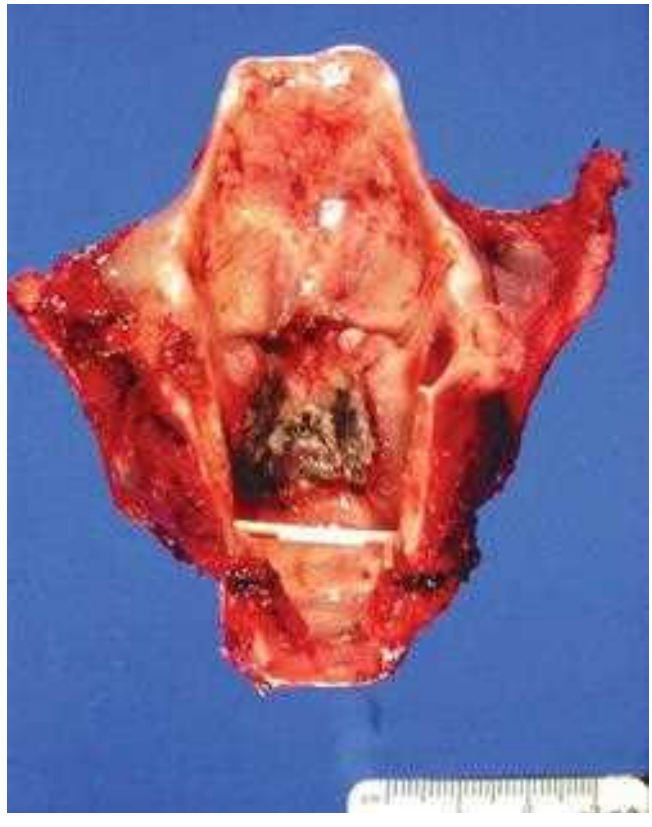

Figure 18-34. Total laryngectomy specimen featuring a locally invasive advanced stage glottic squamous carcinoma.

treatment paradigm is the role of radiotherapy, with or without chemotherapy, with the goal of laryngeal preservation.[66]

Prognostic factors for patients with cancer of the larynx are tumor size, nodal metastasis, perineural invasion, and extracapsular spread of disease in cervical lymph nodes. Patient comorbidities are important to consider when arriving at a treatment plan for patients with laryngeal cancer.

For severe dysplasia or carcinoma in situ of the vocal cord, complete removal of the involved mucosa with microlaryngoscopy is an effective treatment. Patients with limited involvement of the arytenoid or anterior commissure are the best candidates for a good posttreatment vocal quality result with this approach. Multiple procedures may be necessary to control the disease and to prevent progression to an invasive cancer. Close follow-up examinations and smoking cessation are mandatory adjuncts of therapy. For early stage cancers of the glottis and the supraglottis, radiation therapy is equally as effective as surgery in controlling disease.

Critical factors in determining the appropriate treatment modality are comorbid conditions (chronic obstructive pulmonary disease, cardiovascular, and renal disease) and tumor extension. Voice preservation and maintenance of quality of life are key issues and significantly impact therapeutic decisions. The use of radiation therapy for early stage disease of the glottis and supraglottis provides excellent disease control with reasonable, if not excellent, preservation of vocal quality. Partial laryngectomy for small glottic cancers provides excellent tumor control, but vocal quality can vary. For supraglottic cancers without arytenoid or vocal cord extension, standard supraglottic laryngectomy results in excellent disease control with good voice function. For advanced tumors with extension beyond the endolarynx or with cartilage destruction, total laryngectomy followed by postoperative radiation is considered the standard of care.[67] In this setting, reconstruction by means of a pectoralis major flap (Fig. 18-35) or free flap reconstruction is required for lesions with pharyngeal extension.

Subglottic cancers, constituting only 1% of laryngeal tumors, are typically treated with total laryngectomy. Of note, 40% of patients with these tumors present with regional adenopathy and special attention must be directed to the treatment of paratracheal lymph nodes.[68]

Laryngeal Preservation Techniques. Superficial cancers confined to the true vocal cord can be treated with a variety of surgical options. These include endoscopic vocal cord stripping, microflap dissection, partial cordectomy, and CO_2 laser resection. Although using a CO_2 laser can provide excellent hemostasis and minimize damage to the adjacent uninvolved tissue, scarring associated with its use is considered more significant than with conventional "cold" techniques. Microflap dissection, using a subepithelial infusion of a saline-epinephrine solution into Reinke's space, allows for assessment of depth of invasion and the ability to resect the lesion as a single unit. Use of an operative microscope aids the precision of such dissections. Open laryngofissure and cordectomy may be reserved for more invasive tumors.

For larger tumors of the glottis with impaired vocal cord mobility, a variety of partial resections exist that permit preservation of reasonable vocal quality. For lesions involving the anterior commissure with limited subglottic extension, an anterofrontal partial laryngectomy is indicated. For lateralized T2 or T3 glottic tumors without cartilage destruction, a vertical partial laryngectomy is feasible. In this circumstance, reconstruction is accomplished by means of a false vocal cord imbrication to simulate a true vocal cord on the side of the resection.

For T3 glottic lesions not involving the preepiglottic space or cricoarytenoid joint, a supracricoid laryngectomy with cricohyoidopexy or cricohyoidoepiglottopexy (CHEP) are options.[65] The supracricoid laryngectomy technique uses the remaining arytenoids as the phonatory structures, which come into apposition with epiglottic remnant in the CHEP, or with the tongue base in the cricohyoidopexy. Oncologic advantages of this procedure include the complete removal of the paraglottic spaces and thyroid cartilage. The supracricoid laryngectomy with CHEP is associated with excellent disease control and a high rate of tracheostomy decannulation. Favorable deglutition rates and a breathy vocal quality are seen postoperatively with this procedure. For lesions with involvement of the cricoarytenoid joint and/or extension to the level of the cricoid, total laryngectomy is required.

The risk for aspiration is high following certain partial laryngectomies. Patient selection is vital to successful application of these techniques. Presurgical pulmonary assessment may be necessary. One simple measurement of functional reserve is to have the patient climb two flights of stairs. Those able to do so without stopping are more likely to be candidates for conservation surgical procedures.

The approach to the treatment for patients with advanced tumors of the larynx and hypopharynx has evolved over time. Chemoradiation has demonstrated the ability for comparable locoregional disease control and overall survival similar to

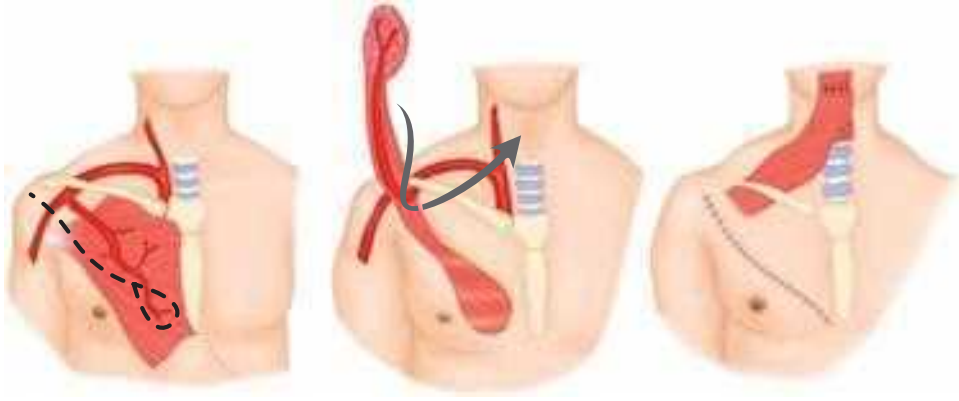

Figure 18-35. Pectoralis flap reconstruction of a laryngectomy patient requires soft-tissue augmentation for pharynx closure.

open surgical approaches. The Radiation Therapy Oncology Group 91-11 trial demonstrated a higher laryngeal preservation rate among patients receiving concomitant chemotherapy and radiotherapy than in those patients receiving radiation alone or sequential chemotherapy followed by radiation therapy.[69] A randomized laryngeal preservation trial of neoadjuvant induction chemotherapy followed by radiation therapy has yielded survival rates similar to those of laryngectomy, with the benefit of preservation of the larynx in 65% of patients.[66] Surgical salvage is available in cases of treatment failure or recurrent disease.

Speech and Swallowing Rehabilitation. Involvement of a speech and swallowing therapist is critical in the preoperative counseling and postoperative rehabilitation of patients with laryngeal cancer. Speech rehabilitation options after total laryngectomy include esophageal speech, tracheoesophageal puncture, and use of an electrolarynx. Esophageal speech is produced by actively swallowing and releasing air from the esophagus which results in vibrations of the esophageal walls and pharynx. The sounds produced can be articulated into words. The ability to create esophageal speech depends on the motivation of patients and their ability to control the upper esophageal sphincter, allowing injection and expulsion of air in a controlled fashion. Unfortunately, less than 20% of postlaryngectomy patients develop fluent esophageal speech.

A tracheoesophageal puncture is a fistula created between the trachea and esophagus that permits placement of a one-way valve that allows air from the trachea to enter the upper esophagus. The valve prevents retrograde passage of food or saliva into the trachea. Patients that undergo placement of a tracheoesophageal puncture have a success rate of >80% in achieving functional speech.

For patients unable to develop esophageal speech, the electrolarynx creates vibratory sound waves when held against the neck or cheek. The vibrations create sound waves that the patient articulates into words. A disadvantage of the electrolarynx is the mechanical quality of the sound produced. This device is most useful in the postoperative period before training for esophageal speech.

Postoperative swallowing rehabilitation is another important task performed by the speech and swallowing team. Patient instruction in various swallowing techniques and evaluation for the appropriate diet consistency allow a patient to initiate oral intake of nutrition while minimizing the risk of aspirating. Flexible fiberoptic laryngoscopy can be performed transnasally and provides valuable information to assist in the assessment of dysphagia. The oral intake of various consistencies of liquids and solids can be observed with endoscopic assessment of laryngeal penetration. A similar assessment may be performed with a modified barium swallow allowing the analysis of the various phases of swallowing.

Unknown Primary Tumors. When patients present with cervical nodal metastases without clinical or radiologic evidence of an upper aerodigestive tract primary tumor, they are referred to as having an unknown primary. Given the difficulty in performing a detailed examination in the clinical setting of the base of tongue, the tonsillar fossa, and the nasopharynx, examination under anesthesia with directed tissue biopsy specimens has been advocated. Ipsilateral tonsillectomy, direct laryngoscopy with base of tongue and pyriform biopsy specimens, examination of the nasopharynx, and bimanual examination can allow for identification of a primary site in a portion of patients previously considered to have an unknown primary. In those individuals in whom a primary site cannot be ascertained, empiric treatment of the mucosal sources of the upper aerodigestive tract at risk (from nasopharynx to hypopharynx) and the cervical lymphatics with concomitant chemoradiation is advocated. For patients with advanced neck disease (N2a or greater) or with persistent lymphadenopathy after radiation, a postradiation neck dissection may be necessary. For patients in whom the primary lesion is identified, a more limited radiation treatment field may be used.

Nose and Paranasal Sinuses

The nose and paranasal sinuses are the sites of a great deal of infectious and inflammatory pathology. The diagnosis of tumors within this region is frequently made after a patient has been unsuccessfully treated for recurrent sinusitis and undergoes diagnostic imaging. Symptoms associated with sinonasal tumors are subtle and insidious. They include chronic nasal obstruction, facial pain, headache, epistaxis, and facial numbness. As such, tumors of the paranasal sinuses frequently present at an advanced stage. Orbital invasion can result in proptosis, diplopia, epiphora, and vision loss. Paresthesia within the distribution of CN V2 is suggestive of pterygopalatine fossa or skull base invasion and is generally a poor prognostic factor. Maxillary sinus tumors can present with loose dentition indicating erosion of the alveolar and/or palatal bones. Tumors found to arise posterior to Ohngren's line are associated with a worse prognosis than are more anteriorly based lesions (Fig. 18-36).[70]

A variety of benign tumors arise in the nasal cavity and paranasal sinuses and include inverted papillomas, hemangiomas, hemangiopericytomas, angiofibromas, minor salivary tumors, and benign fibrous histiocytomas. Fibro-osseous and osseous lesions, such as fibrous dysplasias, ossifying fibromas, osteomas, and myxomas, can also arise in this region. Additionally, herniation of intracranial contents into the nasal cavity can

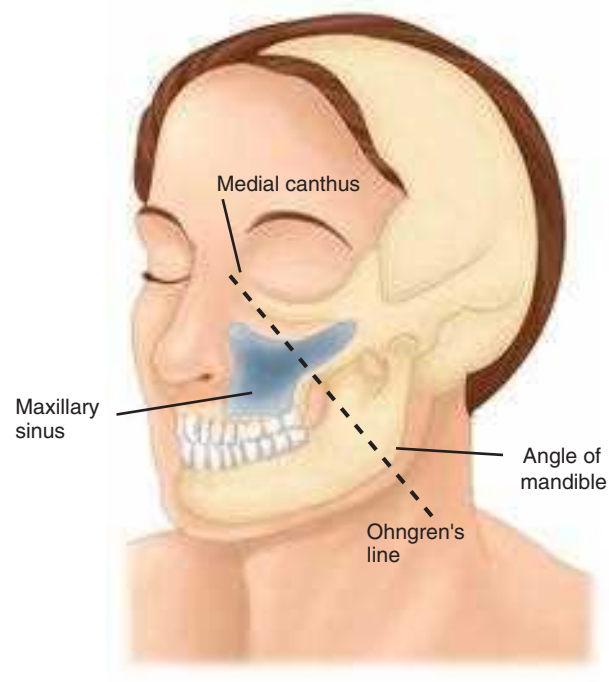

Figure 18-36. Example of the Ohngren's line and the relationship to the maxilla.

occur with the erosion of the anterior skull base with the resultant presentation of a sinonasal mass on clinical examination.

Malignant tumors of the sinuses are predominantly squamous cell carcinomas. Sinonasal undifferentiated carcinoma,[71] adenocarcinoma, mucosal melanoma, lymphoma, olfactory neuroblastoma, rhabdomyosarcoma, and angiosarcoma are some of the other malignancies that have been described. Metastases from the kidney, breast, lung, and thyroid may also present as an intranasal mass. Regional metastasis is uncommon with tumors of the paranasal sinuses (14%–16%) and occurs in the parapharyngeal, retropharyngeal, and subdigastric nodes of the jugular chain.

The diagnosis of an intranasal mass is made with the assistance of a headlight and nasal speculum or nasal endoscopy. The site of origin, involved bony structures, and the presence of vascularity should be assessed. For paranasal sinus tumors, MRI and CT scanning often are complementary studies in determining orbital and intracranial extension.[72] Benign processes frequently present as slow-growing expansile tumors with limited erosion of surrounding bone, compared to the lytic destruction typically associated with malignancies. Skull base foramen should be closely examined for enlargement that may be suggestive of perineural invasion. Examination for cavernous sinus extension, cribriform plate erosion, and dural enhancement is necessary to assess for resectability and the type of surgical approach that is possible. A meningocele or encephalocele will present as a unilateral pulsatile mass. Biopsy of a unilateral nasal mass should be deferred until imaging studies are obtained. An untimely biopsy specimen can result in a CSF leak. If hypervascularity is suspected, biopsy should be performed under controlled conditions in the operating room.

The standard treatment for malignant tumors of the paranasal sinuses is surgical resection with postoperative radiation therapy. Tumors arising along the medial wall of the maxillary sinus may be treated by means of a medial maxillectomy. The treatment of advanced tumors of the paranasal sinuses frequently involves a multispecialty approach. Members of this team include the head and neck surgeon, neurosurgeon, prosthodontist, ophthalmologist, and reconstructive surgeon. Each team member is necessary to facilitate the goal of safe and complete tumor removal. For vascular tumors, preoperative embolization performed within 24 hours of the planned surgical resection may reduce intraoperative hemorrhage.

Prognosis is dependent on tumor location and extension to the surrounding anatomy. Infrastructure maxillectomy, which includes removal of the hard palate and the lower maxillary sinus, is necessary for inferiorly based tumors of the maxillary sinus. For tumors in the upper portion of the maxillary sinus, complete maxillectomy (including removal of the orbital floor) is performed. If there is invasion of the orbital fat, exenteration of the orbital contents is required. Removal of the bony floor of the orbit and preservation of the globe are possible where there is absence of invasion through the orbital periosteum. However, reconstruction of the orbital floor to recreate a stable support for the orbital contents is essential. Removal of anterior cheek skin is indicated when there is tumor extension into the overlying subcutaneous fat and dermis.

For tumors involving the ethmoid sinuses, the integrity of the cribriform plate is assessed with preoperative imaging. Complete sphenoethmoidectomy or medial maxillectomy may suffice if the tumor is localized to the lateral nasal wall. Endoscopic resection with the assistance of image-guidance technology is gaining increasing acceptance for low-grade resectable lesions such as inverted papilloma.

If erosion of the cribriform has occurred, an anterior craniofacial resection is the standard operative approach. The head and neck surgeon and neurosurgeon work in concert to perform this procedure. The neurosurgeon performs a frontal craniotomy for exposure of the anterior cranial fossa floor, whereas the head and neck surgeon proceeds through a transfacial or endoscopic approach to resect the inferior bony attachments. Paranasal sinus malignancies that are deemed unresectable are those with bilateral optic nerve involvement, massive brain invasion, or carotid encasement.[73] Postoperative rehabilitation after orbital exenteration is accomplished by soft-tissue reconstruction and placement of a maxillofacial prosthesis. Combined treatment with surgery and postoperative radiotherapy for squamous cell carcinoma of the sinuses results in survival superior to either radiation or surgery alone. Chemotherapy has a limited application and may be used for specific indications. Rhabdomyosarcoma is primarily treated with chemotherapy followed by radiation therapy. Surgery is reserved for persistent disease after chemoradiation. Sinonasal undifferentiated carcinoma is highly aggressive and typically is not adequately controlled with standard therapy. Chemotherapy in this setting may help to reduce the tumor bulk and allow for orbital preservation.

Nasopharynx

The nasopharynx extends in a plane superior to the hard palate from the choana, to the posterior nasal cavity, to the posterior pharyngeal wall. It includes the fossa of Rosenmüller, the Eustachian tube orifices (torus tubarius), and the site of the adenoid pad. Tumors arising in the nasopharynx are usually of squamous cell origin and range from lymphoepithelioma to well-differentiated carcinoma. However, the differential diagnosis for nasopharyngeal tumors is broad and also includes lymphoma, chordoma, chondroma, nasopharyngeal cyst (Tornwaldt's cyst), angiofibroma, minor salivary gland tumor, paraganglioma, rhabdomyosarcoma, extramedullary plasmacytoma, and sarcoma.

Risk factors for nasopharyngeal carcinoma include area of habitation, ethnicity, and tobacco use. There is an increased incidence of nasopharyngeal cancer in southern China, Africa, Alaska, and in Greenland Eskimos. A strong correlation exists between nasopharyngeal cancer and the presence of EBV infection, such that EBV titers may be used as a means to follow a patient's response to treatment.

Symptoms associated with nasopharyngeal tumors include nasal obstruction, posterior (level V) neck mass, epistaxis, headache, serous otitis media with hearing loss, and otalgia. Cranial nerve involvement is indicative of skull base extension and advanced disease. Lymphatic spread occurs to the posterior cervical, upper jugular, and retropharyngeal nodes. Bilateral regional metastatic spread is common. Distant metastasis is present in 5% of patients at presentation.

Examination of the nasopharynx is facilitated by the use of the flexible or rigid fiber-optic endoscope. Evaluation with imaging studies is important for staging and treatment planning. CT with contrast is used for determining bone destruction, while MRI is used to assess for intracranial and soft-tissue extension. Erosion or enlargement of neural foramina (on CT imaging) or enhancement of cranial nerves (on MRI) is indicative of perineural spread of disease and portends a worse prognosis. The status of the cavernous sinus and optic chiasm should also be assessed.

The standard treatment for nasopharyngeal carcinoma is chemoradiation. Combination therapy produces superior survival rates for nasopharyngeal carcinoma in comparison to radiation alone.[74] Intracavitary radiation boost with implants to the tumor may be included as an adjunct to external beam radiotherapy to improve local control of advanced tumors. Surgical treatment for nasopharyngeal carcinoma is rarely feasible, but may be considered in selected cases as salvage therapy for patients with localized recurrences.

For minor salivary gland and low-grade tumors of the nasopharynx, resection can be performed via a variety of approaches. Lateral rhinotomy or midface degloving approaches can provide good access for removal of tumors in the posterior nasal cavity extending into the nasopharynx. Endoscopic removal is also possible in selected cases. A variety of surgical approaches also exist for more posteriorly located tumors extending to the sphenoid and clivus. Transpalatal approaches used in combination with transmaxillary and transcervical routes can provide good surgical access in addition to providing adequate control of the carotid artery. The emergence of endoscopic techniques has provided a significant advancement in the surgical management of lesions in these two sites.

Ear and Temporal Bone

Tumors of the ear and temporal bone are uncommon and account for less than 1% of all head and neck malignancies. Primary sites include the external ear (pinna), EAC, middle ear, mastoid, or petrous portion of the temporal bone. The most common histology is squamous cell carcinoma. Minor salivary gland tumors, including adenoid cystic carcinoma and adenocarcinoma, may also present in this region. The pinna, because of its exposure to ultraviolet light, is a common site for basal cell and squamous cell carcinoma to arise. Direct extension of tumors from the parotid gland and periauricular skin may occur in this region. Metastases from distant sites occur primarily to the petrous bone and arise in the breast, kidney, lung, and prostate. In the pediatric population, tumors of the temporal bone are most commonly soft-tissue sarcomas. For advanced stage tumors with extensive temporal bone extension, the complex anatomy of the temporal bone makes removal of tumors with functional preservation challenging.

The diagnosis of tumors of the ear and temporal bone is frequently delayed because the initial presentation of these patients is mistaken for benign infectious disease. When patients fail to improve with conservative care and symptoms evolve to potentially include facial nerve paralysis or worsening hearing loss, the need for imaging and biopsy become obvious. Granulation tissue in the EAC or middle ear should be biopsied in patients with atypical presentations or histories consistent with chronic otologic disease.[75]The complexity of the temporal bone anatomy makes the use of imaging studies of paramount importance in the staging and treatment of tumors in this region.

Small skin cancers on the helix of the ear can be readily treated with simple excision and primary closure. Mohs' microsurgery with frozen section margin control also can be used for cancer of the external ear. In lesions that are recurrent or invade the underlying perichondrium and cartilage, rapid spread through tissue planes can occur. Tumors may extend from the cartilaginous external canal to the bony canal and invade the parotid, temporomandibular joint, and skull base. For extensive, pinna-based lesions, procedures such as auriculectomy may be required. Postoperative radiation therapy may be required for advanced skin cancer with positive margins, perineural spread, or multiple involved lymph nodes.

Tumors involving the EAC and middle ear may present with persistent otorrhea, otalgia, EAC or periauricular mass, hearing loss, and facial nerve weakness or paralysis. The patient resembles the presentation of an external otitis unresponsive to standard medical therapy. Sleeve resections are reserved for small superficial tumors involving the cartilaginous external canal. Tumors involving the petrous apex or intracranial structures may present with headache and palsies of CN V and VI. The optimal treatment for tumors of the middle ear and bony external canal is en bloc resection followed by radiation therapy. Management of the regional lymphatics is determined by the site and stage of the tumor at presentation. Temporal bone resections are classified as lateral or subtotal (Fig. 18-37). The lateral temporal bone resection removes the bony and cartilaginous canal, tympanic membrane, and ossicles. The subtotal temporal bone resection includes the removal of the ear canal, middle ear, inner ear, and facial nerve. It is indicated for malignant tumors extending into the middle ear.

Postoperative radiation therapy in the treatment of malignancies of the temporal bone usually is indicated and improves local control over surgery alone. Five-year survival rates are approximately 50% for patients with tumors confined to the external canal and decrease with medial tumor extension. Prognosis is poor when tumor involves the petrous apex.[76]

The purpose of reconstruction after temporal bone resection is to provide vascularized tissue and bulk to the site of resection. Prevention of CSF leak by watertight dural closure and prevention of meningitis are important goals of repair. Additionally, the reconstruction enables protection of vascular structures and the surrounding bone to prepare the patient for postoperative radiation therapy. Commonly used reconstruction methods are regional pedicle myocutaneous flaps (e.g.,

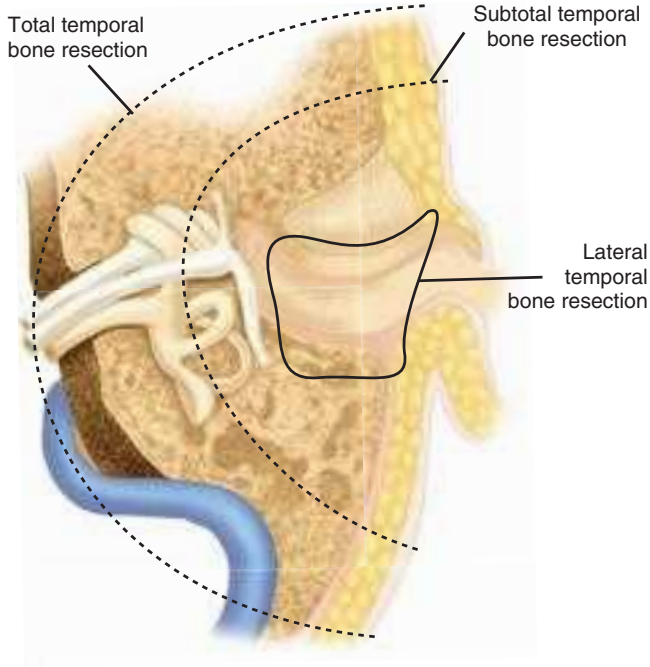

Figure 18-37. Examples of resection specimens for lateral temporal bone resection, subtotal temporal bone resection, and total temporal bone resection.

pectoralis major) and free flaps (e.g., rectus abdominis, radial forearm, or latissimus dorsi). The loss of the pinna produces significant external deformity; however, a prosthetic ear may produce acceptable rehabilitation. When the facial nerve is sacrificed, rehabilitation is necessary and includes the use of interposition nerve grafts, hypoglossal to facial nerve anastomosis, and static or dynamic sling techniques. In patients with poor eye closure, taping of the eyelids and the liberal use of eye lubrication can prevent exposure keratitis. Additionally, tarsorrhaphy, lid-shortening procedures, and the use of gold weight implants can provide upper eyelid closure and protect the cornea.

Neck

The diagnostic evaluation of a neck mass requires a planned approach that does not compromise the effectiveness of future treatment options. A neck mass in a 50-year-old smoker/drinker with a synchronous oral ulcer is different from cystic neck mass in an 18-year-old that enlarges with an upper respiratory infection. As with all diagnoses, a complete history with full head and neck exam, including flexible laryngoscopy, are critical to complete evaluation. The differential diagnosis of a neck mass is dependent on its location and the patient's age. In children, most neck masses are inflammatory or congenital. However, in the adult population, a neck mass >2 cm in diameter has a >80% probability of being malignant. Once the physician has developed a differential diagnosis, interventions to confirm or dispute diagnoses are initiated. Fine-needle aspiration (FNA), with or without the assistance of ultrasound or CT guidance, can provide valuable information for early treatment planning. The use of imaging (CT and/or MRI) is dictated by the patient's clinical presentation. Imaging enables the physician to evaluate the anatomic relationships of the mass to the surrounding anatomy of the neck and sharpen the differential. A cystic lesion may represent benign pathology such as a branchial cleft cyst; however, it may also represent a regional metastasis of a tonsil/base of tongue squamous cell carcinoma or a papillary thyroid carcinoma. In this circumstance, evaluation of these potential primary sites can alter the planned operative intervention.

If a variety of diagnoses are still being entertained after FNA and imaging, an open biopsy may be necessary. For patients with the potential diagnosis of lymphoma, a biopsy sacrificing normal anatomical structures is not necessary. Ensuring appropriate processing of biopsied materials, sent in saline or in formalin, and sparing undue trauma to tissues can decrease the need for re-biopsy. Appropriate placement of the incision for an open biopsy should be considered if the need for neck dissection or composite resection is later required.

Patterns of Lymph Node Metastasis. The regional lymphatic drainage of the neck is divided into seven levels. These levels allow for a standardized format for radiologists, surgeons, pathologists, and radiation oncologists to communicate concerning specific sites within the neck (Fig. 18-38). The levels are defined as the following:

Level I—the submental and submandibular nodes
Level Ia—the submental nodes; medial to the anterior belly of the digastric muscle bilaterally, symphysis of mandible superiorly, and hyoid inferiorly
Level Ib—the submandibular nodes and gland; posterior to the anterior belly of digastric, anterior to the posterior belly of digastric, and inferior to the body of the mandible
Level II—upper jugular chain nodes

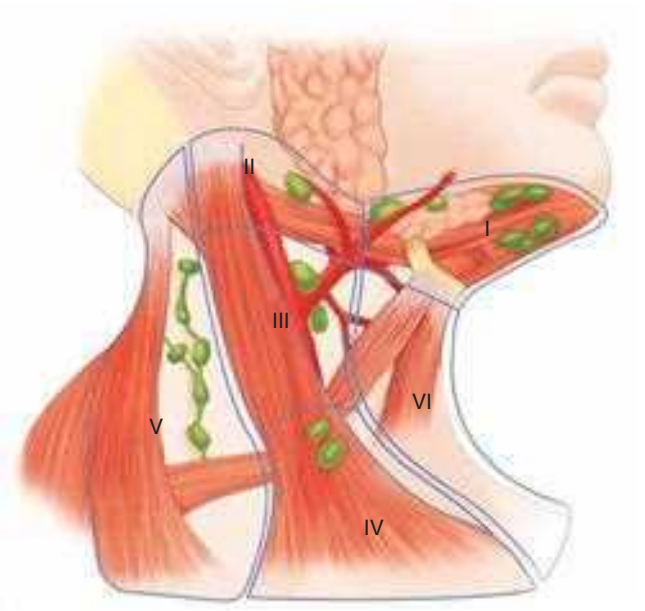

Figure 18-38. Levels of the neck denoting lymph node bearing regions.

Level IIa—jugulodigastric nodes; deep to sternocleidomastoid (SCM) muscle, anterior to the posterior border of the muscle, posterior to the posterior aspect of the posterior belly of digastric, superior to the level of the hyoid, inferior to spinal accessory nerve (CN XI)
Level IIb—submuscular recess; superior to spinal accessory nerve to the level of the skull base
Level III—middle jugular chain nodes; inferior to the hyoid, superior to the level of the cricoid, deep to SCM muscle from posterior border of the muscle to the strap muscles medially
Level IV—lower jugular chain nodes; inferior to the level of the cricoid, superior to the clavicle, deep to SCM muscle from posterior border of the muscle to the strap muscles medially
Level V—posterior triangle nodes
Level Va—lateral to the posterior aspect of the SCM muscle, inferior and medial to splenius capitis and trapezius, superior to the spinal accessory nerve
Level Vb—lateral to the posterior aspect of SCM muscle, medial to trapezius, inferior to the spinal accessory nerve, superior to the clavicle
Level VI—anterior compartment nodes; inferior to the hyoid, superior to suprasternal notch, medial to the lateral extent of the strap muscles bilaterally
Level VII—paratracheal nodes; inferior to the suprasternal notch in the upper mediastinum

Patterns of spread from primary tumor sites in the head and neck to cervical lymphatics are well described.[77] The location and incidence of metastasis vary according to the primary site. Primary tumors within the oral cavity and lip metastasize to the nodes in levels I, II, and III. Skip metastases may occur with oral tongue cancers such that involvement of nodes in level III or IV may occur without involvement of higher echelon nodes (levels I & II). Tumors arising in the oropharynx, hypopharynx, and larynx most commonly spread to the lymph nodes of the lateral neck in levels II, III, and IV. Isolated level V lymphadenopathy

is uncommon with oral cavity, pharyngeal, and laryngeal primaries. Malignancies of the nasopharynx and thyroid commonly spread to level V nodes in addition to the jugular chain nodes. Retropharyngeal lymph nodes are sites for metastasis from tumors of the nasopharynx, soft palate, and lateral and posterior walls of the oropharynx and hypopharynx. Tumors of the hypopharynx, cervical esophagus, and thyroid frequently involve the paratracheal nodal compartment, and may extend to the lymphatics in the upper mediastinum (level VII). The delphian node, a pretracheal lymph node, may become involved by advanced tumors of the glottis with subglottic spread.

The philosophy for the treatment of the cervical lymphatics in head and neck cancer has evolved significantly since the mid-1970s. The presence of cervical metastasis decreases the 5-year survival rate in patients with upper aerodigestive malignancies by approximately 50%. As such, adequate treatment of the N_0 and N_+ neck in these patients has always been viewed as a priority in an effort to increase disease-free survival rates. Traditionally, the gold standard for control of cervical metastasis has been the radical neck dissection (RND) first described by Crile. The classic RND removes levels I to V of the cervical lymphatics in addition to the SCM, internal jugular vein, and the spinal accessory nerve (CN XI). Any modification of the RND that preserves nonlymphatic structures (i.e., CN XI, SCM muscle, or internal jugular vein) is defined as a *modified radical neck dissection* (MRND). A neck dissection that preserves lymphatic compartments normally removed as part of a classic RND is termed a *selective neck dissection* (SND). Bocca and colleagues demonstrated that the MRND, or "functional neck dissection," was equally effective in controlling regional metastasis as the RND, in addition to noting that the functional results in patients were superior.[78] With outcome data supporting the use of SND and MRND, these procedures have become the preferred alternative for the treatment of cervical metastases when indicated.[79,80]

SND options have become increasingly popular given the benefits of improved shoulder function and cosmetic impact on neck contour compared to MRND. The principle behind preservation of certain nodal groups is that specific primary sites preferentially drain their lymphatics in a predictable pattern. Types of SND include the supraomohyoid neck dissection, the lateral neck dissection, and the posterolateral neck dissection.[81] The supraomohyoid dissection, typically used with oral cavity malignancies, removes lymph nodes in levels I to III (Fig. 18-39). The lateral neck dissection, frequently used for laryngeal malignancies, removes those nodes in levels II through IV (Fig. 18-40). The posterolateral neck dissection, used with thyroid cancer, removes the lymphatics in levels II to V (Fig. 18-41). In the clinically negative neck (N_0), if the risk for occult metastasis is >20%, elective treatment of the nodes at risk is generally advocated. This may be in the form of elective neck irradiation or elective neck dissection. An additional role of SND is as a staging tool to determine the need for postoperative radiation therapy. Regional control after selective dissection has been shown to be as effective for controlling regional disease as the MRND in the N_0 patient. Awareness of the potential for "skip metastases," in particular with lateral oral tongue lesions, may require extension of a standard SND to include additional levels for selected lesions.[82] The treatment option selected for the primary site cancer is a significant factor in determining which therapeutic modality will be selected for the treatment of the regional lymphatics.

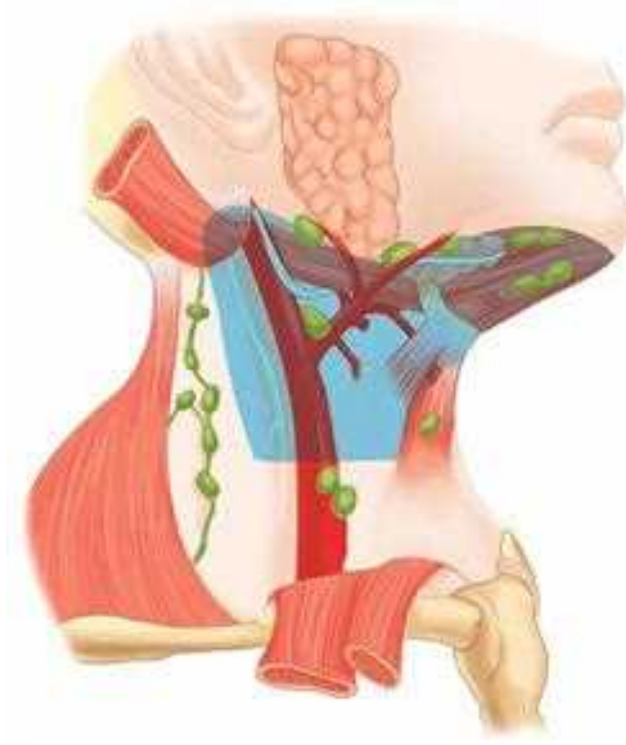

Figure 18-39. Shaded region indicates the region included in a supraomohyoid neck dissection.

For clinically N_+ necks, frequently the surgical treatment of choice is the MRND or RND. SND options have been advocated by some authors for treatment of limited N1 disease, however, they do not have a role in the treatment of advanced N stage disease. When extracapsular spread, perineural invasion,

Figure 18-40. Shaded region indicates the region included in a lateral neck dissection.

Figure 18-41. Shaded region indicates the region included in a posterolateral neck dissection.

vascular invasion, and the presence of multiple involved lymph nodes are noted, surgical management of the neck alone is not adequate.[83] Adjuvant radiation therapy, and possibly chemoradiation, is indicated in these cases.

A planned postradiation neck dissection for patients undergoing radiation as a primary therapy is another indication for the use of neck dissection. In patients with existing advanced N stage disease (N2a or greater) or in patients with a partial response in the neck to therapy, neck dissection is performed 6 to 8 weeks after completion of radiation.

Regional metastases that encase the carotid artery or that demonstrate fixation of nodes to surrounding structures (e.g., prevertebral muscles) decrease 5-year survival rates significantly, to the range of 15% to 22%. The associated morbidity is high with procedures involving carotid resection (e.g., cerebrovascular accident and death) and must be weighed carefully when deciding if surgery is to be pursued. Surgically debulking metastatic disease does not improve survival and is not advocated. Recurrent neck metastasis after comprehensive neck dissection or radiation is associated with very poor survival.

Parapharyngeal Space Masses. The parapharyngeal space is a potential space, shaped like an inverted pyramid spanning the skull base to the hyoid. The boundaries of the space are separated by the styloid process and its associated fascial attachments into the "prestyloid" and "poststyloid" compartments.[84] The contents of the prestyloid space are the parotid, fat, and lymph nodes. The poststyloid compartment is composed of CN's IX to XII, the carotid space contents, cervical sympathetic chain, fat, and lymph nodes. Tumors in this space can produce displacement of the lateral pharyngeal wall medially into the oropharynx (Fig. 18-42), dysphagia, cranial nerve dysfunction, Horner's syndrome, or vascular compression.

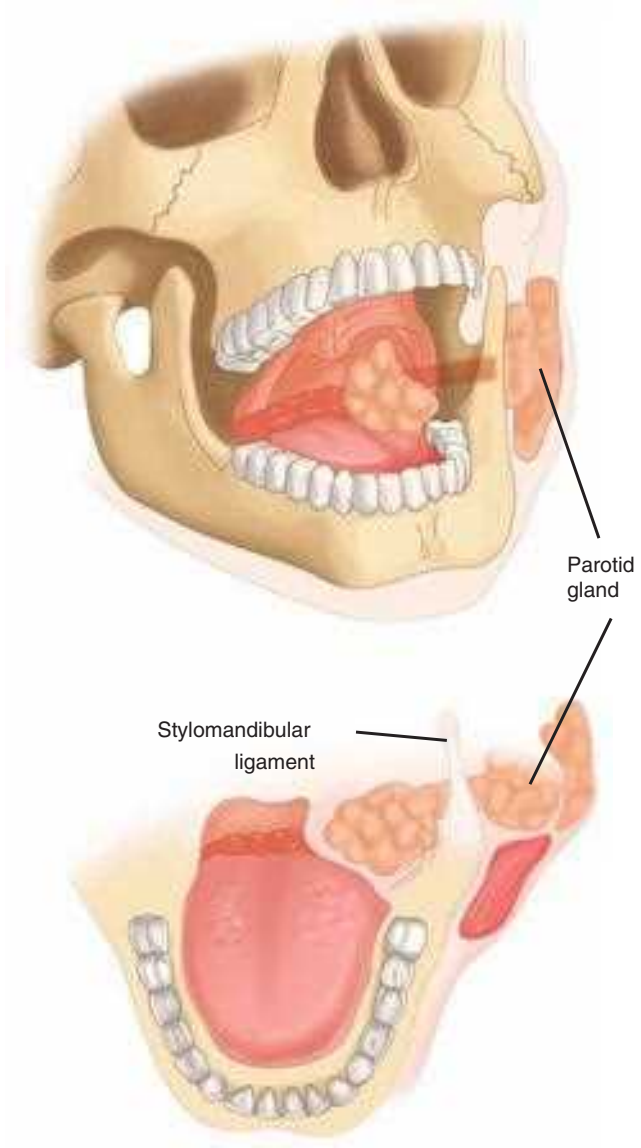

Figure 18-42. Parapharyngeal mass—prestyloid with prominent oropharyngeal presentation typical of a dumbbell tumor.

Of the masses found in the parapharyngeal space, 40% to 50% of the tumors are of salivary gland origin. Tumors of neurogenic origin such as paragangliomas (glomus vagale, carotid body tumor), schwannomas, and neurofibromas are responsible for 20% to 25% of parapharyngeal masses. Lymph node metastases and primary lymphoma represent 15% of lesions. With this in mind, when reviewing preoperative imaging, one can assume that tumors arising anterior to the styloid process are most likely of salivary gland origin, whereas those of the poststyloid compartment are vascular or neurogenic. This is helpful in that angiography is not as necessary for prestyloid lesions as it may be for vascular poststyloid tumors. If a paraganglioma is suspected, a 24-hour urinary catecholamine collection should be obtained to allow for optimal premedication for patients with functional tumors. Embolization may be considered for vascular tumors before surgery in an attempt to decrease intraoperative blood loss.

Surgical access to these tumors may require a transmandibular and/or lateral cervical approach. It is inadvisable to approach parapharyngeal space tumors transorally without

having the necessary exposure and control of the associated vasculature that is afforded by these approaches. Some tumors of the parapharyngeal space (e.g., dumbbell tumors of deep parotid origin) are amenable to removal by a combined transparotid and transcervical approach while allowing for dissection and displacement of the facial nerve to assist removal of tumor.

Benign Neck Masses. A number of benign masses of the neck occur that require surgical management. Many of these masses are seen in the pediatric population. The differential diagnosis includes thyroglossal duct cyst, branchial cleft cyst, lymphangioma (cystic hygroma), hemangioma, and dermoid cyst.

Thyroglossal duct cysts represent the vestigial remainder of the tract of the descending thyroid gland from the foramen cecum, at the tongue base, into the lower anterior neck during fetal development. They present as a midline or paramedian cystic mass adjacent to the hyoid bone. After an upper respiratory infection, the cyst may enlarge or become infected. Surgical management of a thyroglossal duct cyst requires removal of the cyst, the tract, and the central portion of the hyoid bone (Sistrunk procedure), as well as a portion of the tongue base up to the foramen cecum. Before excision of a thyroglossal duct cyst, an imaging study such as ultrasound is performed to identify if normal thyroid tissue exists in the lower neck, and lab assay is performed to assess if the patient is euthyroid.

Congenital branchial cleft remnants are derived from the branchial cleft apparatus that persists after fetal development. There are several types, numbered according to their corresponding embryologic branchial cleft. First branchial cleft cysts and sinuses are associated intimately with the EAC and the parotid gland. Second and third branchial cleft cysts are found along the anterior border of the SCM muscle and can produce drainage via a sinus tract to the neck skin (Fig. 18-43). Secondary infections can occur, producing enlargement, cellulitis, and neck abscess that requires operative drainage. The removal of branchial cleft cysts and fistula requires removal of the fistula tract to the point of origin to decrease the risk of recurrence. The second branchial cleft remnant tract courses between the internal and external carotid arteries and proceeds into the tonsillar fossa. The third branchial cleft remnant courses posterior to the common carotid artery, ending in the pyriform sinus region. Cystic metastasis from squamous cell carcinoma of the tonsil or tongue base to a cervical lymph node can be confused for a branchial cleft cyst in an otherwise asymptomatic patient. Dermoid cysts tend to present as midline masses and represent trapped epithelium originating from the embryonic closure of the midline.

Lymphatic malformations such as lymphangiomas and cystic hygromas can be difficult management problems. They typically present as mobile, fluid-filled masses. Because of their predisposition to track extensively into the surrounding soft tissues, complete removal of these lesions can be challenging. Recurrence and re-growth occur with incomplete removal. Cosmetic deformity and/or nerve injury can result when extensive surgical dissection is performed for large lesions. In newborns and infants, there is higher associated morbidity when cystic hygromas and lymphangiomas become massive, require tracheostomy, and involve the deep neck and mediastinum.

Deep Neck Fascial Planes. The fascial planes of the neck provide boundaries that are clinically applicable because they determine the pathway of spread of an infection. The deep cervical fascia is composed of three layers. These are the investing (superficial deep), pretracheal, and the prevertebral fascias. The superficial layer of the deep cervical fascia forms a cone around the neck and spans from skull base and mandible to the clavicle and manubrium. This layer surrounds the SCM muscle and covers the anterior and posterior triangles of the neck. The pretracheal fascia is found within the anterior compartment, deep to the strap muscles and surrounds the thyroid gland, trachea, and esophagus. This fascia blends laterally to the carotid sheath.

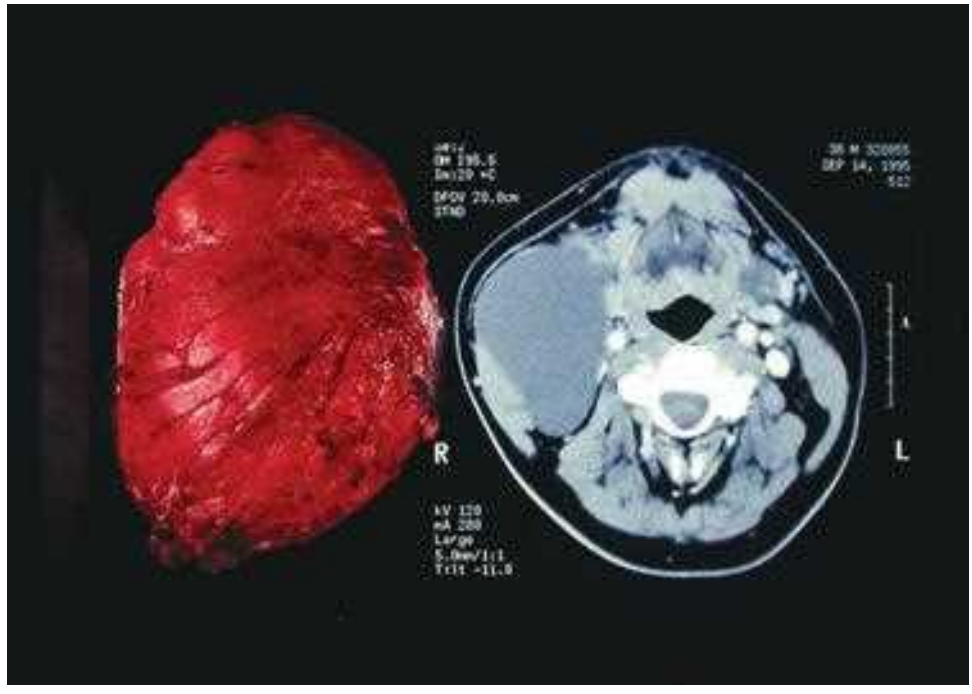

Figure 18-43. CT scan demonstrating a branchial cleft cyst with operative specimen.

Infections in this region may track along the trachea or esophagus into the mediastinum. The prevertebral fascia extends from the skull base to the thoracic vertebra and covers the prevertebral musculature and cervical spine. If an infection were to communicate anteriorly through the prevertebral fascia, it would enter the retropharyngeal space. Infectious extension into this space is complicated by the fact that this region, located posterior to the buccopharyngeal fascia, extends from the skull base to the mediastinum.

6▶

Salivary Gland Tumors

Tumors of the salivary gland are relatively uncommon and represent less than 2% of all head and neck neoplasms. The major salivary glands are the parotid, submandibular, and sublingual glands. Minor salivary glands are found throughout the submucosa of the upper aerodigestive tract with the highest density found within the palate. About 85% of salivary gland neoplasms arise within the parotid gland (Fig. 18-44). The majority of these neoplasms are benign, with the most common histology being pleomorphic adenoma (benign mixed tumor). In contrast, approximately 50% of tumors arising in the submandibular and sublingual glands are malignant. Tumors arising from minor salivary gland tissue carry an even higher risk for malignancy (75%).

Salivary gland tumors are usually slow growing and well circumscribed. Patients with a mass and findings of rapid growth, pain, paresthesias, and facial nerve weakness are at increased risk of harboring a malignancy. The facial nerve, which separates the superficial and deep lobes of the parotid, may be directly involved by tumors in 10% to 15% of patients. Additional findings ominous for malignancy include skin invasion and fixation to the mastoid tip. Trismus suggests invasion of the masseter or pterygoid muscles.[85]

Submandibular and sublingual gland tumors present as a neck mass or floor of mouth swelling, respectively. Malignant tumors of the sublingual or submandibular gland may invade the lingual or hypoglossal nerves, causing paresthesias or paralysis.[86] Bimanual examination is important for determining the size of the tumor and possible fixation to the mandible or involvement of the tongue.

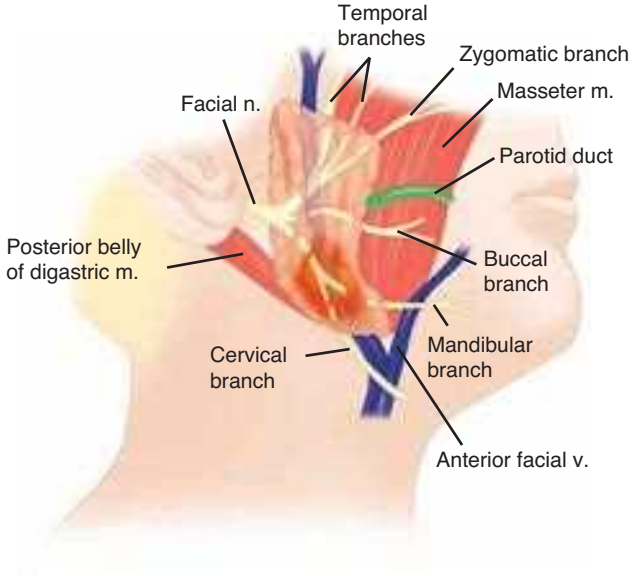

Figure 18-44. Example of a tumor in the parotid with the pattern of the facial nerve and associated anatomy. m. = muscle; n. = nerve; v. = vein.

Minor salivary gland tumors present as painless submucosal masses and are most frequently seen at the junction of the hard and soft palate. Minor salivary gland tumors arising in the prestyloid parapharyngeal space may produce medial displacement of the lateral oropharyngeal wall and tonsil.

The incidence of metastatic spread to cervical lymphatics is variable and depends on the histology, primary site, and stage of the tumor. Parotid gland malignancies can metastasize to the intra- and periglandular nodes. The next echelon of lymphatics for the parotid is the upper jugular nodal chain. Although the risk of lymphatic metastasis is low for most salivary gland malignancies, lesions that are considered high grade or that demonstrate perineural invasion have a higher propensity for regional spread. Tumors arising in patients of advanced age also tend to have more aggressive behavior. Initial nodal drainage for the submandibular gland is the level Ia and Ib lymph nodes and submental nodes followed by the upper and midjugular nodes. Extraglandular extension of tumor and lymph node metastases are adverse prognostic factors for submandibular gland tumors.

Diagnostic imaging is standard for the evaluation of salivary gland tumors. MRI is the most sensitive study to determine soft-tissue extension and involvement of adjacent structures. Unfortunately, imaging studies lack the specificity for differentiating benign and malignant neoplasms. Diagnosis of salivary gland tumors is frequently aided by the use of FNA. In the hands of an experienced cytologist familiar with salivary gland pathology, FNA can provide an accurate preoperative diagnosis in 70% to 80% of cases. This can help the operative surgeon with treatment planning and patient counseling, but should be viewed in the context that a more extensive procedure may be ultimately required. The final histopathologic diagnosis is confirmed by surgical excision.

Benign and malignant tumors of the salivary glands are divided into epithelial, nonepithelial, and metastatic neoplasms. Benign epithelial tumors include pleomorphic adenoma (80%), monomorphic adenoma, Warthin's tumor, oncocytoma, or sebaceous neoplasm. Nonepithelial benign lesions include hemangioma, neural sheath tumor, and lipoma. Treatment of benign neoplasms is surgical excision of the affected gland or, in the case of the parotid, excision of the superficial lobe with facial nerve dissection and preservation. The minimal surgical procedure for neoplasms of the parotid is superficial parotidectomy with preservation of the facial nerve. Enucleation of the tumor mass is not recommended because of the risk of incomplete excision and tumor spillage. Tumor spillage of a pleomorphic adenoma during removal can lead to problematic recurrences.

Malignant epithelial tumors range in aggressiveness from low to high grade. Their behavior depends on tumor histology, degree of invasiveness, and the presence of regional metastasis. The most common malignant epithelial neoplasm of the salivary glands is mucoepidermoid carcinoma. The low-grade mucoepidermoid carcinoma is composed of largely mucin-secreting cells, whereas in high-grade tumors, the epidermoid cells predominate. High-grade mucoepidermoid carcinomas resemble nonkeratinizing squamous cell carcinoma in their histologic features and clinical behavior. Adenoid cystic carcinoma, which has a propensity for neural invasion, is the second most common malignancy in adults. Skip lesions along nerves are common

and can lead to treatment failures because of the difficulty in treating the full extent of invasion. Adenoid cystic carcinomas have a high incidence of distant metastasis, but display indolent growth. It is not uncommon for patients to experience lengthy survival despite the presence of disseminated disease. The most common malignancies in the pediatric population are mucoepidermoid carcinoma and acinic cell carcinoma. For minor salivary glands, the most common malignancies are adenoid cystic carcinoma, mucoepidermoid carcinoma, and low-grade polymorphous adenocarcinoma. Carcinoma ex pleomorphic adenoma is an aggressive malignancy that arises from a preexisting benign mixed tumor.

The primary treatment of salivary malignancies is surgical excision. In this setting, basic surgical principles include the en bloc removal of the involved gland with preservation of all nerves unless directly invaded by tumor. For parotid tumors that arise in the lateral lobe, superficial parotidectomy with preservation of CN VII is indicated. If the tumor extends into the deep lobe of the parotid, a total parotidectomy with nerve preservation is performed. Although malignant tumors may about the facial nerve, if a plane of dissection can be developed without leaving gross tumor, it is preferable to preserve the nerve. If the nerve is encased by tumor (or is noted to be nonfunctional preoperatively) and preservation would result leaving gross residual disease, nerve sacrifice should be considered.

The removal of submandibular malignancies includes en bloc resection of the gland and submental and submandibular lymph nodes. Radical resection is indicated with tumors that invade the mandible, tongue, or floor of mouth. Therapeutic removal of the regional lymphatics is indicated for clinical adenopathy or when the risk of occult regional metastasis exceeds 20%. High-grade mucoepidermoid carcinomas, for example, have a high risk of regional disease and require elective treatment of the regional lymphatics. When gross nerve invasion is found (lingual or hypoglossal), sacrifice of the nerve is indicated with retrograde frozen section biopsy specimens to determine the extent of involvement. If the nerve is invaded at the level of the skull base foramina, a surgical clip may be left in place to mark the area for inclusion in postoperative radiation fields. The presence of skip metastases in the nerve with adenoid cystic carcinoma makes recurrence common with this pathology.

Postoperative radiation treatment plays an important role in the treatment of salivary malignancies. The presence of extraglandular disease, perineural invasion, direct invasion of regional structures, regional metastasis, and high-grade histology are all indications for radiation treatment.

RECONSTRUCTION IN HEAD AND NECK SURGERY

Defects of soft tissue and bony anatomy of the head and neck can occur after oncologic resection. Tumor surgery frequently necessitates removal of structures related to speech and swallowing. Loss of sensation and motor function can produce dysphagia through impairment of food bolus formation, manipulation, and propulsion. Removal of laryngeal, tongue base, and hypopharyngeal tumors can lead to impairment in airway protective reflexes and predispose to aspiration. Cosmetic deformities that result from surgery can also significantly impact the quality of life of a patient. Current surgical management of head and neck tumors requires restoration of form and function through application of contemporary reconstruction techniques.

7▶

Basic principles of reconstruction include attempting to replace resected tissue components (bone, skin, soft tissue) with tissue with similar qualities. However, restoring a patient's functional capacity does not always require strict observation of this rule. The head and neck reconstructive surgeon must consider a patient's preoperative comorbidities and anatomy when constructing a care plan.

A stepladder analogy has been used to describe the escalation in complexity of reconstructive options in the repair of head and neck defects. It is important to remember that the most complex procedure is not always the most appropriate. Progression for closure by secondary intention, primary closure, skin grafts, local flaps, regional flaps, and free-tissue transfer flaps (free flaps) run the gamut of options available. The most appropriate reconstructive technique used is based on the medical condition of the patient, the location and size of the defect to be repaired, and the functional impairment associated with the defect.

Small defects of the skin of the medial canthus, scalp, and nose may be allowed to heal by secondary intention with excellent cosmetic and functional results. When considering primary closure, the excision should be placed in the lines of relaxed skin tension and should attempt to not distort surrounding anatomy such as the hairline, eyelids, or lips.

Skin Grafts

Split and full-thickness skin grafts are used in the head and neck for a variety of defects. Following oral cavity resections, split-thickness grafts can provide adequate reconstruction of the mucosal surface if an adequate vascular tissue bed is available to support the blood supply needed for graft survival. These grafts start to incorporate into the recipient site in approximately 5 days and do not provide replacement of absent soft-tissue bulk; however, they are a simple low morbidity technique for covering mucosal defects that allow for monitoring for local recurrence. Full-thickness grafts are used on the face when local rotational flaps are not available. These grafts have less contracture over time than split-thickness grafts. Grafts can be harvested from the postauricular or supraclavicular areas to maximize the match of skin characteristics. Dermal grafts have been used to provide coverage for exposed vessels in the neck, reconstruct mucosal defects, and assist in providing soft-tissue bulk.

Local Flaps

Local flaps encompass a large number of mainly random-pattern flaps used to reconstruct defects in adjacent areas. It is beyond the scope of this chapter to enumerate all of these flaps, but they should be designed according to the relaxed skin tension lines of the face and neck skin. These lines are tension lines inherent in the facial regions and caused in part by the insertions of muscles of facial animation. Incisions paralleling the relaxed skin tension lines that respect the aesthetic subunits of the face heal with the least amount of tension and camouflage into a more appealing cosmetic result. Poorly designed incisions or flaps result in widened scars and distortion of important aesthetic units.

Regional Flaps

Regional flaps are those that are available as pedicled transfer of soft tissue from areas adjacent to the defect. These flaps have an axial blood supply that traverses the flap longitudinally from proximal to distal between the fascia and subcutaneous tissue. Single-stage reconstruction is possible, and harvest may occur simultaneously with the resection of primary disease resulting in a decrease in overall operative time.

The deltopectoral fasciocutaneous flap is a medially based flap from the anterior chest wall reliant on the perforators of the internal mammary artery. Its pliability permits folding, making it capable for use with reconstruction of pharyngoesophageal defects. A disadvantage is that use of the flap requires a second stage detaching the proximal chest component and completion of insetting approximately 3 to 4 weeks after the original procedure.

Several myocutaneous flaps exist for head and neck reconstruction. The vascular pedicle of these flaps permits a wide arc of rotation, making them ideal for a variety of different reconstructive needs. The trapezius muscle provides a number of soft-tissue flaps that can be rotated to reconstruct a number of defects in the head and neck. The superior trapezius flap is based on paraspinous perforators and is ideal for lateral neck defects. The lateral island trapezius flap, based on the transverse cervical and dorsal scapular vessels, allows for harvest of a soft-tissue paddle below the inferior border of the scapula. This flap is ideal for reconstruction of scalp and lateral skull base defects.

The pectoralis myocutaneous flap is based on the pectoral branch of the thoracoacromial artery (medial) and the lateral thoracic artery (lateral). The latter vessel may be sacrificed to increase the arc of rotation. This workhorse flap includes the pectoralis major muscle, either alone or with overlying anterior chest skin. The pectoralis myocutaneous flap has enjoyed tremendous popularity because of its ease of harvest, the ability to tailor its thickness to the defect, and limited donor site morbidity. It can be used for reconstruction of the oropharynx, oral cavity, and the hypopharynx and in some cases can be tubed to replace cervical esophageal defects. Bulk associated with this flap may make certain applications less practical, and this problem is exacerbated in obese patients. The arc of rotation limits the superior extent of this flap to the zygomatic arch externally and the superior pole of the tonsil internally.

The latissimus dorsi flap provides a large source of soft tissue and has a wide arc of rotation. The flap is based on the thoracodorsal vasculature. This flap can be used as a regional rotational flap or as a free flap. Lateral decubitus positioning is typically required for harvesting this flap, making it less attractive for simultaneous cancer ablation and reconstruction.

Free-Tissue Transfer

Free-tissue transfer with microvascular anastomosis affords the reconstructive surgeon unparalleled ability to replace tissue loss with tissues of similar characteristics. There are a number of donor sites available for various types of flaps, including osteomyocutaneous, myocutaneous, fasciocutaneous, fascial, and myo-osseous flaps. The flaps most popular in head and neck reconstructive armamentarium are those with ease of harvest from a standpoint of patient positioning and those that allow for a two-teamed approach for simultaneous flap harvesting and oncologic resection.[87]

The radial forearm fasciocutaneous flap (Fig. 18-45) is a hardy flap with constant vascular anatomy and a long vascular pedicle, allowing for ease of insetting and choice in anastomotic vascular recipient sites. It is pliable and can be reinnervated as a sensate flap, making it ideal for repair of oral cavity and oropharyngeal defects. It can be tubed to repair hypopharyngeal and upper esophageal defects.[88,89]

The anterolateral thigh flap, based on the descending branch of the lateral circumflex femoral artery, has the capacity for a large pliable skin paddle with muscle that is capable of being tubed and is used to reconstruct similar defects as that of the radial forearm flap while providing more tissue bulk.

The fibular osteocutaneous or osteomyocutaneous flap allows for one-stage reconstruction of resected mandible. In the adult, up to 20 cm of bone can be harvested with a cuff of soleus and flexor hallucis longus muscle for additional soft-tissue bulk. The donor site defect is well tolerated as long as approximately 7 cm of bone are retained proximally and distally for knee and ankle stability.[90]

Iliac crest osteocutaneous flaps are also used for the reconstruction of mandible defects. The natural shape of this donor site bone is similar to the mandibular angle. The thick stock of bone provided by the iliac crest allows for better vertical reconstruction of the mandible while spanning a segmental defect. However, for lengthy mandibular defects (>10 cm), the fibular flap usually is chosen. Additionally, for shorter mandible defects, other free flaps, including osseous components such as scapular and radial forearm flaps, can be used. The scapular flap can provide approximately 12 cm of scapula bone and is based on

Figure 18-45. Radial forearm free flap before harvest from the arm.

the circumflex scapular artery. This flap can be combined with parascapular and scapular skin islands and portions of latissimus dorsi and serratus anterior muscle. The radial forearm osteocutaneous flap can provide a limited quantity of bone with the soft-tissue component of the flap but is associated with an increased risk of donor site fracture.

Large soft-tissue defects can result from trauma, excision of skull base tumors, and tumors involving large segments of skin. Furthermore, after extensive skull base resections in the anterior and lateral skull base, the need for separation of the oropharyngeal and sinonasal tracts from the dura requires soft-tissue interposition between the dura and the contaminated upper aerodigestive tract. The rectus abdominis flap, based on the deep inferior epigastric vessels, provides a large amount of soft tissue and is ideal for closure of wounds of the lateral skull base and dura.

For reconstruction of defects of the hypopharynx and cervical esophagus, both free flaps and regional pedicled flaps are available. The free transfer of a jejunal segment can be performed based on branches of the superior mesenteric artery. Other free flaps used in this area include fasciocutaneous flaps, such as tubed radial forearm flap. The gastric pull-up is a regional flap that is also in use for reconstruction of cervical esophageal defects. The stomach is mobilized and pedicled on the right gastric and gastroepiploic vessels into the defect via tunneling through the thoracic cavity.

TRACHEOSTOMY

Tracheostomy is indicated in the management of patients who require prolonged intubation, access for frequent pulmonary suctioning, and in those patients with neurologic deficits that impair protective airway reflexes. Its use in head and neck surgery is often for the temporary management of the airway in the perioperative period. After surgical resection of oral cavity and oropharyngeal cancers, edema of the upper aerodigestive tract occurs necessitating perioperative tracheostomy to prevent loss of the airway.

The avoidance of prolonged orotracheal and nasotracheal intubation decreases the risk of laryngeal and subglottic injury and potential stenosis, facilitates oral and pulmonary suctioning, and decreases patient discomfort. When the tracheostomy is no longer needed, the tube is removed and closure of the opening usually occurs spontaneously over a 2-week period. Complications of tracheostomy include pneumothorax, RLN injury, tracheal stenosis, wound infection with large-vessel erosion, and failure to close after decannulation. The use of cricothyroidotomy as an alternative to tracheostomy for patients who require prolonged intubation is associated with a higher incidence of vocal cord dysfunction and subglottic stenosis. When cricothyroidotomy is used in the setting of establishing an emergency airway, conversion to a standard tracheostomy should be considered if decannulation is not anticipated within 5 to 7 days.

Placement of a tracheostomy does not obligate a patient to loss of speech. When a large cuffed tracheostomy tube is in place, expecting a patient to be capable of normal speech is impractical. However, after a patient is downsized to an uncuffed tracheostomy tube, intermittent finger occlusion or Passy-Muir valve placement will allow a patient to communicate while still using the tracheostomy to bypass the upper airway. When a patient no longer has the original indication for the tracheostomy and can tolerate capping of the tracheal tube for >24 hours, decannulation is considered safe.

LONG-TERM MANAGEMENT AND REHABILITATION

Palliative Care

For patients with unresectable disease or distant metastases, palliative care options exist. Palliative treatment is aimed at improving a patient's symptoms and may include radiation, chemotherapy, or consultation with a pain specialist. The head and neck surgeon has the options of tracheostomy and gastrostomy tube placement for patients progressing with worsening airway compromise and dysphagia, respectively. Hospice is also an option for patients with a limited short-term outlook; hospice allows a patient to retain dignity at the time of greatest adversity.

Follow-Up Care

Patients diagnosed and treated for a head and neck tumor require follow-up care aimed at monitoring for recurrence and the side effects of therapy. For patients undergoing successful treatment for malignancies of the upper aerodigestive tract, the American Head and Neck Society advocates for follow-up assessment every 1 to 3 months for the first year after treatment, expanding to every 2 to 6 months for years 2 to 4, with an annual follow-up at 5 years posttreatment and thereafter.[91]

In addition to a formal head and neck examination, patients should be questioned about any emerging symptoms related to their primary tumor. New-onset pain, otalgia, and dysphagia are some of the problems that may indicate the need to evaluate further for recurrence. Worsening dysphagia may also be a presenting symptom for a patient developing a pharyngeal stricture. Such a patient may require dilatation and/or placement of a gastrostomy tube for nutrition. Additionally, a number of patients who undergo head and neck radiation will develop hypothyroidism years after treatment. Patients with shoulder dysfunction after surgery should be considered for physical therapy consultation to minimize the long-term effects of their surgical care. Patients with chronic pain-related issues can benefit from consultation with a pain specialist to construct a treatment regimen to provide adequate control of long-term discomfort. Long-term follow-up with a dentist experienced in caring for patients with a history of therapeutic radiation therapy is vital if prevention of osteoradionecrosis is to be achieved.

chapter 19

Chest Wall, Lung, Mediastinum, and Pleura

Katie S. Nason, Michael A. Maddaus, and James D. Luketich

TRACHEA

Anatomy

The trachea is composed of cartilaginous and membranous portions, beginning with the cricoid cartilage, the first complete cartilaginous ring of the airway. The cricoid cartilage consists of an anterior arch and a posterior broad-based plate. Articulating with the posterior cricoid plate are the arytenoid cartilages. The vocal cords originate from the arytenoid cartilages and then attach to the thyroid cartilage. The subglottic space, the narrowest part of the trachea with an internal diameter of approximately 2 cm, begins at the inferior surface of the vocal cords and extends to the first tracheal ring. The remainder of the distal trachea is 10.0 to 13.0 cm long, consists of 18 to 22 rings, and has an internal diameter of 2.3 cm (Fig. 19-1).[1] Bronchoscopically, the tracheal rings are visible as C-shaped hyaline cartilaginous structures that provide rigidity to the anterior and lateral tracheal walls. The open ends of the C-rings are connected by the trachealis smooth muscle and encased in a dense band of connective tissue called perichondrium. The first tracheal ring is attached directly to the cricoid cartilage; there are approximately two rings for every 1 cm of tracheal length.

The tracheal blood supply, which includes the inferior thyroid, subclavian, supreme intercostal, internal thoracic, innominate, and superior and middle bronchial arteries, enters the airway near the junction of the membranous and cartilaginous portions (Fig. 19-2). Each arterial branch supplies a segment of 1.0 to 2.0 cm, thereby limiting circumferential mobilization to that same distance. The vessels are interconnected along the lateral surface of the trachea by an important longitudinal vascular anastomosis that feeds transverse segmental vessels to the soft tissues between the cartilages.

Tracheal Injury

Tracheal injury can result from a variety of causes, including inhalation of smoke or toxic fumes, aspiration of liquids or solid objects, endotracheal intubation, blunt and penetrating trauma, and iatrogenic injury during operative procedures. Early diagnosis is critical to avoid subsequent complications, including respiratory infection and tracheal stenosis. Management of smoke or toxic fume inhalation and liquid aspiration is commonly supportive; use of antibiotics, respiratory support, and airway clearance with flexible bronchoscopy is dictated by the patient's condition. In rare circumstances, extracorporeal membrane oxygenation is required if there is associated injury to the more distal airways and lung parenchyma.

Despite ubiquitous use of high-volume–low-pressure cuffs, overinflation of the endotracheal cuff is the most common

Key Points

1. Historically, non-small cell cancer (NSCLC) subtypes were considered to be a uniform group based on limited understanding of the distinct clinical behaviors of the subtypes as well as the fact that there were few treatment options available. With increasing understanding of the molecular biology underlying these tumor subtypes, however, the approach to diagnosis and management and the terminology used in describing these tumors are evolving rapidly. In particular, the evaluation and management of adenocarcinoma of the lung has shifted dramatically and firm establishment of NSCLC cell type prior to chemotherapy for advanced stage lung cancer is essential.
2. A multidisciplinary approach to evaluation of NSCLC, with standardized criteria and terminology for diagnosis in cytologic and small biopsy specimens, and routine molecular testing for known mutations, such as *EGFR* mutations and *EML4-ALK* fusion oncogenes is now recommended for the evaluation and management of lung nodules due to major advances in targeted therapy. Adequate tissue acquisition at the time of diagnostic workup is critical and facilitates patient care while minimizing the number of procedures to which the patient is subjected.
3. The terms *bronchioloalveolar carcinoma* and *mixed subtype adenocarcinoma* have been eliminated from the classification of lung adenocarcinoma as a result of increased understanding of important clinical, radiologic, pathologic, and genetic differences between mucinous and nonmucinous adenocarcinomas, The new classification system delineated a stepwise pathologic progression, from AAH to invasive adenocarcinoma based on the predominant histologic growth patterns.
4. Lung cancer continues to be a highly lethal and extremely common cancer, with 5-year survival of 16%. Lung cancer incidence is second only to the incidence of prostate cancer in men and breast cancer in women. Squamous cell carcinoma and adenocarcinoma of the lung are the most common subtypes and are rarely found in the absence of a smoking history. Nonsmokers who live with smokers have a 24% increased risk of lung cancer compared to nonsmokers who do not live with smokers.
5. Navigational bronchoscopy is a valuable new tool that can be used to obtain tissue diagnosis for intraparenchymal lesions or small, peripherally located lesions that have historically been difficult to biopsy with transbronchial or transthoracic approaches. It is also a useful tool for tattooing the lung lesion for subsequent operative resection and for placement of fiducial markers for stereotactic body radiation. This technique should become part of the surgeon's armamentarium for the diagnosis and treatment of lung cancer.
6. Impaired exchange of carbon monoxide is associated with a significant increase in the risk of postoperative pulmonary complications, independent of the patient's smoking history. In patients undergoing pulmonary resection, the risk of any pulmonary complication increases by 42% for every 10% decline in the percent carbon monoxide diffusion capacity (%DLCO), and this measure may be a useful parameter in risk stratification of patients for surgery.
7. Maximum oxygen consumption ($\dot{V}O_2$ max) values provide important additional information in those patients with severely impaired DLCO and forced expiratory volume in 1 second. Values of <10 mL/kg per minute generally prohibit any major pulmonary resection, because the mortality in patients with these levels is 26% compared with only 8.3% in patients whose is ≥10 mL/kg per minute; values of >15 mL/kg per minute generally indicate the patient's ability to tolerate pneumonectomy.
8. The assessment of patient risk before thoracic resection is based on clinical judgment and data.
9. Tumor ablative strategies are viable alternatives to surgical resection for early stage lung cancer in inoperable patients. While premature, ablative techniques may ultimately be shown to have efficacy equivalent to lobectomy for the primary treatment of very small peripheral early-stage lung cancers and become primary therapy, even in operable patients. Multidisciplinary collaboration between thoracic surgery, interventional radiology/pulmonology, and radiation oncology is required to ensure that development of these ablative techniques occurs through properly designed and well-controlled prospective studies and will ensure that patients receive the best available therapy, regardless of whether it is surgical resection or ablative therapy.
10. Increasing evidence suggests a significant role for gastroesophageal reflux disease in the pathogenesis of chronic lung diseases such as bronchiectasis and idiopathic pulmonary fibrosis, and it may also contribute to bronchiolitis obliterans syndrome in lung transplant patients.
11. Treatment of pulmonary aspergilloma is individualized. Asymptomatic patients can be observed without any additional therapy. Similarly, mild hemoptysis, which is not life-threatening, can be managed with medical therapy, including antifungals and cough suppressant. Amphotericin B is the drug of choice, although voriconazole has recently been used for treatment of aspergillosis, with fewer side effects and equivalent efficacy. Massive hemoptysis had traditionally been an indication for urgent or emergent operative intervention. However, with the advancement of endovascular techniques, bronchial artery embolization in select centers with experience in these techniques has been effective.
12. In patients with malignant pleural effusion, poor expansion of the lung (because of entrapment by tumor or adhesions) generally predicts a poor result with pleurodesis and is the primary indication for placement of indwelling pleural catheters. These catheters have dramatically changed the management of end-stage cancer treatment because they substantially shorten the amount of time patients spend in the hospital during their final weeks of life.

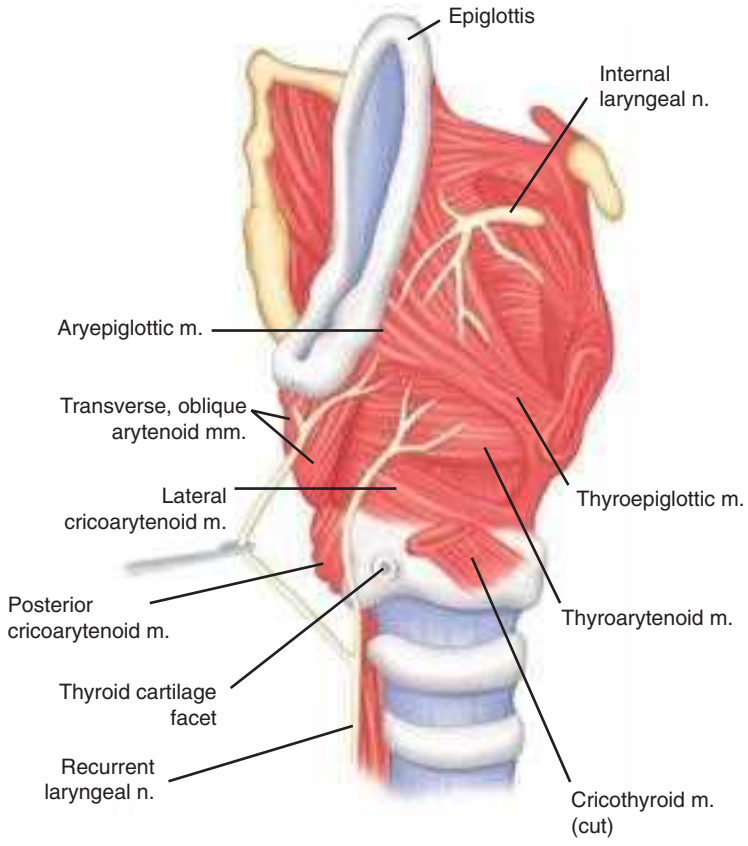

Figure 19-1. Anatomy of the larynx and upper trachea. m. = muscle; n. = nerve.

cause of injury secondary to endotracheal intubation. High cuff pressures can cause ischemia of the contiguous airway wall in as short as 4 hours. Prolonged overinflation can lead to scarring and stenosis; full-thickness injury can result in fistulae between the innominate artery anteriorly and the esophagus posteriorly. Avoidance requires careful cuff management to keep pressures as low as possible; in circumstances of prolonged ventilatory support and high airway pressure, cuff pressure monitoring (to maintain pressures <20 mmHg) is advisable.

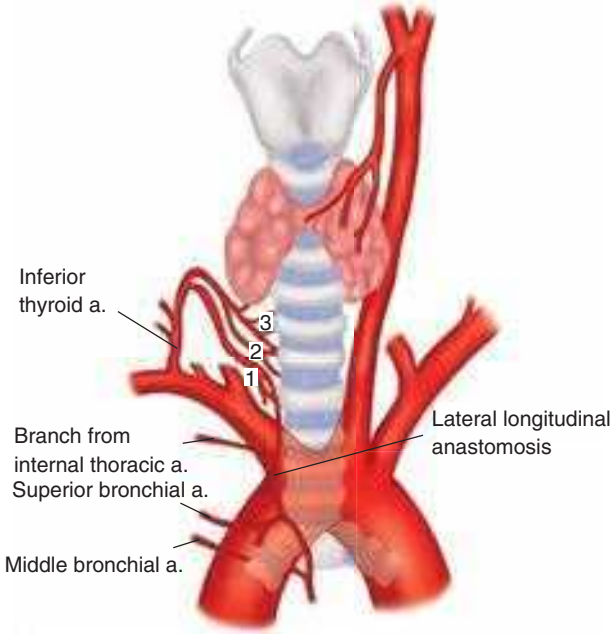

Figure 19-2. Arterial blood supply to the larynx and upper trachea. a. = artery.

Historically, clinically significant tracheal stenosis after tracheostomy occurred in 3% to 12% of cases, with severe stenosis in 1% to 2%.[2] With the use of low-pressure cuffs, the estimated incidence has decreased to 4.9 cases per million patients per year.[3] Intubation-related risk factors include: prolonged intubation; high tracheostomy through the first tracheal ring or cricothyroid membrane; transverse rather than vertical incision on the trachea; oversized tracheostomy tube; prior tracheostomy or intubation; and traumatic intubation. Stenosis is also more common in older patients, in females, after radiation, or after excessive corticosteroid therapy, and in the setting of concomitant diseases such as autoimmune disorders, severe reflux disease, or obstructive sleep apnea and the setting of severe respiratory failure. However, even a properly placed tracheostomy can lead to tracheal stenosis because of scarring and local injury. Mild ulceration and stenosis are frequently seen after tracheostomy removal. Use of the smallest tracheostomy tube possible, rapid downsizing, and a vertical tracheal incision minimize the risk for posttracheostomy stenosis.

Stridor and dyspnea on exertion are the primary symptoms of tracheal stenosis. In the setting of postintubation injury, a significant portion of the cartilaginous structural support to the airway is destroyed by regional ischemic necrosis; during healing, a web-like fibrous growth develops and narrows the airway (Fig. 19-3). In contrast, stenosis caused by tracheostomy is most commonly due to an excess of granulation tissue formation around the tracheal stoma site. Time to onset of symptoms after extubation or tracheostomy decannulation usually ranges from 2 to 12 weeks, but symptoms can appear immediately or as long

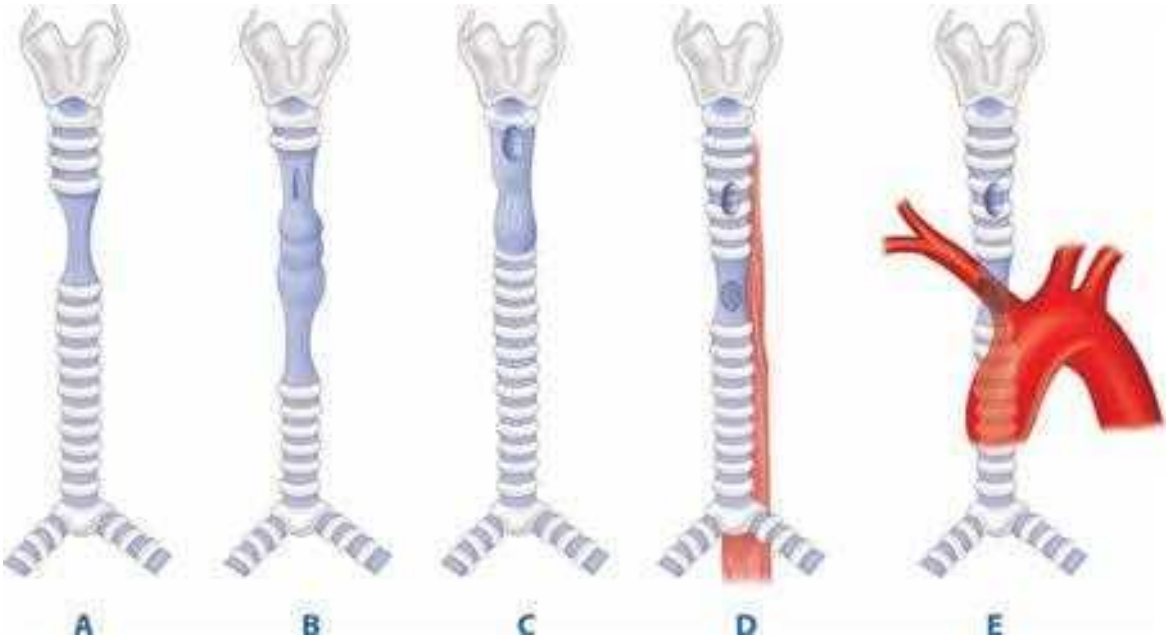

Figure 19-3. Diagram of the principal postintubation lesions. **A.** A circumferential lesion at the cuff site after the use of an endotracheal tube. **B.** Potential lesions after the use of tracheostomy tubes. Anterolateral stenosis can be seen at the stomal level. Circumferential stenosis can be seen at the cuff level (lower than with an endotracheal tube). The segment in between is often inflamed and malacotic. **C.** Damage to the subglottic larynx. **D.** Tracheoesophageal fistula occurring at the level of the tracheostomy cuff; circumferential damage is usual at this level. **E.** Tracheoinnominate artery fistula. *(Adapted with permission from Grillo H. Surgical treatment of postintubation tracheal injuries.* J Thorac Cardiovasc Surg. *1979;78:860. Copyright Elsevier)*

as 1 to 2 years later. Frequently, patients are misdiagnosed as having asthma or bronchitis, and treatment for such illnesses can persist for some time before the correct diagnosis is discovered. Generally, symptom intensity is related to the degree of stenosis and to the patient's underlying pulmonary disease.

Acute Management. A comprehensive bronchoscopic evaluation is critical in the initial phase of evaluation. Stenosis length, location, distance between the vocal cords and proximal stenosis, and distance from the distal aspect to the major carina must be documented. In patients with severe stenosis and respiratory compromise, rigid bronchoscopy can be used to dilate the stenosis; this provides immediate relief of the airway obstruction and facilitates thorough evaluation of the stenosis. Rarely, if ever, is tracheostomy necessary.

Most intubation injuries are located in the upper third of the trachea and can be accessed for resection through a collar incision. Resection typically involves 2 to 4 cm of trachea for benign stenosis. It is critical to fully resect all inflamed and scarred tissue. However, a primary anastomosis can still be performed without undue tension, even if up to one half of the trachea requires resection.[2] Ideally, the patient is extubated in the operating room or shortly thereafter. For patients in whom tracheal resection is not possible, such as patients with significant comorbidities or with an excessively long stenosis, endotracheal stenting, typically silicone T-tubes, can provide palliation. Wire mesh stents should not be used, given their known propensity to erode through the wall of the airway. Balloon dilation, laser ablation, and tracheoplasty have also been described, although the efficacy is marginal.

Tracheal replacement is evolving as an option for management of tracheal stenosis as bioengineering techniques for decellularizing donor trachea have been developed. This removes all antigens against which the recipient immune system might react and enables use of the donor trachea scaffolding without risk of rejection. Following decellularization, the donor tracheal scaffolding is seeded with recipient chondrocytes, to restore tracheal rigidity, and with recipient epithelial cells, to recreate the inner epithelial lining. Several case reports of successful allogeneic tracheal transplantation have been published, but the technique continues to be limited to a few highly specialized centers. This is due, in part, to the scarcity of donor trachea and the need for tissue bioengineering expertise. Current efforts are focused on creation of biosynthetic scaffolding that can be used instead of donor trachea. This would substantially increase the availability of the tracheal replacement material and enable widespread use of the technique.

Tracheal Fistulas

Tracheoinnominate Artery Fistula. Tracheoinnominate artery fistula has two main causes: low placement of a tracheostomy and hyperinflation of the tracheal cuff. Tracheostomy placement should be through the second to fourth tracheal rings without reference to the location of the sternal notch. When placed below the fourth tracheal ring, the inner curve of the tracheostomy cannula will be positioned to exert pressure on the posterior aspect of the innominate artery, leading to arterial erosion. Similarly, the tracheal cuff, when hyperinflated, will cause ischemic injury to the anterior airway and subsequent erosion into the artery. Most cuff-induced fistulas will develop within 2 weeks after placement of the tracheostomy.

Clinically, tracheoinnominate artery fistulas present with bleeding. A premonitory hemorrhage often occurs and, although it is usually not massive, must not be ignored or simply attributed to general airway irritation or wound bleeding. With significant

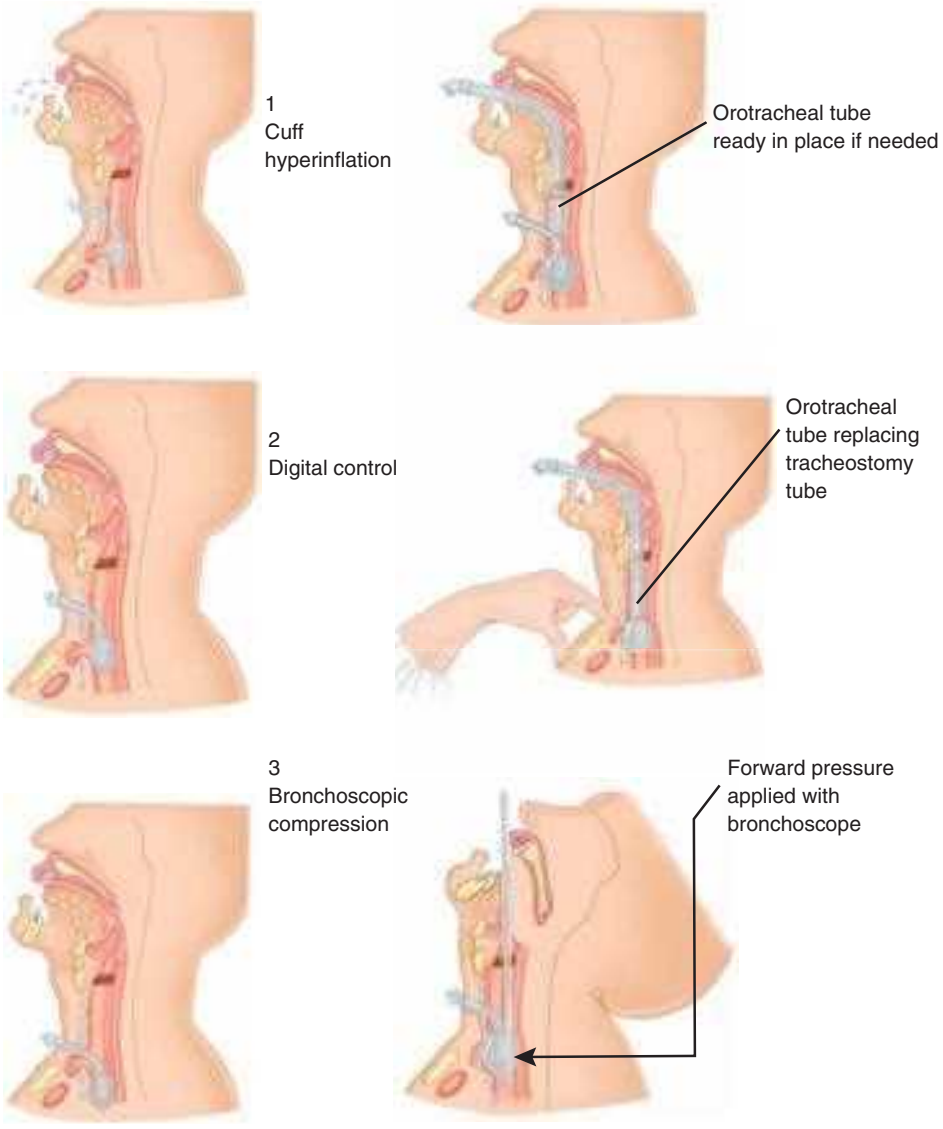

Figure 19-4. Steps in the emergency management of a tracheoinnominate artery fistula.

bleeding, the tracheostomy cuff can be hyperinflated to temporarily occlude the arterial injury. If such an effort is unsuccessful, the tracheostomy incision should be immediately opened widely and a finger inserted to compress the artery against the manubrium (Fig. 19-4). The patient can then be orally intubated, and the airway suctioned free of blood. Emergent surgical resection of the involved segment of artery is performed, usually without reconstruction.

Tracheoesophageal Fistula. Tracheoesophageal fistulas (TEFs) occur primarily in patients receiving prolonged mechanical ventilatory support concomitant with an indwelling nasogastric tube.[4] Cuff compression of the membranous trachea against the nasogastric tube leads to airway and esophageal injury and fistula development. Clinically, airway suctioning reveals saliva, gastric contents, or tube feedings. Gastric insufflation, secondary to positive pressure ventilation, can occur. Bronchoscopy is diagnostic; with the bronchoscope inserted, the endotracheal tube is withdrawn and the fistula at the cuff site is exposed. Alternatively, esophagoscopy demonstrates the cuff of the endotracheal tube in the esophagus.

Treatment, first and foremost, requires removing tubes from the esophagus and weaning the patient from the ventilator. The cuff of the endotracheal tube should be placed below the fistula, avoiding overinflation. To minimize aspiration, a gastrostomy tube should be placed for gastric decompression (to prevent reflux) and a jejunostomy tube for feeding. If aspiration persists, esophageal diversion with cervical esophagostomy can be performed. Once weaned from the ventilator, tracheal resection and primary anastomosis, repair of the esophageal defect, and interposition of a muscle flap between the trachea and esophagus can be performed (Fig. 19-5).[5]

Tracheal Neoplasms

Although extremely rare, the most common primary tracheal neoplasms are squamous cell carcinomas (related to smoking) and adenoid cystic carcinomas. Clinically, tracheal tumors present with cough, dyspnea, hemoptysis, stridor, or symptoms of invasion of contiguous structures (such as the recurrent laryngeal nerve or the esophagus). The most common radiologic finding of tracheal malignancy is tracheal stenosis, but is found in only 50% of cases. With tumors other than squamous cell carcinomas, symptoms may persist for months because of slow tumor growth rates. Stage of presentation is advanced, with approximately 50% of patients presenting with stage IV disease.

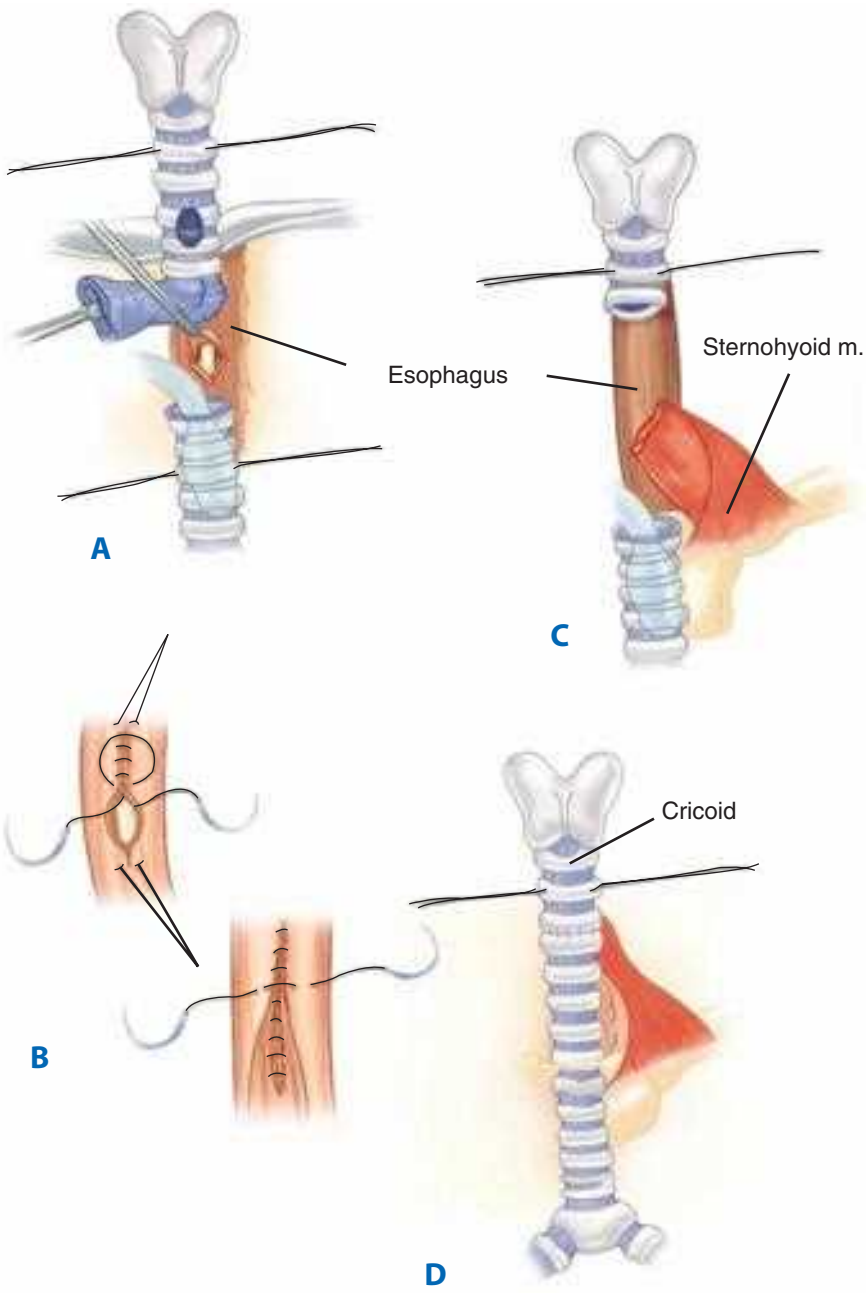

Figure 19-5. Single-stage operation for closure of a tracheoesophageal fistula and tracheal resection. **A.** The fistula is divided and the trachea is transected below the level of damage. **B.** The fistula is closed on the tracheal side in a single layer and the esophageal side in a double layer. The damaged trachea segment is resected. **C.** View of completed tracheal anastomosis. m. = muscle.

Five-year survival for all tracheal neoplasms is 40% but falls to 15% for those with stage IV disease.[6]

Squamous cell carcinomas often present with regional lymph node metastases and are frequently unresectable at presentation. Their biologic behavior is similar to that of squamous cell carcinoma of the lung. Adenoid cystic carcinomas, a type of salivary gland tumor, are generally slow-growing, spread submucosally, and tend to infiltrate along nerve sheaths and within the tracheal wall. Although indolent in nature, adenoid cystic carcinomas are malignant and can spread to regional lymph nodes, lung, and bone. Squamous cell carcinoma and adenoid cystic carcinomas represent approximately 65% of all tracheal neoplasms. The remaining 35% is comprised of small cell carcinomas, mucoepidermoid carcinomas, adenocarcinomas, lymphomas, and others.[7]

Therapy. Evaluation and treatment of patients with tracheal tumors should include neck and chest computed tomography (CT) and rigid bronchoscopy. Rigid bronchoscopy permits general assessment of the airway and tumor; it also allows debridement or laser ablation of the tumor to provide relief of dyspnea. If the tumor is judged to be completely resectable, primary resection and anastomosis is the treatment of choice for these tumors (Fig. 19-6). Up to 50% of the length of the trachea can be resected with primary anastomosis. In most tracheal resections, anterolateral tracheal mobilization and suturing of the chin to the sternum for 7 days are done routinely. Use of laryngeal and hilar release is determined at the time of surgery, based on the surgeon's judgment of the degree of tension present. For longer resections, specialized maneuvers are necessary such as laryngeal release and right hilar release to minimize tension on the anastomosis.

Postoperative mortality, which occurs in up to 10% of patients, is associated with the length of tracheal resection, use of laryngeal release, the type of resection, and the histologic

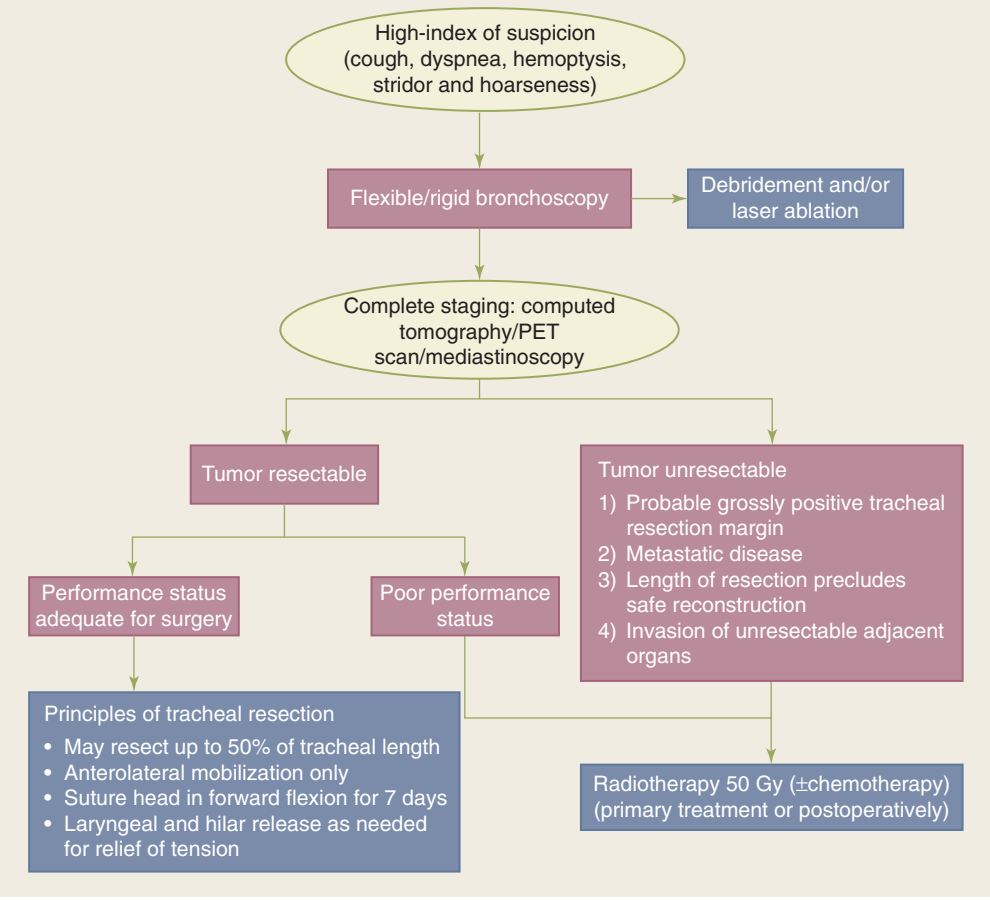

Figure 19-6. Algorithm for evaluation and treatment of tracheal neoplasm. PET = positron emission tomography.

type of the cancer. Factors associated with improved long-term survival include complete resection and use of radiation as adjuvant therapy in the setting of incomplete resection.[8] Due to their radiosensitivity, radiotherapy is frequently given postoperatively after resection of both adenoid cystic carcinomas and squamous cell carcinomas.[9] A dose of 50 Gy or greater is usual. Nodal positivity does not seem to be associated with worse survival. Survival at 5 and 10 years is much better for adenoid cystic (73% and 57%, respectively) than for tracheal cancers (47% and 36%, respectively; $P < .05$). For patients with unresectable tumors, radiation may be given as the primary therapy to improve local control, but is rarely curative. For recurrent airway compromise, stenting or laser therapies should be considered part of the treatment algorithm.

LUNG

Anatomy

Segmental Anatomy. The segmental bronchial and vascular anatomy of the lungs allows subsegmental and segmental resections, if the clinical situation requires it or if lung tissue can be preserved[10] (Fig. 19-7). Note the continuity of the pulmonary parenchyma between adjacent segments of each lobe.

Lymphatic Drainage. Lymph nodes that drain the lungs are divided into two groups according to the tumor-node-metastasis (TNM) staging system for lung cancer: the pulmonary lymph nodes (N1) and the mediastinal nodes (N2) (Fig. 19-8).

The N1 lymph nodes constitute the following: (a) intrapulmonary or segmental nodes that lie at points of division of segmental bronchi or in the bifurcations of the pulmonary artery; (b) lobar nodes that lie along the upper, middle, and lower lobe bronchi; (c) interlobar nodes located in the angles formed by the main bronchi bifurcating into the lobar bronchi; and (d) hilar nodes along the main bronchi. The interlobar lymph nodes lie in the depths of the interlobar fissure on each side and constitute a lymphatic sump for each lung, referred to as the *lymphatic sump of Borrie*; all of the pulmonary lobes of the corresponding lung drain into this group of nodes (Fig. 19-9). On the right, the nodes of the lymphatic sump lie around the bronchus intermedius (bounded above by the right upper lobe bronchus and below by the middle lobe and superior segmental bronchi). On the left, the lymphatic sump is confined to the interlobar fissure, with the lymph nodes in the angle between the lingular and lower lobe bronchi and in apposition to the pulmonary artery branches.

The N2 lymph nodes consist of four main groups. (a) The anterior mediastinal nodes are located in association with the upper surface of the pericardium, the phrenic nerves, the ligamentum arteriosum, and the left innominate vein. (b) The posterior mediastinal group includes paraesophageal lymph nodes within the inferior pulmonary ligament and, more superiorly, between the esophagus and trachea near the arch of the azygos vein. (c) The tracheobronchial lymph nodes are made up of three subgroups that are located near the bifurcation of the trachea. These include the subcarinal nodes, which lie in the obtuse angle between the trachea and each main stem bronchus, and the nodes that lay anterior to the lower end of the trachea. (d) Paratracheal lymph nodes are located in proximity to the

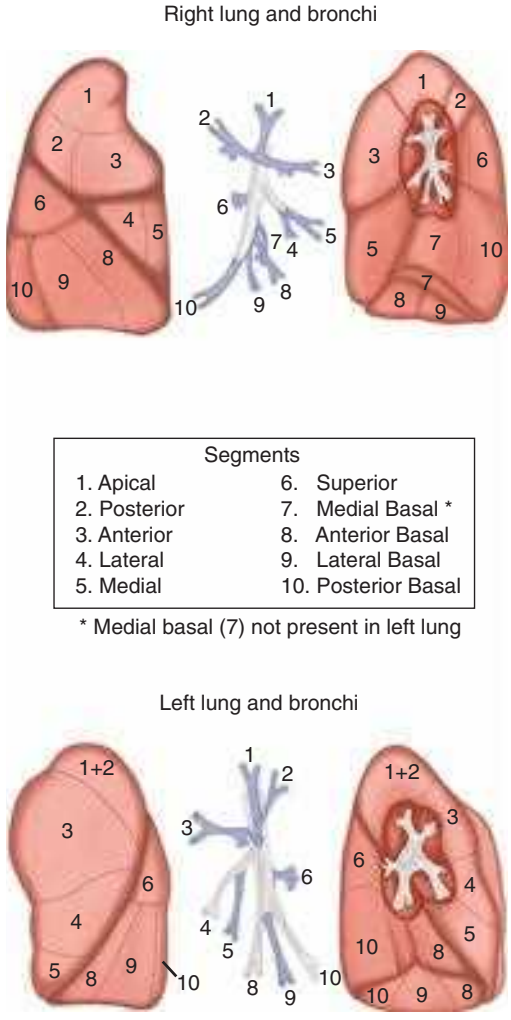

Figure 19-7. Segmental anatomy of the lungs and bronchi.

trachea in the superior mediastinum. Those on the right side form a chain with the tracheobronchial nodes inferiorly and with some of the deep cervical nodes above (scalene lymph nodes).

Lymphatic drainage to the mediastinal lymph nodes from the right lung is ipsilateral, except for occasional bilateral drainage to the superior mediastinum. In contrast, in the left lung, particularly the left lower lobe, lymphatic drainage occurs with equal frequency to ipsilateral and contralateral superior mediastinal nodes.

Normal Lung Histology

The lung can be conveniently viewed as two linked components: the tracheobronchial tree (or conducting airways component) and the alveolar spaces (or gas exchange component). The tracheobronchial tree consists of approximately 23 airway divisions to the level of the alveoli. It includes the main bronchi, lobar bronchi, segmental bronchi (to designated bronchopulmonary segments), and terminal bronchioles (i.e., the smallest airways still lined by bronchial epithelium and without alveoli). The tracheobronchial tree is normally lined by pseudostratified ciliated columnar cells and mucous (or goblet) cells, which both derive from basal cells (Fig. 19-10). Ciliated cells predominate. Goblet cells, which release mucus, can significantly increase in number in acute bronchial injury, such as exposure to cigarette smoke. The normal bronchial epithelium also contains bronchial submucosal glands, which are mixed salivary-type glands containing mucous cells, serous cells, and neuroendocrine cells called Kulchitsky cells, which are also found within the surface epithelium. The bronchial submucosal glands can give rise to salivary gland–type tumors, including mucoepidermoid carcinomas and adenoid cystic carcinomas.

Two cell types, called type I and type II pneumocytes, make up the alveolar epithelium. Type I pneumocytes comprise 40% of the total number of alveolar epithelial cells, but cover 95% of the surface area of the alveolar wall. These cells are not

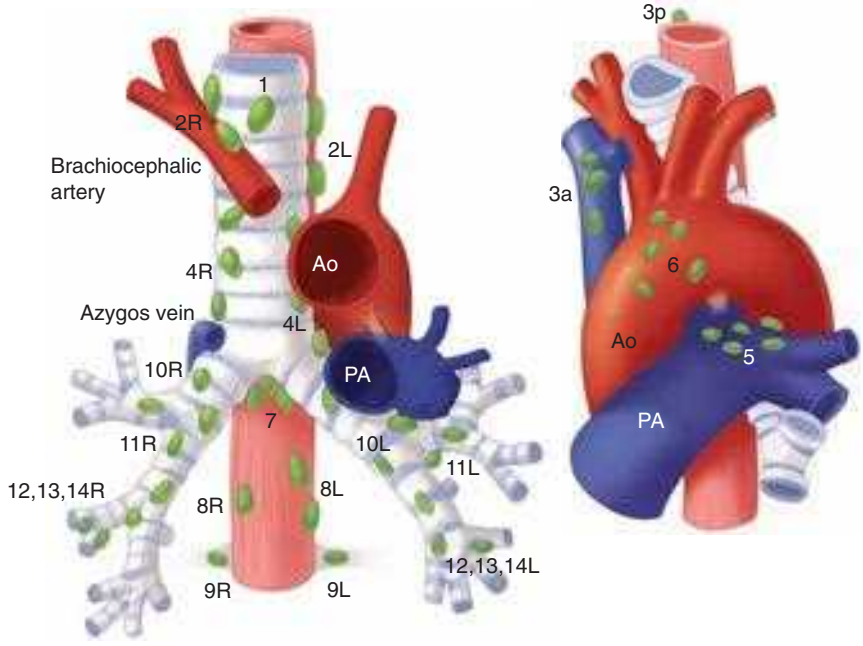

Figure 19-8. The location of regional lymph node stations for lung cancer. *(Reproduced with permission from Mountain CF, Dresler CM. Regional lymph node classification for lung cancer staging.* Chest. *1997;111:1718.)*

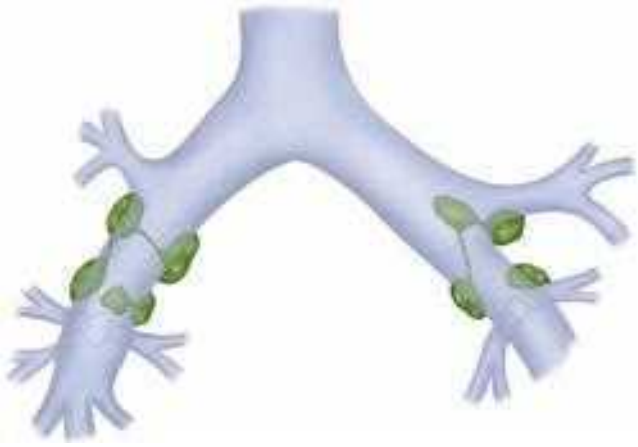

Figure 19-9. The lymphatic sump of Borrie includes the groups of lymph nodes that receive lymphatic drainage from all pulmonary lobes of the corresponding lung.

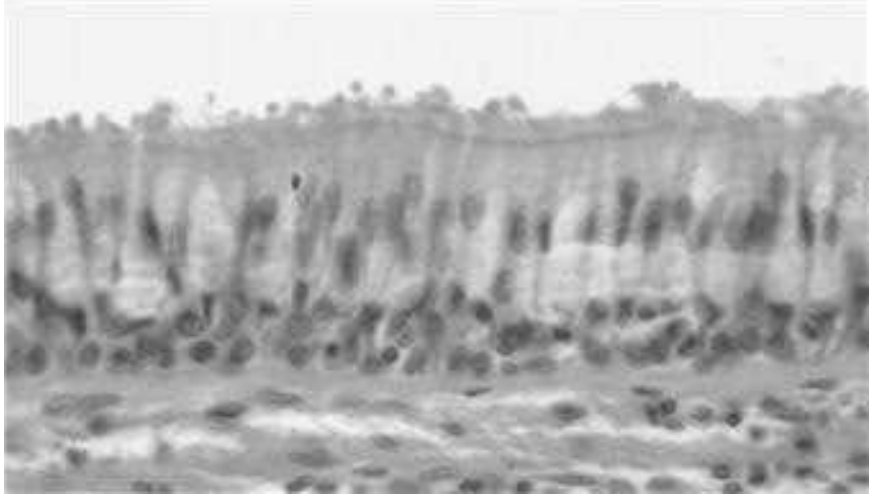
capable of regeneration because they have no mitotic potential. Type II pneumocytes cover only 3% of the alveolar surface, but comprise 60% of the alveolar epithelial cells. In addition, clusters of neuroendocrine cells are seen in the alveolar spaces.

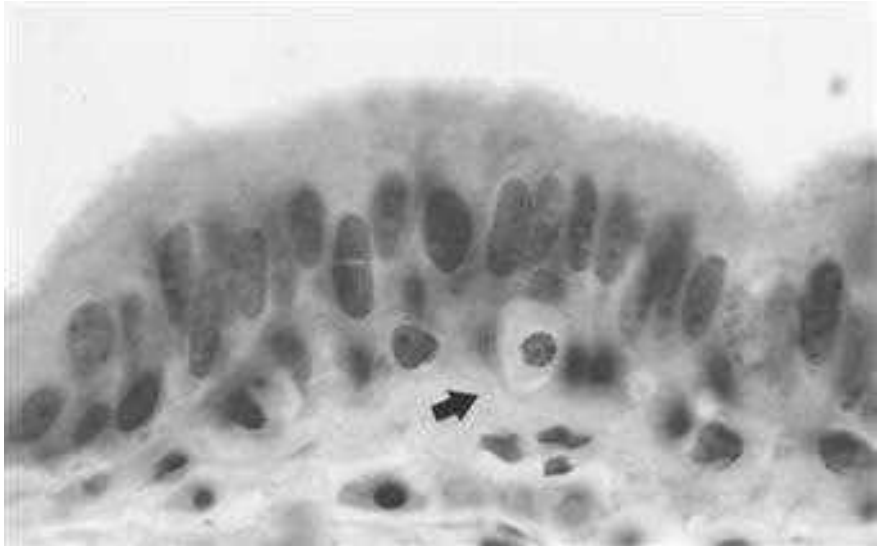
Preinvasive Lesions

The term "precancerous" does not mean that an inevitable progression to invasive carcinoma will occur, but such lesions, particularly those with high-grade dysplasia,[11,12] do constitute a clear marker for potential development of invasive cancer. Three precancerous lesions of the respiratory tract are currently recognized.

1. **Squamous dysplasia and carcinoma in situ.** Cigarette smoke can induce a transformation of the tracheobronchial pseudostratified epithelium to metaplastic squamous mucosa, with subsequent evolution to dysplasia as cellular abnormalities accumulate. Dysplastic changes include



A



B

Figure 19-10. Normal lung histology. **A.** Pseudostratified ciliated columnar cells and mucous cells normally line the tracheobronchial tree. **B.** A Kulchitsky cell is depicted (*arrow*).

altered cellular polarity and increased cell size, number of cell layers, nuclear-to-cytoplasmic ratio, and number of mitoses. Gradations are considered mild, moderate, or severe. Carcinoma in situ represents carcinoma still confined by the basement membrane.

2. **Atypical adenomatous hyperplasia (AAH).** AAH is a lesion smaller than 5.0 mm, comprising epithelial cells lining the alveoli that are similar to type II pneumocytes. Histologically, AAH is similar to adenocarcinoma in situ; it represents the beginning stage of a stepwise evolution to adenocarcinoma in situ and then to adenocarcinoma. With the availability of thin-section CT, it is possible to detect preinvasive adenocarcinoma lesions as early as AAH. These lesions can be multiple, are typically small (5 mm or less), and have a ground-glass appearance.
3. **Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia.** This rare lesion represents a diffuse proliferation of neuroendocrine cells, but without invasion of the basement membrane. It can exist as a diffuse increase in the number of single neuroendocrine cells, or as small lesions less than 5.0 mm in diameter. Lesions over 5.0 mm in size or that breach the basement membrane are carcinoid tumors.

Invasive or Malignant Lesions

The pathologic diagnosis of lung cancer is currently based on light microscopic criteria and is broadly divided into two main groups: *non–small cell lung carcinoma* and neuroendocrine tumors.[13] Immunohistochemical staining and electron microscopy are used as adjuncts in diagnosis, particularly in the assessment of potential neuroendocrine tumors.

Non–Small Cell Lung Carcinoma. The term *non–small cell lung carcinoma (NSCLC)* includes many tumor cell types, including large cell, squamous cell, and adenocarcinoma. Historically, these subtypes were considered to be a uniform group based on limited understanding of the distinct clinical behaviors of the subtypes as well as the fact that there were few treatment options available. With increasing understanding of the molecular biology underlying these tumor subtypes, however, the approach to diagnosis and management and the terminology used in describing these tumors are evolving rapidly.

Adenocarcinoma. The incidence of adenocarcinoma has increased over the last several decades, and it is now the most common lung cancer, accounting for 30% of lung cancers in male smokers and 40% of lung cancers in female smokers. Adenocarcinoma is the histologic subtype for 80% and 60% of lung cancers in nonsmoking females and males, respectively. It occurs more frequently in females than in males. It is the most frequent histologic subtype in women, patients who are under 45 years of age, and Asian populations.[14]

Histologic Subtyping of Adenocarcinoma. Increasing understanding of lung adenocarcinoma, such as important clinical, radiologic, pathologic, and genetic differences between mucinous and nonmucinous adenocarcinomas, prompted multiple changes in the classification system in 2011.[15] Based on consensus, the international working group proposed a multidisciplinary approach, with standardized criteria and terminology for diagnosis in cytologic and small biopsy specimens, and routine molecular testing for known mutations, such as *EGFR* and *KRAS* mutations (Table 19-1). The new classification system delineated a stepwise pathlogic progression, from AAH to invasive adenocarcinoma based on the predominant histologic growth patterns; the terms *bronchioloalveolar carcinoma* and *mixed subtype adenocarcinoma* were eliminated in favor of more biologically driven classification (Table 19-2).

Table 19-1

Difference between invasive mucinous adenocarcinoma and nonmucinous adenocarcinoma in situ/minimally invasive adenocarcinoma/lepidic predominant adenocarcinoma

	INVASIVE MUCINOUS ADENOCARCINOMA (FORMERLY MUCINOUS BAC)	NONMUCINOUS AIS/MIA/LPA (FORMERLY NONMUCINOUS BAC)
Female	49/84 (58%)[52,120–123]	101/140 (72%)[52,120–123]
Smoker	39/87 (45%)[52,120–122,124]	75/164 (46%)[52,120–122,124]
Radiographic appearance	Majority consolidation; air bronchogram[125]	Majority ground-glass attenuation[23,56,58,103,129–134]
	Frequent multifocal and multilobar presentation[56,125–128]	
Cell type	Mucin-filled, columnar, and/or goblet[50–52,125,135]	Type II pneumocyte and/or Clara cell[50–52,125,135]
Phenotype		
CK7	Mostly positive (~88%)[a54,55,136–139]	Positive (~98%)[a54,55,136–139]
CK20	Positive (~54%)[a54,55,136–139]	Negative (~5%)[a54,55,136–139]
TTF-1	Mostly negative (~17%)1 [a54,55,120,137–139]	Positive (~67%)[a54,55,120,137–139]
Genotype		
KRAS mutation	Frequent (~76%)[a55,94,121,127,140–144]	Some (~13%)[a55,121,127,140–144]
EGFR mutation	Almost none (~3)[a55,121,127,140–142]	Frequent (~45%)[a55,121,127,140–142]

BAC = bronchioloalveolar carcinoma; IASLC = International Association for the Study of Lung Cancer; ATS = American Thoracic Society; ERS = European Respiratory Society.

1. **Adenocarcinoma in situ (AIS).** AISs are small (≤3 cm) solitary adenocarcinomas that have pure lepidic growth; lepidic growth is characterized by tumor growth within the alveolar spaces. These lesions are not invasive into the stroma, vascular system, or pleura and do not have papillary or micropapillary patterns or intra-alveolar tumor cells. They are very rarely mucinous, consisting of type II pneumocytes or Clara cells. These patients are expected to have 100% disease-specific survival with complete surgical resection. On CT scan, AIS can appear as a pure ground-glass neoplasm, but occasionally will present as part of a solid or part-solid nodule. Mucinous AIS is more likely to appear solid or to have the appearance of consolidation. As with AAH, the lesions can be single or multiple; the ground-glass changes in AIS, however, tend to have a higher attenuation compared to AAH.
2. **Minimally invasive adenocarcinoma (MIA).** In the same size solitary lesion, if less than 5 mm of invasion are noted within a predominantly lepidic growth pattern, the lesion is termed *minimally invasive adenocarcinoma (MIA)* to indicate a patient group with near 100% survival when the lesion is completely resected. This differentiates patients with AIS, but recognizes the fact that the presence of invasion becomes prognostically significant when the size of the invasive component reaches 5 mm or greater in size.[16] If multiple areas of microscopic invasion are found within the lepidic growth, the size of the largest invasive area, measured in the largest dimension, is used; this area must be ≤5 mm to be considered MIA. As with AIS, MIA is very rarely mucinous. The invasive component histologically is acinar, papillary, micropapillary, and/or solid and shows tumor cells infiltrating into the surrounding myofibroblastic stroma. On CT scan, the appearance of MIA is often a part-solid nodule (≤5 mm) with a predominant ground-glass component, but can be highly variable.
3. **Lepidic predominant adenocarcinoma (LPA).** If lymphovascular invasion, pleural invasion, tumor necrosis, or more than 5 mm of invasion are noted in a lesion that has lepidic growth as its predominant component, MIA is excluded and the lesion is called *lepidic predominant adenocarcinoma (LPA)*, and the size of the invasive component is recorded for the T stage.
4. **Invasive adenocarcinoma.** The new classification system now recommends classifying invasive adenocarcinoma by the most predominant subtype after histologic evaluation of the resection specimen. To determine the predominant subtype, histologic sections are evaluated and the patterns are determined, in 5% increments, throughout the specimen. This semiquantitative method encourages the viewer to identify and quantify all patterns present, rather than focusing on a single pattern. In the pathology report, the tumor is classified by the predominant pattern, with percentages of the subtypes also reported (Fig. 19-11).Subtypes include:
   a. Lepidic predominant
   b. Acinar predominant
   c. Papillary predominant
   d. Micropapillary predominant
   e. Solid predominant

   Adenocarcinoma is often peripherally located and frequently discovered incidentally on routine chest radiographs, unlike squamous cell cancers. When symptoms occur, they are due to pleural or chest wall invasion (pleuritic or chest wall pain) or pleural seeding with malignant pleural effusion. Invasive adenocarcinoma is usually solid by CT scan, but can also be part-solid and even a ground-glass nodule. Occasionally, a lobar ground-glass opacification may be present, which is often associated with significant respiratory compromise and can be mistaken for lobar pneumonia. Bubble-like or cystic lucencies on CT scan in small (≤2 cm) adenocarcinomas or extensive associated ground-glass components correlate with slow growth and well-differentiated tumors and a more favorable prognosis. Intratumoral air bronchograms are usually indicative of well-differentiated tumor, whereas spiculations that are coarse and thick (≥2 mm) portend vascular invasion and nodal metastasis and are associated with decreased survival following complete surgical resection. Pleural retraction is also a poor prognostic indicator.
5. Additional histologic variants include colloid adenocarcinoma (formerly mucinous cystadenocarcinoma), fetal adenocarcinoma, and enteric adenocarcinoma. Clear cell and signet ring cell types are no longer considered to be distinct subtypes as they are found in association with most of the five dominant histologic patterns (lepidic, acinar, papillary, micropapillary, and solid). However, they are still notable, as they can signal clinically relevant molecular changes, such as the presence of the *EML4-ALK* fusion gene in solid tumors with signet ring features.

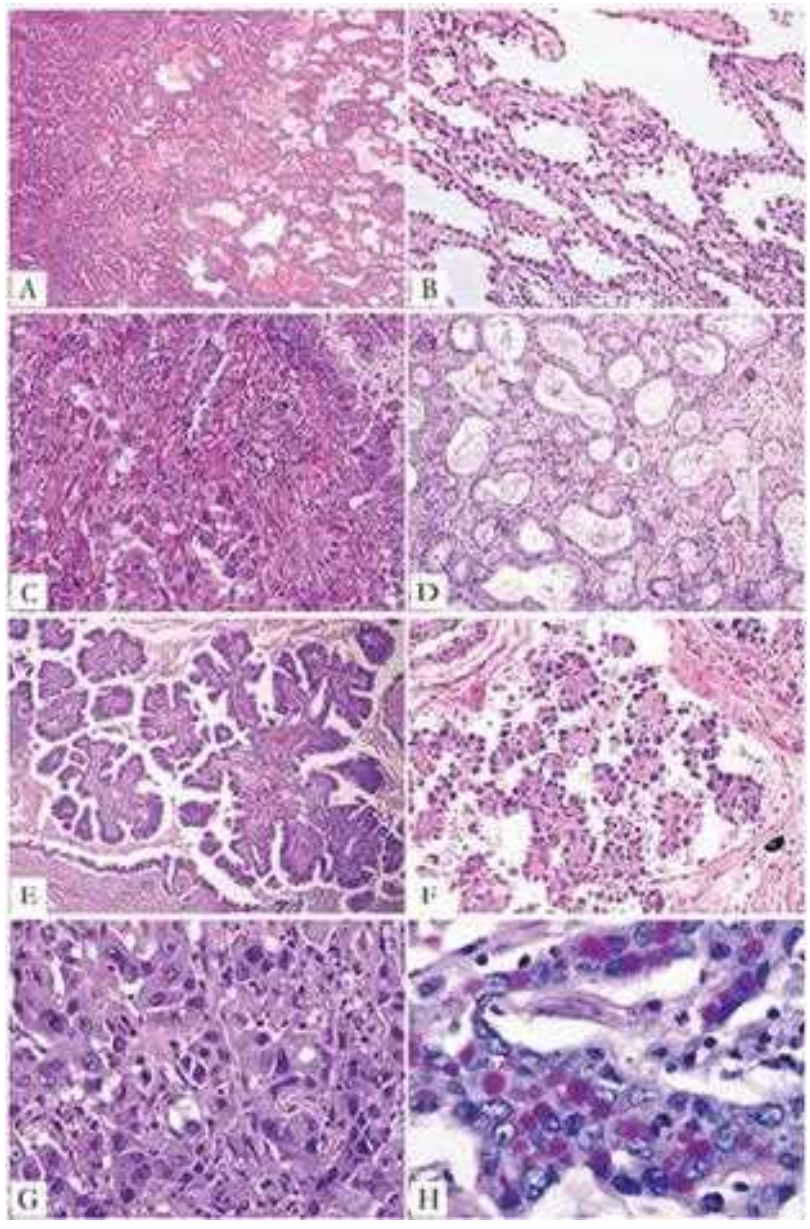

Figure 19-11. Major histologic patterns of invasive adenocarcinoma. **A.** Lepidic predominant pattern with mostly lepidic growth (*right*) and a smaller area of invasive acinar adenocarcinoma (*left*). **B.** Lepidic pattern consists of a proliferation type II pneumocytes and Clara cells along the surface alveolar walls. **C.** Area of invasive acinar adenocarcinoma (same tumor as in **A** and **B**). **D.** Acinar adenocarcinoma consists of round to oval-shaped malignant glands invading a fibrous stroma. **E.** Papillary adenocarcinoma consists of malignant cuboidal to columnar tumor cells growing on the surface of fibrovascular cores. **F.** Micropapillary adenocarcinoma consists of small papillary clusters of glandular cells growing within this airspace, most of which do not show fibrovascular cores. **G.** Solid adenocarcinoma with mucin consisting of sheets of tumor cells with abundant cytoplasm and mostly vesicular nuclei with several conspicuous nucleoli. No acinar, papillary, or lepidic patterns are seen, but multiple cells have intracytoplasmic basophilic globules that suggest intracytoplasmic mucin. **H.** Solid adenocarcinoma with mucin. Numerous intracytoplasmic droplets of mucin are highlighted with this diastase-periodic acid Schiff stain. *(Reproduced with permission from Travis W, Brambilla E, Noguchi M, et al. International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society: International multidisciplinary classification of lung adenocarcinoma.* J Thorac Oncol. *2011;6:244.)*

Squamous Cell Carcinoma. Representing 30% to 40% of lung cancers, squamous cell carcinoma is the most frequent cancer in men and highly correlated with cigarette smoking. They arise primarily in the main, lobar, or first segmental bronchi, which are collectively referred to as the central airways. Symptoms of airway irritation or obstruction are common, and include cough, hemoptysis, wheezing (due to high-grade airway obstruction), dyspnea (due to bronchial obstruction with or without postobstructive atelectasis), and pneumonia (caused by airway obstruction with secretion retention and atelectasis).

Occasionally a more peripherally based squamous cell carcinoma will develop in a tuberculosis scar or in the wall of a bronchiectatic cavity. Histologically, cells develop a pattern of clusters with intracellular bridges and keratin pearls. Central necrosis is frequent and may lead to the radiographic findings

of a cavity (possibly with an air-fluid level). Such cavities may become infected, with resultant abscess formation.

Large Cell Carcinoma. Large cell carcinoma accounts for 10% to 20% of lung cancers and may be located centrally or peripherally. These tumors have cell diameters of 30 to 50 μm, which are often admixed with various other malignant cell types. Large cell carcinoma can be confused with a large cell variant of neuroendocrine carcinoma, but can be differentiated by special immunohistochemical stains.

Salivary Gland–Type Neoplasms. Salivary-type submucosal bronchial glands throughout the tracheobronchial tree can give rise to tumors that are histologically identical to those seen in the salivary glands. The two most common are adenoid cystic carcinoma and mucoepidermoid carcinoma. Both tumors occur centrally due to their site of origin. Adenoid cystic carcinoma is a slow-growing tumor that is locally and systemically invasive, growing submucosally and infiltrating along perineural sheaths. Mucoepidermoid carcinoma consists of squamous and mucous cells and is graded as low or high grade, depending on the mitotic rate and degree of necrosis.

Neuroendocrine Neoplasms. Neuroendocrine lung tumors are classified into neuroendocrine hyperplasia and three separate grades of neuroendocrine carcinoma (NEC). Immunohistochemical staining for neuroendocrine markers (including chromogranins, synaptophysin, CD57, and neuron-specific enolase) is essential to accurately diagnose most tumors.[17]

Grade I NEC (classic or typical carcinoid) is a low-grade NEC; 80% arise in the epithelium of the central airways. It occurs primarily in younger patients. Because of the central location, it classically presents with hemoptysis, with or without airway obstruction and pneumonia. Histologically, tumor cells are arranged in cords and clusters with a rich vascular stroma. This vascularity can lead to life-threatening hemorrhage with even simple bronchoscopic biopsy maneuvers. Regional lymph node metastases are seen in 15% of patients, but rarely spread systemically or cause death.

Grade II NECs (atypical carcinoid) have a much higher malignant potential and, unlike grade I NEC, are etiologically linked to cigarette smoking and are more likely to be peripherally located. Histologic findings may include areas of necrosis, nuclear pleomorphism, and higher mitotic rates. Lymph node metastases are found in 30% to 50% of patients. At diagnosis, 25% of patients already have remote metastases.

Grade III NEC large cell–type tumors occur primarily in heavy smokers and in the mid to peripheral lung fields. They are often large with central necrosis and a high mitotic rate. Their neuroendocrine nature is revealed by positive immunohistochemical staining for at least one neuroendocrine marker.

Grade IV NEC (small cell lung carcinoma [SCLC]) is the most malignant NEC and accounts for 25% of all lung cancers; these NECs often have early, widespread metastases. These cancers also arise primarily in the central airways. As with squamous cell cancers, symptoms include cough, hemoptysis, wheezing (due to high-grade airway obstruction), dyspnea (due to bronchial obstruction with or without postobstructive atelectasis), and pneumonia (caused by airway obstruction with secretion retention and atelectasis). Evaluation includes expert pathology review and comprehensive evaluation for metastatic disease. Three groups of grade IV NEC are recognized: pure small cell carcinoma (sometimes referred to as oat cell carcinoma), small cell carcinoma with a large cell component, and combined (mixed) tumors.

Grade IV NECs consist of smaller cells (diameter 10 to 20 μm) with little cytoplasm and very dark nuclei; they can be difficult to distinguish from lymphoproliferative lesions and atypical carcinoid tumors. Histologically, a high mitotic rate with easily visualized multiple mitoses and areas of extensive necrosis are characteristic. Importantly, very small bronchoscopic biopsies can distinguish NSCLC from SCLC, but crush artifact may make NSCLC appear similar to SCLC. If uncertainty exists, special immunohistochemical stains or rebiopsy (or both) will be necessary. These tumors are the leading producer of paraneoplastic syndromes.

Lung Cancer Epidemiology

Lung cancer is the leading cancer killer and second most frequently diagnosed cancer in the United States, accounting for nearly 28% of all cancer deaths—more than cancers of the breast, prostate, ovary, and colon and rectum combined (Fig. 19-12). In 2008, it was estimated that 1 in 13 men and 1 in 16 women would develop lung cancer in their lifetime. The overall 5-year survival for all patients with lung cancer is 16%, making lung cancer the most lethal of the leading four cancers (Fig. 19-13A, B) It is encouraging, however, that the average annual death rate declined by 2.8% per year for men and 1.1% per year for women from 2005 to 2009.[18] Unfortunately, most patients are still diagnosed at an advanced stage of disease, so therapy is rarely curative.

Prognostic markers for lung cancer survival include female sex (5-year survival of 18.3% for women vs. 13.8% for men), younger age (5-year survival of 22.8% for those <45 years vs. 13.7% for those >65 years), and white race (5-year survival of 16.1% for whites vs. 12.2% for blacks). When access to advanced medical care is unrestricted, as for the military population, the racial difference in survival disappears, suggesting that, at least in part, differences in survival may be explained by less access to advanced medical care and later diagnosis.[19]

Risk Factors for Lung Cancer. Cigarette smoking was implicated as a causal factor in approximately 75% of all lung cancers worldwide in 2007. According to the U.S. Surgeon General's report in 2004, 90% of lung cancers in men and nearly 80% in women can be attributed to cigarette smoking or secondhand cigarette smoke exposure. Two lung cancer types—squamous cell and small cell carcinoma—are extraordinarily rare in the absence of cigarette smoking. The risk of developing lung cancer escalates with the number of cigarettes smoked, the number of years of smoking, and the use of unfiltered cigarettes. Conversely, the risk of lung cancer declines with smoking cessation, but never drops to that of never smokers, regardless of the length of abstinence (Table 19-3).[20] Radon exposure accounts for the vast majority of the remaining cancers. Approximately 25% of all lung cancers worldwide and 53% of cancers in women are not related to smoking, and most of them (62%) are adenocarcinomas. Table 19-4 summarizes the existing data regarding the etiology of lung cancer in nonsmokers.[21]

Nearly 3500 deaths from lung cancer each year are attributable to secondhand (environmental) smoke exposure, which confers an excess risk for lung cancer of 24% when a nonsmoker lives with a smoker.[22] Risk is conferred by exposure to any burning tobacco, including cigars. The amount of secondhand exposure from one large cigar is equivalent to the exposure from 21 cigarettes. As with active smoking, risk of developing lung

Leading New Cancer Cases and Deaths – 2012 Estimates

Figure 19-13. (*Continued*)

4▶ cancer increases with longer duration and higher level of exposure to environmental tobacco.

Over 7000 chemicals have been identified in tobacco smoke, and more than 70 of the compounds are known to be carcinogens. The main chemical carcinogens are polycyclic aromatic hydrocarbons, which are actively or passively inhaled in the tobacco smoke and absorbed; these compounds are activated by specific enzymes and become mutagenic, bind to macromolecules such as deoxyribonucleic acid (DNA), and induce genetic mutations. In treating any patient with a previous smoking history, it is important to remember that there has been field cancerization of the entire aerodigestive tract. The patient's risk is increased for cancers of the oral cavity, pharynx, larynx, tracheobronchial tree and lung, and esophagus. In examining such patients, a detailed history and physical examination of these organ systems must be performed.

Table 19-3

Relative risk of lung cancer in smokers

SMOKING CATEGORY	RELATIVE RISK
Never smoked	1.0
Currently smoke	15.8–16.3
Formerly smoked	
Years of abstinence	
1–9	5.9–19.5
10–19	2.0–6.1
>20	1.9–3.7

Other causes of lung cancer include exposure to a number of industrial compounds, including asbestos, arsenic, and chromium compounds. In fact, the combination of asbestos and cigarette smoke exposure has a multiplicative effect on risk. Pre-existing lung disease confers an increased risk of lung cancer—up to 13%—for individuals who have never smoked. Patients with chronic obstructive pulmonary disease are at higher risk for lung cancer than would be predicted based on smoking risk alone. Patients with secondary scar formation related to a history of tuberculosis also have a higher risk of primary lung carcinoma. This increase is thought to be related to poor clearance of inhaled carcinogens and/or to the effects of chronic inflammation.

Screening for Lung Cancer in High-Risk Populations

In 2002, the National Lung Screening Trial (NLST) was launched to determine whether screening with CT in high-risk populations would reduce mortality from lung cancer. The study randomized 53,353 eligible patients age 55 to 74 years to either three annual low-dose helical CT scans (LDCT; aka spiral CT) or posteroanterior view chest radiograph. Patients were eligible

Table 19-4

Summary of selected studies of risk factors for lung cancer in individuals who never smoked

RISK FACTOR	RISK ESTIMATE (95% CI)	COMMENTS	REFERENCE
Environmental tobacco smoke	1.19 (90% CI: 1.04–1.35)	Meta-analysis of 11 U.S. studies of spousal exposure (females only)	225
	1.21 (1.13–1.30)	Meta-analysis of 44 case-control studies worldwide of spousal exposure	226
	1.22 (1.13–1.33)	Meta-analysis of 25 studies worldwide of workplace exposure	226
	1.24 (1.18–1.29)	Meta-analysis of 22 studies worldwide of workplace exposure	227
Residential radon	8.4% (3.0%–15.8%) per 100 Bq m^3 increase in measured radon	Meta-analysis of 13 European studies	228
	11% (0%–28%) per 100 Bq m^3	Meta-analysis of 7 North American studies	229
Cooking oil vapors	2.12 (1.81–2.47)	Meta-analysis of 7 studies from China and Taiwan (females who never smoked)	230
Indoor coal and wood burning	2.66 (1.39–5.07)	Meta-analysis of 7 studies from China and Taiwan (both sexes)	230
	1.22 (1.04–1.44)	Large case-control study (2861 cases and 3118 controls) from Eastern and Central Europe (both sexes)	231
	2.5 (1.5–3.6)	Large case-control study (1205 cases and 1541 controls) from Canada (significant for women only)	232
Genetic factors: family history, CYP1A1 Ile462Val polymorphism, *XRCC1* variants	1.51 (1.11–2.06)	Meta-analysis of 28 case-control, 17 cohort, and 7 twin studies	233
	2.99 (1.51–5.91)	Meta-analysis of 14 case-control studies of Caucasian never smokers	234
	2.04 (1.17–3.54)	Meta-analysis of 21 case-control studies of Caucasian and Asian never smokers (significant for Caucasians only)	235
	No association	Meta-analysis of 13 case-control studies	236
	No association overall; reduced risk 0.65 (0.46–0.83) with Arg194Trp polymorphism and 0.56 (0.36–0.86) with Arg280His for heavy smokers	Large case-control study from Europe (2188 cases and 2198 controls)	237
	Increased risk for never smokers 1.3 (1.0–1.8) and decreased risk for heavy smokers 0.5 (0.3–1.0) with Arg299Gln	Large case-control study from the United States (1091 cases and 1240 controls)	238
Viral factors: HPV 16 and 18	10.12 (3.88–26.4) for never smoking women >60 y	Case-control study (141 cases, 60 controls) from Taiwan of never smoking women	239

Bq = becquerels; CI = confidence interval; CYP1A1 = cytochrome P450 enzyme 1A1; HPV = human papilloma virus.

for the trial if they had a greater than 30 pack-year history of cigarette smoking; had smoked within the past 15 years if a former smoker; had no prior history of lung cancer; had no history of other life-threatening cancers in the prior 5 years; did not have symptoms suggestive of an undiagnosed lung cancer (such as hemoptysis or weight loss); and had not had a chest CT scan in the prior 18 months. Accrual to the study was excellent, and the primary endpoint of a 20% relative reduction in mortality was achieved in 2010. An absolute risk reduction of lung cancer death of four per 1000 individuals screened by LDCT was realized. Interestingly, all-cause mortality was also reduced by nearly 7% in the LDCT group, further emphasizing the impact of lung cancer on the mortality of smokers and former smokers.[23] An estimated 320 individuals need to be screened to save one life from lung cancer. Additional considerations require further evaluation before widespread LDCT screening will become reality. First, there was a 7% false-positive rate in this trial. False-positive scans lead to patient anxiety, invasive testing, and potentially morbid procedures to further evaluate the finding. The impact of these issues on patient quality of life and cost-effectiveness has yet to be elucidated. It is also critical that regulatory guidelines for patient eligibility, frequency of screening, interpretation of the scans, processes for further evaluation and management of positive findings, and dose of radiation are

well established and well accepted to ensure the generalizability of the results for patients who will be screened in the general medical community rather than in the specialized centers that performed the trial.

Solitary Pulmonary Nodule

A solitary pulmonary nodule is typically described as a single, well-circumscribed, spherical lesion that is 3 cm or less in diameter and completely surrounded by normal aerated lung parenchyma.[24] Lung atelectasis, hilar enlargement, and pleural effusion are absent. The majority are detected incidentally on chest radiographs (CXRs) or CT scans obtained for some other purpose. About 150,000 solitary nodules are found incidentally each year. The clinical significance of such a lesion depends on whether or not it represents a malignancy.

The differential diagnosis of a solitary pulmonary nodule should include a broad variety of congenital, neoplastic, inflammatory, vascular, and traumatic disorders. The probability of cancer in a solitary pulmonary nodule increases if the patient has a history of smoking (50% or higher for smokers compared to 20%–40% in never smokers). It is also more likely to be malignant if it is symptomatic or the patient is older, male, or has had occupational exposures.

Solitary pulmonary nodules were defined by findings on CXR, but with the increased sensitivity of low-dose screening CT, up to 50% of solitary lesions are found to be associated with multiple (one to six) other, usually subcentimeter, nodules. In the Early Lung Cancer Action project, almost 7% of healthy volunteers were found to have between one and three nodules and 25% had up to six nodules. CT scanning is necessary to characterize nodule number, location, size, margin morphology, calcification pattern, and growth rate.[25] Spiral (helical) CT allows continuous scanning as the patient is moved through a scanning gantry, allowing the entire thorax to be imaged during a single breath hold (Fig. 19-14). Compared to conventional CT, this provides a superior image quality, because motion artifacts are eliminated, and improves detection of pulmonary nodules and central airway abnormalities.[26] The shorter acquisition time of spiral CT also allows for consistent contrast filling of the great vessels, resulting in markedly improved visualization of pathologic states and anatomic variation contiguous to vascular structures. In addition, three-dimensional spiral CT images can

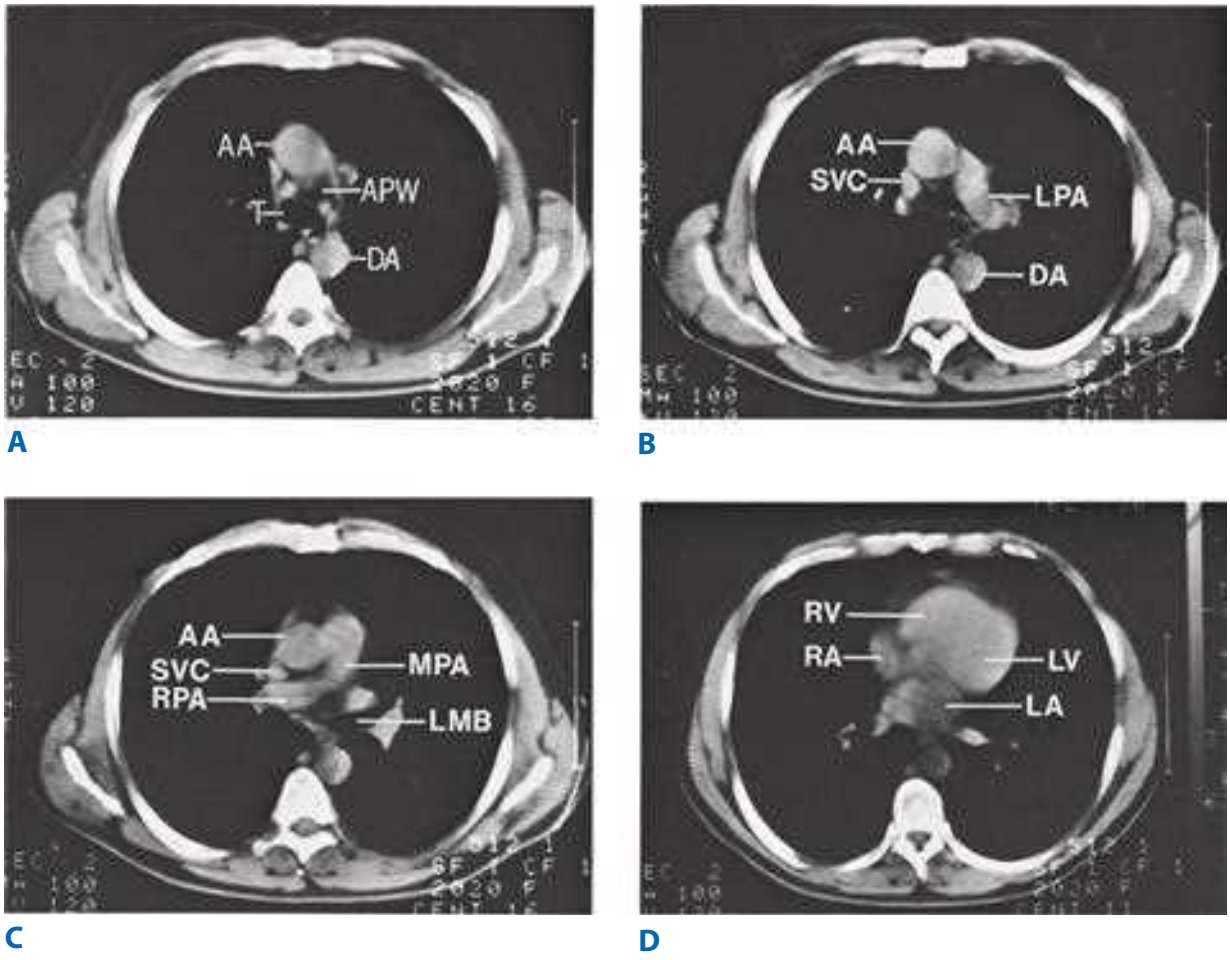

Figure 19-14. Spiral computed tomography scan showing normal transverse chest anatomy at four levels. **A.** At the level of the tracheal bifurcation, the aorticopulmonary window can be seen. **B.** The origin of the left pulmonary artery can be seen at a level 1 cm inferior to **A**. **C.** The origin and course of the right pulmonary artery can be seen at this next most cephalad level. The left upper lobe bronchus can be seen at its origin from the left main bronchus. **D.** Cardiac chambers and pulmonary veins are seen in the lower thorax. AA = ascending aorta; APW = aorticopulmonary window; DA = descending aorta; LA = left ventricle; LMB = left main bronchus; LPA = left pulmonary artery; MPA = main pulmonary artery; RA = right atrium; RPA = right pulmonary artery; RV = right ventricle; SVC = superior vena cava; T = trachea.

be reconstructed for enhanced visualization of spatial anatomic relationships.[27] Thin sections (1–2 mm collimation) at 1-cm intervals should be used to evaluate pulmonary parenchyma and peripheral bronchi. If the goal is to find any pulmonary metastases, thin sections at intervals of 5 to 7 mm collimation are recommended. For assessing the trachea and central bronchi, collimation of 3 to 5 mm is recommended. Providing accurate clinical history and data is of paramount importance to obtaining appropriate imaging.

CT findings characteristic of benign lesions include small size, calcification within the nodule, and stability over time. Four patterns of benign calcification are common: diffuse, solid, central, and laminated or "popcorn." Granulomatous infections such as tuberculosis can demonstrate the first three patterns, whereas the popcorn pattern is most common in hamartomas. In areas of endemic granulomatous disease, differentiating benign versus malignant can be challenging. Infectious granulomas arising from a variety of organisms account for 70% to 80% of this type of benign solitary nodules; hamartomas are the next most common single cause, accounting for about 10%.

CT findings characteristic of malignancy include growth over time; increasing density on CT scan (40%–50% of partial solid lesions are malignant compared to only 15% of subcentimeter solid or nonsolid nodules); size >3 cm; irregular, lobulated, or spiculated edges; and the finding of the corona radiata sign (consisting of fine linear strands extending 4–5 mm outward and appearing spiculated on radiographs) (Fig. 19-15). Calcification that is stippled, amorphous, or eccentric is usually associated with cancer.

Growth over time is an important characteristic for differentiating benign and malignant lesions. Lung cancers have volume-doubling times from 20 to 400 days; lesions with shorter doubling times are likely due to infection, and longer doubling times suggest benign tumors, but can represent slower-growing lung cancer. Positron emission tomography (PET) scanning can differentiate benign from malignant nodules[28]; most lung tumors have increased signatures of glucose uptake, as compared with healthy tissues and, thus, glucose metabolism can be measured using radio-labeled ^{18}F-fluorodeoxyglucose (FDG). Meta-analysis estimates 97% sensitivity and 78% specificity for predicting malignancy in a nodule. False-negative results can occur (especially in patients who have AIS, MIA, or LPA, carcinoids, and tumors <1 cm in diameter), as well as false-positive results (because of confusion with other infectious or inflammatory processes).

Multiple fine striations extend perpendicularly from the surface of the nodule like the spokes of a wheel. **B.** A biopsy-proven adenocarcinoma demonstrating spiculation. **C.** A lesion with a scalloped border, an indeterminate finding suggesting an intermediate probability for malignancy.

Metastatic Lesions to the Lung

The cause of a new pulmonary nodule(s) in a patient with a previous malignancy can be difficult to discern.[29] Features suggestive of metastatic disease are multiplicity; smooth, round borders on CT scan; and temporal proximity to the original primary lesion. One must always entertain the possibility that a single new lesion is a primary lung cancer. The probability of a new primary cancer vs. metastasis in patients presenting with solitary lesions depends on the type of initial neoplasm. The highest likelihood of a new primary lung cancer is in patients with a history of uterine (74%), bladder (89%), lung (92%), and head and neck (94%) carcinomas.

Surgical resection of pulmonary metastases has a role in properly selected patients.[30] The best data regarding outcomes of resection of pulmonary metastases come from the International Registry of Lung Metastases (IRLM). The registry was established in 1991 by 18 thoracic surgery departments in Europe, the United States, and Canada, and included data on 5206 patients. About 88% of patients underwent complete resection. Survival analysis at 5, 10, and 15 years (grouping all primary tumor types) was performed (Table 19-5). Multivariate analysis showed a better prognosis for patients with germ cell tumors, osteosarcomas, a disease-free interval over 36 months, and a single metastasis.[31] Depicted in Fig. 19-16, survival after metastasectomy in a variety of cancers is optimal when metastatic

Table 19-5

15 years	22	—

disease is resectable, solitary, and identified 36 or more months after initial treatment. When any or all of these optimal characteristics are absent, survival progressively declines.

The general principles of patient selection for metastasectomy are listed in Table 19-6. The technical aim of pulmonary metastasectomy is complete resection of all macroscopic tumors. In addition, any involved adjacent structures should be resected en bloc (i.e., chest wall, diaphragm, and pericardium). Multiple lesions and/or hilar lesions may require lobectomy. Pneumonectomy is rarely justified or employed.

Pulmonary metastasectomy can be approached through a thoracotomy or via video-assisted thoracic surgery (VATS) techniques. McCormack and colleagues reported their experience at Memorial Sloan-Kettering in a prospective study of 18 patients who presented with no more than two pulmonary metastatic lesions and underwent VATS resection.[32] A thoracotomy was performed during the same operation; if palpation identified any additional lesions, they were resected. The study concluded that the probability that a metastatic lesion will be missed by VATS excision is 56%. Patients in the Memorial study were evaluated before the advent of spiral CT scanning, however, and it remains controversial whether metastasis resection should be performed via VATS. Proponents of VATS argue that the resolution of spiral CT scanning is so superior that prior studies using standard CT scanners are no longer relevant. Indeed, a recent study suggested that only 18% of malignant nodules would be missed using a VATS approach in the current era while another study from the United Kingdom found equivalent outcomes with regard to missed lesions and pulmonary progression comparing open and VATS approaches. To date, no prospective study using spiral CT scan has been performed to resolve this clinical dilemma.

Primary Lung Cancer-Associated Signs and Symptoms

Lung cancer displays one of the most diverse presentation patterns of all human maladies (Table 19-7). The wide range of symptoms and signs is related to (a) histologic features, which often help determine the anatomic site of origin in the lung; (b) the specific tumor location in the lung and its relationship to surrounding structures; (c) biologic features and the production of a variety of paraneoplastic syndromes; and (d) the presence or absence of metastatic disease. Symptoms related to the local intrathoracic effect of the primary tumor can be conveniently divided into two groups: pulmonary and nonpulmonary thoracic.

Pulmonary Symptoms. Pulmonary symptoms result from the direct effect of the tumor on the bronchus or lung tissue. Symptoms (in order of frequency) include cough (secondary to irritation or compression of a bronchus), dyspnea (usually due to central airway obstruction or compression, with or without atelectasis), wheezing (with narrowing of a central airway of >50%), hemoptysis (typically, blood streaking of mucus that is rarely massive; indicates a central airway location), pneumonia (usually due to airway obstruction by the tumor), and lung abscess (due to necrosis and cavitation, with subsequent infection).

Nonpulmonary Thoracic Symptoms. Nonpulmonary thoracic symptoms result from invasion of the primary tumor directly into a contiguous structure (e.g., chest wall, diaphragm, pericardium, phrenic nerve, recurrent laryngeal nerve, superior vena cava, and esophagus), or from mechanical compression of a structure (e.g., esophagus or superior vena cava) by enlarged tumor-bearing lymph nodes.

Peripherally located tumors (often adenocarcinomas) extending through the visceral pleura lead to irritation or growth into the parietal pleura and potentially to continued growth into the chest wall structures. Three types of symptoms, depending on the extent of chest wall involvement, are possible: (a) **pleuritic pain**, from noninvasive contact of the parietal pleura with inflammatory irritation or direct parietal pleural invasion; (b) **localized chest wall pain**, from deeper invasion and involvement of the rib and/or intercostal muscles; and (c) **radicular pain**, from involvement of the intercostal nerve(s). Radicular pain may be mistaken for renal colic in the case of tumors invading the inferoposterior chest wall.

Other specific nonpulmonary thoracic symptoms include:

1. **Pancoast's syndrome.** Tumors originating in the superior sulcus (posterior apex) elicit: apical chest wall and/or shoulder pain (from involvement of the first rib and chest wall); Horner's syndrome (unilateral enophthalmos, ptosis, miosis, and facial anhidrosis from invasion of the stellate sympathetic ganglion); and radicular arm pain (from invasion of T1, and occasionally C8, brachial plexus nerve roots).
2. **Phrenic nerve palsy.** The phrenic nerve traverses the hemithorax along the mediastinum, parallel and posterior to the superior vena cava and anterior to the pulmonary hilum. Tumors at the medial lung surface or anterior hilum can directly invade the nerve; symptoms include shoulder pain (referred), hiccups, and dyspnea with exertion because of diaphragm paralysis. Radiographically, unilateral diaphragm elevation on CXR is present; the diagnosis is confirmed by fluoroscopic examination of the diaphragm with breathing and sniffing (the "sniff" test).
3. **Recurrent laryngeal nerve palsy.** Recurrent laryngeal nerve (RLN) involvement most commonly occurs on the left side, given the hilar location of the left RLN as it passes under the aortic arch. Paralysis results from: (a) invasion of the vagus nerve above the aortic arch by a medially based left upper lobe tumor; or (b) direct invasion of the RLN by hilar tumor and/or hilar or aortopulmonary lymph node metastases. Symptoms include voice change, often referred to as hoarseness, but more typically a loss of tone associated with a breathy quality, and coughing, particularly when drinking liquids.
4. **Superior vena cava (SVC) syndrome.** As a result of bulky enlargement of involved mediastinal lymph nodes compressing or a medially based right upper lobe tumor invading the SVC, SVC syndrome symptoms include variable degrees of swelling of the head, neck, and arms; headache;

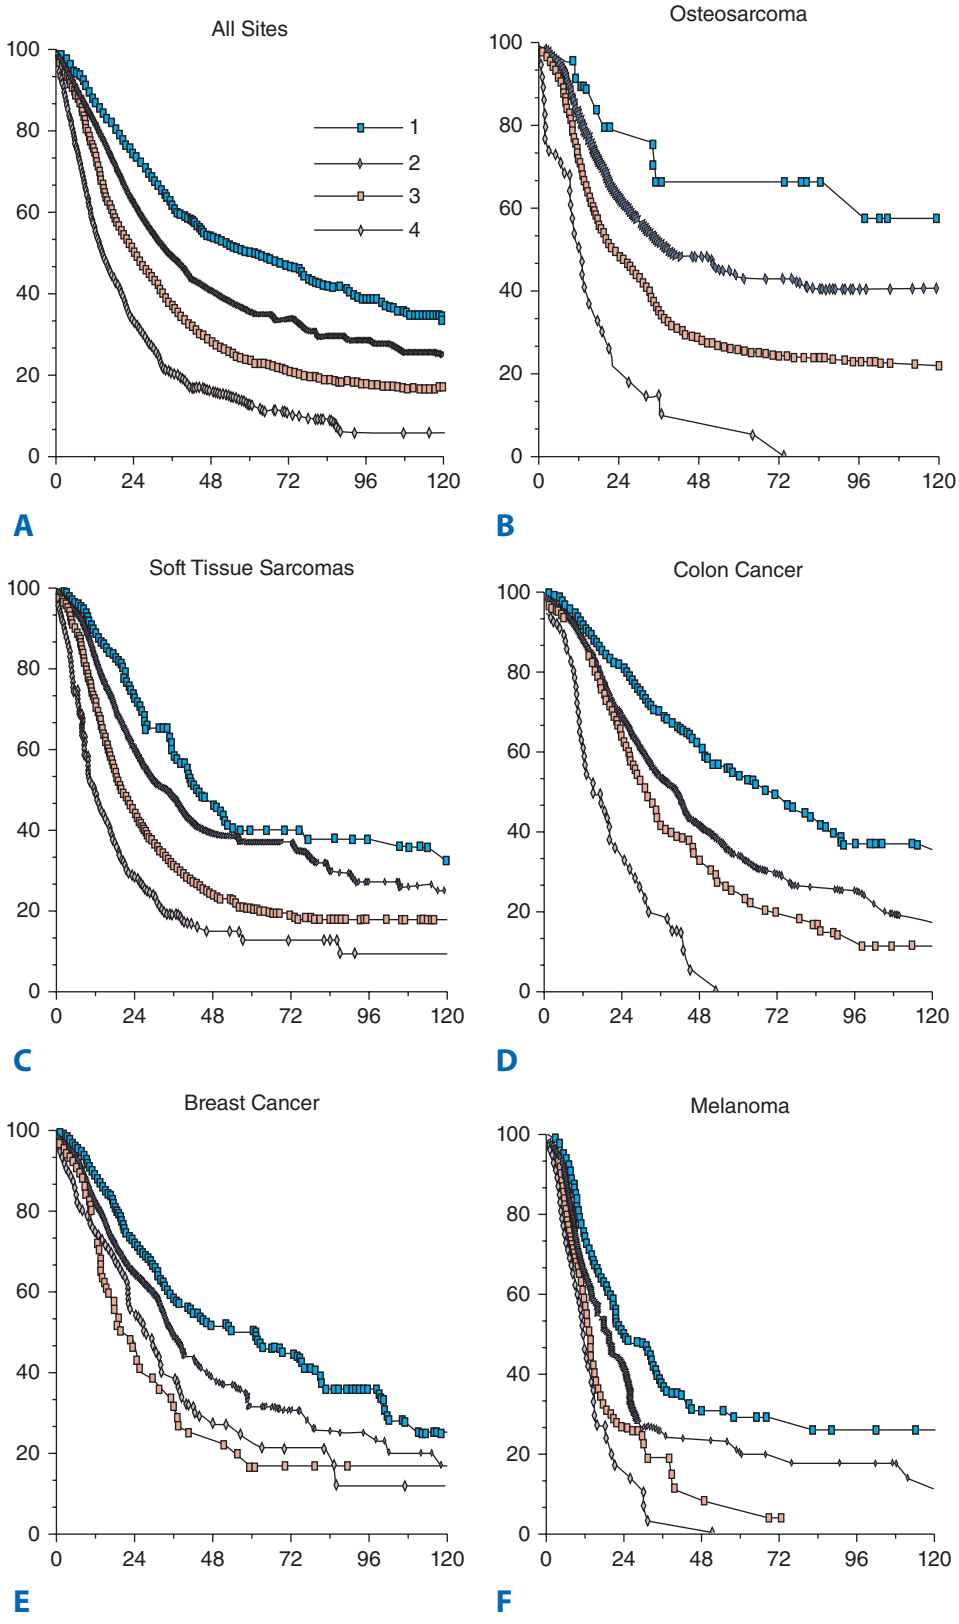

Figure 19-16. The actuarial survival after metastasectomy is depicted for patients with various tumor types further categorized into four groups according to resectability, solitary or multiple, the interval between primary resection and metastesectomy, and a combination of factors known in our work and in others, as follows: (1) resectable, solitary, and disease-free interval (DFI) greater than or equal to 36 months; (2) resectable, solitary, or DFI 36+ months; (3) resectable, multiple metastases, and DFI <36 months; and (4) unresectable. *(Reprinted with permission from Pastorino, U. (2010). The Development of an International Registry.* J Thorac Oncol. **5***(6): S196-S197*)

Table 19-6

General principles governing appropriate selection of patients for pulmonary metastasectomy

1. Primary tumor must already be controlled.
2. Patient must be able to tolerate general anesthesia, potential single-lung ventilation, and the planned pulmonary resection.
3. Metastases must be completely resectable based on computed tomographic imaging.
4. There is no evidence of extrapulmonary tumor burden.
5. Alternative superior therapy must not be available.

and conjunctival edema. It is seen most commonly with NEC grade IV (small cell) lung cancer.

5. **Pericardial tamponade.** Pericardial effusions (benign or malignant), associated with increasing levels of dyspnea and/or arrhythmias, and pericardial tamponade occur with direct pericardial invasion. Diagnosis requires a high index of suspicion in the setting of a medially based tumor with symptoms of dyspnea and is confirmed by CT scan or echocardiography.
6. **Back pain.** Results from direct invasion of a vertebral body and is often localized and severe. If the neural foramina are involved, radicular pain may also be present.
7. **Other local symptoms.** Dysphagia is usually secondary to external esophageal compression by enlarged lymph nodes involved with metastatic disease, usually with lower lobe tumors. Finally, dyspnea, pleural effusion, or referred shoulder pain can result from invasion of the diaphragm by a tumor at the base of a lower lobe.

Table 19-7

Clinical presentation of lung cancer

CATEGORY	SYMPTOM	CAUSE
Pulmonary symptoms	Cough	Bronchus irritation or compression
	Dyspnea	Airway obstruction or compression
	Wheezing	>50% airway obstruction
	Hemoptysis	Tumor erosion or irritation
	Pneumonia	Airway obstruction
Nonpulmonary thoracic symptoms	Pleuritic pain	Parietal pleural irritation or invasion
	Local chest wall pain	Rib and/or muscle involvement
	Radicular chest pain	Intercostal nerve involvement
	Pancoast's syndrome	Stellate ganglion, chest wall, brachial plexus involvement
	Hoarseness	Recurrent laryngeal nerve involvement
	Swelling of head and arms	Bulky involved mediastinal lymph nodes
		Medially based right upper lobe tumor

Associated Paraneoplastic Syndromes All lung cancer histologies are capable of producing a variety of paraneoplastic syndromes, most often from systemic release of tumor-derived biologically active materials (Table 19-8). Paraneoplastic

syndromes may produce symptoms even before any local symptoms are produced by the primary tumor, thereby aiding in early diagnosis. Their presence does not influence resectability or treatment options. Symptoms often abate with successful treatment; paraneoplastic symptom recurrence may herald tumor recurrence. The majority of such syndromes are associated with grade IV NEC (small cell carcinoma), including many endocrinopathies.

1. **Hypertrophic pulmonary osteoarthropathy (HPO).** Often severely debilitating, symptoms of HPO may antedate the diagnosis of cancer by months. Clinically, ankle, feet, forearm, and hand tenderness and swelling are characteristic, resulting from periostitis of the fibula, tibia, radius, metacarpals, and metatarsals. Clubbing of the digits may occur in up to 30% of patients with grade IV NEC (Fig. 19-17). Plain radiographs show periosteal inflammation and elevation, while bone scans demonstrate intense but symmetric uptake in the long bones. Aspirin or nonsteroidal anti-inflammatory agents provide temporary relief; treatment requires successful surgical or medical tumor eradication.
2. **Hypercalcemia.** Up to 10% of patients with lung cancer will have hypercalcemia, most often due to metastatic disease. Ectopic parathyroid hormone secretion by the tumor, most often squamous cell carcinoma, is causative in up to 15%, however, and should be suspected if metastatic bone disease is not present. Symptoms of hypercalcemia include lethargy, depressed level of consciousness, nausea, vomiting, and dehydration. Most patients have resectable tumors, and, following complete resection, the calcium level will normalize. Unfortunately, tumor recurrence is extremely common and may manifest as recurrent hypercalcemia.
3. **Hyponatremia.** Characterized by confusion, lethargy, and possible seizures, hyponatremia can result from the inappropriate secretion of antidiuretic hormone from the tumor into the systemic circulation (syndrome of inappropriate secretion of antidiuretic hormone [SIADH]) in 10% to 45% of patients with grade IV NEC (small cell). It is diagnosed by the presence of hyponatremia, low serum osmolality, and high urinary sodium and osmolality. Another cause of hyponatremia can be the ectopic secretion of atrial natriuretic peptide (ANP).
4. **Cushing's syndrome.** Autonomous tumor production of an adrenocorticotropic hormone (ACTH)-like molecule leads to rapid serum elevation of ACTH and subsequent severe hypokalemia, metabolic alkalosis, and hyperglycemia. Symptoms are primarily related to the metabolic changes while the physical signs of Cushing's syndrome (e.g., truncal obesity, buffalo hump, striae) are unusual due to the rapidity of ACTH elevation. Diagnosis is made by demonstrating hypokalemia (<3.0 mmol/L); nonsuppressible elevated plasma cortisol levels that lack the normal diurnal variation; elevated blood ACTH levels; or elevated

urinary 17-hydroxycorticosteroids, all of which are not suppressible by administration of exogenous dexamethasone. Immunoreactive ACTH is present in nearly all extracts of SCLC, and a high percentage of patients with SCLC have elevated ACTH levels by radioimmunoassay, yet fewer than 5% have symptoms of Cushing's syndrome.

5. **Peripheral and central neuropathies.** Unlike other paraneoplastic syndromes, which are usually due to ectopic secretion of an active substance, these syndromes are felt to be immune mediated. Cancer cells are thought to secrete antigens normally expressed only by the nervous system, generating antibodies leading either to interference with neurologic function or to immune neurologic destruction. Up to 16% of lung cancer patients have neuromuscular disability, and, of these, half have grade IV NEC (small cell) and 25% have squamous cell carcinomas. In patients with neurologic or muscular symptoms, central nervous system (CNS) metastases must be ruled out with CT or magnetic resonance imaging (MRI) of the head. Other metastatic disease leading to disability must also be excluded.
6. **Lambert-Eaton syndrome.** This myasthenia-like syndrome is caused by tumor secretion of immunoglobulin G (IgG) antibodies targeting voltage-gated calcium channels, which causes a neuromuscular conduction defect by decreasing the amount of acetylcholine released from presynaptic sites at the motor end plate. Symptoms, including gait abnormalities from proximal muscle weakness and impaired coordination, may actually precede radiographic evidence of the tumor. Therapy is directed at the primary tumor with resection, radiation, and/or chemotherapy. Many patients have dramatic improvement after successful therapy. For patients with refractory symptoms, treatment consists of guanidine hydrochloride, immunosuppressive agents such as prednisone and azathioprine, and occasionally plasma exchange. Unlike with myasthenia gravis patients, neostigmine is usually ineffective.

Symptoms Associated with Metastatic Lung Cancer. Lung cancer metastasizes most commonly to the CNS, vertebral bodies, bone, liver, adrenal glands, lungs, skin, and soft tissues. CNS metastases are present at diagnosis in 10% of patients; another 10% to 15% will develop CNS metastases following diagnosis. Focal symptoms, including headache, nausea, vomiting, seizures, hemiplegia, and dysarthria, are common. Lung cancer is the most common cause of spinal cord compression, either by primary tumor invasion of an intervertebral foramen or direct extension of vertebral metastases. Bony metastases are identified in 25% of all patients with lung cancer. They are primarily lytic and produce pain locally; thus any new and localized skeletal symptoms must be evaluated radiographically. Liver metastases are most often an incidental finding on CT scan. Adrenal metastases are also typically asymptomatic and are usually discovered by routine CT scan. They may lead to adrenal hypofunction. Skin and soft tissue metastases occur in 8% of patients dying of lung cancer and generally present as painless subcutaneous or intramuscular masses. Occasionally, the tumor erodes through the overlying skin, with necrosis and creation of a chronic wound; excision may then be necessary for both mental and physical palliation.

Nonspecific Cancer-Related Symptoms. Lung cancer often produces a variety of nonspecific symptoms such as anorexia, weight loss, fatigue, and malaise. The cause of these symptoms is often unclear, but should raise concern about possible metastatic disease.

Lung Cancer Management

Role of Histologic Diagnosis and Molecular Testing. Establishing a clear histologic diagnosis early in the evaluation and management of lung cancer is critical to effective treatment. Molecular signatures are also key determinants of treatment algorithms for adenocarcinoma and will likely become important for squamous cell carcinoma as well. Currently, differentiation between adenocarcinoma and squamous cell carcinoma in cytologic specimens or small biopsy specimens is imperative in patients with advanced stage disease, as treatment with pemetrexed or bevacizumab-based chemotherapy is associated with improved progression-free survival in patients with adenocarcinoma but not squamous cell cancer. Furthermore, life-threatening hemorrhage has occurred in patients with squamous cell carcinoma who were treated with bevacizumab. Finally, *EGFR* mutation predicts response to EGFR tumor kinase inhibitors and is now recommended as first-line therapy in advanced adenocarcinoma. Because adequate tissue is required for histologic assessment and molecular testing, each institution should have a clear, multidisciplinary approach to patient evaluation, tissue acquisition, tissue handling/processing, and tissue analysis (Fig. 19-18). In many cases, tumor morphology differentiates adenocarcinoma from the other histologic subtypes. If no clear morphology can be identified, then additional testing for one immunohistochemistry marker for adenocarcinoma and one for squamous cell carcinoma will usually enable differentiation. Immunohistochemistry for neuroendocrine markers is reserved for lesions exhibiting neuroendocrine morphology. Additional molecular testing should be performed on all adenocarcinoma specimens for known predictive and prognostic tumor markers (e.g. *EGFR*, *KRAS*, and *EML4-ALK* fusion gene). Ideally, use of tissue sections and cell block material is limited to the minimum necessary at each decision point. This emphasizes the importance of a multidisciplinary approach; surgeons and radiologists must work in direct cooperation with the cytopathologist to ensure that tissue samples are adequate for morphologic diagnosis as well as providing sufficient cellular material to enable molecular testing. With adoption of endobronchial and endoscopic ultrasound, electromagnetic navigational bronchoscopy, VATS, and even transthoracic image-guided fine-needle and core-needle biopsy, surgeons are increasingly involved in the acquisition of diagnostic tissue for primary, metastatic, and recurrent intrathoracic disease, and a thorough understanding of key issues is necessary to ensure optimal treatment and patient outcomes.

Patient Evaluation. Evaluation prior to treatment encompasses three areas: diagnosis and assessment of the primary tumor, assessment for metastatic disease, and determination of functional status (the patient's ability to tolerate the prescribed treatment regimen). A discrete approach to each area allows the surgeon to systematically evaluate the patient, perform accurate clinical staging, and enable assessment of the patient's functional suitability for therapy, including pulmonary resection (Table 19-9).

Assessment of the Primary Tumor. Assessment of the primary tumor begins with the history and directed questions regarding the presence or absence of pulmonary, nonpulmonary, thoracic, and paraneoplastic symptoms. Because patients often present to

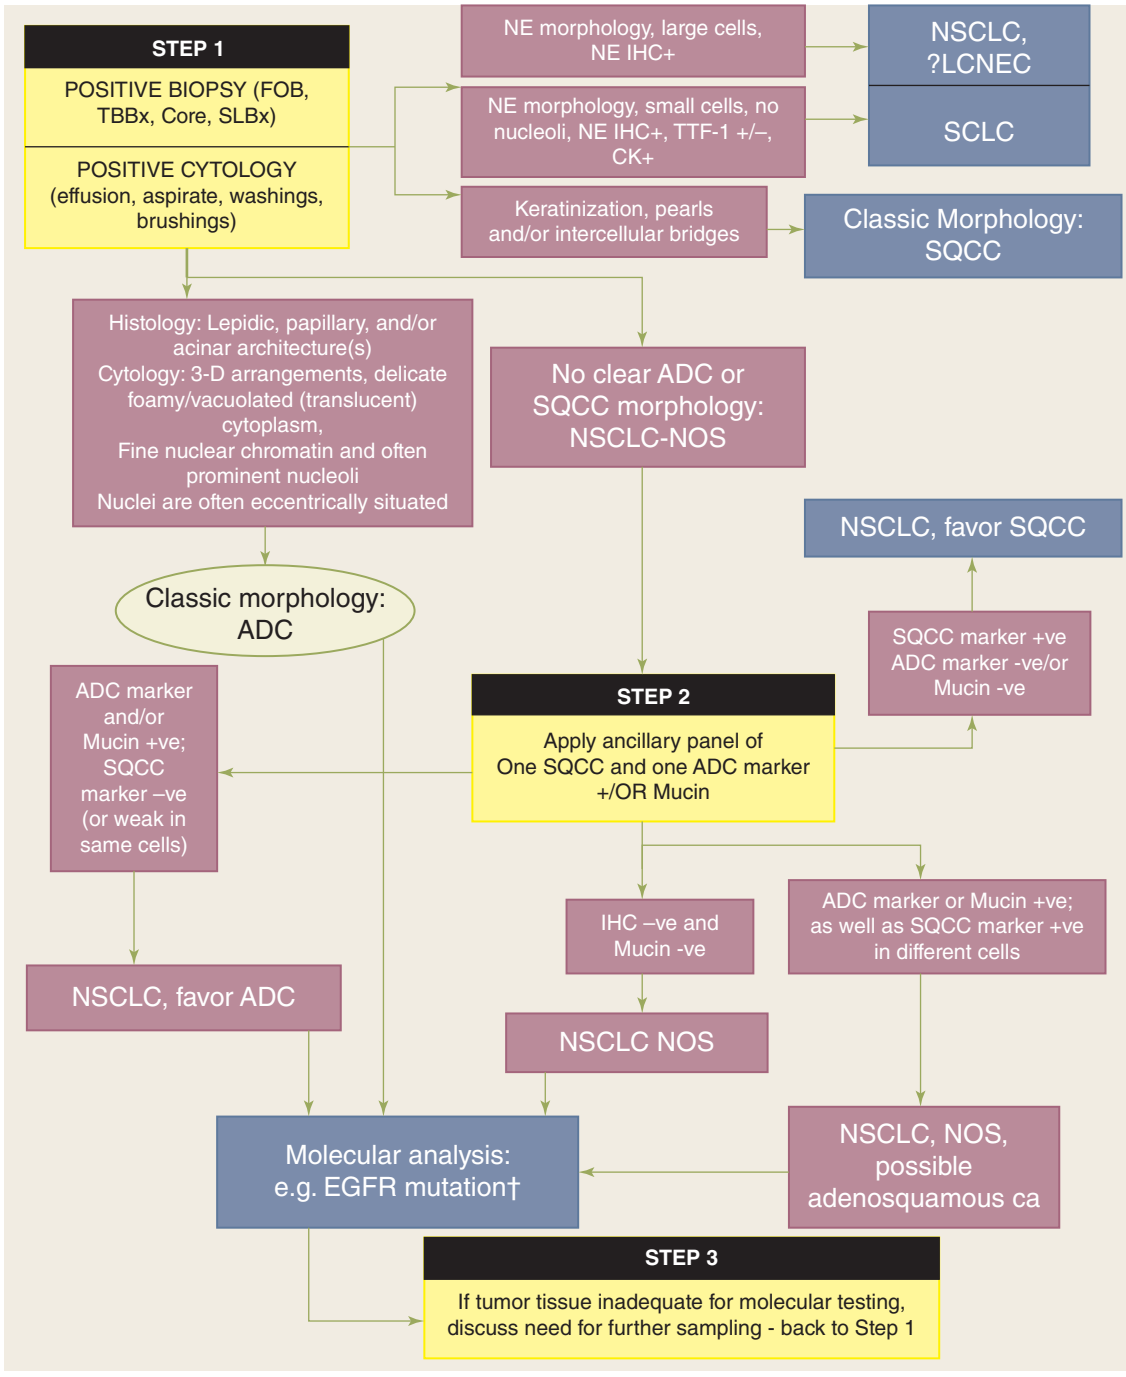

Figure 19-18. Algorithm for adenocarcinoma diagnosis in small biopsies and/or cytology. Step 1: When positive biopsies (fiberoptic bronchoscopy [FOB], transbronchial [TBBx], core, or surgical lung biopsy [SLBx]) or cytology (effusion, aspirate, washings, and brushings) show clear adenocarcinoma (ADC) or squamous cell carcinoma (SQCC) morphology, the diagnosis can be firmly established. If there is neuroendocrine (NE) morphology, the tumor may be classified as small cell carcinoma (SCLC) or non–small cell lung carcinoma (NSCLC), probably large cell neuroendocrine carcinoma (LCNEC) according to standard criteria (+ = positive, – = negative, and ± = positive or negative). If there is no clear ADC or SQCC morphology, the tumor is regarded as NSCLC–not otherwise specified (NOS). Step 2: NSCLC-NOS can be further classified based on (a) immunohistochemical stains, (b) mucin (DPAS or mucicarmine) stains, or (c) molecular data. If the stains all favor ADC-positive ADC marker(s) (i.e., TTF-1 and/or mucin positive) with negative SQCC markers, then the tumor is classified as NSCLC, favor ADC. If SQCC markers (i.e., p63 and/or CK5/6) are positive with negative ADC markers, the tumor is classified as NSCLC, favor SQCC. If the ADC and SQCC markers are both strongly positive in different populations of tumor cells, the tumor is classified as NSCLC-NOS, with a comment it may represent adenosquamous carcinoma. If all markers are negative, the tumor is classified as NSCLC-NOS. †EGFR mutation testing should be performed in (1) classic ADC, (2) NSCLC, favor ADC, (3) NSCLC-NOS, and (4) NSCLC-NOS, possible adenosquamous carcinoma. In NSCLC-NOS, if EGFR mutation is positive, the tumor is more likely to be ADC than SQCC. Step 3: If clinical management requires a more specific diagnosis than NSCLC-NOS, additional biopsies may be indicated. CD = cluster designation; CK = cytokeratin; DPAS = diastase-periodic acid Schiff; DPAS +ve = periodic-acid Schiff with diastase; EGFR = epidermal growth factor receptor; IHC = immunohistochemistry; NB = of note; TTF-1 = thyroid transcription factor-1; –ve = negative; +ve = positive. *(Reproduced with permission from Travis W, Brambilla E, Noguchi M, et al. International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society: International multidisciplinary classification of lung adenocarcinoma.* J Thorac Oncol. *2011;6:244.*

Table 19-9

Evaluation of patients with lung cancer

	PRIMARY TUMOR	METASTATIC DISEASE	FUNCTIONAL ASSESSMENT
History	Pulmonary	Weight loss	Ability to walk up two flights of stairs
	Nonpulmonary thoracic	Malaise	Ability to walk on a flat surface indefinitely
	Paraneoplastic	New bone pain	
		Neurologic signs or symptoms	
		Skin lesions	
Physical examination	Voice	Supraclavicular node palpation	Accessory muscle usage
		Skin examination	Air flow by auscultation
		Neurologic examination	Force of cough
Radiographic examination	Chest CT	Chest CT, PET	Chest CT: tumor anatomy, atelectasis
Tissue analysis	Bronchoscopy	Bone scan, head MRI, abdominal CT	Quantitative perfusion scan
	Transthoracic needle aspiration and biopsy	Bronchoscopic lymph node FNA	
		Endoscopic ultrasound	
		Mediastinoscopy	
		Biopsy of suspected metastasis	
Other	Thoracoscopy	—	Pulmonary function tests (FEV_1, DLCO, O_2 consumption)

CT = computed tomography; DLCO = carbon monoxide diffusion capacity; FEV_1 = forced expiratory volume in 1 second; FNA = fine-needle aspiration; MRI = magnetic resonance imaging; O_2 = oxygen; PET = positron emission tomography.

the surgeon with a CXR or CT scan demonstrating the lesion, the location of the tumor can help direct the clinician in performing the history and physical examination.

If the patient does not already have a chest CT scan, this should be performed expeditiously as the next stage in evaluating a new patient. A routine chest CT scan should include intravenous contrast material to enable assessment of the primary tumor, delineation of mediastinal lymph nodes relative to normal mediastinal structures, and the tumor's relationship to surrounding and contiguous structures. Recommendations for treatment and options for obtaining tissue diagnosis require a thorough understanding and assessment of CT findings.

Concern for contiguous invasion of adjacent structures often is raised in response to a combination of symptom history, location of the primary tumor, and CT imaging. It is common to see the primary tumor abutting the chest wall without clear radiographic evidence of rib destruction. In this circumstance, a history of pain in the area is an accurate guide to the likelihood of parietal pleural, rib, or intercostal nerve involvement. Similar observations apply to tumors abutting the recurrent laryngeal nerve, phrenic nerve, diaphragm, vertebral bodies, and chest apex. Thoracotomy should not be denied because of presumptive evidence of invasion of the chest wall, vertebral body, or mediastinal structures; proof of invasion may require thoracoscopy or even thoracotomy.

MRI of pulmonary lesions and mediastinal nodes, overall, offers no real improvement over CT scanning. It is an excellent modality, however, for defining a tumor's relationship to a major vessel, given its excellent imaging of vascular structures. This is especially true if the use of iodine contrast material is contraindicated. Thus, use of MRI in lung cancer patients is reserved for those with contrast allergies or with suspected mediastinal, vascular, or vertebral body invasion.

Options for Tissue Acquistion. The surgeon must have an evidence-based algorithm for approaching the diagnosis and treatment of a pulmonary nodule and masses (Fig. 19-19).[24] Depending on nodule size, proximity to the bronchial tree, and the prevalence of cancer in the population being sampled, bronchoscopy has 20% to 80% sensitivity for detecting neoplastic processes within a pulmonary lesion. Diagnostic tissue from bronchoscopy can be obtained by one of four methods:

1. Brushings and washings for cytology
2. Direct forceps biopsy of a visualized lesion
3. Endobronchial ultrasound-guided fine-needle aspiration (FNA) of an externally compressing lesion without visualized endobronchial tumor
4. Transbronchial biopsy with fluoroscopy to guide forceps to the lesion or electromagnetic navigational bronchoscopy

Electromagnetic navigation bronchoscopy is a recent addition to the surgeon's armamentarium for transbronchial biopsy of peripheral lung lesions. Using electromagnetic markers that create a three-dimensional image and align the recorded CT images to the patient's true anatomy, a catheter is advanced transbronchially and brushings, FNA, cup biopsy, and washings can be performed. Diagnostic yield using electromagnetic navigation bronchoscopy as an adjunct to standard bronchoscopy is reported as high as 80%. The

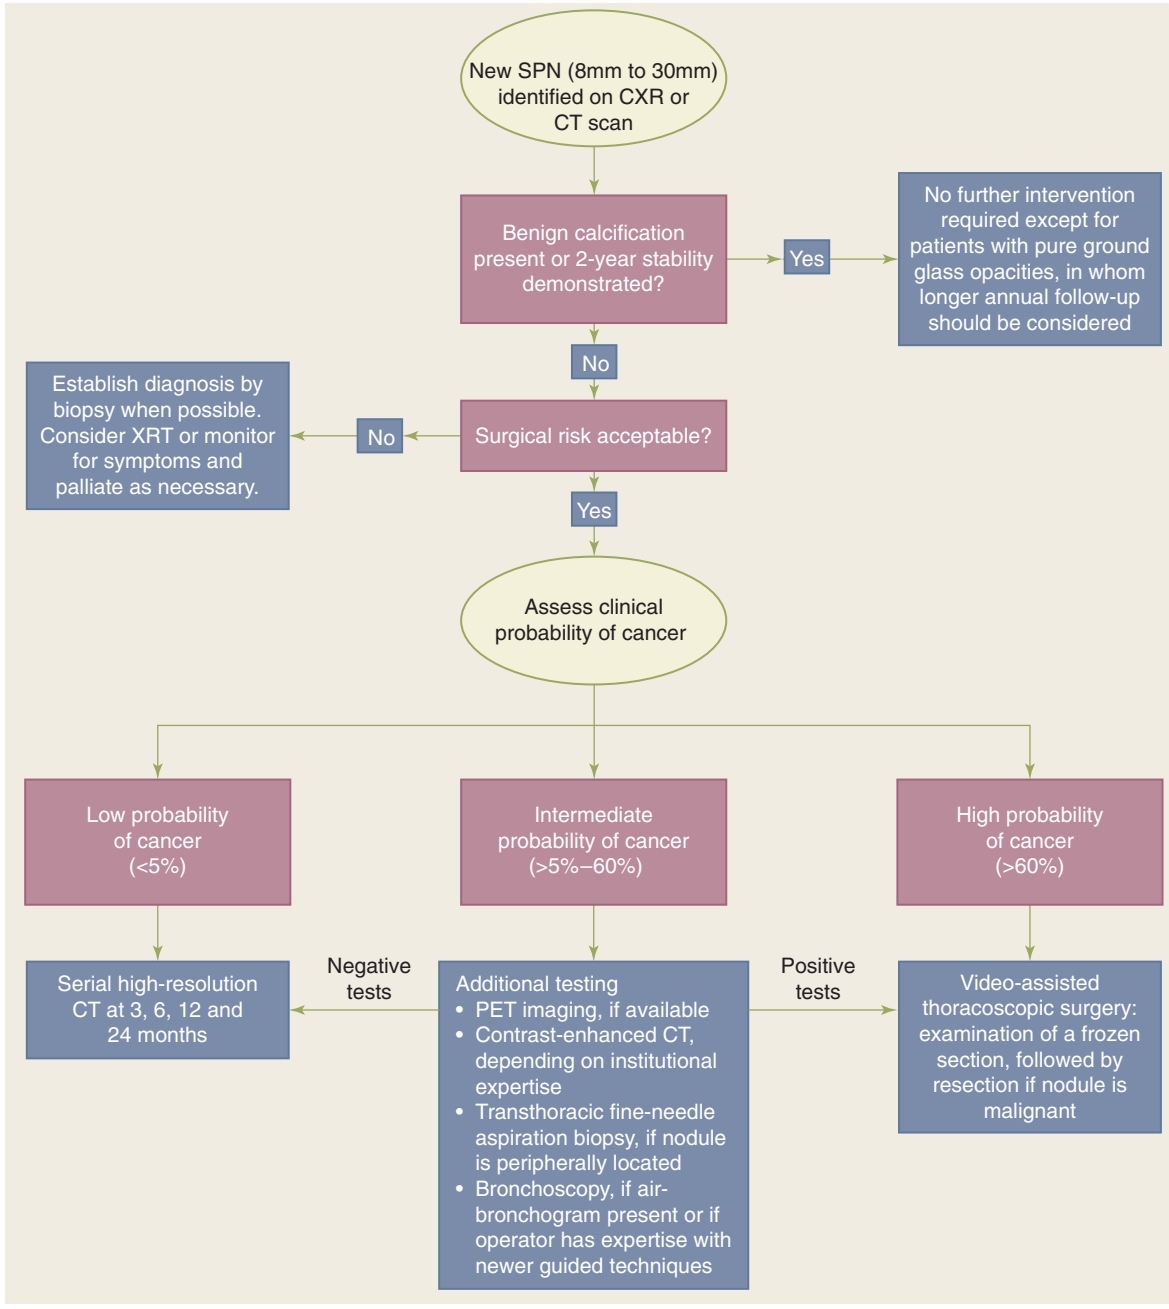

Figure 19-19. Recommended management algorithm for patients with solitary pulmonary nodules (SPNs) measuring 8 mm to 30 mm in diameter. CT = computed tomography; CXR = chest radiograph; PET = positron emission tomography; XRT = radiotherapy. *(Reproduced with permission from the American College of Chest Physicians from Gould MK, et al. Evaluation of patients with pulmonary nodules: when is it lung cancer?: ACCP Evidence-based Clinical Practice Guidelines. (2nd edition)* Chest. *2007;132:108S.)*

approach can also be used for placement of fiducial markers for subsequent stereotactic body radiation therapy and for tattooing the perilesional region to guide subsequent video-assisted thoracoscopic resection. Pneumothorax rates with this approach are approximately 1% in larger series and up to 3.5% in reports of early experience.

5▶ For peripheral lesions (roughly the outer half of the lung), transbronchial biopsy is performed first, followed by brushings and washings. This improves diagnostic yield by disrupting the lesion with the biopsy forceps and mobilizing additional cells. For central lesions, direct forceps biopsy by bronchoscopic visualization is often possible. For central lesions with external airway compression but no visible endobronchial lesions, endobronchial ultrasound (EBUS) is highly accurate and safe for transbronchial biopsies of both the primary tumor (when it abuts the central airways) as well as the mediastinal lymph nodes.[33]

Image-guided transthoracic FNA (ultrasound or CT FNA) biopsy can accurately diagnose appropriately selected peripheral pulmonary lesions in up to 95% of patients. Three biopsy results are possible after image-guided biopsy procedures: malignant, a specific benign process, or indeterminate. Because false-negative rates range from 3% to 29%, further diagnostic efforts are warranted in the absence of a specific benign diagnosis (such as granulomatous inflammation or hamartoma) because malignancy is not ruled out.[34] The primary complication is pneumothorax in as many as 30% of cases. Intrapulmonary bleeding occurs, but rarely causes clinically significant hemoptysis or respiratory compromise.

Some groups advocate use of video-assisted thoracoscopic biopsy as the first option for diagnosis, citing superior diagnostic accuracy and low surgical risk. With VATS, the nodule can be excised with a wedge or segmental resection, if less than 3 cm, or a core-needle biopsy can be performed under direct vision for larger lesions. VATS can also provide valuable staging information, including sampling/dissection of mediastinal lymph nodes and assessing whether the primary tumor has invaded a contiguous structure (such as the chest wall or mediastinum). Lesions most suitable for VATS are those that are located in the outer one third of the lung. The surgeon should avoid direct manipulation of the nodule or violation of the visceral pleura overlying the nodule. In addition, the excised nodule must be extracted from the chest within a bag to prevent seeding of the chest wall. If the patient's pulmonary reserve is adequate, the surgeon can proceed to lobectomy (either VATS or open) after frozen section diagnosis.

A thoracotomy is occasionally necessary to diagnose and stage a primary tumor. Although this occurs rarely, two circumstances may require such an approach: (a) a deep-seated lesion that yielded an indeterminate needle biopsy result or that could not be biopsied for technical reasons; or (b) inability to determine invasion of a mediastinal structure by any method short of palpation. In the circumstance of a deep-seated lesion without a diagnosis, tissue can be obtained via thoracotomy using FNA, core-needle biopsy, or excisional biopsy. Intraoperative frozen-section analysis is required; if the open biopsy frozen-section result is indeterminate, a lobectomy may be necessary in extremely rare situations. If a pneumonectomy is required to remove the lesion, a tissue diagnosis of cancer *must* be made before proceeding.

Assessment for Metastatic Disease. Distant metastases are found in approximately 40% of patients with newly diagnosed lung cancer. The presence of lymph node or systemic metastases may imply inoperability. As with the primary tumor, assessment for the presence of metastatic disease should begin with the history and physical examination, focusing on the presence or absence of new bone pain, neurologic symptoms, and new skin lesions. In addition, constitutional symptoms (e.g., anorexia, malaise, and unintentional weight loss of >5% of body weight) suggest either a large tumor burden or the presence of metastases. Physical examination should focus on the patient's overall appearance, noting any evidence of weight loss such as redundant skin or muscle wasting, and a complete examination of the head and neck, including evaluation of cervical and supraclavicular lymph nodes and the oropharynx. This is particularly true for patients with a significant tobacco history. The skin should be thoroughly examined. Routine laboratory studies include serum levels of hepatic enzymes (e.g., serum glutamic oxaloacetic transaminase and alkaline phosphatase), as well as those of serum calcium (to detect bone metastases or the ectopic parathyroid syndrome). Elevation of either hepatic enzymes or serum calcium levels typically occurs with extensive metastases.

Mediastinal Lymph Nodes. Chest CT scanning permits assessment of possible metastatic spread to the mediastinal lymph nodes. It continues to be the most effective noninvasive method available to assess the mediastinal and hilar nodes for enlargement. However, a positive CT result (i.e., nodal diameter >1.0 cm) predicts actual metastatic involvement in only about 70% of lung cancer patients. Thus even with enlarged mediastinal lymph nodes on a CT scan, up to 30% of such nodes are enlarged from noncancerous reactive causes such as inflammation due to atelectasis or pneumonia secondary to the tumor. Therefore, no patient should be denied an attempt at curative resection just because of a positive CT result for mediastinal lymph node enlargement. Any CT finding of metastatic nodal involvement must be confirmed histologically. The negative predictive value of normal-appearing lymph nodes by CT (lymph nodes <1.0 cm) is better than the positive predictive value of a suspicious-appearing lymph node, particularly with small squamous cell tumors. With normal-size lymph nodes and a T1 tumor, the false-negative rate is less than 10%, leading many surgeons to omit mediastinoscopy. However, the false-negative rate increases to nearly 30% with centrally located and T3 tumors. It has also been demonstrated that T1 adenocarcinomas or large cell carcinomas have a higher rate of early micrometastasis. Therefore, all such patients should undergo mediastinoscopy.

Mediastinal lymph node staging by PET scanning appears to have greater accuracy than CT scanning. PET staging of mediastinal lymph nodes has been evaluated in two meta-analyses. The overall sensitivity for mediastinal lymph node metastasis was 79% (95% confidence interval 76%–82%), with a specificity of 91% (95% CI 89%–93%) and an accuracy of 92% (95% CI 90%–94%).[35]

In comparing PET with CT scans in patients who also underwent lymph node biopsies, PET had a sensitivity of 88% and a specificity of 91%, whereas CT scanning had a sensitivity of 63% and a specificity of 76%. Combining CT and PET scanning may lead to even greater accuracy.[36] In one study of CT, PET, and mediastinoscopy in 68 patients with potentially operable NSCLC, CT correctly identified the nodal stage in 40 patients (59%). It understaged the tumor in 12 patients and overstaged it in 16 patients. PET correctly identified the nodal stage in 59 patients (87%). It understaged the tumor in five patients and overstaged it in four. For detecting N2 and N3 disease, the combination of PET and CT scanning yielded a sensitivity, specificity, and accuracy of 93%, 95%, and 94%, respectively. CT scan alone yielded 75%, 63%, and 68%, respectively. Studies examining combined PET-CT consistently show improved accuracy compared to PET or CT alone; accuracy for PET-CT nodal positivity confirmed by mediastinoscopy is approximately 75%, with a negative predictive value of approximately 90%. Right upper lobe lesions were more likely to have occult N2 disease than other lobes of the lung.[37-40] PET-positive mediastinal lymph nodes require histologic verification of node positivity, either by EBUS-guided FNA/core-needle biopsy or mediastinoscopy, to minimize the risk of undertreatment. Assuming node positivity without histologic confirmation relegates the patient to, at a minimum, induction chemotherapy. If there is a suggestion of N3 disease, the patient would be incorrectly staged as having IIIB disease and would not be considered a candidate for potentially curative surgical resection.

It is important for surgeons who are managing patients with lung cancer to have a clear algorithm for invasive mediastinal staging. In general, invasive staging is underused, placing many patients at risk for over- or understaging and, thus, inappropriate treatment. An absolute indication for obtaining a tissue diagnosis is mediastinal lymph node enlargement greater than 1.0 cm by CT scan. There are several options for invasive mediastinal staging:

1. Less invasive than mediastinoscopy, EBUS enables image-guided transtracheal and transbronchial FNA cytologic

samples from hilar masses and lymph nodes from level 4R and 4L, level 7, level 10, and level 11. A core-needle biopsy device recently became available for the EBUS and will improve the diagnostic yield when sampling mediastinal lymphadenopathy. Rapid onsite pathologic evaluation with expert cytopathologist evaluation greatly increases the diagnostic accuracy of the procedure; importantly, the intraoperative evaluation will confirm whether the target lesion is being sampled and greatly facilitates acquisition of satisfactory samples for determining the morphologic diagnosis as well as sufficient material for cell block for immunohistochemistry and molecular testing. Like mediastinoscopy, EBUS does not allow assessment of level 3, 5, or 6 nodal stations.

2. Endoscopic ultrasound (EUS) can accurately visualize mediastinal paratracheal lymph nodes (stations 4R, 7, and 4L) and other lymph node stations (stations 8 and 9) and is able to visualize primary lung lesions contiguous with or near the esophagus (see Fig. 19-8). Using FNA or core-needle biopsy, samples of lymph nodes or primary lesions can be obtained. Diagnostic yield is improved with intraoperative cytologic evaluation, which can be performed with the cytopathologist in the operating room. Limitations of EUS include the inability to visualize the anterior (pretracheal) mediastinum; thus, EUS does not replace mediastinoscopy for complete mediastinal nodal staging. However, it may not be necessary to perform mediastinoscopy if findings on EUS are positive for N2 nodal disease, particularly if more than one station is found to harbor metastases.
3. Cervical mediastinoscopy provides tissue sampling of all paratracheal and subcarinal lymph nodes and permits visual determination of the presence of extracapsular extension of nodal metastasis (Fig. 19-20). With complex hilar or right paratracheal primary tumors, it allows direct biopsies and assessment of invasion into the mediastinum. When the size of mediastinal lymph nodes is normal, mediastinoscopy is generally recommended for centrally located tumors, for T2 and T3 primary tumors, and occasionally for T1 adenocarcinomas or large cell carcinomas (due to their higher rate of metastatic spread). Some surgeons perform mediastinoscopy in all lung cancer patients because of the poor survival associated with surgical resection of N2 disease.
   It is important to note that EBUS or EUS can be used for initial diagnosis in enlarged lymph nodes, but the predictive value of a negative EBUS in a patient with radiographically suspicious mediastinal disease is not sufficient to accurately guide treatment. At the authors' institutions, it is standard to begin mediastinal lymph node staging with EBUS-guided FNA of clinically suspicious mediastinal lymphadenopathy. If the FNA is negative by intraoperative rapid onsite cytologic evaluation, cervical video mediastinoscopy is performed in the same operative setting to ensure accurate staging of the mediastinal nodes. However, if the FNA is positive, mediastinoscopy is not performed and the patient is referred to medical oncology for induction chemotherapy; avoiding a pretreatment mediastinoscopy in this manner facilitates the safe performance of a postinduction mediastinoscopy for restaging of the mediastinum in patients who respond favorably to induction therapy.
4. Left video-assisted thoracoscopic lymph node sampling may be needed for patients with left upper lobe tumors who have localized regional spread to station 5 and 6 lymph nodes, without mediastinal paratracheal involvement (see Fig. 19-8). If there is a low index of suspicion for nodal metastasis, the patient can be schedule for VATS biopsy and lobectomy under the same anesthesia; the procedure begins by sampling the level 5 and 6 nodes for frozen section, and if the nodes are negative, the anatomic lung resection is performed. If the index of suspicion is high, the VATS biopsy is performed as a separate procedure. Cervical mediastinoscopy should precede VATS biopsy, even if patients have normal paratracheal lymph nodes. Additional diagnostic evaluation of the lymph nodes in station 5 and 6 may be unnecessary if the mediastinal lymph nodes are proven to be benign with biopsy during cervical mediastinoscopy and the preoperative CT scan suggests complete respectability of the tumor. There are, however, several indications for prethoracotomy biopsy of station 5 and 6 lymph nodes, which are listed in Table 19-10. It is particularly important to prove that mediastinal lymph nodes are pathologically involved and not just radiographically suspicious for nodal metastasis prior to deciding that the patient is *not* a candidate for resection.

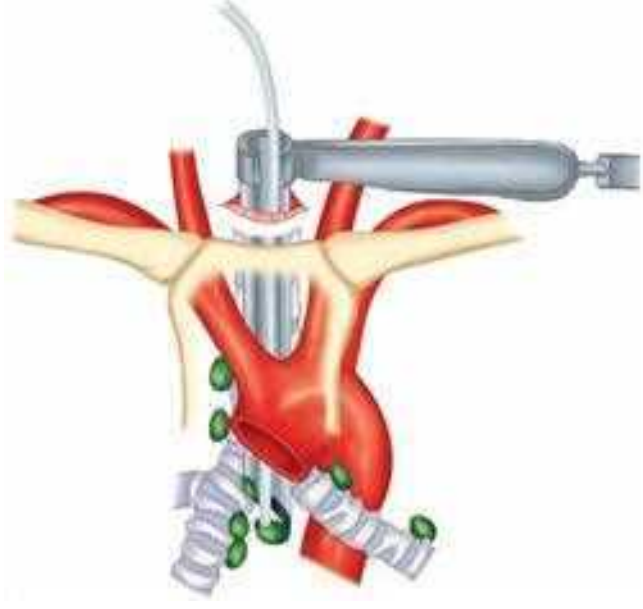

Figure 19-20. Cervical mediastinoscopy. Paratracheal and subcarinal lymph node tissues (within the pretracheal space) can be sampled using a mediastinoscope introduced through a suprasternal skin incision.

Pleural Effusion. The presence of pleural effusion on radiographic imaging should not be assumed to be malignant.

Table 19-10

Indications for prethoracotomy biopsy of station 5 and 6 lymph nodes

1. Enrollment criteria for induction therapy protocol require pathologic confirmation of N2 disease.
2. Computed tomographic scan shows evidence of bulky nodal metastases or extracapsular spread that could prevent complete resection.
3. Tissue diagnosis of a hilar mass or of lymph nodes causing recurrent laryngeal nerve paralysis is needed.

Pleural effusion may be secondary to atelectasis or consolidation, seen with central tumors, reactive, or secondary to cardiac dysfunction. Pleural effusion associated with a peripherally based tumor, particularly one that abuts the visceral or parietal pleural surface, does have a higher probability of being malignant, which would alter the pathologic stage of the disease to stage IV by the American Joint Committee on Cancer (AJCC) 7th edition TNM staging criteria. If this is the only site concerning for metastatic disease, pathologic confirmation is mandatory. Cytology reveals malignant cells in 50% of malignant effusions. Thoracoscopy, performed as part of a separate staging procedure, often with mediastinoscopy or immediately before a planned thoracotomy, may be needed to rule out pleural metastases in select patients.

Distant Metastases. Currently, chest CT and PET are routine in the evaluation of patients with lung cancer. Integrated PET-CT scanners have become standard and have substantially improved accuracy of detection and localization of lymph node and distant metastases, as compared with independently performed PET and CT scans (Fig. 19-21). This technology overcomes the imprecise information on the exact location of focal abnormalities seen on PET and has become the standard imaging modality for lung cancer. Compared to routine chest or abdominal CT and bone scans, PET scanning detects 10% to 15% more distant metastases, but should be confirmed with MRI and/or biopsies if the patient otherwise has early-stage disease. Brain MRI should be performed when the suspicion or risk of brain metastases is increased, such as in patients with clinical stage III disease. In the absence of neurologic symptoms or signs, the probability of a negative head CT scan is 95%. Liver abnormalities that are not clearly simple cysts or hemangiomas and adrenal enlargement, nodules, or masses are further evaluated by MRI scanning and, occasionally, by needle biopsy. Adrenal adenomas have a high lipid content (secondary to steroid production), but metastases and most primary adrenal malignancies contain little if any lipid; thus MRI is usually able to distinguish the two.

Tumor, Node, and Metastasis: Lung Cancer Staging. The staging of any tumor is an attempt to estimate the extent of disease and determine the patient's prognosis; in a given patient, tumors are typically classified into a clinical stage and a pathologic stage. Clinical staging information includes the history and physical examination, radiographic test results, and diagnostic biopsy information. Therapeutic plans are generated based on clinical stage. After surgical resection of the tumor and lymph nodes, a postoperative pathologic stage (pTNM) is determined, providing further prognostic information.

The staging of solid epithelial tumors is based on the TNM staging system. The primary tumor "T" status provides information about tumor size and relationship to surrounding structures; the "N" status provides information about regional lymph nodes; and the "M" status provides information about the presence or absence of metastatic disease. The designation of lymph nodes as N1, N2, or N3 requires familiarity with the lymph node mapping system[41] (see Fig. 19-8). Based on clearly delineated anatomic boundaries, accurate and reproducible localization of thoracic lymph nodes is possible, which facilitates detailed nodal staging for individual patients and standardization of nodal assessment between surgeons.

Pathologic staging criteria are based on the predicted survival relative to each combination of tumor, node, and metastasis status. In 2010, the AJCC 7th edition incorporated multiple changes into the staging system for NSCLC based on analysis of survival predictors from more than 100,000 patients worldwide. Table 19-11 shows the clinical and pathologic criteria for each

American Joint Committee on Cancer Seventh Edition Staging of Non–Small Cell Lung Cancer

CLINICAL Extent of disease before any treatment	STAGE CATEGORY DEFINITIONS		PATHOLOGIC Extent of disease through completion of definitive surgery
❑ y clinical–staging completed after neoadjuvant therapy but before subsequent surgery	TUMOR SIZE: —————	LATERALITY: ❑ LEFT ❑ RIGHT ❑ BILATERAL	❑ y pathologic–staging completed after neoadjuvant therapy AND subsequent surgery
	PRIMARY TUMOR (T)		
❑ TX	Primary tumor cannot be assessed		❑ TX
❑ TO	No evidence of primary tumor		❑ TO
❑ Tis	Tis Carcinoma *in situ*		❑ Tis
❑ T1	Tumor ≤3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)*		❑ T1
❑ T1a	Tumor ≤2 cm in greatest dimension		❑ T1a
❑ T1b	Tumor > 2 cm but ≤3 cm in greatest dimension		❑ T1b
❑ T2	Tumor > 3 cm but ≤7 cm or tumor with any of the following features (T2 tumors with these features are classified T2a if ≤5 cm)		❑ T2
❑ T2a	Involves main bronchus, ≥2 cm distal to the carina		❑ T2a
❑ T2b	Invades visceral pleura (PL1 or PL2)		❑ T2b
❑ T3	Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung		❑ T3
❑ T4	Tumor > 3 cm but ≤5 cm in greatest dimension Tumor > 5 cm but ≤7 cm in greatest dimension Tumor > 7 cm or one that directly invades any of the following: parietal pleural (PL3) chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium; or tumor in the main bronchus (< 2 cm distal to the carina* but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung or separate tumor nodule(s) in the same lobe Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina, separate tumor nodule(s) in a different ipsilateral lobe		❑ T4
	* The uncommon superficial spreading tumor of any size with its invasive component limited to the bronchial wall, which may extend proximally to the main bronchus, is also classified as T1a.		
	REGIONAL LYMPH NODES (N)		
❑ NX	Regional lymph nodes cannot be assessed		❑ NX
❑ NO	No regional lymph node metastasis		❑ NO
❑ N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension		❑ N1
❑ N2	Metastasis in ipsilateral mediastinal and/or subcarinal llymph node(s)		❑ N2
❑ N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)		❑ N3
	DISTANT METASTASIS (M)		
❑ MO	No distant metastasis (no pathologic MO; use clinical M to complete stage group)		❑ M1
	Distant metastasis		❑ M1a
❑ M1	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural (or pericardial) effusion**		
❑ M1a	Distant metastasis		❑ M1b
❑ M1b	**Most pleural (and pericardial) effusions with lung cancer are due to tumor. In a few patients, however, multiple cytopathologic examinations of pleural (pencardial) fluid are negative for tumor, and the fluid is nonbloody and is not an exudate. Where these elements and clinical judgement dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging element and the patient should be classified as MO.

of the TNM descriptors currently used in staging NSCLC and the overall stage classifications. In addition to the TNM stage, it is recommended that histologic grade, presence or absence of pleural/elastic layer invasion, separate tumor nodules, lymphovascular invasion, and residual tumor after treatment also be recorded into cancer registries to facilitate evaluation of these potential predictors in future analysis of staging criteria.

Staging for small cell lung cancer (SCLC) is typically based on the extent of disease. SCLC presenting with bulky locoregional disease confined to the ipsilateral hemithorax, with no evidence for distant metastatic disease, is termed "limited" SCLC. Limited disease must be treatable within a tolerable field of radiation. Using AJCC descriptors, this includes any T stage, any N stage, without metastatic disease (M0). The only exception is when multiple lung nodules are widely spread throughout the ipsilateral lung in the same hemithorax; in these patients, the size of the involved area would preclude a "safe" radiation field. In contrast, in "disseminated" disease, tumor is beyond the ipsilateral hemithorax or widely spread within the ipsilateral lung and to distant sites. Metastases to the pleura and pericardium, with resultant effusions, are considered disseminated disease. Metastases to brain, bone, bone marrow, and the pleural and pericardial spaces are common.

Assessment of Functional Status. Patients with potentially resectable tumors require careful assessment of their functional status and ability to tolerate either lobectomy or pneumonectomy. The surgeon should first estimate the likelihood

of pneumonectomy, lobectomy, or possibly sleeve resection, based on the CT images. A sequential process of evaluation then unfolds.

A patient's history is the most important tool for gauging risk. Specific questions regarding performance status should be routinely asked. If the patient can walk on a flat surface indefinitely, without oxygen and without having to stop and rest secondary to dyspnea, he will be very likely to tolerate lobectomy. If the patient can walk up two flights of stairs (up two standard levels), without having to stop and rest secondary to dyspnea, she will likely tolerate pneumonectomy. Finally, nearly all patients, except those with carbon dioxide (CO_2) retention on arterial blood gas analysis, will be able to tolerate periods of single-lung ventilation and wedge resection.

Current smoking status and sputum production are also pertinent. Current smokers and patients with a greater than 60 pack-year history of smoking have a significantly increased risk of postoperative pulmonary complications; heavy smokers are 2.5 times more likely to develop pulmonary complications and three times more likely to develop pneumonia compared to patients with a ≤60 pack-year history (odds ratio [OR] 2.54; 95% CI 1.28–5.04; $P = .0008$). Impaired exchange of CO_2 is also predictive of increased risk, independent of the smoking history. For every 10% decline in percent carbon monoxide diffusion capacity (%DLCO), the risk of any pulmonary complication increased by 42% (OR 1.42; 95% CI 1.16–1.75; $P = .008$).[42] Risk reduction requires smoking cessation at least 8 weeks preoperatively, a requirement that is often not feasible in a cancer patient. Nevertheless, abstinence for at least 2 weeks before surgery should be encouraged. Smoking cessation on the day of surgery leads to increased sputum production and potential secretion retention postoperatively, and some authors have reported increased rates of pulmonary complications in this group.[43] Patients with chronic daily sputum production will have more problems postoperatively with retention and atelectasis; they are also at higher risk for pneumonia. Sputum culture, antibiotic administration, and bronchodilators may be warranted preoperatively.

6▶

Pulmonary function studies are routinely performed when any resection greater than a wedge resection will be performed. Of all the measurements available, the two most valuable are forced expiratory volume in 1 second (FEV_1) and carbon monoxide diffusion capacity (DLCO). General guidelines for the use of FEV_1 in assessing the patient's ability to tolerate pulmonary resection are as follows: greater than 2.0 L can tolerate pneumonectomy, and greater than 1.5 L can tolerate lobectomy. It must be emphasized that these are guidelines only. It is also important to note that the raw value is often imprecise because normal values are reported as "percent predicted" based on corrections made for age, height, and gender. For example, a raw FEV_1 value of 1.3 L in a 62-year-old, 75-inch male has a percent predicted value of 30% (because the normal expected value is 4.31 L); in a 62-year-old, 62-inch female, the predicted value is 59% (normal expected value 2.21 L). The male patient is at high risk for lobectomy, while the female could potentially tolerate pneumonectomy.

To calculate the predicted postoperative value for FEV_1 or DLCO, the percent predicted value of FEV_1 or DLCO is multiplied by the fraction of remaining lung after the proposed surgery. For example, with a planned right upper lobectomy, a total of three segments will be removed. Therefore, three of a total 20 segments will leave the patient with $(20 - 3/20) \times 100 = 85\%$

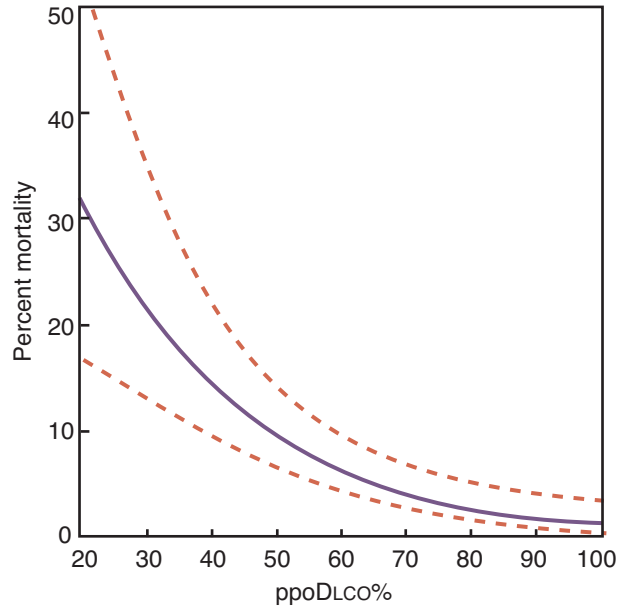

Figure 19-22. Operative mortality after major pulmonary resection for non–small cell lung cancer (334 patients) as a function of percent predicted postoperative carbon monoxide diffusion capacity (ppoDLCO%). *Solid line* indicates logistic regression model; dashed lines indicate 95% confidence limits. *(Adapted with permission from Wang J, Olak K, Ferguson M. Diffusing capacity predicts operative mortality but not long-term survival after resection for lung cancer.* J Thorac Cardiovasc Surg. *1999;117:582. Copyright Elsevier.)*

of their original lung capacity. In the two patients mentioned earlier, the man will have a predicted postoperative FEV_1 of $30\% \times 0.85 = 25\%$, whereas the woman will have a predicted postoperative FEV_1 of 50%. Percent predicted value of less than 50% for either FEV_1 or DLCO correlates with risk for postoperative complications, particularly pulmonary complications; the risk of complications increases in a stepwise fashion for each 10% decline. Figure 19-22 shows the relationship between predicted postoperative DLCO and estimated operative mortality.

Quantitative perfusion scanning is used in select circumstances to help estimate the functional contribution of a lobe or whole lung. Such perfusion scanning is most useful when the impact of a tumor on pulmonary physiology is difficult to discern. With complete collapse of a lobe or whole lung, the impact is apparent, and perfusion scanning is usually unnecessary. Figure 19-23 shows a tumor with significant right main stem airway obstruction with associated atelectasis and volume loss of the right lung. At presentation, the patient was dyspneic with ambulation, and the FEV_1 was 1.38 L. Six months prior, this patient could walk up two flights of stairs without dyspnea. The surgeon can anticipate that the patient will tolerate pneumonectomy because the lung is already not functioning due to main stem airway obstruction, and may, in fact, be contributing to a shunt. However, with centrally located tumors associated with partial obstruction of a lobar or main bronchus or of the pulmonary artery, perfusion scanning may be valuable in predicting the postoperative result of resection. For example, if the quantitative perfusion to the right lung is measured to be 21% (normal is 55%) and the patient's percent predicted FEV_1 is 60%, the predicted postoperative FEV_1 after a right pneumonectomy would be $60\% \times 0.79 = 47\%$, indicating the ability to tolerate pneumonectomy. If the perfusion value is 55%, the predicted

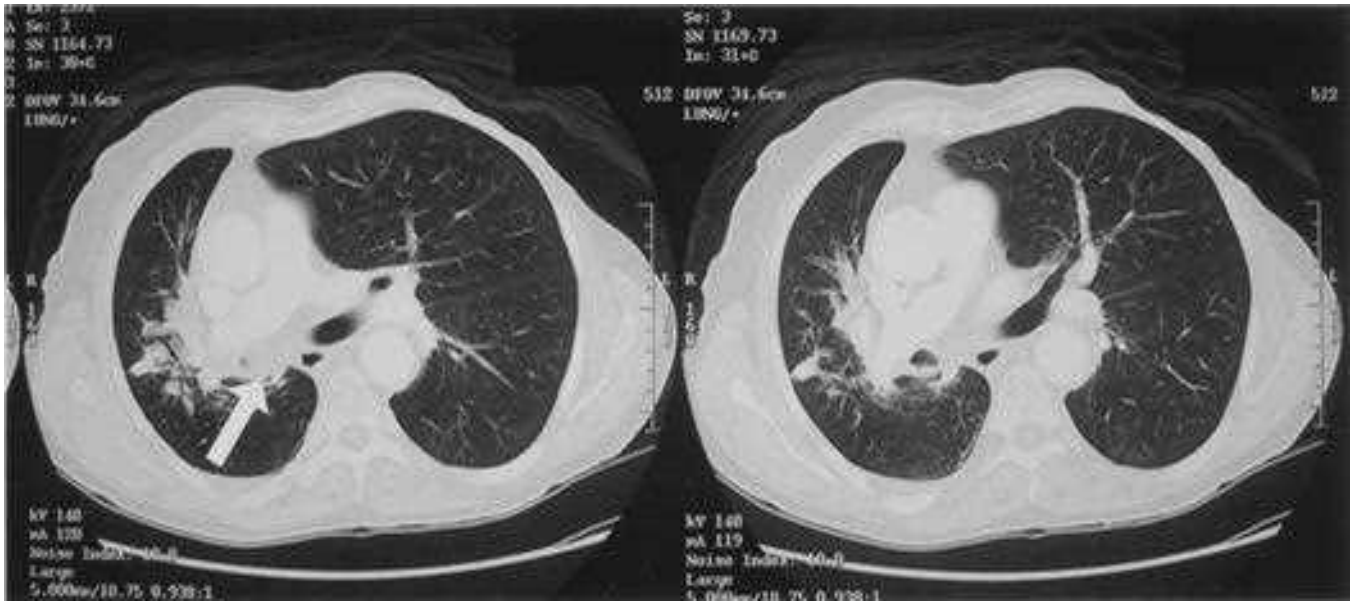

Figure 19-23. Chest computed tomography scan of an obstructing right main stem lung tumor. *Arrow* indicates location of right main bronchus. The right lung volume is much less than the left lung volume.

postoperative value would be 27%, and pneumonectomy would pose a significantly higher risk.

It is not uncommon to encounter patients with significant reductions in their percent predicted FEV_1 and DLCO whose history shows a functional status that is inconsistent with the pulmonary function tests. In these circumstances, exercise testing that yields maximal oxygen consumption ($\dot{V}O_2$ max) has emerged as a valuable decision-making technique to help patients with abnormal FEV_1 and DLCO (Table 19-12). Values of less than 10 mL/kg/min are associated with a 26% mortality after major pulmonary resection compared to only 8.3% with $\dot{V}O_2$ max ≥10 mL/kg/min. Values greater than 15 mL/kg/min generally indicate the patient's ability to tolerate pneumonectomy.

The risk assessment of a patient is an amalgam of clinical judgment and data. The risk assessment described earlier must be integrated with the experienced clinician's sense of the patient and with the patient's attitude toward the disease and toward life. Figure 19-24 provides a useful algorithm for determining suitability for lung resection.[44]

Lung Cancer Treatment

Grade IV NEC (Small Cell) Lung Carcinoma. In rare circumstances where SCLC presents as an isolated lung lesion, lobectomy followed by chemotherapy is warranted after surgical mediastinal staging has confirmed the absence of N2 disease. Often, ultrasound-guided FNA provides a definitive positive diagnosis and more invasive approaches are not needed. However, less than 5% are stage I, and there is no benefit from surgical resection for more advanced-stage disease; treatment is chemotherapy with or without radiation therapy depending on the extent of disease and the patient performance status.

Early-Stage Non–Small Cell Lung Cancer. Early-stage disease includes T1 and T2 tumors (with or without N1 nodal involvement) and T3 tumors (without N1 nodal involvement). This group represents a small but increasing proportion of the total number of patients diagnosed with lung cancer each year (approximately 20% of 101,844 patients from 1989 to 2003).[45] Surgical resection is the current standard, ideally accomplished by video-assisted lobectomy or pneumonectomy, depending on the tumor location.

Despite the term "early-stage," the overall 5-year survival rate for stage I is 65% and only 41% for stage II. Median survival

for untreated patients with stage IA NSCLC is 14 months, and 5-year survival rate is 22%.[46] After surgical resection of postoperative pathologic stage IA disease, 5-year survival is better than with no treatment, but still only 67%.[41] Survival declines with higher stages. Advanced age at diagnosis, male sex, low socioeconomic status, nonsurgical treatment, and poor histologic grade are associated with increased mortality risk on multivariate analysis.[45]

Depending on tumor size and location, lobectomy, sleeve lobectomy, and occasionally pneumonectomy, with mediastinal lymph node dissection or sampling, are appropriate for patients with clinical early-stage disease. Sleeve resection is performed for tumors located at airway bifurcations when an adequate bronchial margin cannot be obtained by standard lobectomy. Pneumonectomy is rarely performed; primary indications for pneumonectomy in early-stage disease include large central tumors involving the distal main stem bronchus and inability to completely resect involved N1 lymph nodes. The latter circumstance occurs with bulky adenopathy or with extracapsular nodal spread.

Management of Early-Stage Lung Cancer in the High-Risk Patient. Lobectomy may not be an option for some patients with early-stage disease, due to poor cardiopulmonary function or other comorbid illnesses. The ultimate decision that a patient is not operable, both with regard to the ability of the patient to tolerate surgery and the likelihood of successful resection, should be accepted only after evaluation by an expert surgeon. Surgeons with limited expertise, when faced with a complicated patient, should refer the patient to a high-volume center for further evaluation if they are unable to offer the patient surgical resection in their own center.

Rationale for Limited Resection in Early-Stage Lung Cancer. Limited resection, defined as segmentectomy or wedge resection, is a viable option for achieving local control in high-risk patients. Historically, limited resection with wedge or segmentectomy has been considered a compromise operation due to unacceptably high rates of local recurrence and concerns for worse survival.[47,48] Subsequent meta-analysis of the literature shows that the difference in death rate is likely negligible[49] (Table 19-13). The high rates of local recurrence demonstrated by Ginsberg and others, however, remain a significant concern and continue to restrict the use of limited resection for early-stage lung cancer to the high-risk patient.

With the recent publication of a 20% reduction in lung cancer mortality with screening CT scans in high-risk populations, the topic of limited resection is again the subject of intensive review. Studies investigating anatomic segmentectomy (or extended wedge resection) with hilar and mediastinal lymph node dissection suggest that close attention to the ratio of surgical margin to tumor diameter and a careful assessment of the lymph nodes substantially reduce local recurrence.[50-52] Recurrence rates were 6.2%, comparable to rates associated with lobectomy, when the margin-to-tumor diameter ratio exceeded 1, compared to 25% if the margin-to-tumor diameter ratio was less than 1.[50] In most centers, this requires use of a thoracotomy, although increasing experience with VATS in high-volume centers shows that limited resection is safe and feasible, with perioperative adverse outcomes that are comparable to lobectomy.[52-55]

Rationale for Tumor Ablation in the Management of Primary Lung Cancer. Limited resection, by definition, requires that the patient has sufficient cardiopulmonary reserve to undergo a general anesthesia and loss of at least one pulmonary segment. For the high-risk or nonoperable patient, as determined by experience pulmonary surgeons, tumor ablation techniques have been developed for treatment of early-stage lung cancers.

Current limitations of this approach include the absence of nodal staging, lack of tissue for molecular profiling, chemoresistance, or sensitivity testing, concerns about definitions of locoregional recurrence, and a lack of uniformity across centers. Surgeons typically define locoregional recurrence as tumor growth within the operative field, including resectable lymph nodes, whereas local recurrence after ablation is most commonly defined as tumor growth within the field of treatment. Despite the fact that in-transit or lymph node metastases are present in up to 27% of clinically stage I NSCLCs at resection, any tumor growth outside the field of ablative treatment is not be considered treatment failure.[56]

Despite these limitations, tumor ablative strategies are increasingly proposed as viable alternatives to surgical resection, even in potentially operable patients.[57-62] While premature, ablative techniques may ultimately be shown to have efficacy equivalent to lobectomy for the primary treatment of very small peripheral early-stage lung cancers. Multidisciplinary collaboration between thoracic surgery, interventional radiology/pulmonology, and radiation oncology is required to ensure that development of these ablative techniques occurs through properly designed and well-controlled prospective studies and will ensure that patients receive the best available therapy, regardless of whether it is surgical resection or ablative therapy.

9▶

The two most commonly applied ablation techniques are radiofrequency ablation and stereotactic body radiotherapy.

1. **Radiofrequency ablation.** Radiofrequency ablation is performed using either monopolar or bipolar delivery of electrical current to electrodes placed within the tumor tissue. In lung tumors, the electrodes are typically inserted into the tumor mass under CT guidance. An electrical current is delivered; the current is converted by means of friction into heat, which quickly leads to immediate and irreparable tissue destruction in the tissue surrounding the electrode. The efficacy of radiofrequency ablation for controlling the primary tumor and improving survival in poor operative candidates (either due to significant comorbid diseases precluding general anesthesia or poor pulmonary function excluding lung resection) is safe and feasible for peripheral lung nodules. In tumors <3.5 cm, the rate of radiographic resolution of tumor is up to 80% and cancer-specific survival at 2 years was approximately 90%, indicating excellent local control of the primary site.[57-59,63] It has become the preferred modality for small peripheral tumors over standard external-beam radiation in centers where the technique is available.

   Radiofrequency ablation is an excellent modality for the patient at risk for adverse outcomes with pulmonary resection or for patients who refuse surgery, and surgeons should have an algorithm for determining which patients are optimal for this modality.[64-69] (see Fig. 19-24). Target lesions larger than 5 cm, tumor abutting the hilum, associated malignant pleural or pericardial effusion, greater than three lesions in one lung, and the presence of pulmonary hypertension are all contraindications to radiofrequency ablation.[64] Proximity to a large vessel is a contraindication not only due to the risk of massive bleeding, but also

Table 19-13

because large blood vessels act as a heat sink and lethal cellular temperatures are less likely to be achieved. For these patients, stereotactic body radiotherapy may provide local tumor control with less risk of major complications. Combination therapy with either external-beam radiation or stereotactic body radiotherapy is also under investigation.

2. **Stereotactic body radiotherapy.** Stereotactic body radiotherapy applies highly focused, high-intensity, three-dimensional conformal radiation to the target lesion over a few sessions. Tumor motion quantification and image guidance technologies have significantly improved the delivery of radiation with high levels of precision to the target lesion. This accuracy is important because the lung is extremely sensitive to radiation injury and the majority of patients with early-stage lung cancer who are currently considered candidates for ablative therapy have marginal lung function; excessive injury to normal surrounding lung tissue is not desirable. Importantly, these techniques allow the safe delivery of up to 66 Gy of radiation to the target tumors without exceeding the maximum-tolerated dose.[62,83] A phase II North American multicenter study recently demonstrated the safety and efficacy of this approach in 59 nonoperable patients.[62] Patients with biopsy-proven, node-negative peripheral NSCLCs less than 5 cm in diameter (T1 or T2) were treated with stereotactic body radiotherapy after they were deemed inoperable, based on coexisting medical conditions, by a thoracic surgeon and/or pulmonologist. Primary tumor control was excellent; at 3 years, 97.6% were deemed to have primary tumor control by the authors and 90.6% had local control. However, it is important

to note that primary tumor failure was defined specifically as at least a 20% increase in the longest diameter of the gross tumor volume by CT scan *and* evidence of tumor viability either by biopsy confirming carcinoma or by demonstration of FDG avidity on PET scan. For viability to be confirmed with PET scan, the uptake was required to be of similar intensity to the pretreatment staging PET scan. Failure beyond a 1.5- to 2-cm margin around the primary tumor volume was considered local failure. Failure in regional node basins was seen in two patients. When compared to locoregional control rates of approximately 6.5% with limited resection, the 3-year locoregional recurrence was higher at 12.8%.

Patient selection for stereotactic body radiotherapy, as with limited resection and radiofrequency ablation, is important. Because the radiation field is so precise, patients with severe emphysema and chronic obstructive pulmonary disease can be safely treated without significant concern for worsening lung function. However, patients with central tumors near the mediastinum and hilum have increased incidence of significant hypoxia, hemoptysis, atelectasis, pneumonitis, and reduced pulmonary function.[83] In the multicenter trial detailed earlier, treated tumors were required to be greater than 2 cm from the proximal bronchial tree in all directions (which they defined as the distal 2 cm of the trachea, carina, and named major lobar bronchi up to their first bifurcation).[62]

Rationale for Chemotherapy in the Management of Early-Stage NSCLC. The role of chemotherapy in early-stage (stage I and II) NSCLC is evolving, with several prospective phase II studies having shown a potential benefit.[84,85] Initial concerns that induction chemotherapy may result in increased perioperative morbidity or mortality appear to be unwarranted, as the incidence of perioperative morbidity and mortality is not different between the two groups, except in patients undergoing right-sided pneumonectomy after induction chemotherapy.[86] As shown in Table 19-14, an absolute survival benefit of 4% to 7% can be realized using induction for all stages of lung cancer, and in situations where use of adjuvant chemotherapy is anticipated, induction chemotherapy is an acceptable alternative.

Table 19-14

Five-year stage-specific survival after induction chemotherapy followed by surgery

STAGE	5-YEAR SURVIVAL (%)	ABSOLUTE BENEFIT (%)	NEW 5-YEAR SURVIVAL (%)
IA	75	4	79
IB	55	6	61
IIA	50	7	57
IIB	40	7	47
IIIA	15–35	6–7	21–42
IIIB	5–10	3–5	8–15

National Comprehensive Cancer Network guidelines currently recommend observation for T1a (≤2 cm) and T1b (>2–≤3 cm), node-negative, completely resected NSCLCs (T1abN0M0). For patients with larger tumors (T2a tumor >3 cm but ≤5 cm; T2b tumor >5 cm but ≤7 cm) that are node-negative, it is recommended that chemotherapy be considered in high-risk patients, ideally in the setting of a clinical trial. High-risk tumor characteristics include poorly differentiated tumors, moderately to poorly differentiated lung neuroendocrine tumors, vascular invasion, resection limited to wedge resection only, tumors >4 cm in size, visceral pleural involvement, and when lymph node sampling at the time of resection was incomplete (Nx).

Evaluation and Management of Locally Advanced NSCLC. Five-year relative survival in patients with locoregional disease is 25%, but there is significant heterogeneity within the group. Stage III disease includes patients with small tumors that have metastasized to the mediastinal lymph nodes as well as large tumors invading unresectable structures or the major carina with no nodal metastasis at all. Patients with clinically evident N2 disease (i.e., bulky adenopathy present on CT scan or mediastinoscopy, with lymph nodes often replaced by tumor) have a 5-year survival rate of 5% to 10% with surgery alone. In contrast, patients with microscopic N2 disease discovered incidentally in one lymph node station after surgical resection have a 5-year survival rate that may be as high as 30%. As a result, many surgeons and oncologists differentiate between microscopic and bulky N2 lymphadenopathy and the number of involved N2 nodal stations in determining whether to proceed with resection following induction therapy. It is generally accepted that surgical resection is appropriate for patients with a single-station metastasis with a single lymph node smaller than 3 cm, although randomized trials specifically investigating resection following induction therapy for patients with single-station microscopic disease have not yet been performed.

Histologic confirmation of N2 nodal metastases is imperative; false-positive findings on PET scan are unacceptably high, and reliance on this modality will lead to significant undertreatment of patients with earlier stage cancers. This is particularly true in regions with high incidence of granulomatous diseases. When N2 nodes are found, incidentally, to harbor metastasis at the time of planned anatomic lung resection, the decision to proceed with resection varies depending on surgeon preference; it is acceptable to either proceed with anatomic resection and mediastinal lymph node sampling/dissection or to stop the procedure, refer the patient for induction therapy, and re-evaluate for resection after induction therapy is completed. When histologically confirmed metastases are found during preoperative staging evaluation, patients should be referred for induction chemotherapy; patients in whom the mediastinal nodes are sterilized by induction therapy have a better prognosis, and surgical resection is generally warranted as part of a multimodal approach. As with preinduction evaluation, histologic confirmation of persistent N2 disease after induction therapy is imperative; patients should not be denied surgical resection following induction chemotherapy based on radiographic evidence for N2 disease because the survival for resected NSCLC is significantly better than with definitive chemotherapy.

Surgery in T4 and Stage IV Disease. Surgery is occasionally appropriate for highly selected patients with tumors invading the SVC, carinal or vertebral body involvement, or satellite nodules in the same lobe (T3, N0-1, M0) or in T4, N0-1 tumors

with limited invasion into the mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, or carina through direct extension. Surgery generally does *not* have a role in the care of patients with any tumor with N3 disease or T4 tumors with N2 disease. Survival rates remain extremely low for these patients. Simlarly, the treatment of patients with stage IV disease is chemotherapy. However, on occasion, patients with a single site of metastasis are encountered, particularly with adenocarcinomas presenting with a solitary brain metastasis. In this highly select group, 5-year survival rates of 10% to 15% can be achieved with surgical excision of the brain metastasis and the primary tumor, assuming it is early stage.

Surgery for Management of Pancoast's Tumor. Carcinoma arising in the extreme apex of the chest with associated arm and shoulder pain, atrophy of the muscles of the hand, and Horner's syndrome presents a unique challenge to the surgeon. Any tumor of the superior sulcus, including tumors without evidence for involvement of the neurovascular bundle, is now commonly known as Pancoast's tumors, after Henry Pancoast who described the syndrome in 1932. The designation is reserved for tumors involving the parietal pleura or deeper structures overlying the first rib. Chest wall involvement at or below the second rib is not a Pancoast's tumor.[74] Treatment is multidisciplinary; due to the location of the tumor and involvement of the neurovascular bundle that supplies the ipsilateral extremity, preserving postoperative function of the extremity is critical. For this reason, resection should only be performed in patients who are proven negative for mediastinal lymph node involvement. Survival with N2 positive nodes is poor, and the morbidity and mortality associated with surgical resection are high. If bulky lymphadenopathy is present, EBUS- or EUS-guided FNA/core-needle biopsy may prove nodal involvement. However, a negative FNA is not sufficient for proving the absence of mediastinal involvement and should be followed by mediastinoscopy to ensure accurate and complete evaluation of the mediastinum.

Because Pancoast's tumors have high rates of local recurrence and incomplete resection, induction chemoradiotherapy followed by surgery is recommended. This treatment regimen was well tolerated in a study performed by the Southwest Oncology Group, with 95% of patients completing induction treatment. Complete resection was achieved in 76%. Five-year survival was 44% overall and 54% when complete resection was achieved. Disease progression with this regimen was predominantly at distant sites, with the brain being the most common.[75] The current treatment algorithm for Pancoast's tumors is presented in Fig. 19-25.

Surgical excision is performed via thoracotomy with en bloc resection of the chest wall and vascular structures and anatomic lobectomy. A portion of the lower trunk of the brachial plexus and the stellate ganglion are also typically resected. With chest wall involvement, en bloc chest wall resection, along with lobectomy, is performed, with or without chest wall reconstruction.

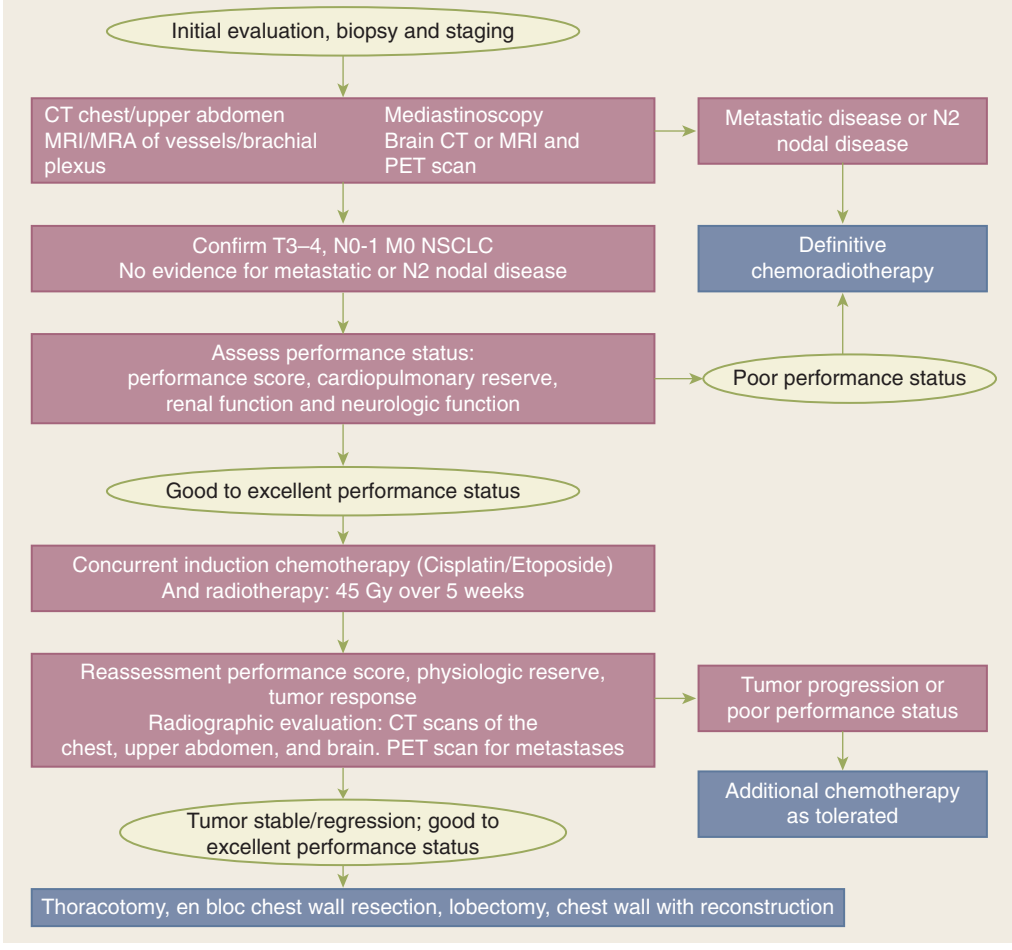

Figure 19-25. Treatment algorithm for Pancoast's tumors. CT = computed tomography; MRA = magnetic resonance angiography; MRI = magnetic resonance imaging; NSCLC = non–small cell lung cancer; PET = positron emission tomography.

For small rib resections or those posterior to the scapula, chest wall reconstruction is usually unnecessary. Larger defects (two rib segments or more) are usually reconstructed with Gore-Tex to provide chest wall contour and stability. En bloc resection is also used for other locally advanced tumors (T3) with direct invasion of the adjacent chest wall, diaphragm, or pericardium. If a large portion of the pericardium is removed, reconstruction with thin Gore-Tex membrane will be required to prevent cardiac herniation and venous obstruction.

Preoperative (Induction) Chemotherapy for NSCLC. The use of chemotherapy before anatomic surgical resection has a number of potential advantages:

1. The tumor's blood supply is still intact, allowing better chemotherapy delivery and avoiding tumor cell hypoxia (in any residual microscopic tumor remaining postoperatively), which would increase radioresistance.
2. The primary tumor may be downstaged, enhancing resectability.
3. Patients are better able to tolerate chemotherapy before surgery and are more likely to complete the prescribed regimen than after surgery.
4. It functions as an in vivo test of the primary tumor's sensitivity to chemotherapy.
5. Response to chemotherapy can be monitored and used to guide decisions about additional therapy.
6. Systemic micrometastases are treated.
7. It identifies patients with progressive disease/non-responders and spares them a pulmonary resection.

Potential disadvantages include:

1. There is a possible increase in the perioperative complication rate in patients requiring right pneumonectomy after induction chemotherapy.
2. While the patient is receiving chemotherapy, potentially curative resection is delayed; if the patient does not respond, this delay could result in tumor spread.

In stage IIIA N2 disease, the response rates to induction chemotherapy are high, in the range of 70%. The treatment is generally safe, as it does not cause a significant increase in perioperative morbidity. Two randomized trials have now compared surgery alone for patients with N2 disease to preoperative chemotherapy followed by surgery. Both trials were stopped before complete accrual because of a significant increase in survival for the chemotherapy arm. The initially observed survival differences have been maintained for up to 3 years and beyond (5-year data not shown). Given these results, induction chemotherapy with cisplatin-based regimens (two to three cycles) has become standard for patients with N2 disease. Table 19-15 summarizes the findings of a systematic review and meta-analysis reporting response rates, progression-free survival, and overall survival after induction chemotherapy followed by surgical resection.

Postoperative (Adjuvant) Chemotherapy for NSCLC. Postoperative adjuvant chemotherapy was previously thought to confer no benefit based on multiple prospective randomized trials, in part because patients who had undergone thoracotomy and lung resection had difficulty tolerating the adjuvant regimens. More recently, however, newer, more effective agents have shown promise and adjuvant therapy is better tolerated after minimally invasive lung resection (i.e., VATS or robotic anatomic resection). Targeted therapies, which have been shown to be beneficial in advanced-stage lung cancer, are of particular interest.

Any patient with nodal metastasis (N1 or N2) or with T3 tumors (defined as tumors >7 cm; invading chest wall, diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium, or main bronchus tumor <2 cm distal to the carina; causing atelectasis or obstructive pneumonitis; or with separate nodules in the same lobe of the lung) should receive adjuvant chemotherapy if they are able to tolerate the regimens. In the situation where the margins of resection are positive, re-resection is recommended. If not possible, concurrent chemoradiation is recommended for macroscopic residual tumor and sequential chemoradiation for microscopic residual tumor.

Definitive Nonsurgical Treatment for NSCLC. Recent advances in targeted therapies have changed the management of advanced NSCLC from a generalized, platinum-based approach to one in which molecular analysis and targeted, personalized therapies are now standard of care. It is now mandatory that the pathologist clearly differentiate between squamous cell carcinoma and adenocarcinoma because the therapeutic options are different and use of bevacizumab, while beneficial in patients with adenocarcinoma, has been found to cause excessive pulmonary hemorrhage in patients with squamous histology. For the surgeon, this requirement translates into a much more aggressive approach to tissue diagnosis. At our institution, the cytopathologist provides onsite rapid assessment of the fine-needle aspirate to determine whether tumor cells are present and confirm that sufficient tumor cells are present to enable molecular testing. This has increased the number of passes performed during an EBUS-guided FNA or during CT-guided aspiration of a pulmonary or intrathoracic lesion; typically, an additional two passes are made for cell block material after confirming the presence of tumor cells in the target area. When insufficient cells are obtained for molecular testing, despite having a diagnosis, additional sampling is warranted; this is mandatory in patients with adenocarcinoma and likely to become necessary for other non–small cell histologic types as advances in targeted therapies become available for clinical use. Acquiring adequate tissue for diagnosis may require mediastinoscopy or VATS; close communication between the oncologist, surgeon, pathologist, and patient is needed to ensure that the benefits to the patient clearly outweigh the risks and that results obtained through more aggressive diagnostic measures are needed to direct subsequent care.

Once a treatment plan has been devised, two strategies for delivery are available. "Sequential" chemoradiation involves full-dose systemic chemotherapy (i.e., cisplatin combined with a second agent) followed by standard radiotherapy (approximately 60 Gy). The combination of chemotherapy followed by radiation has improved 5-year survival from 6% with radiotherapy alone to 17%.[89] An alternative approach, referred to as "concurrent chemoradiation," administers chemotherapy and radiation at the same time. Certain chemotherapeutic agents sensitize tumor cells to radiation and, thus, enhance the radiation effect. The advantages of this approach are improved primary tumor and locoregional lymph node control and elimination of the delay in administering radiotherapy that occurs with sequential treatment. A disadvantage, however, is the necessary reduction in chemotherapy dosage in order to diminish overlapping toxicities; this can potentially lead to undertreatment of systemic micrometastases. Randomized trials have shown a

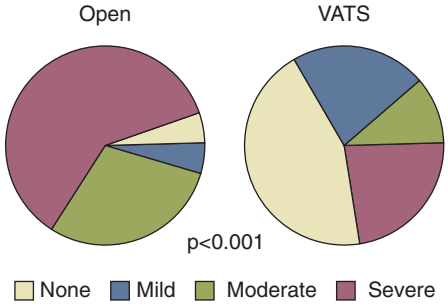

Figure 19-26. Pie chart comparison of pain control at 3 weeks after lobectomy by standard thoracotomy or video-assisted thoracic surgery (VATS). The pie charts show that patients undergoing VATS have significantly less pain ($P < .01$) as measured by the most potent analgesic still required: severe—schedule II narcotic; moderate—schedule III or lower narcotic; mild—nonsteroidal anti-inflammatory drug (NSAID) or acetaminophen. *(Reproduced with permission from Demmy TL, Nwogu C. Is video-assisted thoracic surgery lobectomy better? Quality of life considerations.* Ann Thorac Surg. *2008;85:S719. Copyright Elsevier.)*

modest 5-year survival benefit as compared with chemotherapy. In a systematic review of 47 trials and six meta-analyses, an absolute survival benefit of 4% at 2 years was seen when concurrent platinum-based chemoradiation was given compared to sequential radiation.[98]

Definitive radiotherapy is predominantly used for palliation of symptoms in patients with poor performance status; cure rates with radiation as a single modality in patients with N2 or N3 disease is less than 7%. Recent improvement has been seen with three-dimensional conformal radiotherapy and altered fractionation. Such poor results for patients with stage III lung cancer reflect the limitations of locoregional treatment in a disease where death results from systemic metastatic spread.

Options for Thoracic Surgical Approaches

Thoracic surgical approaches have changed over recent years with advancements in minimally invasive surgery. A surgeon trained in advanced minimally invasive techniques can now perform pleural-based, pulmonary and mediastinal procedures through multiple thoracoscopic ports without the need for a substantial, rib-spreading incision. Subjective measures of quality of life after VATS, such as pain (Fig. 19-26) and perceived functional recovery, consistently and reproducibly favor VATS over thoracotomy. Objective measures such as functional status as measured by 6-minute walk, return to work, and ability to tolerate chemotherapy also favor VATS over thoracotomy. Finally, recovery of respiratory function occurs earlier in VATS patients. These findings are pronounced in patients with chronic obstructive pulmonary disease and in the elderly—populations whose quality of life can be dramatically impacted by changes in their respiratory symptoms and function, thoracic pain, and physical performance. Table 19-16 provides a summary of populations that may benefit from VATS approaches.

Video-Assisted Thoracoscopic Surgery. VATS has become the recommended approach to diagnosis and treatment of pleural effusions, recurrent pneumothoraces, lung biopsies, lobectomy or segmental resection, resection of bronchogenic and mediastinal cysts, and intrathoracic esophageal mobilization for esophagectomy.[99] It is also utilized for pneumonectomy in some centers of excellence with very high volumes of VATS lung resection. VATS is performed via two to four incisions measuring 0.5 to 1.2 cm in length to allow insertion of the thoracoscope

Table 19-16

Special circumstances under which lobectomy by video-assisted thoracic surgery may be preferable

CONDITION	EXAMPLES
Pulmonary compromise	Poor FEV_1/DLCO, heavy smoking, sleep apnea, recent pneumonia
Cardiac dysfunction	Congestive heart failure, severe coronary artery disease, recent myocardial infarction, valvular disease
Extrathoracic malignancy	Solitary brain metastasis from lung cancer, deep pulmonary metastases requiring lobectomy
Poor physical performance	Performance status equivalent to a Zubrod score of 2 or 3, morbid obesity
Rheumatologic/orthopedic condition	Spinal disease, severe rheumatoid arthritis, severe kyphosis, lupus erythematosus, osteomyelitis
Advanced age	Age >70 years
Vascular problems	Aneurysm, severe peripheral vascular disease
Recent or impending major operation	Urgent abdominal operation, joint replacement requiring use of crutches, need for contralateral thoracotomy
Psychological/neurologic conditions	Substance abuse, poor command following, pain syndromes
Immunosuppression/ impaired wound healing	Recent transplantation, diabetes

DLCO = carbon monoxide diffusion capacity; FEV_1 = forced expiratory volume in 1 second.

and instruments. An access incision, typically in the fourth or fifth intercostal space in the anterior axillary line, is used for dissection of the hilum during lung resection. The incision location varies according to the procedure. With respect to VATS lobectomy, port placement varies according to the lobe being resected and is highly variable among surgeons.[100] The basic principle is to position the ports high enough on the thoracic cage to have access to the hilar structures Endoscopic staplers are used to divide the major vascular structures and bronchus (Fig. 19-27).

Open approaches to Thoracic Surgery. When video-assisted thoracoscopic approach is not possible, an open approach, most frequently the posterolateral thoracotomy, is used to gain access to the intrathoracic space.[101,102] The posterolateral thoracotomy

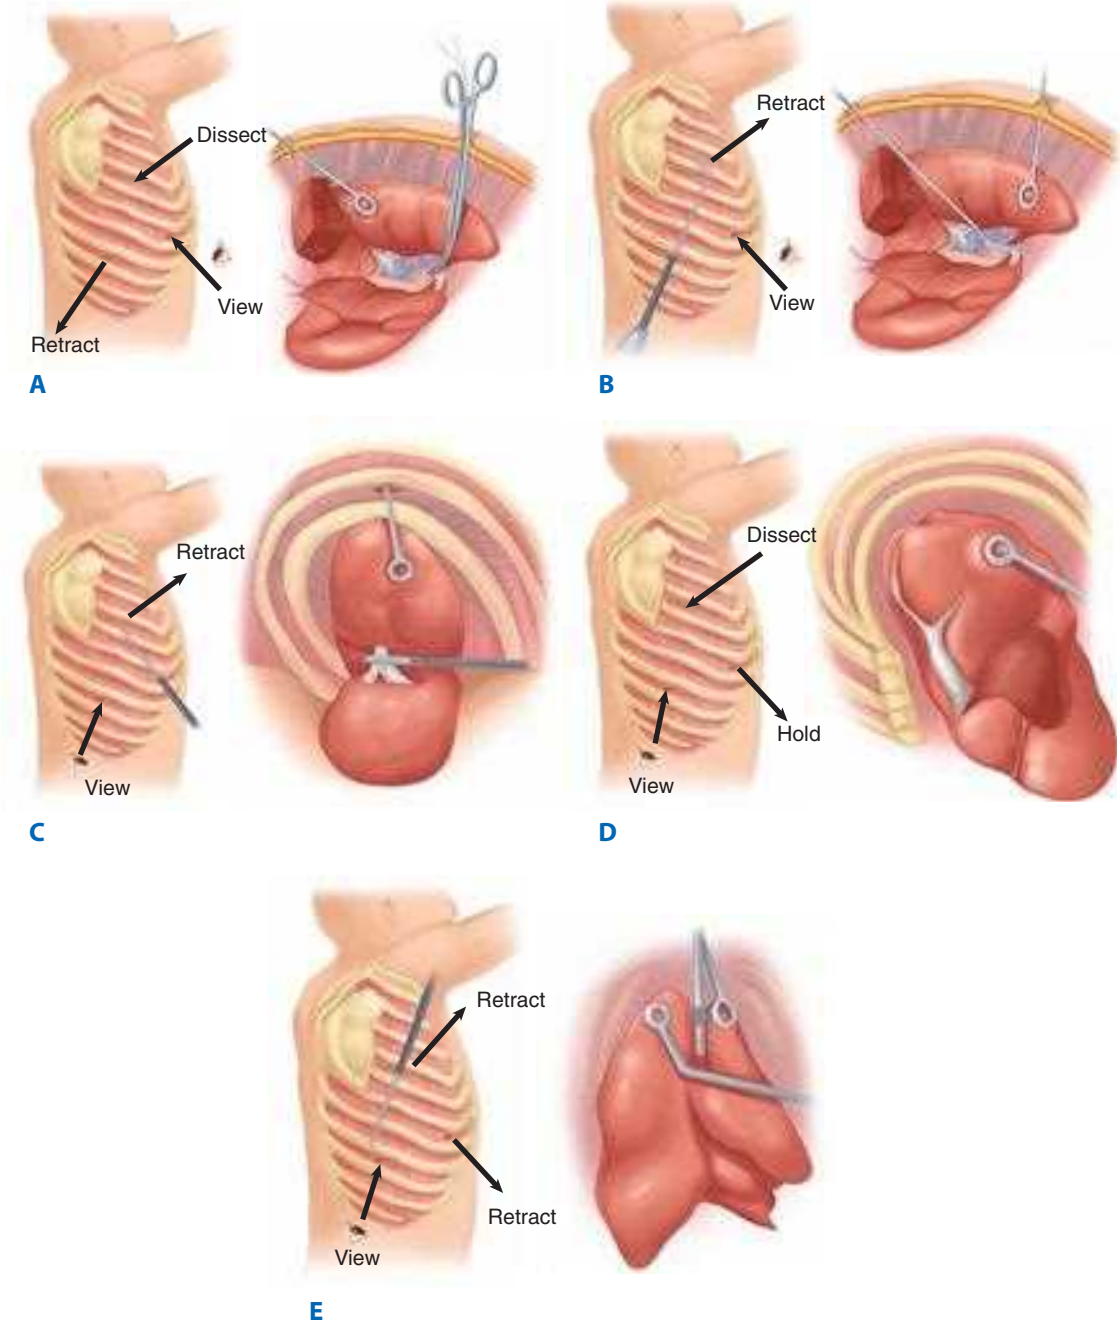

Figure 19-27. Selected video-assisted thoracic surgery lobectomy maneuvers. All the maneuvers are shown with the patient positioned in the left lateral decubitus position. The same maneuvers can be performed in mirror image for left-sided work. **A.** Medial viewing and inferior holding of lung to allow dissection through the access incision. Example shows dissection of the apical hilum. **B.** Medial viewing and access holding of lung to allow stapling of hilar structures from below. Example shows division of the apical pulmonary artery trunk to the right upper lobe (upper lobe branch of vein divided and reflected away). **C.** Standard viewing and use of working port to dissect and divide structures while lung is retracted through access incision. Example shows use of stapler to divide pulmonary artery to right lower lobe. **D.** Standard viewing and use of working port to retract lung and access incision to dissect structures. This method is commonly used to dissect the pulmonary artery in the major fissure. Example shows inferior pulmonary vein after the pulmonary ligament was divided using this maneuver. **E.** Standard viewing and use of access incision to deliver stapler to divide fissures. Example shows division of the posterior fissure between the right lower lobe and the upper lobe. *(Reproduced with permission from Demmy et al.[100] Copyright Elsevier.)*

incision can be used for most pulmonary resections, esophageal operations, and operations in the posterior mediastinum and vertebral column (Fig. 19-28). The anterolateral thoracotomy has traditionally been used in trauma victims. This approach allows quick entry into the chest with the patient supine. In the face of hemodynamic instability, the lateral decubitus position significantly compromises control over the patient's cardiopulmonary system and resuscitation efforts, whereas the supine position allows the anesthesiologist full access to the patient. A bilateral anterior thoracotomy incision with a transverse sternotomy ("clamshell" thoracotomy) is a standard operative approach to the heart and mediastinum in certain elective circumstances. It is the preferred incision for double-lung transplantation in many centers. A partial median sternotomy can also be added to an anterior thoracotomy ("trap-door" or "hemiclamshell" thoracotomy) for access to mediastinal structures. A hypesthetic nipple is a frequent complication of this approach. The median sternotomy incision allows exposure of anterior mediastinal structures and is principally used for cardiac operations. Although the surgeon has access to both pleural cavities, incision into the pleural cavity can be avoided if entry is unnecessary (Fig. 19-29).

Postoperative Care

Chest Tube Management. At the conclusion of most thoracic operations, the pleural cavity is drained with a chest tube(s). If the visceral pleura has not been violated and there is no concern

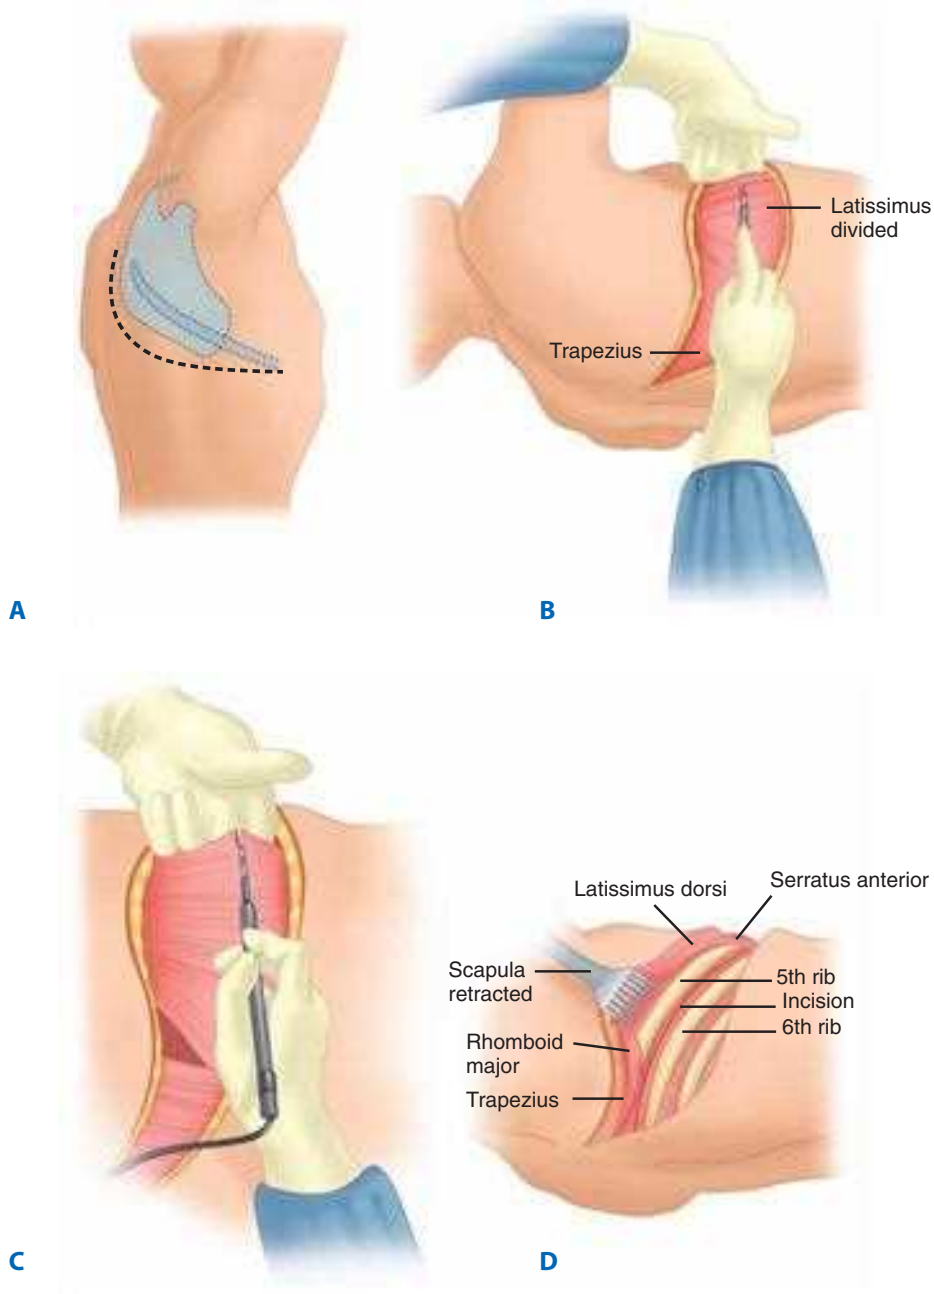

Figure 19-28. The posterolateral thoracotomy incision. **A.** Skin incision from the anterior axillary line to the lower extent of the scapula tip. **B** and **C.** Division of the latissimus dorsi and shoulder girdle musculature. **D.** The pleural cavity is entered after dividing the intercostal muscles along the lower margin of the interspace, taking care not to injure the neurovascular bundle lying below each rib.

for pneumo- or hemothorax (e.g., after VATS sympathectomy), a chest tube is unnecessary. After chest tube placement, the lung is re-expanded with positive-pressure ventilation. There are two reasons for the use of pleural tubes in this setting: first, the tube allows evacuation of air if an air leak is present; second, blood and pleural fluid can be drained, thereby preventing accumulation within the pleural space that would compromise the patient's respiratory status. The tube is removed when the air leak is resolved and when the volume of drainage decreases below an acceptable level over 24 hours.

Historically, many surgeons have somewhat arbitrarily required less than 150 mL of drainage volume over 24 hours prior to removing a chest tube to minimize risk of reaccumulation. The pleural lymphatics, however, can absorb up to 0.40 mL/kg per hour in a healthy individual, which may be as much as 500 mL over a 24-hour period. In fact, studies have shown that pleural tubes can be removed after VATS lobectomy or thoracotomy with 24-hour drainage volumes as high as 400 mL, without subsequent development of pleural effusions.[103] It is our current practice to remove chest tubes with 24-hour outputs of 400 mL or less after lobectomy or lesser pulmonary resections. In settings where normal pleural fluid dynamics have been altered, such as malignant pleural effusion, pleural space infections or inflammation, and pleurodesis, strict adherence to a volume requirement before tube removal is appropriate (typically 100–150 mL over 24 hours).

For operations involving lung resection or parenchymal injury, suction levels of –20 cm H_2O are routinely used to eradicate residual air spaces and to control postoperative parenchymal air leaks for the first 12 to 24 hours. The following day, however, the decision to continue suction or place the patient to water seal (off suction) must be made. Applying suction to an air leak has been shown to prolong the duration of the air leak and extend the time frame during which tube thoracostomy is needed.[104] The main guidelines for the continued use of suction if an air leak is present depend on the expansion of the remaining lung as determined by CXR. If the lung is well-expanded, the chest tube can remain to water seal drainage. If an undrained pneumothorax is present on CXR, the chest tube and its attached tubing should be examined to ensure that the chest tube is patent and the attached tubing is not kinked or mechanically obstructed, such as occurs when the patient is lying on the tube. If the tube is a small caliber tube (aka pigtail catheter), it should be flushed with sterile saline through a three-way stopcock that has been cleaned with alcohol because these tubes tend to become clogged with fibrin. These catheters are also prone to kinking at the insertion site into the skin. Once the surgeon has confirmed that the chest tube is patent, the patient is asked to voluntarily cough or perform the Valsalva maneuver. This maneuver increases the intrathoracic pressure and will push air that is contained within the hemithorax out of the chest tube. During the voluntary cough, the fluid level in the water seal chamber should move up and down with the cough and with deep respiration, reflecting the pleural pressure changes occurring with these maneuvers. A stationary fluid level implies either a mechanical blockage (e.g., due to external tube compression or to a clot/debris within the tube) or pleurodesis of the pleural space. If bubbles pass through the water seal chamber, an air leak is presumed. If the leak is significant enough to induce atelectasis or collapse of the lung during use of water seal, suction should be used to achieve lung re-expansion.

Pain Control. Good pain control after intrathoracic procedures is critical; it permits the patient to actively clear and manage secretions and promotes ambulation and a feeling of well-being. The most common techniques of pain management are epidural, paravertebral, and intravenous. Epidural catheters are commonly used, although we prefer to use paravertebral catheters in our center. To maximize efficacy, epidural catheters should be inserted at about the T6 level, roughly at the level of the scapular tip. Lower placement risks inadequate pain control, and higher placement may provoke hand and arm numbness. Typically, combinations of fentanyl at 0.3 µg/mL with either bupivacaine (0.125%) or ropivacaine (0.1%) are used. Ropivacaine has less cardiotoxicity than bupivacaine; thus, the potential for refractory complete heart block, in the case of inadvertent intravenous injection, is significantly less with ropivacaine. Paravertebral blocks can be placed using the same epidural catheter kit 2.5 cm lateral to the spinous process at T4 to T6. Combinations of narcotic and topical analgesia are then infused as with the epidural catheter.

When properly placed, a well-managed epidural can provide outstanding pain control without significant systemic sedation.[105] Thoracic epidurals do not commonly cause urinary retention, although a low thoracic epidural may block the sensory fibers to the bladder. Motor function, however, remains

intact. In some patients who are having difficulty voiding, it may be possible to avoid Foley catheterization by simply reminding the patient to void on a regular basis. In male patients with voiding difficulty prior to surgery, urinary catheterization may be required. In addition, the use of local anesthetics may cause sympathetic outflow blockade, leading to vasodilation and hypotension often requiring intravenous vasoconstrictors (an α-agonist such as phenylephrine) and/or fluid administration. In such circumstances, fluid administration for hypotension may be undesirable in pulmonary surgery patients, particularly after pneumonectomy. Paravertebral catheters provide equivalent pain control with less effect on hemodynamics.[106]

Alternatively, intravenous narcotics via patient-controlled analgesia can be used, often in conjunction with ketorolac and intravenous Tylenol. Dosing must be titrated to balance the degree of pain relief with the degree of sedation. Oversedated patients are as ominous as patients without adequate pain control, because of the significant risk of secretion retention, atelectasis/pneumonia, and pulmonary aspiration. These concerns are particularly relevant in elderly patients who should be carefully assessed for aspiration risk when ordered for dietary advancement. Proper pain control with intravenous narcotics requires a carefully regulated balance between pain relief and sedation; maximizing the benefits of pain control while minimizing these very real and potentially life-threatening complications.

Whether on epidural, paravertebral, or intravenous pain control, the patient is typically transitioned to oral pain medication on the third or fourth postoperative day. During both the parenteral and oral phase of pain management, a standardized regimen of stool softeners and laxatives is advisable in order to prevent severe constipation.

Respiratory Care. The best respiratory care is achieved when the patient is able to deliver an effective cough to clear secretions and results from the commitment and proper training of all involved healthcare providers. The process begins preoperatively, with clear instructions on using pillows (or other support techniques) over the wound and then applying pressure. Postoperatively, proper pain control (as outlined earlier) is essential, without oversedation. Daily morning rounds should include a careful assessment of the patient's pulmonary status, reminders to the patient and family about the importance of coughing and deep breathing, including use of adjunctive respiratory equipment if ordered, and mobilization of the patient. Early transition to a chair and to ambulation is the best respiratory therapy and should be strongly encouraged. When available, physical and/or cardiopulmonary rehabilitation services are vital additional members of the care team.

In patients whose pulmonary function is significantly impaired preoperatively, generating an effective cough postoperatively may be nearly impossible. In this setting, routine nasotracheal suctioning can be employed, but is uncomfortable for the patient. A better alternative is placement of a percutaneous transtracheal suction catheter at the time of surgery. This catheter is well-tolerated by most patients and allows regular and convenient suctioning.

Postoperative Complications

Postoperative complications after pulmonary resection range from minor to life-threatening. Strict attention to volume status, early and aggressive pulmonary toilet, and good pain control can reduce the risk of most complications, but does not completely eliminate them, even in centers of excellence. The most devastating complication after pulmonary resection is postpneumonectomy pulmonary edema, which occurs in 1% to 5% of patients undergoing pneumonectomy and more often after right compared to left pneumonectomy. Clinically, symptoms of respiratory distress manifest hours to days after surgery. Radiographically, diffuse interstitial infiltration or frank alveolar edema is seen. The pathophysiologic causes are related to factors that increase permeability and filtration pressure and decrease lymphatic drainage from the affected lung. Judicious use of intravenous fluids perioperatively, including use of vasopressors rather than fluid boluses for hypotension intraoperatively and postoperatively, is critical to minimizing the risk of this syndrome. Treatment consists of ventilatory support, fluid restriction, and diuretics. Extracorporeal membrane oxygenation may be life-saving in centers where this option is available. The syndrome reportedly has a nearly 100% mortality rate despite aggressive therapy.

Other postoperative complications include air leak and bronchopleural fistula. Although these are two very different problems, distinguishing between them may be difficult. Postoperative air leaks are common after pulmonary resection, particularly in patients with emphysematous lung, because the fibrosis and destroyed blood supply impairs healing of surface injuries. Prolonged air leaks (i.e., those lasting >5 days) may be treated by diminishing or discontinuing suction (if used), by continuing chest drainage, or by instilling a pleurodesis agent, usually doxycycline or talcum powder, which will cause pleurodesis of the lung within the chest cavity and minimize the possible collapse of the lung due to persistent air leak. This is useful only in patients in whom full lung expansion is achieved, either with suction or on water seal, as patients with a persistent pneumothorax on CXR will not have adequate lung-to-parietal pleural apposition to achieve adequate pleurodesis.

If the leak is moderate to large, a high index of suspicion for bronchopleural fistula from the resected bronchial stump should be maintained, particularly if the patient is immunocompromised or had induction chemotherapy and/or radiation therapy. If a bronchopleural fistula is suspected, flexible bronchoscopy is performed to evaluate the bronchial stump. Management options include continued prolonged chest tube drainage, reoperation, and reclosure (with stump reinforcement with an intercostal muscle flap or a pedicled serratus muscle flap). If the fistula is very small (<4 mm), bronchoscopic fibrin glue application has been used successfully to seal the hole in some patients. Patients often have concomitant empyema, and open drainage may be necessary.

Spontaneous Pneumothorax

Spontaneous pneumothorax is secondary to intrinsic abnormalities of the lung and can be classified as primary and secondary. Primary spontaneous pneumothorax is defined as a spontaneous pneumothorax without underlying lung disease. The most common cause is rupture of an apical subpleural bleb. The cause of these blebs is unknown, but they occur more frequently in smokers and males, and they tend to predominate in young postadolescent males with a tall thin body habitus. Treatment is generally chest tube insertion with water seal. If a leak is present and persists for greater than 3 days, thoracoscopic management (i.e., bleb resection with pleurodesis by talc or pleural abrasion) is performed. Recurrences or complete lung collapse with the first episode are generally indications for thoracoscopic intervention.[107] Additional indications for intervention on the first

episode include occupational hazards such as air travel, deep-sea diving, or travel to remote locations. CT findings of multiple small bullae or a large bleb are associated with an increased risk of recurrent pneumothorax.[108] Many surgeons are now using screening CT scan to recommend VATS bleb resection with pleurodesis for first-episode spontaneous pneumothorax.

Secondary spontaneous pneumothorax occurs in the setting of underlying lung disease, such as emphysema (rupture of a bleb or bulla), cystic fibrosis, acquired immunodeficiency syndrome (AIDS), metastatic cancer (especially sarcoma), asthma, lung abscess, and occasionally primary lung cancer. Catamenial pneumothorax, a rare but interesting cause of spontaneous pneumothorax in women in their second and third decades, occurs within 72 hours of the onset of menses and is possibility related to endometriosis. Management of pneumothorax in these circumstances is similar to that of primary spontaneous pneumothorax in that drainage and lung re-expansion are required. Additional therapy, however, is often tied to therapy of the specific disease process and may involve lung resection, thoracoscopic pleurectomy, or talc pleurodesis.

Pulmonary Infections

Lung Abscess. A *lung abscess* is a localized area of pulmonary parenchymal necrosis caused by an infectious organism; tissue destruction results in a solitary or dominant cavity measuring at least 2 cm in diameter. Less often, there may be multiple, smaller cavities (<2 cm). In that case, the infection is typically referred to as a necrotizing pneumonia. An abscess that is present for more than 6 weeks is considered chronic.

Based on the etiology (Table 19-17), lung abscesses are further classified as primary or secondary. A primary lung abscess occurs, for example, in immunocompromised patients, as a result of highly virulent organisms inciting a necrotizing pulmonary infection, or in patients who have a predisposition to aspirate oropharyngeal or gastrointestinal secretions. A secondary lung abscess occurs in patients with an underlying condition such as a partial bronchial obstruction, a lung infarct, or adjacent suppurative infections (subphrenic or hepatic abscesses).[109]

Pathogenesis. Lung abscesses result when necrotizing microorganisms infect the lower respiratory tract via inhalation of aerosolized particles, aspiration of oropharyngeal secretions, or hematogenous spread from distant sites. Direct extension from a contiguous site is less frequent. Most primary lung abscesses are suppurative bacterial infections secondary to aspiration. Risk factors for pulmonary aspiration include advanced age, conditions of impaired consciousness, suppressed cough reflex, dysfunctional esophageal motility, laryngopharygeal reflux disease, and centrally acting neurologic diseases (e.g., stroke). At the time of aspiration, the composition of the oropharyngeal flora determines the etiologic organisms. With increasing use of proton pump inhibitors to suppress acid secretion in the stomach, the oropharyngeal flora has shifted and the risk of developing bacterial lung infections after an aspiration event has increased.[110] Secondary lung abscesses occur most often distal to an obstructing bronchial carcinoma. Infected cysts or bullae are not considered true abscesses.

Microbiology. Normal oropharyngeal secretions contain many more *Streptococcus* species and more anaerobes (approximately 1×10^8 organisms/mL) than aerobes (approximately 1×10^7 organisms/mL). Pneumonia that follows from aspiration, with or without abscess development, is typically polymicrobial.

Table 19-17

Causes of lung abscess

I. Primary
  A. Necrotizing pneumonia
    1. *Staphylococcus aureus, Klebsiella, Pseudomonas, Mycobacterium*
    2. *Bacteroides, Fusobacterium, Actinomyces*
    3. *Entamoeba, Echinococcus*
  B. Aspiration pneumonia
    1. Anesthesia
    2. Stroke
    3. Drugs or alcohol
  C. Esophageal disease
    1. Achalasia, Zenker's diverticulum, gastroesophageal reflux
  D. Immunodeficiency
    1. Cancer (and chemotherapy)
    2. Diabetes
    3. Organ transplantation
    4. Steroid therapy
    5. Malnutrition
II. Secondary
  A. Bronchial obstruction
    1. Neoplasm
    2. Foreign body
  B. Systemic sepsis
    1. Septic pulmonary emboli
    2. Seeding of pulmonary infarct
  C. Complication of pulmonary trauma
    1. Infection of hematoma or contusion
    2. Contaminated foreign body or penetrating injury
  D. Direct extension from extraparenchymal infection
    1. Pleural empyema
    2. Mediastinal, hepatic, subphrenic abscess

Source: Adapted with permission from Rusch VW, et al. Chest wall, pleura, and mediastinum. In: Schwartz SI, et al, eds. *Principles of Surgery.* 7th ed. New York: McGraw-Hill; 1999:735.

An average of two to four isolates present in large numbers have been cultured from lung abscesses sampled percutaneously. Overall, at least 50% of these infections are caused by purely anaerobic bacteria, 25% are caused by mixed aerobes and anaerobes, and 25% or fewer are caused by aerobes only. In nosocomial pneumonia, 60% to 70% of the organisms are gram-negative bacteria, including *Klebsiella pneumoniae, Haemophilus influenzae, Proteus* species, *Pseudomonas aeruginosa, Escherichia coli, Enterobacter cloacae,* and *Eikenella corrodens*. Immunosuppressed patients may develop abscesses because of the usual pathogens as well as less virulent and opportunistic organisms such as *Salmonella* species, *Legionella* species, *Pneumocystis carinii,* atypical mycobacteria, and fungi.

Clinical Features and Diagnosis. The typical presentation may include productive cough, fever (>38.9°C), chills, leukocytosis (>15,000 cells/mm^3), weight loss, fatigue, malaise, pleuritic chest pain, and dyspnea. Lung abscesses may also present in a more indolent fashion, with weeks to months of cough, malaise, weight loss, low-grade fever, night sweats, leukocytosis, and anemia. After aspiration pneumonia, 1 to 2 weeks typically elapse before cavitation occurs; 40% to 75% of such patients produce putrid, foul-smelling sputum. Severe complications

such as massive hemoptysis, endobronchial spread to other portions of the lungs, rupture into the pleural space and development of pyopneumothorax, or septic shock and respiratory failure are rare in the modern antibiotic era. The mortality rate is about 5% to 10%, except in the presence of immunosuppression, where rates range from 9% to 28%.

The CXR is the primary tool for diagnosing a lung abscess (Fig. 19-30). Its distinguishing characteristic is a density or mass with a relatively thin-walled cavity. An air-fluid level observed within the abscess indicates communication with the tracheobronchial tree. CT scan of the chest clarifies the diagnosis when CXR is equivocal and identifies endobronchial obstruction and/or an associated mass and other pathologic anomalies. A cavitating lung carcinoma is frequently mistaken for a lung abscess. Differential diagnosis also includes loculated or interlobar empyema, infected lung cysts or bullae, tuberculosis, bronchiectasis, fungal infections, and noninfectious inflammatory conditions (e.g., Wegener's granulomatosis).

Ideally, the specific etiologic organism is identified before antibiotic administration. Bronchoscopy, which is essential to rule out endobronchial obstruction due to tumor or foreign body, is ideal for obtaining uncontaminated cultures using bronchoalveolar lavage. Culture samples can also be obtained by percutaneous, transthoracic FNA under ultrasound or CT guidance. Routine sputum cultures are often of limited usefulness because of contamination with upper respiratory tract flora.

Actinomycosis and nocardiosis, although rare, are particularly virulent infections associated with lung abscess, and diagnosis can be difficult.[111] Both frequently masquerade as other clinical syndromes; thus, it is important for the surgeon to keep these bacteria in mind when considering the differential diagnosis for cavitary lung lesions. *Actinomyces*, a normal oropharyngeal bacterium, causes extensive pulmonary damage as the result of aspiration. Actinomycosis lung infection typically begins as acute pneumonitis after an aspiration. The symptoms mimic pulmonary tuberculosis, including chronic cough, night sweats, weight loss, and hemoptysis. Ongoing infection leads to chronic inflammation and fibrosis; cavitation occurs due to destruction of the pulmonary tissues. Without treatment, the infection continues to destroy surrounding structures, which can result in fistula formation into the adjacent structures, including the adjacent lung, interlobar fissures, pleural space, chest wall, and mediastinum. *Actinomyces israelii* is the most common cause of disease among the *Actinomyces* species. Nocardiosis is also a rare opportunistic infection that usually occurs in an immunocompromised host (human immunodeficiency virus [HIV] or cancer patients) and causes both local and systemic suppurative infections. The most common site is pulmonary, caused by *Nocardia asteroides* in 90% of cases; one series, however, reported a high prevalence of the particularly virulent species, *Nocardia farcinica*. Similar to actinomycosis, infection is slowly progressive, with weight loss, fatigue, cough, and hemoptysis. An acute pulmonary infection is common, with necrotizing pneumonia and cavitation or slowly enlarging pulmonary nodule(s). In some cases, empyema also develops.

Management of Lung Abscess. Systemic antibiotics directed against the causative organism represent the mainstay of therapy. The duration of antimicrobial therapy varies from 3 to 12 weeks for necrotizing pneumonia and lung abscess. It is likely best to treat until the cavity is resolved or until serial radiographs show significant improvement. Parenteral therapy is generally used until the patient is afebrile and able to demonstrate consistent enteral intake. Oral therapy can then be used to complete the course of therapy. For community-acquired infections secondary to aspiration, likely pathogens are oropharyngeal streptococci and anaerobes. Penicillin G, ampicillin, and amoxicillin are the main therapeutic agents, but a β-lactamase inhibitor or metronidazole should be added to cover the increasing prevalence of gram-negative anaerobes that produce β-lactamase. Clindamycin is also a primary therapeutic agent. For hospital-acquired infections, *Staphylococcus aureus* and aerobic gram-negative bacilli are common organisms of the oropharyngeal flora. Piperacillin or ticarcillin with a β-lactamase inhibitor (or equivalent alternatives) provide better coverage of likely pathogens.

Surgical drainage of lung abscesses is uncommon since drainage usually occurs spontaneously via the tracheobronchial tree. Indications for intervention are listed in Table 19-18. Drainage and resection may be required for actinomycosis and nocardiosis; diagnosis is often delayed because the bacteria are difficult to culture; invasion of the infection into surrounding structures is, therefore, common. Once identified, long-term antibiotics (months to years) are typically required along with drainage, debridement, and resection as needed. While penicillin derivatives are effective against most *Actinomyces* species, the infections are typically polymicrobial, and broad-spectrum parenteral antibiotics may be required. *Nocardia* species, in contrast, are highly variable; specific identification of the infecting species with antibiotic sensitivities is needed to direct appropriate therapy. Evaluation for malignant spread, particularly to the brain, is also required in the management of nocardiosis, as systemic dissemination occurs early and frequently.

External drainage may be accomplished with tube thoracostomy, percutaneous drainage, or surgical cavernostomy. The choice between tube thoracostomy versus radiographically guided catheter placement depends on the treating physician's preference and the availability of interventional radiology. Surgical resection is required in fewer than 10% of lung abscess patients. Lobectomy is the preferred intervention for bleeding from a lung abscess or pyopneumothorax. An important intraoperative consideration is to protect the contralateral lung with a double-lumen tube, bronchial blocker, or contralateral main stem intubation. Surgical treatment has a 90% success rate, with an associated mortality of 1% to 13%.

Bronchiectasis. Bronchiectasis is defined as a pathologic and permanent dilation of bronchi with bronchial wall thickening. This condition may be localized to certain bronchial segments, or it may be diffuse throughout the bronchial tree, typically affecting the medium-sized airways. Overall, this is a rare clinical entity in the United States with a prevalence of less than 1 in 10,000, although the incidence has increased in recent years and noncystic fibrosis–related bronchiectasis is now thought to affect 27.5 out of every 10,000 persons over age 75.

Pathogenesis. Development of bronchiectasis can be attributed to either congenital or acquired causes. The principal congenital diseases that lead to bronchiectasis include cystic fibrosis, primary ciliary dyskinesia, and immunoglobulin deficiencies (e.g., selective IgA deficiency). Congenital causes tend to produce a diffuse pattern of bronchial involvement. Acquired causes are categorized broadly as infectious and inflammatory. Bronchial obstruction from cancer, inhaled objects, extrinsic airway compression, or inspissated sputum promotes localized infection and subsequent medium airway destruction. Diffuse pneumonic processes from pathogens including necrotizing bacterial

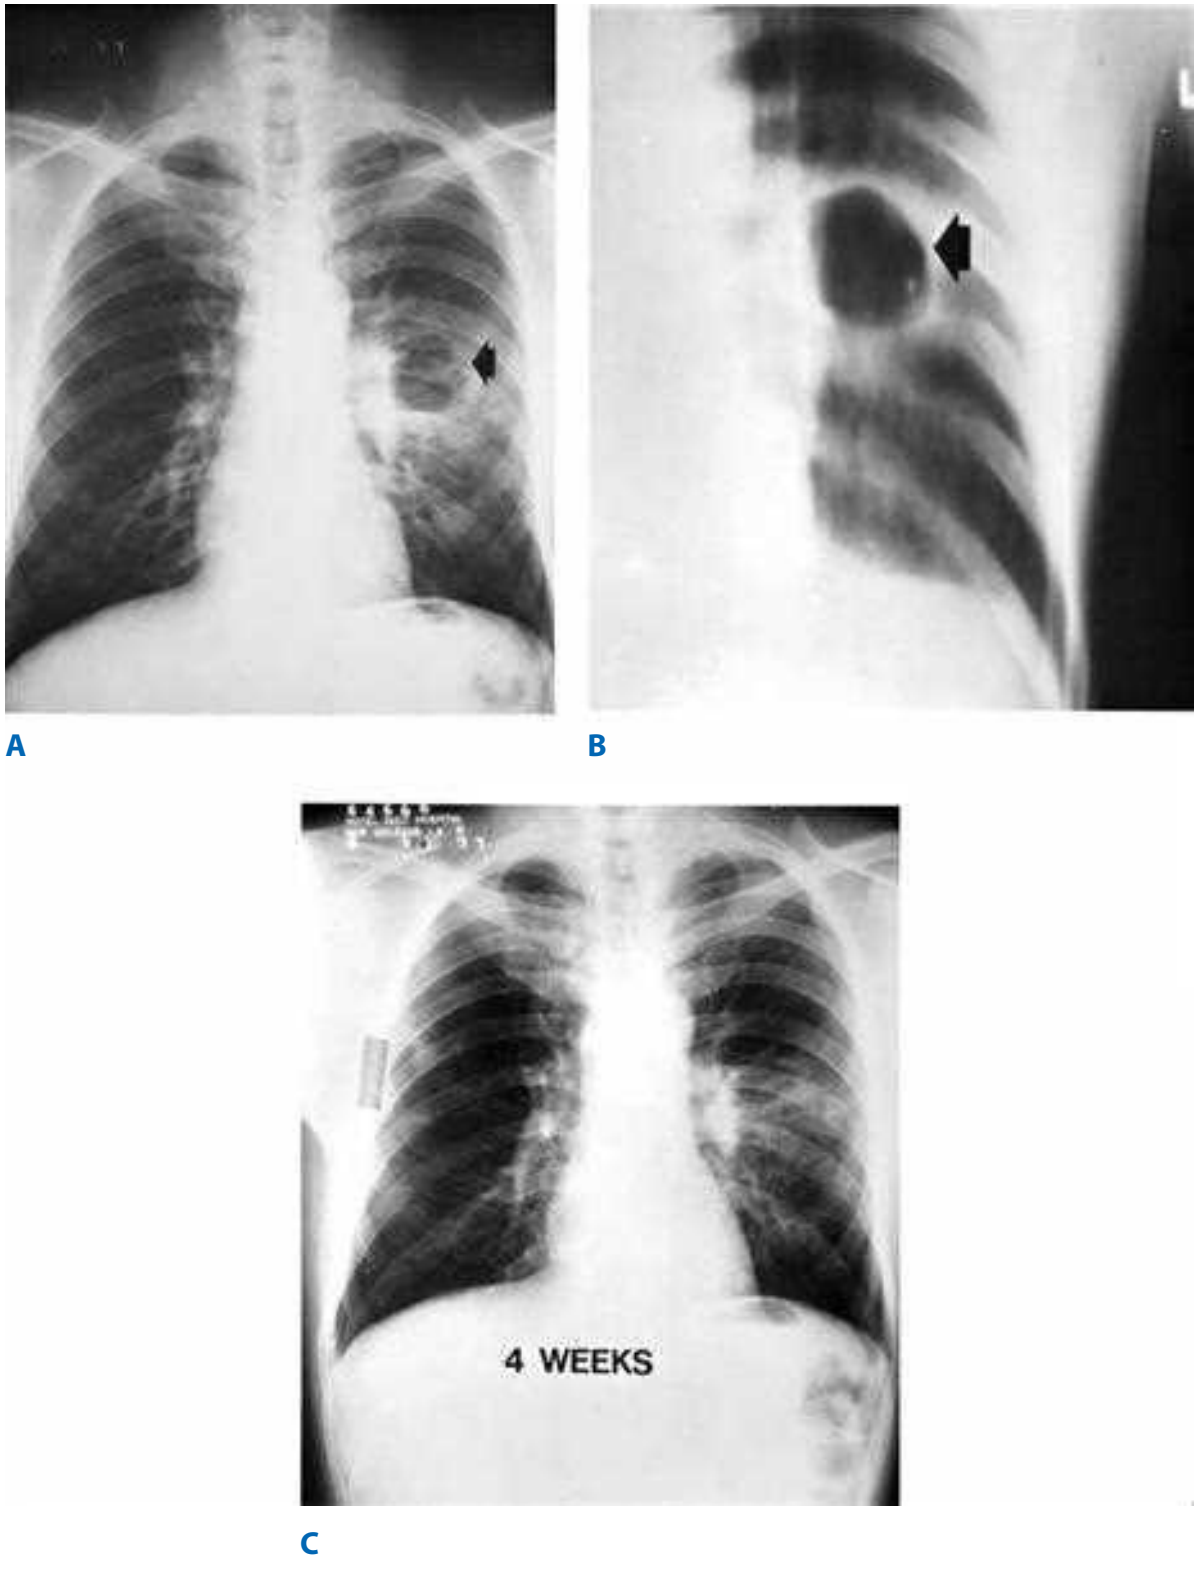

Figure 19-30. Lung abscess resulting from emesis and aspiration after an alcoholic binge. **A.** Chest x-ray showing an abscess cavity in the left upper lobe. **B.** A coronal tomogram highlights the thin wall of the abscess. **C.** Healing of the abscess cavity after 4 weeks of antibiotic therapy and postural drainage.

Table 19-18

Indications for surgical drainage procedures for lung abscesses

1. Failure of medical therapy
2. Abscess under tension
3. Abscess increasing in size during appropriate treatment
4. Contralateral lung contamination
5. Abscess >4–6 cm in diameter
6. Necrotizing infection with multiple abscesses, hemoptysis, abscess rupture, or pyopneumothorax
7. Inability to exclude a cavitating carcinoma

Figure 19-31. Multiple cystic-type bronchiectatic cavities can be seen on a cut section of right lower lobe lung.

pneumonia, pertussis and measles pneumonia, severe influenza, or varicella pneumonia can lead to widespread bronchiectasis. Chronic granulomatous disease, immunodeficiency disorders, and hypersensitivity disorders can also lead to diffuse bronchiectasis.

Noninfectious causes of bronchiectasis include inhalation of toxic gases such as ammonia, which results in severe and destructive airway inflammatory responses. Allergic bronchopulmonary aspergillosis, Sjögren's syndrome, and α_1-antitrypsin deficiency are some additional examples of presumed immunologic disorders that may be accompanied by bronchiectasis.

In addition, recent studies have suggested an association between chronic gastroesophageal reflux disease, acid suppression, and nontuberculous mycobacterial infection with bronchiectasis.[112,113] This interaction is thought to be related to chronic aspiration of colonized gastric secretions in the setting of acid suppression; while not proven to be causative, these findings suggest a role for gastroesophageal reflux disease in the pathogenesis of bronchiectasis.

10▶

The process shared by all causes of bronchiectasis is impairment of airway defenses or deficits in immunologic mechanisms, which permit bacterial colonization and chronic infection. Common organisms include *Haemophilus* species (55%), *Pseudomonas* species (26%), and *Streptococcus pneumoniae* (12%).[114] Both the bacterial organisms and the inflammatory cells recruited to thwart the bacteria elaborate proteolytic and oxidative molecules, which progressively destroy the muscular and elastic components of the airway walls; those components are then replaced by fibrous tissue. Thus chronic airway inflammation is the essential pathologic feature of bronchiectasis. The dilated airways are usually filled with thick purulent material; more distal airways are often occluded by secretions or obliterated by fibrous tissue. Bronchial wall vascularity increases, bronchial arteries become hypertrophied, and abnormal anastomoses form between the bronchial and pulmonary arterial circulation.

There are three principal types of bronchiectasis, based on pathologic morphology: cylindrical—uniformly dilated bronchi; varicose—an irregular or beaded pattern of dilated bronchi; and saccular (cystic)—peripheral balloon-type bronchial dilation. The saccular type is the most common after bronchial obstruction or infection (Fig. 19-31).

Clinical Manifestations and Diagnosis. Typical symptoms are a daily persistent cough and purulent sputum production; the quantity of daily sputum production (10 mL to >150 mL) correlates with disease extent and severity. Other patients may appear asymptomatic or have a dry nonproductive cough ("dry bronchiectasis"). These patients are prone to have involvement of the upper lobes. The clinical course is characterized by progressive symptoms and respiratory impairment. Increasing resting and exertional dyspnea are the result of progressive airway obstruction. Acute exacerbations may be triggered by viral or bacterial pathogens. Bleeding attributable to chronically inflamed, friable airway mucosa causes increasingly more frequent hemoptysis with disease progression. Massive bleeding may result from erosion of the hypertrophied bronchial arteries.

Both mild and severe forms of bronchiectasis are readily demonstrated with chest CT scanning because it provides a highly detailed, cross-sectional view of bronchial architecture. CXRs, although less sensitive, may reveal characteristic signs of bronchiectasis such as lung hyperinflation, bronchiectatic cysts, and dilated, thick-walled bronchi forming track-like patterns radiating from the lung hila. Sputum culture may identify characteristic pathogens. Sputum acid-fast bacillus smears and cultures should be performed to evaluate for the presence of nontuberculous mycobacteria, which is common in this setting. Spirometry provides an assessment of the severity of airway obstruction and can be followed to track the course of disease.

Management of Bronchiectasis. Standard therapy includes optimizing airway clearance, use of bronchodilators to reverse any airflow limitation, and correction of reversible underlying causes whenever possible.[115] Chest physiotherapy based on vibration, percussion, and postural drainage is widely accepted, although randomized trials demonstrating efficacy are lacking. Acute exacerbations should be treated with a 2- to 3-week course of broad-spectrum intravenous antibiotics tailored to culture and sensitivity profiles, followed by an oral regimen; this will result in a longer-lasting remission.

Macrolide antibiotics have been shown to decrease sputum production, inhibit cytokine release, and inhibit neutrophil adhesion and formation of reactive oxygen species. They also inhibit migration of *Pseudomonas*, disrupt biofilm, and prevent release of virulence factors.[116] While macrolide therapy does appear to be efficacious, it is important to remember that macrolides have significant activity against nontuberculous mycobacteria, and widespread prophylactic use for patients with bronchiectasis may lead to multidrug-resistant nontuberculous mycobacterial species. It has also been suggested that inhaled antibiotics, such

as tobramycin and colistin, improve rates of bacterial clearance and slow the decline in pulmonary function associated with bronchiectasis, but large, randomized trials showing overall clinical benefit have not yet been published.[117,118]

In addition to antibiotics, daily nebulized hypertonic saline appears to be effective. A recent randomized crossover study comparing lung function and quality of life has shown that 7% normal saline, compared to isotonic saline, results in a statistically significant 15% increase in FEV_1 and an 11% increase in forced vital capacity (compared to 1.8% and 0.7%, respectively, with isotonic saline). Antibiotic use and emergency room utilization were significantly decreased; from this, hypertonic saline appears to be a reasonable adjunct to maintaining quality of life and decreasing exacerbations by reducing sputum volume, improving mucociliary clearance, and slowing the decline in lung function.[119] Studies supporting mucolytics such as DNase and N-acetylcysteine for non-cystic fibrosis bronchiectasis have shown either no change or a worsening of pulmonary status and require further study in the non-cystic fibrosis population.

Surgical resection of a localized bronchiectatic segment or lobe, preserving as much functional lung as possible, may benefit patients with refractory symptoms while on maximal medical therapy. Multifocal disease must be excluded before any attempt at surgery; any uncorrectable predisposing factor (e.g., ciliary dyskinesia) must also be excluded. Patients with end-stage lung disease from bronchiectasis may be potential candidates for a bilateral lung transplant. Surgical resection is also indicated in patients with significant hemoptysis, although bronchial artery embolization is the preferred first option. Antireflux surgery may also prove beneficial in patients with chronic aspiration, but further studies are required. It is particularly important to recognize that antireflux surgery in patients with severe underlying pulmonary dysfunction has higher risk for perioperative adverse outcomes than in the general population. It should be undertaken only by very experienced surgeons with direct involvement of the pulmonary medicine physicians to minimize postoperative pulmonary compromise.

Mycobacterial Infections

Epidemiology. Tuberculosis is a widespread problem that affects nearly one third of the world's population. Between 8.3 and 9 million new cases of tuberculosis and 12 million prevalent cases (range 10–13 million) were estimated worldwide in 2011 according to the World Health Organization. Only 10,521 new cases were reported to the World Health Organization in the United States in 2011. HIV infection is the strongest risk factor for developing active tuberculosis. The elderly, minorities, and recent immigrants are the most common populations to have clinical manifestations of infection, yet no age group, sex, or race is exempt from infection. In most large urban centers, reported cases of tuberculosis are more numerous among the homeless, prisoners, and drug-addicted populations. Immunocompromised patients additionally contribute to an increased incidence of tuberculosis infection, often developing unusual systemic as well as pulmonary manifestations.[120] As compared with past decades, presently surgical intervention is required more frequently in patients with multidrug-resistant tuberculosis organisms (MDRTB) who do not respond to medical treatment and in selected patients with nontuberculous mycobacterial infections (NTM).

Microbiology. Mycobacterial species are obligate aerobes. They are primarily intracellular parasites with slow rates of growth. Their defining characteristic is the property of acid-fastness, which is the ability to withstand decolorization by an acid-alcohol mixture after being stained. *Mycobacterium tuberculosis* is the highly virulent bacillus of this species that produces invasive infection among humans, principally pulmonary tuberculosis.[121] Infections with *M. tuberculosis* are primary when they are the first infection in a previously unsensitized host and secondary or postprimary when reactivation of a previous infection occurs.

Because of improper application of antimycobacterial drugs and multifactorial interactions, MDRTB organisms, defined by their resistance to at least two of the first-line antimycobacterial drugs (isoniazid and rifampin), have emerged. It is estimated that 1.4% of new tuberculosis cases and 7.6% of retreatment cases in the United States in 2011 are from MDRTB organisms. In addition, there is another rare variant termed *extensively drug-resistant tuberculosis*, which is resistant to isoniazid and rifampin, all fluoroquinolones, and at least one of the injectable second-line drugs (e.g., capreomycin, amikacin, kanamycin). It is estimated that 9% of all MDRTB cases are extensively drug resistant.

The more important NTM organisms include *Mycobacterium kansasii, M. avium* and *M. intracellulare* complex (MAC), and *M. fortuitum*. The highest incidence of *M. kansasii* infection is in midwestern U.S. cities among middle-aged males from good socioeconomic surroundings. MAC organisms are important infections in elderly and immunocompromised patient groups. *M. fortuitum* infections are common complications of underlying severe debilitating disease. None of these organisms are as contagious as *M. tuberculosis*.

Pathogenesis and Pathology. The main route of transmission is via airborne inhalation of viable mycobacteria. Three stages of primary infection have been described. In the first stage, alveolar macrophages become infected through ingesting the bacilli. In the second stage, from days 7 to 21, the patient typically remains asymptomatic while the bacteria multiply within the infected macrophages. The third stage is characterized by the onset of cell-mediated immunity ($CD4^+$ helper T cells) and delayed-type hypersensitivity. Activated macrophages acquire an increased capacity for bacterial killing. Macrophage death increases, resulting in the formation of a granuloma, the characteristic lesion found on pathologic examination.

Tuberculous granulomas are composed of blood-derived macrophages, degenerating macrophages or epithelioid cells, and multinucleated giant cells (fused macrophages with nuclei around the periphery; also known as Langerhans cells). The low oxygen content of this environment inhibits macrophage function and bacillary growth, with subsequent central caseation as macrophage death occurs. A Ghon complex is a single, small lung lesion that is often the only remaining trace of a primary infection. The primary infection is usually located in the peripheral portion of the middle zone of the lungs.

Reactivation tuberculosis may occur after hydrolytic enzymes liquefy the caseum. Typically, the apical and posterior segments of the upper lobes and the superior segments of the lower lobes are involved. Edema, hemorrhage, and mononuclear cell infiltration are also present. The tuberculous cavity may become secondarily infected with other bacteria, fungi, or yeasts, all of which may contribute to enhanced tissue destruction.

The pathologic changes caused by NTM organisms are similar to those produced by *M. tuberculosis*. *M. intracellulare* complex infections commonly occur, not only in immunocompromised patients, but also in patients with previously damaged lungs. Caseous necrosis is uncommon and is characterized by

clusters of tissue macrophages filled with mycobacteria. It has a poor granulomatous response and confinement of immune cell infiltration to the interstitium and alveolar walls. Cavitary disease is infrequent, although nodules may be noted.

Clinical Presentation and Diagnosis. The clinical course of infection and the presentation of symptoms are influenced by many factors, including the site of primary infection, the stage of disease, and the degree of cell-mediated immunity. About 80% to 90% of tuberculosis patients present with clinical disease in the lungs. In 85% to 90% of these patients, involution and healing occur, leading to a dormant phase that may last a lifetime. The only evidence of tuberculosis infection may be a positive skin reaction to tuberculin challenge or a Ghon complex observed on CXR. Within the first 2 years of primary infection, reactivation may occur in up to 10% to 15% of infected patients. In 80%, reactivation occurs in the lungs; other reactivation sites include the lymph nodes, pleura, and the musculoskeletal system.

After primary infection, pulmonary tuberculosis is frequently asymptomatic. Systemic symptoms of low-grade fever, malaise, and weight loss are subtle and may go unnoticed. A productive cough may develop, usually after tubercle cavitation. Many radiographic patterns can be identified at this stage, including local exudative lesions, local fibrotic lesions, cavitation, bronchial wall involvement, acute tuberculous pneumonia, bronchiectasis, bronchostenosis, and tuberculous granulomas. Hemoptysis often develops from complications of disease such as bronchiectasis or erosion into vascular malformations associated with cavitation. Extrapulmonary involvement is due to hematogenous or lymphatic spread from pulmonary lesions. Virtually any organ can become infected, giving rise to the protean manifestations of tuberculosis. The pleura, chest wall, and mediastinal organs may all be involved. More than one third of immunocompromised patients have disseminated disease, with hepatomegaly, diarrhea, splenomegaly, and abdominal pain.

The definitive diagnosis of tuberculosis requires identification of the mycobacterium in a patient's bodily fluids or involved tissues. Skin testing using purified protein derivative is important for epidemiologic purposes and can help exclude infection in uncomplicated cases. For pulmonary tuberculosis, sputum examination is inexpensive and has a high diagnostic yield. Bronchoscopy with alveolar lavage may also be a useful diagnostic adjunct and has high diagnostic accuracy. Chest CT scan can delineate the extent of parenchymal disease.

Management. Medical therapy is the primary treatment of pulmonary tuberculosis and is often initiated before a mycobacterial pathogen is definitively identified. Combinations of two or more drugs are routinely used in order to minimize resistance, which inevitably develops with only single-agent therapy. A current treatment algorithm is outlined in Fig. 19-32. Generally, therapy lasts about 18 months. The overall response rate is satisfactory in 70% to 80% of patients with *M. kansasii* infection. Surgical intervention is rarely required in the 20% to 30% of patients who are not responsive to medical therapy. In contrast, pulmonary *M. intracellulare* complex infections respond poorly, even to combinations of four or more drugs, and most of the patients will eventually require surgical intervention. Overall, sputum conversion is achieved in only 50% to 80% of NTM infections, and relapses occur in up to 20% of patients.

In the United States, surgical intervention is most often required in order to treat patients with MDRTB organisms whose lungs have been destroyed and who have persistent thick-walled cavitation.[122] The indications for surgery related to mycobacterial pulmonary infections are presented in Table 19-19. The governing principle of mycobacterial surgery is to remove all gross disease while preserving any uninvolved lung tissue. Scattered nodular disease may be left intact, given its low mycobacterial burden. Antimycobacterial medications should be given preoperatively (for about 3 months) and continued postoperatively for 12 to 24 months. Overall, more than 90% of patients who were deemed good surgical candidates are cured when appropriate medical and surgical therapy is used.

Pulmonary Fungal Infections. The incidence of fungal infections has increased significantly, with many new opportunistic fungi emerging. This increase is attributed to the growing population of immunocompromised patients (e.g., organ transplant recipients, cancer patients undergoing chemotherapy, HIV patients, and young and elderly patients) who are more likely to become infected with fungi.[123] Clinically significant examples include species of *Aspergillus, Cryptococcus, Candida,* and *Mucor*. Other at-risk patient populations include those who are malnourished, severely debilitated, or diabetic or who have hematologic disorders. Patients receiving high-dose, intensive antibiotic therapies are also susceptible. There are, however, some fungi that are primary or true pathogens, able to cause infections in otherwise healthy patients. Some endemic examples in the United States include species of *Histoplasma, Coccidioides,* and *Blastomyces*.[124]

Direct identification of the organism in body exudates or tissues, preferably as growth in culture, provides definitive diagnosis. Serologic testing to identify mycotic-specific antibodies may also be useful. Several new classes of antifungal agents have proven effective against many life-threatening fungi and are less toxic than older agents. In addition, thoracic surgery may be a useful therapeutic adjunct for patients with pulmonary mycoses.

Aspergillosis. The genus *Aspergillus* comprises over 150 species and is the most common cause of mortality due to invasive mycoses in the United States. It is typically acute in onset and life-threatening and occurs in the setting of neutropenia, chronic steroid therapy, or cytotoxic chemotherapy. It can also occur in the general intensive care unit population of critically ill patients, including patients with underlying chronic obstructive pulmonary disease (COPD), postoperative patients, patients with cirrhosis or alcoholism, and postinfluenza patients, without any of these factors present. The species most commonly responsible for clinical disease include *A. fumigatus, A. flavus, A. niger*, and *A. terreus*. *Aspergillus* is a saprophytic, filamentous fungus with septate hyphae. Spores (2.5–3 μm in diameter) are released and easily inhaled by susceptible patients; because the spores are microns in size, they are able to reach the distal bronchi and alveoli.

Aspergillosis can manifest as one of three clinical syndromes: *Aspergillus* hypersensitivity lung disease, aspergilloma, or invasive pulmonary aspergillosis. Overlap occurs between these syndromes, depending on the patient's immune status.[125] *Aspergillus* hypersensitivity manifests as a productive cough, fever, wheezing, pulmonary infiltrates, eosinophilia, and elevation of IgE antibodies to *Aspergillus*, whereas aspergilloma (fungal ball) is a matted sphere of hyphae, fibrin, and inflammatory cells that tends to colonize pre-existing intrapulmonary cavities. Grossly, aspergilloma appears as a round or oval, friable,

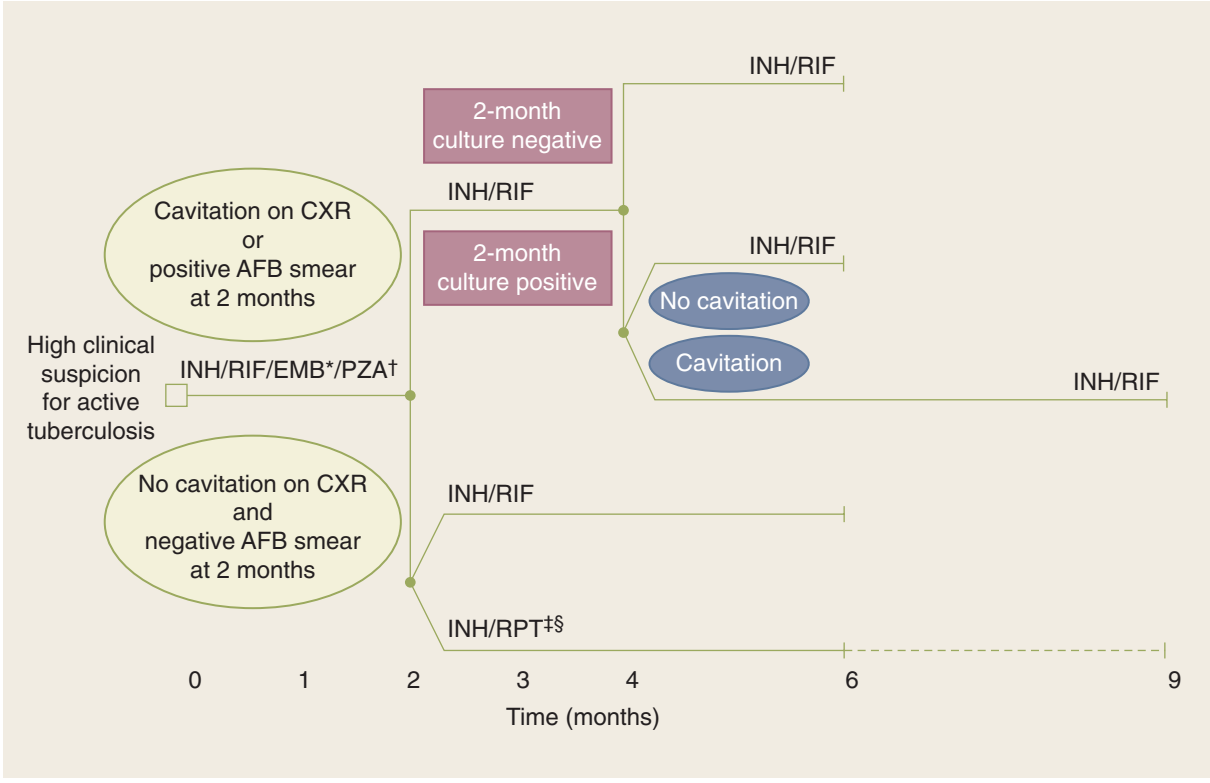

Figure 19-32. Treatment algorithm for tuberculosis. Patients in whom tuberculosis is proven or strongly suspected should have treatment initiated with isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB) for the initial 2 months. A repeat smear and culture should be performed when 2 months of treatment has been completed. If cavities were seen on the initial chest radiograph (CXR) or the acid-fast bacillus (AFB) smear results are positive at completion of 2 months of treatment, the continuation phase of treatment should consist of INH and RIF daily or twice daily for 4 months to complete a total of 6 months of treatment. If cavitation was present on the initial CXR and the culture results at the time of completion of 2 months of therapy are positive, the continuation phase should be lengthened to 7 months (total of 9 months of treatment). If the patient has HIV infection and the $CD4^+$ cell count is <100/μL, the continuation phase should consist of daily or three times weekly INH and RIF. In HIV-uninfected patients with no cavitation on CXR and negative results on AFB smears at completion of 2 months of treatment, the continuation phase may consist of either once weekly INH and rifapentine (RPT) or daily or twice weekly INH and RIF to complete a total of 6 months of treatment (*bottom*). For patients receiving INH and RPT whose 2-month culture results are positive, treatment should be extended by an additional 3 months (total of 9 months). *EMB may be discontinued when results of drug susceptibility testing indicate no drug resistance. †PZA may be discontinued after it has been taken for 2 months (56 doses). ‡RPT should not be used in HIV-infected patients with tuberculosis or in patients with extrapulmonary tuberculosis. §Therapy should be extended to 9 months if results of 2-month culture are positive. *(Reproduced with permission of the American Thoracic Society. Table 19-19

Indications for surgery to treat mycobacterial pulmonary infections

1. Complications resulting from previous thoracic surgery to treat tuberculosis
2. Failure of optimized medical therapy (e.g., progressive disease, lung gangrene, or intracavitary aspergillosis superinfection)
3. Need for tissue acquisition for definitive diagnosis
4. Complications of pulmonary scarring (e.g., massive hemoptysis, cavernomas, bronchiectasis, or bronchostenosis)
5. Extrapulmonary thoracic involvement
6. Pleural tuberculosis
7. Nontuberculous mycobacterial infection

gray (or red, brown, or even yellow), necrotic-looking mass (Fig. 19-33). This form is the most common presentation of noninvasive pulmonary aspergillosis. The most common symptoms are hemoptysis, chronic and productive cough, clubbing, malaise, or weight loss. CXR can suggest the diagnosis by the finding of a crescentic radiolucency above a rounded radiopaque lesion (Monad sign).

The natural history varies greatly between patients and, therefore, treatment is individualized. Factors associated with poor prognosis include severe underlying pulmonary disease, growth in the number or size of the aspergilloma(s) during observation, immunosuppression or HIV infection, history of lung transplantation, chronic pulmonary sarcoidosis, and increasing *Aspergillus*-specific IgG titers. Asymptomatic patients can be observed without any additional therapy. Antifungals have limited utility due to the poor blood supply to the aspergilloma. Amphotericin B is the drug of

Figure 19-33. Pulmonary aspergilloma. **A.** The chest x-ray shows a solid mass within a cavity surrounded by a rim of air between the mass and cavity wall (Monad sign, *arrows*). **B.** A cut section shows the "fungus ball" occupying an old, fibrotic cavity. **C.** Histologic stain reveals characteristic *Aspergillus* hyphae invading the wall of the cavity.

choice, although voriconazole has recently been used for treatment of aspergillosis, with fewer side effects and equivalent efficacy. Hemoptysis is a harbinger of erosion of the disease into adjacent bronchial arteries and typically requires intervention. In the setting of very mild hemoptysis (e.g., blood-streaked sputum), cough suppression is warranted while further therapeutic evaluation is performed.

Bronchial artery embolization is the first-line therapy for massive hemoptysis and may be definitive therapy.[126] This is particularly important to consider for patients with severely impaired pulmonary function who may not have sufficient reserve to tolerate even a very small pulmonary resection. Operative intervention may be required for recurrent hemoptysis, particularly after bronchial artery embolization, chronic cough with systemic symptoms, progressive infiltrate around the mycetoma, and a pulmonary mass of unknown cause.[127]

When operative intervention is indicated, the surgeon must remain cognizant of the goals of the procedure. As this disease typically occurs in patients with significantly impaired pulmonary function, attempts should be made to excise all diseased tissue with as limited a resection as possible. Once resection is completed, the postresection space in the hemithorax should be obliterated with a pleural tent, pneumoperitoneum, decortication of the remaining lung, intrathoracic rotation of a muscle or omental flap, or thoracoplasty. Long-term follow-up is necessary, given that the recurrence rate after surgery is about 7%.

Invasive pulmonary aspergillosis typically affects immunocompromised patients who have dysfunctional cellular immunity, namely defective polymorphonuclear leukocytes. Invasion of pulmonary parenchyma and blood vessels by a necrotizing bronchopneumonia may be complicated by thrombosis, hemorrhage, and then dissemination. Patients present with fever that is nonresponsive to antibiotic therapy in the setting of neutropenia. They may also have pleuritic chest pain, cough, dyspnea, or hemoptysis. Characteristic signs on CT scan include the halo sign and cavitary lesions. Treatment with voriconazole must be prompt and aggressive, including reversal of neutropenia, if there is to be any chance for recovery. Mortality ranges from 93% to 100% in bone marrow transplant recipients, to approximately 38% in kidney transplant recipients, although this improves to approximately 60% at 12 weeks with voriconazole therapy. Several other advances in diagnosis and treatment, including CT scans in high-risk populations and development of additional triazoles and echinocandins, have improved the early identification and response to therapy in this patient population. Additional treatment considerations include the use of hematopoietic growth factors to minimize the neutropenic period, which contributes to uncontrolled disease. Surgical removal of the infectious nidus is advocated by some groups because medical treatment has such poor outcomes. Treatment continues until microbiologic clearance is achieved and clinical signs and radiographic imaging indicate resolution of disease. In addition, the patient should no longer be immunosuppressed. If continuation of immunosuppressive medications is required, antifungal therapy should also continue to prevent recurrence of invasive disease.

Cryptococcosis. Cryptococcosis is a subacute or chronic infection caused by *Cryptococcus neoformans,* a round, budding yeast (5–20 µm in diameter) that is sometimes surrounded by a characteristic wide gelatinous capsule. Cryptococci are typically present in soil and dust contaminated by pigeon droppings. When inhaled, such droppings can cause a nonfatal disease primarily affecting the pulmonary and central nervous systems. At present, cryptococcosis is the fourth most common opportunistic infection in patients with HIV infection, affecting 6% to 10% of that population. Four basic pathologic patterns are seen in the lungs of infected patients: granulomas; granulomatous pneumonia; diffuse alveolar or interstitial involvement; and proliferation of fungi in alveoli and lung vasculature. Symptoms are nonspecific, as are the radiographic findings. *Cryptococcus* may be isolated from sputum, bronchial washings, percutaneous needle aspiration of the lung, or cerebrospinal fluid. If disease is suspected, serum cryptococcal antigen titers should be obtained; if positive or if the patient has persistent fever, evidence of progression, physiologic compromise, or dissemination, treatment should be promptly initiated. Multiple antifungal agents are effective against *C. neoformans,* including amphotericin B and the azoles. The choice of antifungal and duration of treatment depend on the severity of disease. Duration of therapy is longer in patients who are immunocompromised.

Candidiasis. *Candida* organisms are oval, budding cells (with or without mycelial elements) that colonize the oropharynx of many healthy individuals. The fungi of this genus are common hospital and laboratory contaminants. Usually, *Candida albicans* causes disease in the oral or bronchial mucosa, among other anatomic sites. Other potentially pathogenic *Candida* species include *C. tropicalis, C. glabrata,* and *C. krusei*. Historically, *C. albicans* was the most common pathogen to cause invasive candidal infection. However, more recent reports suggest that other *Candida* species, particularly *C. glabrata* and *C. krusei,* are becoming more prevalent and now account for between 40% and 50% of all cases. These species are relatively resistant to fluconazole, and the shift is likely related to the widespread use of this antifungal agent.[128]

The incidence of *Candida* infections has increased and is no longer confined to immunocompromised patients. Increasing incidence of infection has been identified in patients with any of the following risk factors: critical illness of long duration; use of long-term antibiotics, particularly multiple; indwelling urinary or vascular catheter; gastrointestinal perforation; or burn wounds.[129] With respect to the thorax, such patients commonly have candidal pneumonia, pulmonary abscess, esophagitis, and mediastinitis. Pulmonary candidal infections typically result in an acute or chronic granulomatous reaction. Because *Candida* can invade blood vessel walls and a variety of tissues, systemic or disseminated infections can occur, but are less common.

Treatment for candidal infection includes both fungicidal and fungistatic agents. The fungicidal medications include polyenes (amphotericin B deoxycholate [AmB-D] and various lipid-associated amphotericin B preparations) and the echinocandins (caspofungin, micafungin, and anidulafungin). Fungistatic drugs include the triazoles (fluconazole, itraconazole, voriconazole, and posaconazole).[128] The availability of multiple effective therapies allows for specific tailoring of treatment, including combination regimens, based on the patient's ability to tolerate associated toxicities, the microbiologic information for the specific candidal species, and the route of administration. While demonstrated efficacy is similar, the triazoles and echinocandins appear to have fewer side effects and are better tolerated than the other classes of antifungal drugs.

In addition to prompt institution of antifungal therapy, it is advisable to remove all central venous catheters. For fungemia, an eye examination should be performed. Treatment should continue for at least 2 weeks after the last positive blood culture. For patients with *Candida* mediastinitis (which has a mortality rate of >50%), surgical intervention to debride all infected tissues is required, in addition to prolonged administration of antifungal drugs.

Mucormycosis. The *Mucor* species, rare members of the class Zygomycetes, are responsible for rapidly fatal disease in immunocompromised patients. Other disease-causing species of the class Zygomycetes include *Absidia, Rhizopus,* and *Mortierella*.[130] Characteristic of these fungi are nonseptate, branching hyphae that are difficult to culture. Infection occurs via inhalation of spores. Immunocompromised patients, including patients with neutropenia, acidosis, diabetes, and hematologic malignancy all predispose to clinical susceptibility. In the lungs, disease consists of blood vessel invasion, thrombosis, and infarction of infected organs. Tissue destruction is significant, along with cavitation and abscess formation. Initial treatment is to correct underlying risk factors and administer antifungal therapies, although the optimal duration and optimal total dose are unknown. Lipid formulations of amphotericin B are recommended at this time. Surgical resection of any localized disease should be performed after initial medical treatment attempts fail.

Primary Fungal Pathogens

Histoplasma capsulatum. *Histoplasma capsulatum* is a dimorphic fungus existing in mycelial form in soil contaminated by

fowl or bat excreta and in yeast form in human hosts. The most common of all fungal pulmonary infections, histoplasmosis primarily affects the respiratory system after spores are inhaled. It is endemic in the Midwest and Mississippi River Valley of the United States, where about 500,000 new cases arise each year. In immunocompromised patients, the infection becomes systemic and more virulent; because cell-mediated immunity is impaired, uninhibited fungal proliferation occurs within pulmonary macrophages and then spreads. Acute forms of the disease present as primary or disseminated pulmonary histoplasmosis; chronic forms present as pulmonary granulomas (histoplasmomas), chronic cavitary histoplasmosis, mediastinal granulomas, fibrosing mediastinitis, or bronchiolithiasis. Histoplasmosis is definitively diagnosed by fungal smear, culture, direct biopsy of infected tissues, or serologic testing.

The clinical presentation depends on the inoculum size and on host factors. Symptoms of acute pulmonary histoplasmosis are fever, chills, headache, chest pain, musculoskeletal pain, and nonproductive cough. CXRs may be normal or may show mediastinal lymphadenopathy and patchy parenchymal infiltrates. Most patients improve in a few weeks; mild to moderate disease can be treated with itraconazole. Amphotericin B is the treatment of choice if moderate symptoms persist for 2 to 4 weeks or if the illness is extensive, including dyspnea and hypoxia, and if patients are immunosuppressed.[131]

As the pulmonary infiltrates from acute histoplasmosis heal, consolidation into an asymptomatic solitary nodule or histoplasmoma may occur and is usually seen incidentally on radiographs as a coin-shaped lesion. Central and concentric calcification may occur; if so, no further treatment is required. Noncalcification of the lesion requires further diagnostic workup including chest CT scan, needle biopsy, or surgical excision to rule out a malignancy. Figure 19-34 demonstrates the differences in pathologic findings between infections in normal and immunocompromised hosts.[132]

When lymph nodes and pulmonary granulomas calcify over time, pressure atrophy on the bronchial wall may result in erosion and migration of the granulomatous mass into the bronchus, causing bronchiolithiasis. Typical symptoms include cough, hemoptysis, and dyspnea. Life-threatening complications include massive hemoptysis or bronchoesophageal fistula. In addition to radiography, bronchoscopy should be performed to aid in diagnosis. Definitive treatment requires surgical excision of the bronchial mass and repair of the airway and contiguous structures. Endobronchial debridement is not advised as this can result in massive, fatal bleeding.

Fibrosing mediastinitis is an uncommon manifestation of histoplasmosis but can be fatal due to progressive distortion and compression of the major vessels and central airways. Diagnosis can be difficult and symptoms may be present for extended periods, even years, before the diagnosis is made. The differential diagnosis for the disease process includes granulomatous mediastinitis related to recent infection, malignancy, and chronic pulmonary thromboembolism. A trial of itraconazole is worthwhile, although it is not proven to be effective. In cases where radiographic or physiologic improvement is achieved after a trial of 12 week of therapy, continuation of therapy is considered for a full 12 months. In the majority of patients, however, antifungal therapy has not been proven effective. There is no role for corticosteroids at this time or for antifibrotics. Occasionally, intravascular stents have been helpful for severe vascular compromise. Balloon dilatation and endobronchial silicone stents may be needed for airway compromise, although this should be directed by a surgeon with expertise in mediastinal and airway disease management.

Chronic pulmonary histoplasmosis occurs in about 10% of patients who become symptomatic after infection. Most such patients have pre-existing lung pathology, particularly emphysema, which becomes colonized. Subsequent pneumonitis and necrosis, cavity enlargement, new cavity formation, and pulmonary dissemination occur. Nonspecific symptoms, such as cough, sputum production, fever, weight loss, weakness, and hemoptysis are common. Chest radiography may reveal intrapulmonary cavitation and scarring. Occasionally, partial resolution of the inflammatory changes may be observed. Itraconazole provides effective therapy, but must be given for 12 to 24 months. It is superior to ketoconazole and fluconazole; these should only be used if itraconazole is not tolerated. Voriconazole and posaconazole have been found to be useful for salvage therapy. Serum itraconazole levels should be monitored to ensure that the drug is being absorbed. Occasionally, lipid-associated amphotericin B is necessary for more severe infections. Surgical excision should be considered in patients with adequate pulmonary reserve and localized, thick-walled cavities that have been unresponsive to antifungal therapy.

Disseminated histoplasmosis occurs most frequently in patients who are severely immunocompromised, such as post-transplantation patients, patients with HIV, and patients using immunosuppressive medications. Presentation ranges from nonspecific signs of fever, weight loss, and malaise, to shock, respiratory distress, and multiorgan failure. Diagnosis can be made with a combination of *Histoplasma* urine antigen, serologic assay, and fungal culture and should be suspected in patients with the above symptoms in any endemic area, particularly if the patient is immunosuppressed.[133] Any of the antifungal therapies can be used in treatment of disseminated histoplasmosis. Use of amphotericin B has decreased the mortality rate to less than 25% in this type of serious infection.

Coccidioides immitis. *Coccidioides immitis* is an endemic fungus found in soil and dust of the southwestern United States. Agricultural workers, military personnel, and other occupations with extensive exposure to soil, especially in areas of endemic growth, are at highest risk, as are immunocompromised individuals.[134] Spores (arthroconidia) are inhaled, swell into spherules, and subdivide into endospores, and subsequent infection develops. Diagnosis can be achieved through serum analysis for anticoccidioidal antibody, spherule identification in tissue, or by isolating the fungus in cultures from sputum, other body fluid, or tissue.

Inhalation of the fungus causes pulmonary involvement in 95% of patients with symptomatic disease. Three main categories of pulmonary involvement, based on the associated signs and symptoms, are possible: primary; complicated; and residual pulmonary coccidioidomycosis. Primary pulmonary coccidioidomycosis occurs in about 40% of people who inhale spores. The other 60% will remain asymptomatic and develop life-long immunity. The constellation of symptoms of "valley fever," including fever, chills, headache, erythema multiforme, erythema nodosum, polyarthralgias, nonproductive cough, and chest pain, and a CXR showing hilar and paratracheal adenopathy are highly suggestive of pulmonary coccidioidomycosis. In many patients, initial diagnosis is community-acquired pneumonia, and it is only when the patient fails to respond to appropriate antibiotic therapy that pulmonary coccidioidomycosis

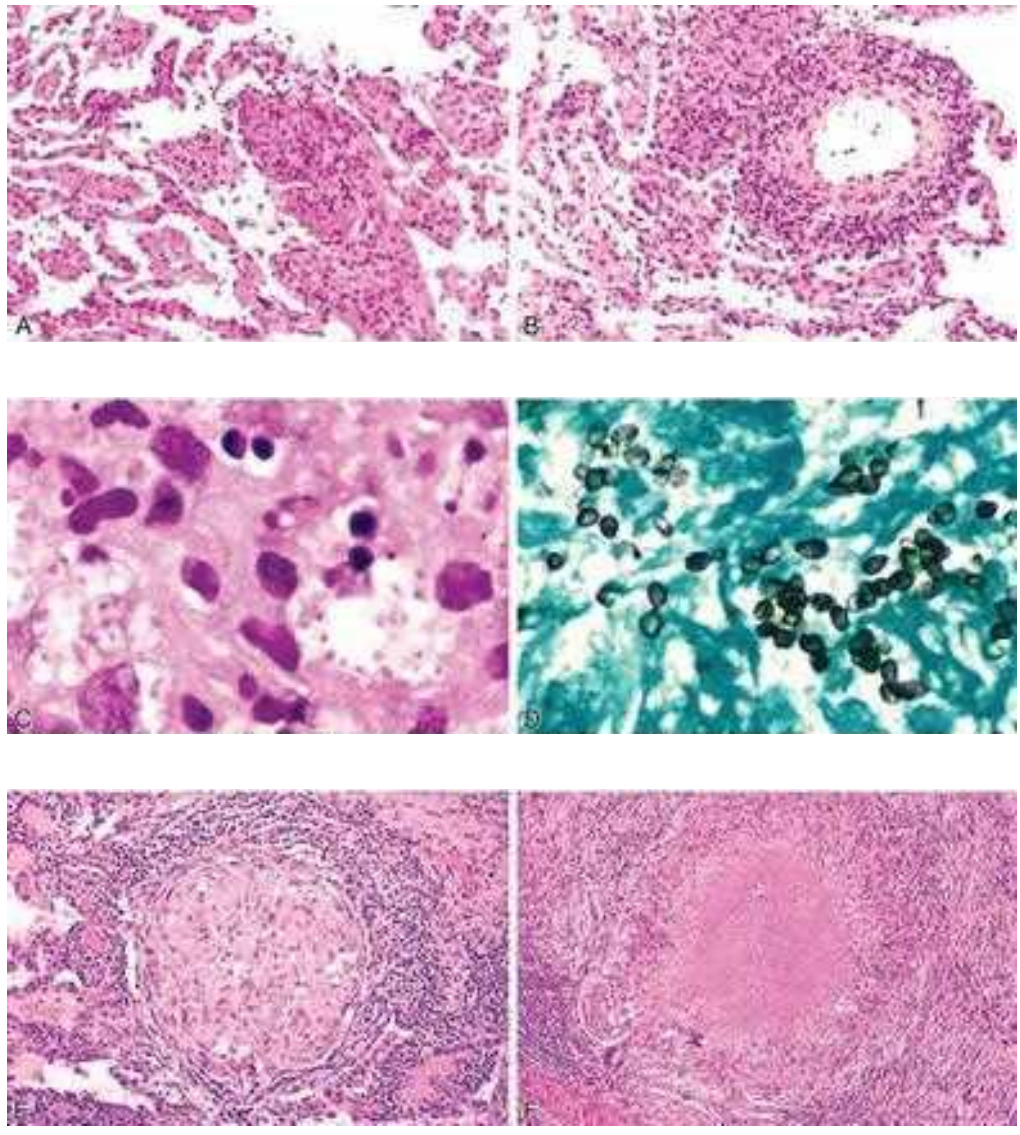

Figure 19-34. Pathologic findings of infection in normal and immunocompromised hosts. Histopathologic preparations are shown contrasting acute diffuse pulmonary involvement in a lung segment of a normal host with a probable primary infection (**A** through **D**) with pulmonary granulomas from an immunocompromised patient who had an opportunistic reinfection with *Histoplasma capsulatum* (**E, F**). **A.** Diffuse interstitial pneumonitis in an adult (normal host) with recent heavy environmental exposure and subsequent development of progressive pulmonary disease. There is an inflammatory cell infiltrate primarily involving the interalveolar interstitial spaces but present within many alveolar spaces as well. The exudate consists mostly of mononuclear phagocytes, lymphocytes, and occasional plasma cells. Many of the alveolar walls are markedly thickened (hematoxylin and eosin stain [H&E], ×50). **B.** Another area from the same lung as in **A** showing focal vasculitis with an infiltrate of lymphocytes and macrophages (H&E, ×25). **C.** Relatively large alveolar macrophages packed with single and budding yeasts 2 to 4 µm in diameter (same lung as in **A** and **B**). The basophilic cytoplasm of these yeasts is retracted from their thin outer cell walls, leaving halo-like clear areas that can be confused with capsules (H&E, ×500). **D.** Intracellular and extracellular yeasts, 2 to 4 µm in diameter, some of which are single, budding, or in short chains (Gomori methenamine silver stain, ×500). **E.** Nonnecrotizing (sometimes called epithelioid cell or noncaseating) granuloma from a patient who had recently received chemotherapy for a germ cell tumor (different patient than in **A** through **D**). This lesion consists of a focal collection of macrophages (sometimes referred to as histiocytes or epithelioid cells) plus lymphocytes and occasional plasma cells. A few multinucleated macrophages are present. A thin layer of fibroblasts circumscribes the lesion. Yeasts of *H. capsulatum*, probably present within macrophages of this lesion at an earlier stage, were not identified in this granuloma or in any of several other nonnecrotizing granulomas within the specimen. Lesions of this type often undergo necrosis to become necrotizing granulomas (H&E, ×50). **F.** Necrotizing (sometimes referred to as caseating) granuloma from the same lung as in **E**. This lesion has a necrotic center surrounded by macrophages, encapsulating fibroblasts, fibrous connective tissue in the periphery, and scattered lymphocytes. A prominent giant cell is present in the lower left of the granuloma (at approximately 8 o'clock). Microorganisms are usually present only in relatively small numbers in these types of lesions. They are most frequently detected within the most central necrotic material in these granulomas (H&E, ×25). *(Reproduced with permission from Hage et al.*[132]*)*

is considered. The disease is self-limited in the majority of patients, and treatment is not required in these cases.

Therapy should be considered for (a) patients with impaired cellular immunity; (b) comorbid illnesses that are adversely impacted by the infection, including chronic pulmonary dysfunction, renal failure, and congestive heart failure; and (c) when symptoms and radiographic findings persist for more than 6 to 8 weeks, at which time the disease is considered to be persistent coccidioidal pneumonia and occurs in approximately 1% of patients. Progression to caseous nodules, cavities, and calcified, fibrotic, or ossified lesions indicates complicated or residual stages of coccidioidomycosis.

There are several relative indications for surgery in pulmonary coccidioidomycosis. A rapidly expanding (>4 cm) cavity that is close to the visceral pleura is a high risk for rupture into the pleural space and subsequent empyema. Other indications for operative intervention include life-threatening hemoptysis; hemoptysis that is persistent despite medical therapy; symptomatic fungus ball; bronchopleural fistula; cavitary lesions with persistent positive sputum; and pulmonary nodules that degenerate over time. Finally, any nodule with signs that are concerning for malignancy should undergo further evaluation, including biopsy or resection, to determine the underlying etiology.

Diagnosis of coccidioidomycosis is confirmed by histopathologic, mycologic, and serologic evaluation. Extrapulmonary disease may develop in approximately 0.5% of infected patients, with involvement of meninges, bones, joints, skin, or soft tissues. Immunocompromised patients are especially susceptible to disseminated coccidioidomycosis, which carries a mortality rate over 40%. Treatment options for this disease vary depending on the severity of the disease as well as the stage. Amphotericin B deoxycholate or the triazoles continue to be the primary antifungal medications. If meningeal involvement is identified, fluconazole or itraconazole therapy is required for the remainder of the patient's life. Intrathecal amphotericin B can also be administered in some cases.

Blastomyces dermatitidis. *Blastomyces dermatitidis* is a round, single-budding yeast with a characteristic thick, refractile cell wall. It resides in the soil as a nonmotile spore called conidia. Exposure occurs when contaminated soil is disturbed and the conidia are aerosolized. The spore is inhaled and transforms into a yeast phase at body temperature.[135] Infection is typically self-limited. A small minority of patients will develop chronic pulmonary infection or disseminated disease, including cutaneous, osteoarticular, and genitourinary involvement. *B. dermatitidis* has a worldwide distribution; in the United States, it is endemic in the central states.[136] With chronic infection, the organism induces a granulomatous and pyogenic reaction with microabscesses and giant cells; caseation, cavitation, and fibrosis may also occur. Symptoms are nonspecific and consistent with chronic pneumonia in 60% to 90% of patients. They include cough, mucoid sputum production, chest pain, fever, malaise, weight loss, and, uncommonly, hemoptysis. In acute disease, radiographs are either completely negative or have nonspecific findings; in chronic disease, fibronodular lesions (with or without cavitation) similar to tuberculosis are noted. Pulmonary parenchymal abnormalities in the upper lobe(s) may be noted. Mass lesions similar to carcinoma are frequent, and lung biopsy is frequently used. Over 50% of patients with chronic blastomycosis also have extrapulmonary manifestations, but less than 10% of patients present with severe clinical manifestation.[135]

Once a patient manifests symptoms of chronic blastomycosis, antifungal treatment is required to achieve resolution. Mortality approaches 60% if untreated.[135] While controversial, a short course of triazole therapy (oral itraconazole 200 mg daily) for 6 months is the treatment of choice for most patients with mild to moderate forms of the disease. Because itraconazole has poor CNS penetration, the most common site of recurrence after apparently successful therapy is in the CNS. In the absence of therapy, close follow-up is warranted for evidence of progression to chronic or extrapulmonary disease. Amphotericin B is warranted for patients with severe or life-threatening disease, CNS involvement, disseminated disease, or extensive lung involvement and in immunocompromised patients. After adequate drug therapy, surgical resection of known cavitary lesions should be considered because viable organisms are known to persist in such lesions.

Massive Hemoptysis

Massive hemoptysis is generally defined as expectoration of over 600 mL of blood within a 24-hour period. It is a medical emergency associated with a mortality rate of 30% to 50%. Most clinicians would agree that losing over a liter of blood via the airway within 1 day is significant, yet use of an absolute volume criterion presents difficulties. First, it is difficult for the patient or caregivers to quantify the volume of blood being lost. Second, and most relevant, the rate of bleeding necessary to incite respiratory compromise is highly dependent on the individual's prior respiratory status. For example, the loss of 100 mL of blood over 24 hours in a 40-year-old male with normal pulmonary function would be of little immediate consequence, because his normal cough would ensure his ability to clear the blood and secretions. In contrast, the same amount of bleeding in a 69-year-old male with severe COPD, chronic bronchitis, and an FEV_1 of 1.1 L may be life-threatening.

Anatomy. The lungs have two sources of blood supply: the pulmonary and bronchial arterial systems. The pulmonary system is a high-compliance, low-pressure system, and the walls of the pulmonary arteries are very thin and delicate. The bronchial arteries, part of the systemic circulation, have systemic pressures and thick walls; most branches originate from the proximal thoracic aorta. Most cases of massive hemoptysis involve bleeding from the bronchial artery circulation or from the pulmonary circulation pathologically exposed to the high pressures of the bronchial circulation. In many cases of hemoptysis, particularly those due to inflammatory disorders, the bronchial arterial tree becomes hyperplastic and tortuous. The systemic pressures within these arteries, combined with a disease process within the airway and erosion, lead to bleeding.

Causes. Significant hemoptysis occurs as a result of pulmonary, extrapulmonary, and iatrogenic causes. Table 19-20 summarizes the most common causes of hemoptysis. Most are secondary to inflammatory processes. Aneurysms of the pulmonary artery (referred to as Rasmussen's aneurysm) can develop within pulmonary cavities and can result in massive bleeding. Hemoptysis due to lung cancer is usually mild, resulting in blood-streaked sputum. Massive hemoptysis in patients with lung cancer is typically caused by malignant invasion of pulmonary artery vessels by large central tumors. Although rare, it is often a terminal event.

Management. Life-threatening hemoptysis is best managed by a multidisciplinary team of intensive care physicians,

Table 19-20

Pulmonary and extrapulmonary causes of massive hemoptysis

PULMONARY	EXTRAPULMONARY	IATROGENIC
Pulmonary parenchymal disease	Congestive heart failure	Intrapulmonary catheter
Bronchitis	Coagulopathy	
Bronchiectasis	Mitral stenosis	
Tuberculosis	Medications

Cystic fibrosis		
Pulmonary hemosiderosis		

interventional radiologists, and thoracic surgeons. Treatment priorities begin with respiratory stabilization; intubation with isolation of the bleeding lung may be required to prevent asphyxiation. This can be done with main-stem intubation into the nonbleeding lung, endobronchial blockers into the bleeding lung, or double-lumen endotracheal intubation, depending on the urgency of the situation and the expertise of the providers. Once adequate ventilation has been achieved, the bleeding site should be localized; bronchoscopy can often provide direct visualization of blood coming from a specific area of the tracheobronchial anatomy. Control of the hemorrhage is then achieved endobronchially with laser or bronchial occlusion, endovascularly with bronchial and/or pulmonary artery embolization, or surgically with resection of the involved area.[137] The order of priorities in management is detailed in Table 19-21.

The clinically pragmatic definition of massive hemoptysis is a degree of bleeding that threatens respiratory stability. Therefore, clinical judgment of respiratory compromise is the first step in evaluating a patient.[138,139] Two scenarios are possible: (1) bleeding is significant and persistent, but its rate allows a rapid, sequential diagnostic and therapeutic approach, or (2) bleeding is so rapid that emergency airway control and therapy are necessary.

Table 19-21

Treatment priorities in the management of massive hemoptysis

1. Achieve respiratory stabilization and prevent asphyxiation.
2. Localize the bleeding site.
3. Control the hemorrhage.
4. Determine the cause.
5. Definitively prevent recurrence.

Scenario 1: Significant, Persistent, but Nonmassive Bleeding. Although bleeding is brisk in scenario 1, the patient may be able to maintain clearance of the blood and secretions with his or her own respiratory reflexes. Immediate measures are admission to an intensive care unit; strict bed rest; Trendelenburg positioning with the affected side down (if known); administration of humidified oxygen; cough suppression; monitoring of oxygen saturation and arterial blood gases; and insertion of large-bore intravenous catheters. Strict bed rest with sedation may lead to slowing or cessation of bleeding, and the judicious use of intravenous narcotics or other relaxants to mildly sedate the patient and diminish some of the reflexive airway activity is often necessary. Also recommended are administration of aerosolized adrenaline, intravenous antibiotic therapy if needed, and correction of abnormal blood coagulation study results. Finally, unless contraindicated, intravenous vasopressin (20 U over 15 minutes, followed by an infusion of 0.2 U/min) can be given.

A CXR is the first test and often proves to be the most revealing. Localized lesions may be seen, but the effects of blood soiling of other areas of the lungs may predominate, obscuring the area of pathology. Chest CT scan provides more detail and is nearly always performed if the patient is stable. Pathologic areas may be obscured by blood soiling.

Flexible bronchoscopy is the next step in evaluating the patient's condition. Some clinicians argue that rigid bronchoscopy should always be performed. However, if the patient is clinically stable and the ongoing bleeding is not imminently threatening, flexible bronchoscopy is appropriate. It allows diagnosis of airway abnormalities and will usually permit localization of the bleeding site to either a lobe or even a segment. The person performing the bronchoscopy must be prepared with excellent suction and must be able to perform saline lavage with a dilute solution of epinephrine.

Most cases of massive hemoptysis arise from the bronchial arterial tree; therefore, the next therapeutic option frequently is selective bronchial arteriography and embolization. Bronchoscopy

prior to arteriogram is extremely useful to direct the angiographer. However, if bronchoscopy fails to localize the bleeding site, then bilateral bronchial arteriograms can be performed. More recently, use of multidetector CT angiography in patients with hemoptysis that is not immediately life-threatening has been shown to facilitate endovascular intervention; reformatting of the images in multiple projections allows clear delineation of the pulmonary vascular anatomy.[126] With this approach, abnormal bronchial and nonbronchial arteries can be visualized and subsequently targeted for therapeutic arterial embolization.[140] Once the targeted arterial system has been embolized, immediate control and cessation of the hemoptysis is achieved in more than 80% of patients. If bleeding persists after bronchial artery embolization, a pulmonary artery source should be suspected and a pulmonary angiogram performed at the same setting.

Recurrence is seen in 30% to 60% of cases and is very common in the setting of invasive fungal infections such as aspergilloma. Recurrence after bronchial artery embolization is less common in the setting of malignancy and active tuberculosis but does occur and can ultimately result in patient death.[141] Repeat embolization can be effective and is warranted for initial management of recurrent hemoptysis, but early surgical intervention should be considered, particularly in the setting of aspergilloma or other cavitary lesions.[126]

If respiratory compromise is impending, orotracheal intubation should be performed. After intubation, flexible bronchoscopy should be performed to clear blood and secretions and to attempt localization of the bleeding site. Depending on the possible causes of the bleeding, bronchial artery embolization or (if appropriate) surgery can be considered.

Scenario 2: Significant, Persistent, and Massive Bleeding. Life-threatening bleeding requires emergency airway control and preparation for potential surgery. Such patients are best cared for in an operating room equipped with rigid bronchoscopy. Immediate orotracheal intubation may be necessary to gain control of ventilation and suctioning. However, rapid transport to the operating room with rigid bronchoscopy should be facilitated. Rigid bronchoscopy allows adequate suctioning of bleeding with visualization of the bleeding site; the nonbleeding side can be cannulated with the rigid scope and the patient ventilated. After stabilization, ice-saline lavage of the bleeding site can then be performed (up to 1 L in 50-mL aliquots); bleeding stops in up to 90% of patients.[142]

Alternatively, blockade of the main stem bronchus of the affected side can be accomplished with a double-lumen endotracheal tube, with a bronchial blocker, or by intubation of the nonaffected side by an uncut standard endotracheal tube. Placement of a double-lumen endotracheal tube is challenging in these circumstances, given the bleeding and secretions. Proper placement and suctioning may be difficult, and attempts could compromise the patient's ventilation. The best option is to place a bronchial blocker in the affected bronchus with inflation. Endovascular embolization can be performed to stop the bleeding after control has been achieved with the bronchial blocker. The blocker is left in place for 24 hours; after 24 hours, the area is re-examined bronchoscopically.

Surgical Intervention. In most patients, bleeding can be stopped, recovery can occur, and plans to definitively treat the underlying cause can be made. In scenario 1 (significant, persistent, but nonmassive bleeding), the patient may undergo further evaluation as an inpatient or outpatient. A chest CT scan and pulmonary function studies should be obtained preoperatively. In scenario 2 (patients with significant, persistent, and massive bleeding), surgery, if appropriate, will usually be performed during the same hospitalization as the rigid bronchoscopy or main stem bronchus blockade. In a small number of patients (<10%), immediate surgery will be necessary due to the extent of bleeding. The bleeding site in these patients is localized using rigid bronchoscopy with immediate thoracotomy or sternotomy to follow.

Table 19-22

General indications for urgent operative intervention for massive hemoptysis

1. Presence of a fungus ball
2. Presence of a lung abscess
3. Presence of significant cavitary disease
4. Failure to control the bleeding

Surgical treatment is individualized according to the source of bleeding and the patient's medical condition, prognosis, and pulmonary reserve. General indications for urgent surgery are presented in Table 19-22. In patients with significant cavitary disease or with fungus balls, the walls of the cavities are eroded and necrotic; rebleeding will likely ensue. In addition, bleeding from cavitary lesions may be due to pulmonary artery erosion, which requires surgery for control.

End-Stage Lung Disease

Lung Volume Reduction Surgery. The ideal patient for lung volume reduction surgery (LVRS) has heterogeneous emphysema with apical predominance, meaning the worst emphysematous changes are in the apex (seen on chest CT scan) of the lungs. The physiologic lack of function of these areas is demonstrated by quantitative perfusion scan, which shows minimal or no perfusion. By surgically excising these nonfunctional areas, the volume of the lung is reduced, theoretically restoring respiratory mechanics. Diaphragm position and function are improved, and there may be an improvement in the dynamic small airway collapse in the remaining lung.

Operative mortality in the initial experience was 16.9%, with a 1-year mortality of 23%. In response, the National Emphysema Treatment Trial (NETT) performed a randomized trial of 1218 patients in a noncrossover design to medical vs. surgical management after a 10-week pretreatment pulmonary rehabilitation program. Subgroup analysis demonstrated that in patients with the anatomic changes delineated by Cooper and colleagues, LVRS significantly improved exercise capacity, lung function, quality of life, and dyspnea compared to medical therapy. After 2 years, functional improvements began to decline toward baseline. Similar parameters in medically treated patients steadily decline below baseline. LVRS was associated with increased short-term morbidity and mortality and did not confer a survival benefit over medical therapy.[143]

Lung Transplantation. The most common indications for lung transplant are COPD and idiopathic pulmonary fibrosis (IPF). Most patients with IPF and older patients with COPD are offered a single-lung transplant. Younger COPD patients and patients with α_1-antitrypsin deficiency and severe hyperinflation of the native lungs are offered a bilateral-lung transplant.

Most patients with primary pulmonary hypertension and almost all patients with cystic fibrosis are treated with a bilateral-lung transplant. A heart-lung transplant is reserved for patients with irreversible ventricular failure or uncorrectable congenital cardiac disease.

Patients with COPD are considered for placement on the transplant waiting list when their FEV_1 has fallen to below 25% of its predicted value. Patients with significant pulmonary hypertension should be listed earlier. IPF patients should be referred when their forced vital capacity has fallen to less than 60% or their DLCO has fallen to less than 50% of their predicted values.

In the past, patients with primary pulmonary hypertension and New York Heart Association (NYHA) class III or IV symptoms were listed for a lung transplant. However, treatment of such patients with intravenous prostacyclin and other pulmonary vasodilators has now markedly altered that strategy. Virtually all patients with primary pulmonary hypertension are now treated with intravenous epoprostenol. Several of these patients have experienced a marked improvement in their symptoms associated with a decrease in their pulmonary arterial pressures and an increase in exercise capacity. Listing of these patients is deferred until they develop NYHA class III or IV symptoms or until their mean pulmonary artery pressure rises above 75 mmHg.

Medium-term and bronchiolitis obliterans syndrome (BOS)-free survival rates of patients who underwent a lung transplant during a recent 5-year period at the University of Minnesota are shown in Figs. 19-35 and 19-36. The mortality of patients while waiting for transplants is about 10%. In an effort to expand the number of lung donors, many transplant groups have liberalized their criteria for donor selection. Still, the partial pressure of arterial oxygen (Pao_2) should be greater than 300 mmHg on a fraction of inspired oxygen (FIO_2) of 100%. In special circumstances, lungs may be used from donors with a smoking history; from donors older than 50 years of age; and from donors with positive Gram stains or infiltrates on CXR.[144,145] The use of two living donors, each donating a single lower lobe, is another strategy for increasing the donor pool. Recipient outcomes are similar to those with cadaver donors in carefully selected patients.

Most of the early mortality after lung transplant is related to primary graft failure resulting from a severe ischemia-reperfusion injury to the lung(s) (Fig. 19-37). Reperfusion injury is characterized radiographically by interstitial and alveolar edema and clinically by hypoxia and ventilation-perfusion mismatch. Donor neutrophils and recipient lymphocytes probably play an important role in the pathogenesis of reperfusion injury. The most important impediment to longer-term survival after a lung transplant is the development of BOS, a manifestation of chronic rejection. Episodes of acute rejection are the major risk factors for developing BOS. Other injuries to the lung (including early reperfusion injury and chronic gastroesophageal reflux disease) may also adversely affect long-term outcomes of patients.[146,147]

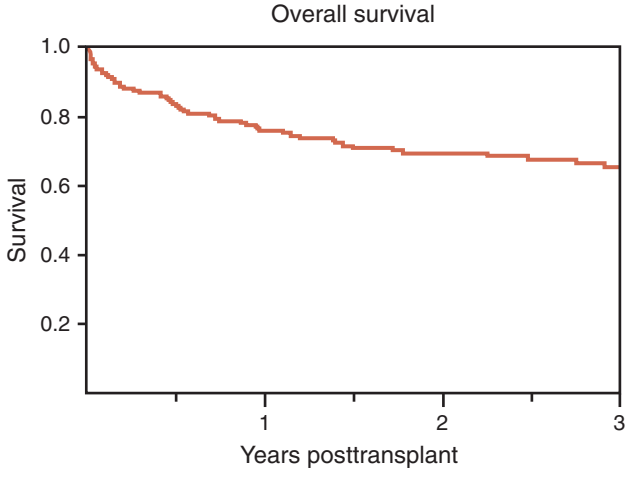

Figure 19-35. The overall survival rate after lung transplantation at the University of Minnesota.

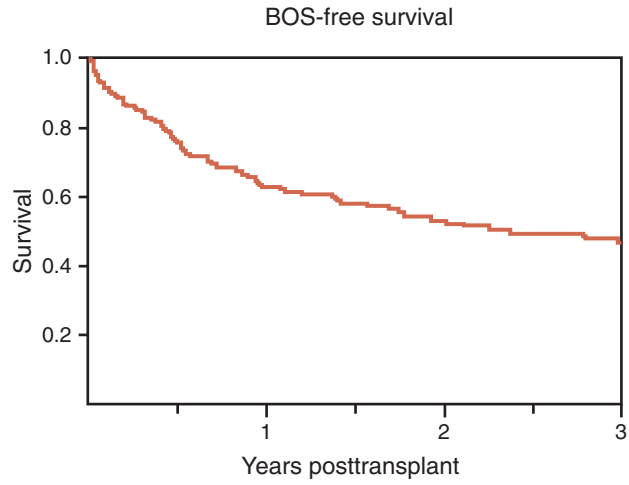

Figure 19-36. The survival rate after lung transplantation in the absence of bronchiolitis obliterans syndrome (BOS) at the University of Minnesota.

CHEST WALL

Chest Wall Mass

Clinical Approach. Surgeons confronted with a patient with a chest wall mass must be cognizant that their approach to diagnosis

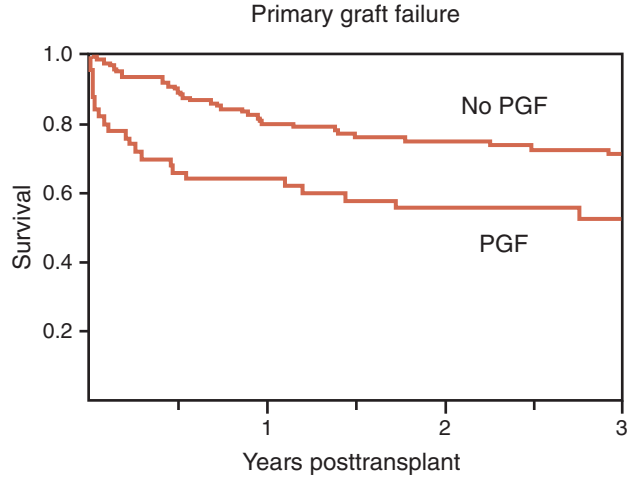

Figure 19-37. The survival rate after lung transplantation at the University of Minnesota as a function of primary graft failure (PGF).

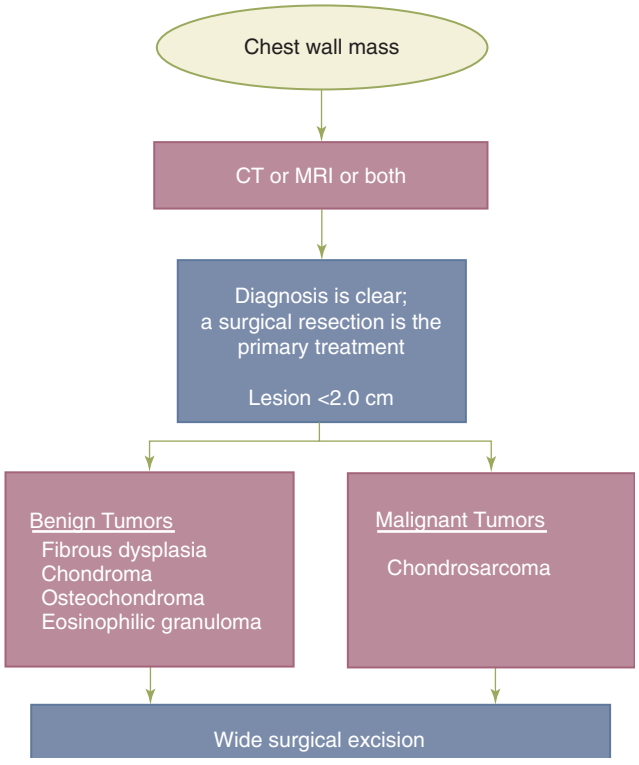

Figure 19-38. Systematic approach for evaluating a chest wall mass when the clinical scenario is uncomplicated and initial imaging studies suggest a clear diagnosis. CT = computed tomography; MRI = magnetic resonance imaging.

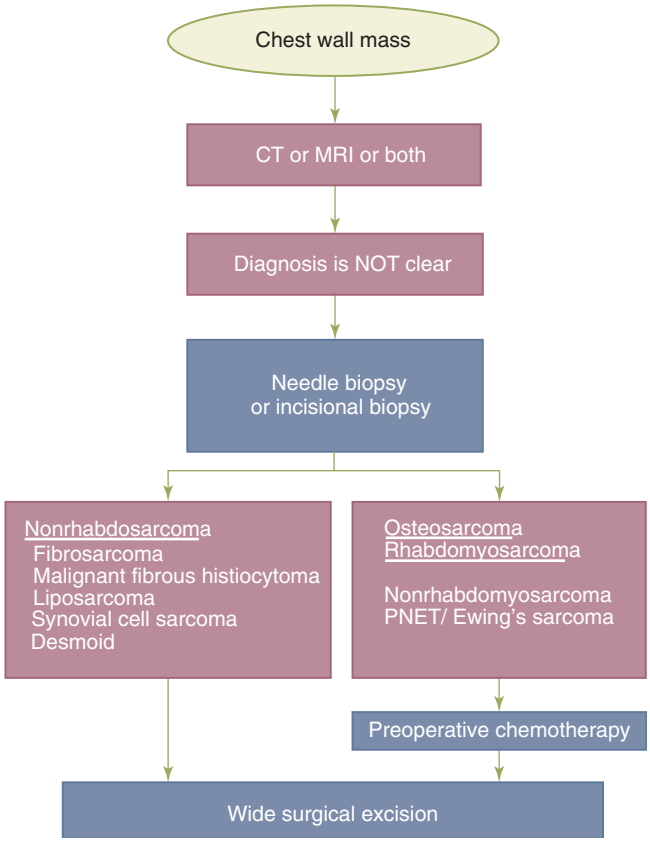

Figure 19-39. Systematic approach for evaluating a chest wall mass for which the diagnosis is not unequivocal. A tissue diagnosis is critical for effective management of chest wall masses. CT computed tomography; MRI magnetic resonance imaging; PNET primitive neuroectodermal tumor.

and treatment has significant impact on the patient's chances for long-term survival. All chest wall tumors should be considered malignant until proven otherwise. It is critically important that the surgeon(s) be mindful of this tenet and well-versed in the diagnostic and treatment principles for chest wall malignancies. These tenets must be applied from the initial biopsy, as the placement of the incision can impact significantly on the successful complete resection and reconstruction of the chest wall. Complete resection is imperative if there is any hope for cure and/or long-term survival. A general approach is outlined in Figs. 19-38 and 19-39.

Patients with chest wall tumors, regardless of etiology, typically complain of a slowly enlarging palpable mass (50%–70%), chest wall pain (25%–50%), or both. Interestingly, growing masses are often not noticed by the patient until they suffer a trauma to the area. Pain from a chest wall mass is typically localized to the area of the tumor; it occurs more often and more intensely with malignant tumors, but it can also be present in up to one third of patients with benign tumors. With Ewing's sarcoma, fever and malaise may also be present. Benign chest wall tumors tend to occur in younger patients (average age 26 years), whereas malignant tumors tend to be found in older patients (average age 40 years). Overall, between 50% and 80% of chest wall tumors are malignant.

Evaluation and Management. Laboratory evaluations are useful in assessing chest wall masses for the following:

1. **Plasmacytoma:** Serum protein electrophoresis demonstrates a single monoclonal spike, which is measuring the overproduction of one immunoglobulin from the malignant plasma cell clone.
2. **Osteosarcoma:** Alkaline phosphatase levels may be elevated.
3. **Ewing's sarcoma:** Erythrocyte sedimentation rates may be elevated.

Radiography. CXR may reveal rib destruction, calcification within the lesion, and if old films are available, a clue to growth rate. CT scanning, however, is necessary to determine the relationship of the chest wall mass to contiguous structures (e.g., mediastinum, lung, soft tissues, and other skeletal elements), evaluate for pulmonary metastases, and assess for extraosseous bone formation and bone destruction, both typically seen with osteosarcoma.

Because MRI provides multiple planes of imaging (coronal, sagittal, and oblique), better definition of the relationship between tumor and muscle, and tumor and contiguous or nearby neurovascular structures or the spine, it is an important radiographic adjunct for preoperative planning. Compared to CT scan alone, MRI may further delineate tissue abnormalities, potentially enhancing the ability to distinguish benign from malignant sarcoma.

Biopsy. The first step in the management of all chest wall tumors is to obtain a tissue diagnosis. Inappropriate or misguided attempts at tissue diagnosis through casual open biopsy techniques have the potential (if the lesion is a sarcoma) to seed surrounding tissues and contiguous body cavities (e.g., the pleural space) with tumor cells, potentially compromising local tumor control and patient survival. Tissue diagnosis is accomplished using one of three methods: needle biopsy (typically

CT-guided FNA or a core biopsy), incisional biopsy, or excisional biopsy in limited and specific situations.

1. **Needle biopsy:** Pathologists experienced with sarcomas can accurately diagnose approximately 90% of patients using FNA cytology. A needle biopsy (FNA or core) has the advantage of avoiding wound and body cavity contamination (a potential complication with an incisional biopsy).
2. **Incisional biopsy:** If a needle biopsy is nondiagnostic, an incisional biopsy may be performed, with caveats. First, the skin incision must be placed directly over the mass and oriented to allow subsequent scar excision; skin flaps and drains should be avoided. However, if the surgeon believes a hematoma is likely to develop, a drain is useful for limiting soft tissue contamination by tumor cells. At the time of definitive surgical resection, the en bloc resection includes the biopsy scar and the drain tract along with the tumor.
3. **Excisional biopsy:** Any lesion less than 2.0 cm can be excised as long as the resulting wound is small enough to close primarily. Otherwise, excisional biopsy is performed only when the initial diagnosis (based on radiographic evaluation) indicates that the lesion is benign or when the lesion has the classic appearance of a chondrosarcoma (in which case, definitive surgical resection can be undertaken).

Benign Chest Wall Neoplasms

1. **Chondroma.** Chondromas, seen primarily in children and young adults, are one of the more common benign tumors of the chest wall. They usually occur at the costochondral junction anteriorly and may be confused with costochondritis, except that a painless mass is present. Radiographically, the lesion is lobulated and radiodense; it may have diffuse or focal calcifications; and it may displace the bony cortex without penetration. Chondromas may grow to huge sizes if left untreated. Treatment is surgical resection with a 2-cm margin. Large chondromas may harbor well-differentiated chondrosarcoma and should be managed with a 4-cm margin to prevent local recurrence.[148]
2. **Fibrous dysplasia.** As with chondromas, fibrous dysplasia most frequently occurs in young adults and may be associated with trauma. Pain is an infrequent complaint, and the lesion is typically located in the posterolateral aspect of the rib cage. Radiographically, an expansile mass is present, with cortical thinning and no calcification. Local excision with a 2-cm margin is curative.
3. **Osteochondroma.** Osteochondromas, often found incidentally as a solitary lesion on radiograph, are the most common benign bone tumor. Osteochondromas occur in the first two decades of life, and they arise at or near the growth plate of bones. Osteochondromas in the thorax arise from the rib cortex. They are one of several components to the autosomal dominant syndrome, hereditary multiple exostoses. When part of this syndrome, osteochondromas have a high rate of degeneration into chondrosarcomas. Any patient with hereditary multiple exostoses syndrome who develops new pain at the site of an osteochondroma or who notes gradual growth in the mass over time should be carefully evaluated for osteosarcoma. Local excision of a benign osteochondroma is sufficient. If malignancy is determined, wide excision is performed with a 4-cm margin.
4. **Eosinophilic granuloma.** Eosinophilic granulomas are benign osteolytic lesions. Eosinophilic granulomas of the ribs can occur as solitary lesions or as part of a more generalized disease process of the lymphoreticular system termed Langerhans cell histiocytosis (LCH). In LCH, the involved tissue is infiltrated with large numbers of histiocytes (similar to Langerhans cells seen in skin and other epithelia), which are often organized as granulomas. The cause is unknown. Of all LCH bone lesions, 79% are solitary eosinophilic granulomas, 7% involve multiple eosinophilic granulomas, and 14% belong to other forms of more systemic LCH. Isolated single eosinophilic granulomas can occur in the ribs or skull, pelvis, mandible, humerus, and other sites. They are diagnosed primarily in children between the ages of 5 and 15 years. Because of the associated pain and tenderness, they may be confused with Ewing's sarcoma or with an inflammatory process such as osteomyelitis. Healing may occur spontaneously, but the typical treatment is limited surgical resection with a 2-cm margin.
5. **Desmoid tumors.** Soft tissue neoplasms arising from fascial or musculoaponeurotic structures, desmoid tumors consist of proliferations of benign-appearing fibroblastic cells, abundant collagen, and few mitoses. Desmoid tumors possess alterations in the adenomatous polyposis coli (APC)/β-catenin pathway. Cyclin D1 dysregulation is thought to play a significant role in their pathogenesis.[149] Associations with other diseases and conditions are well documented, especially those with similar alterations in the APC pathway, such as familial adenomatous polyposis (Gardner's syndrome). Other conditions with increased risk of desmoid tumor formation include increased estrogen states (pregnancy) and trauma. Surgical incisions (abdominal and thorax) have been the site of desmoid development, either in or near the scar.

   Clinically, patients are usually in the third to fourth decade of life and have pain, a chest wall mass, or both. The tumor is usually fixed to the chest wall, but not to the overlying skin. There are no typical radiographic findings, but MRI may delineate muscle or soft tissue infiltration. Desmoid tumors do not metastasize, but they have a significant propensity to recur locally, with reported rates ranging from 5% to 50%, sometimes despite complete initial resection with histologically negative margins.[150] Such locally aggressive behavior is secondary to microscopic tumor infiltration of muscle and surrounding soft tissues and prompts some to consider them a low-grade form of fibrosarcoma.

   Because the lesions have low cellularity and poor yield with FNA, an open incisional biopsy for lesions over 3 to 4 cm is often necessary, following the caveats listed earlier (see biopsy section). Surgery consists of wide local excision with a 2- to 4-cm margin and intraoperative frozen section assessment of resection margins. Typically, chest wall resection, including the involved rib(s) and one rib above and below the tumor with a 4- to 5-cm margin of rib, is required. A margin of less than 1 cm results in much higher local recurrence rates. If a major neurovascular structure would have to be sacrificed, leading to high morbidity, then a margin of less than 1 cm would have to suffice. Survival after wide local excision with negative margins is 90% at 10 years.[151]

Primary Malignant Chest Wall Tumors

Malignant tumors of the chest wall are either metastatic lesions from another primary tumor or sarcoma. Soft tissue sarcomas of

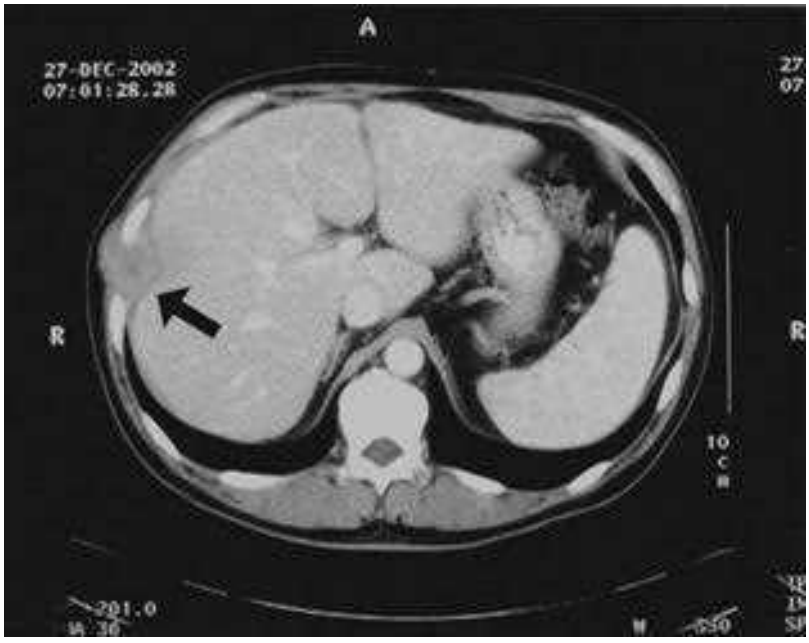

Figure 19-40. Chest computed tomography scan showing a right chest wall tumor (*arrow*). Tissue diagnosis revealed that this mass was a leiomyosarcoma.

the chest wall include fibrosarcomas, liposarcomas, malignant fibrous histiocytomas (MFHs), rhabdomyosarcomas, angiosarcomas, and other extremely rare lesions (Fig. 19-40). Despite the prevalence of localized disease, soft tissue sarcomas of the chest wall have significantly worse survival than similar tumors located on the extremities or the head and neck region. The factors impacting on risk of death from soft tissue sarcomas of the chest wall are presented in Table 19-23. All sarcomas have a propensity to spread to the lungs.

While many varieties of sarcoma exist, the primary features affecting prognosis are histologic grade and responsiveness to chemotherapy (Table 19-24). Preoperative (neoadjuvant) chemotherapy offers the ability to: (a) assess tumor chemosensitivity by the degree of tumor size reduction and microscopic necrosis; (b) determine tumor sensitivity to specific chemotherapeutic agents; and (c) improve resectability by reducing tumor size. Patients whose tumors are responsive to preoperative chemotherapy have a much better prognosis than those with a poor response. Information about tumor response to chemotherapy, the patient's physiologic state and capacity to receive treatment, and metastatic disease status is used to determine optimal therapy. The initial treatment is either: (a) preoperative chemotherapy (for patients with osteosarcoma, rhabdomyosarcoma, primitive neuroectodermal tumor, or Ewing's sarcoma) followed by surgery and postoperative chemotherapy; (b) primary surgical resection and reconstruction (for patients with nonmetastatic MFH, fibrosarcoma, liposarcoma, or synovial sarcoma); or (c) preoperative chemotherapy followed by surgical resection if indicated in patients presenting with metastatic soft tissue sarcomas. Contiguous involvement of underlying lung or other soft tissues or the presence of pulmonary metastases does not preclude successful surgery. In fact, patients receiving surgical intervention have significantly better overall survival. Median survival with surgical resection is 25 months compared to 8 months without resection Additional prognostic variables that are important for long-term survival include tumor size, grade, stage, and negative re-resection margin.[152] With the exception of rhabdomyosarcomas, the primary treatment of these lesions is wide surgical resection with 4-cm margins and reconstruction.[153]

The following is an overview of several chest wall sarcomas.

1. **Chondrosarcoma.** Chondrosarcomas are the most common primary chest wall malignancy. As with chondromas, they usually arise anteriorly from the costochondral arches. CT scan shows a radiolucent lesion often with stippled calcifications pathognomonic for chondrosarcomas (Fig. 19-41). The involved bony structures are also destroyed. Most chondrosarcomas are slow-growing, low-grade tumors; these often painful masses can reach massive proportions.[148] For this reason, any lesion in the anterior chest wall likely to be a low-grade chondrosarcoma should be treated with wide (4-cm) resection after metastatic disease to the lungs or bones is ruled out. Chondrosarcomas are not sensitive to radiation or chemotherapy. Prognosis is determined by tumor grade and extent of resection. With a low-grade tumor and wide resection, patient survival at 5 to 10 years can be as high as 60% to 80%.
2. **Osteosarcoma.** While osteosarcomas are the most common bone malignancy, they represent only 10% to 15% of all malignant chest wall tumors.[154,155] They primarily occur in young adults as rapidly enlarging, painful masses; however, osteosarcomas can occur in older patients as well, sometimes in association with previous radiation, Paget's disease, or chemotherapy. Radiographically, the typical appearance consists of spicules of new periosteal bone formation producing a sunburst appearance. Osteosarcomas have a propensity to spread to the lungs, and up to one third of patients present with metastatic disease. Osteosarcomas are potentially sensitive to chemotherapy. Currently, preoperative chemotherapy is common. After chemotherapy, complete resection is performed with wide (4-cm) margins, followed by reconstruction. In patients presenting with lung metastases that are potentially amenable to surgical resection, induction chemotherapy may be given, followed by surgical resection of the primary tumor and of the pulmonary metastases. Following surgical treatment of known disease, additional maintenance chemotherapy is usually recommended.

Table 19-24

Classification of sarcomas by therapeutic response

TUMOR TYPE	CHEMOTHERAPY SENSITIVITY
Osteosarcoma	+
Rhabdomyosarcoma	+
Primitive neuroectodermal tumor	+
Ewing's sarcoma	+
Malignant fibrous histiocytoma	±
Fibrosarcoma	±
Liposarcoma	±
Synovial sarcoma	±

3. **Malignant fibrous histiocytoma.** Originally thought to derive from histiocytes because of the microscopic appearance of cultured tumor cells, these tumors likely originate from the fibroblast. MFHs are generally the most common soft tissue sarcoma of late adult life, although they are rare on the chest wall. The typical age at presentation is between age 50 and 70 years. Presentation is pain, with or without a palpable mass. Radiographically, a mass is usually evident, with destruction of surrounding tissue and bone. Treatment is wide resection with a margin of 4 cm or more and reconstruction. Over two thirds of patients suffer from distant metastasis or local recurrence.
4. **Liposarcoma.** Liposarcomas make up 15% of chest wall sarcomas. Most liposarcomas are low-grade tumors that have a propensity to recur locally, given their infiltrative nature. They typically present as a painless mass. Treatment is wide resection and reconstruction. Intraoperative

Figure 19-41. Chest computed tomography scan showing a right posterior lung tumor. In the appropriate clinical setting, stippled calcifications (white streaks in right lung mass) are highly indicative of chondrosarcomas.

margins should be evaluated (as with all sarcomas) and resection continued, if feasible, until margins are negative. Local recurrence can be treated with re-excision, with occasional use of radiotherapy.

5. **Fibrosarcoma.** Often presenting as a large, painful mass, these lesions are visible on plain radiograph or CT, with surrounding tissue destruction. Treatment is wide local excision with intraoperative frozen-section analysis of margins, followed by reconstruction. Local and systemic recurrence is frequent. Patient survival at 5 years is about 50% to 60%.
6. **Rhabdomyosarcoma.** Rhabdomyosarcomas are rare tumors of the chest wall. Microscopically, they are a spindle cell tumor. The diagnosis often depends on immunohistochemical staining for muscle markers. Rhabdomyosarcomas are sensitive to chemotherapy. Treatment consists of preoperative chemotherapy with subsequent surgical resection.

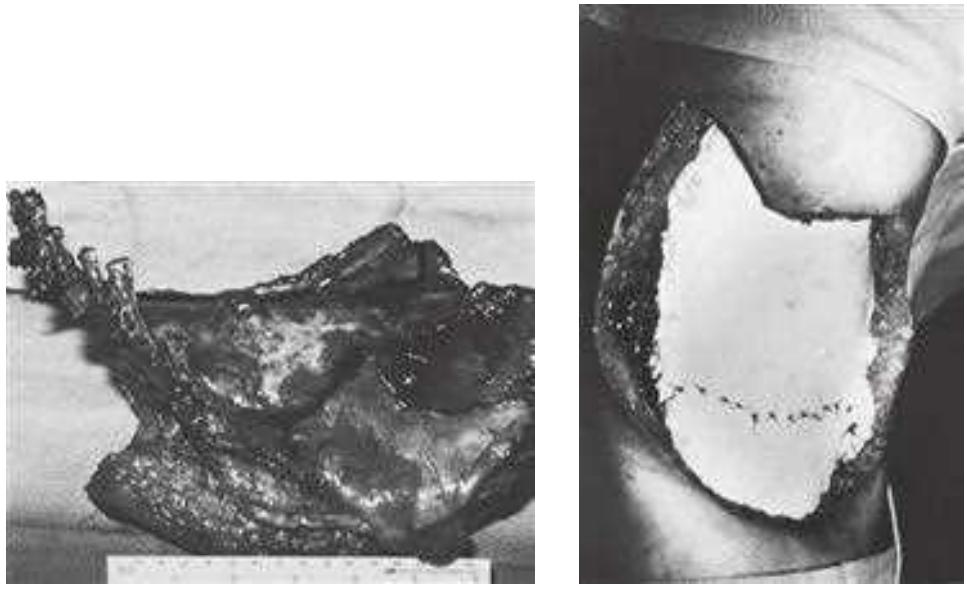
Other Tumors of the Chest Wall

1. **Primitive neuroectodermal tumors (PNETs) and Ewing's sarcoma.** PNETs (neuroblastomas, ganglioneuroblastomas, and ganglioneuromas) derive from primordial neural crest cells that migrate from the mantle layer of the developing spinal cord. Histologically, PNETs and Ewing's sarcomas are small, round cell tumors; both possess a translocation between the long arms of chromosomes 11 and 22 within their genetic makeup. They also share a consistent pattern of proto-oncogene expression and have been found to express the product of the *MIC2* gene. Ewing's sarcoma occurs in adolescents and young adults who present with progressive chest wall pain, but without the presence of a mass. Systemic symptoms of malaise and fever are often present. Laboratory studies reveal an elevated erythrocyte sedimentation rate and mild white blood cell elevation. Radiographically, the characteristic onion peel appearance is produced by multiple layers of periosteum in the bone formation. Evidence of bony destruction is also common. The diagnosis can be made by a percutaneous needle biopsy or an incisional biopsy.

   These tumors have a strong propensity to metastasize to the lungs and skeleton; patient survival rates are thus only 50% or less at 3 years. Increasing tumor size is associated with decreasing survival. Treatment has improved significantly and now consists of multiagent chemotherapy, radiation therapy, and surgery. Patients are typically treated preoperatively with chemotherapy and re-evaluated with radiologic imaging. When residual disease is identified, surgical resection and reconstruction are performed followed by maintenance chemotherapy.
2. **Plasmacytoma.** Solitary plasmacytomas of the chest wall are very rare, with approximately 25 to 30 cases per year in the United States.[154] The typical presentation is pain without a palpable mass. Plain radiographs show an osteolytic lesion in the region of the pain. As with other chest wall tumors, a needle biopsy under CT guidance is performed for diagnosis. Histologically, the lesion is identical to multiple myeloma, with sheets of plasma cells. It occurs at an average age of 55 years. Evaluation for systemic myeloma is performed with bone marrow aspiration, testing of calcium levels, and measurement of urinary Bence Jones proteins. If the results of these studies are negative, then a solitary plasmacytoma is diagnosed. Surgery is usually limited to a biopsy only, which may be excisional.[155] Treatment consists of radiation with doses of 4000 to 5000 cGy. Up to 75% of patients develop systemic multiple myeloma with 10-year survival of approximately 20%.

Chest Wall Reconstruction

The primary determinant of long-term freedom from recurrence and overall survival is margin status; therefore, adequate margins of normal tissue must be included in the en bloc resection. En bloc resection should include involved ribs, sternum, superior sulcus, or spine if necessary; invasion of these structures should not be considered a contraindication to surgery in an otherwise fit patient. The resection should include at least one normal adjacent rib above and below the tumor, with all intervening intercostal muscles and pleura. In addition, an en bloc resection of overlying chest wall muscles is often necessary, such as of the



A B

Figure 19-42. Principles of reconstruction after resection of a chest wall tumor (osteogenic sarcoma) are shown. **A.** En bloc resection of the involved chest wall, including normal ribs above and below the tumor as well as pulmonary parenchyma, must be performed. The resected specimen is shown. **B.** A prosthesis has been sewn in place. In the lower third of the prosthesis, the line of diaphragm reattachment is seen. The skin defect was closed with a myocutaneous flap from the ipsilateral rectus muscle.

pectoralis minor or major, serratus anterior, or latissimus dorsi. When the periphery of the lung is involved with the neoplasm, it is appropriate to resect the adjacent part of the pulmonary lobe in continuity (Fig. 19-42). Involvement of the sternum by a malignant tumor requires total resection of the sternum with the adjacent cartilage. Techniques for postoperative respiratory support are now good enough that resection should not be compromised because of any concern about the patient's ability to be adequately ventilated in the early postoperative period.

The extent of resection depends on the tumor's location and on any involvement of contiguous structures. Laterally based lesions often require simple wide excision, with resection of any contiguously involved lung, pleura, muscle, or skin. Anteriorly based lesions contiguous with the sternum require partial sternectomy. Primary malignant tumors of the sternum may require complete sternectomy. Posterior lesions involving the rib heads over their articulations with the vertebral bodies may, depending on the extent of rib involvement, require partial en bloc vertebrectomy.

Optimal management of larger tumors includes careful preoperative planning and execution of the surgery by the thoracic surgeon and an experienced plastic surgeon, in order to ensure optimal physiologic and cosmetic results. With this, reconstruction at the same operation can be accomplished.[156] Reconstruction of a large defect in the chest wall requires the use of some type of material to prevent lung herniation and to provide stability for the chest wall (see Fig. 19-42). Mild degrees of paradoxical motion are often well tolerated if the area of instability is relatively small. Historically, a wide variety of materials have been used to re-establish chest wall stability, including rib autografts, steel struts, acrylic plates, and numerous synthetic meshes. The current preference is either a 2-mm polytetrafluoroethylene (Gore-Tex) patch or a double-layer polypropylene (Marlex) mesh sandwiched with methylmethacrylate. There are several properties that make Gore-Tex an excellent material for use in chest wall reconstruction: (a) it is impervious to fluid, which prevents pleural fluid from entering the chest wall and minimizes the formation of seromas, which can compromise the myocutaneous flap viability and provide a nidus for infection; and (b) it provides excellent rigidity and stability when secured taut to the surrounding bony structure and, as a result, provides a firm platform for myocutaneous flap reconstruction. Except for smaller lesions, tissue coverage requires the use of myocutaneous flaps (latissimus dorsi, serratus anterior, rectus abdominis, or pectoralis major muscles).[157,158]

MEDIASTINUM

Anatomy and Pathologic Entities

The mediastinum can be divided into compartments for classification of anatomic components and disease processes, which, despite substantial overlap, facilitates understanding of general concepts of surgical interest. Several classification schemes exist, but for the purposes of this chapter, the three-compartment model is used (Fig. 19-43). The anterior compartment lies between the sternum and the anterior surface of the heart and great vessels. The visceral or middle compartment is located between the great vessels and the trachea. As the name implies, the posterior compartment lies posterior and includes the paravertebral sulci, bilaterally, and the paraesophageal area.

The normal content of the anterior compartment includes the thymus gland or its remnant, the internal mammary artery and vein, lymph nodes, and fat. The thymus gland is large during childhood, occupying the entire anterior mediastinum (Fig. 19-44) but decreases in both thickness and length after adolescence and takes on a more fatty content, with only residual islands of thymic cellular components (Fig. 19-45). The middle mediastinal compartment contains the pericardium and its contents, the ascending and transverse aorta, the superior and

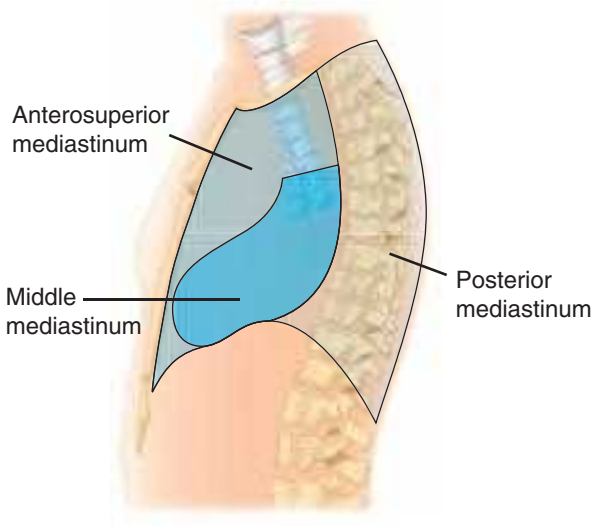


Figure 19-43. Anatomic division of the mediastinum.

inferior venae cavae, the brachiocephalic artery and vein, the phrenic and upper vagus nerves, the trachea and main bronchi and corresponding lymph nodes, and the central portions of the pulmonary arteries and veins. The posterior compartment contains the descending aorta, esophagus, thoracic duct, azygos and hemiazygos veins, and lymph nodes. Numerous pathologic variants may be present in the various compartments, with much overlap. Table 19-25 includes the most common pathologic entities listed by compartment.[159,160]

History and Physical Examination

Mediastinal pathology varies significantly by patient age. In children, neurogenic tumors of the posterior mediastinum are most common, followed by lymphoma, which is usually located in the anterior or middle compartment. Thymoma in childhood is rare (Table 19-26). In adults, the most common tumors include neurogenic tumors of the posterior compartment, benign cysts occurring in any compartment, and thymomas of the anterior mediastinum (Table 19-27). In both age groups, about 25% of mediastinal tumors are malignant. Pediatric tumors will be discussed in Chapter 39.

Up to two thirds of mediastinal tumors in adults are discovered as asymptomatic abnormalities on radiologic studies ordered for other problems, particularly now that screening CT examinations are more prevalent. When symptomatic, these tumors are significantly more likely to be malignant. Characteristics such as size, location, rate of growth, and associated inflammation are important factors that correlate with symptoms. Large, bulky tumors, expanding cysts, and teratomas can cause compression of mediastinal structures, in particular the trachea, and lead to cough, dyspnea on exertion, or stridor. Chest pain or dyspnea may be reported secondary to associated pleural effusions, cardiac tamponade, or phrenic nerve involvement. Occasionally, a mediastinal mass near the aortopulmonary window may be identified in a workup for hoarseness because of left recurrent laryngeal nerve involvement. The patient in Fig. 19-46 presented with hoarseness due to nodal compression of the left recurrent laryngeal nerve from a primary lung cancer with metastases to the level 5 and 6 lymph nodes in the region of the aortopulmonary window.

The history and physical examination in conjunction with the imaging findings may suggest a specific diagnosis (Table 19-28). In one recent series, systemic symptoms were present in 50% of patients with a mediastinal mass and a lymphoproliferative disorder, as compared with only 29% of patients with other masses (such as thymic or neurogenic). Laboratory signs of inflammation were also noted; the erythrocyte sedimentation rate and C-reactive protein levels were elevated and leukocytosis was present in 86% of patients with a lymphoproliferative disorder, as compared with only 58% of patients with other types of mediastinal masses.

Imaging and Serum Markers

Chest CT or MRI is required to fully delineate the anatomy.[161] A contrast-enhanced CT scan enables clear delineation of the soft tissue structures from the vasculature and is preferred over noncontrast studies. If there is concern for invasion of vascular structures or spinal involvement, MRI is more accurate than CT scan and provides important information regarding respectability.

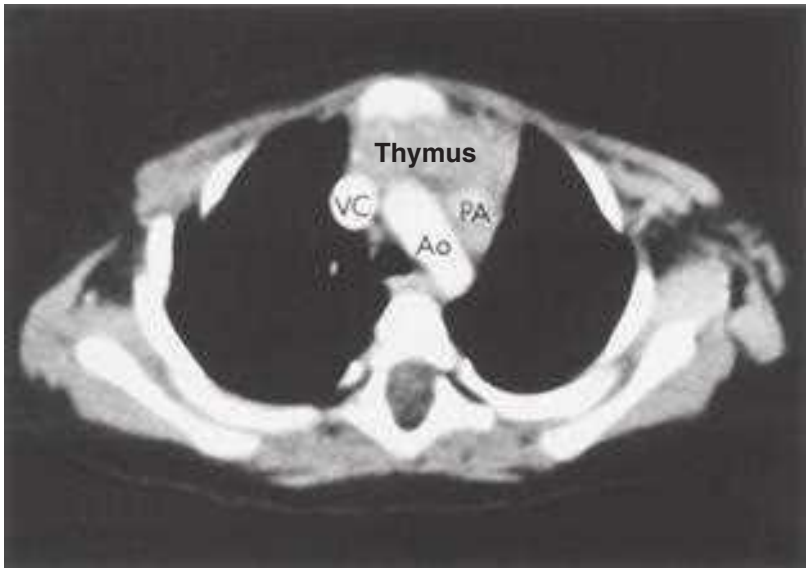

Figure 19-44. Normal appearance of the thymus gland in childhood. Ao = aorta; PA = pulmonary artery; VC = vena cava.

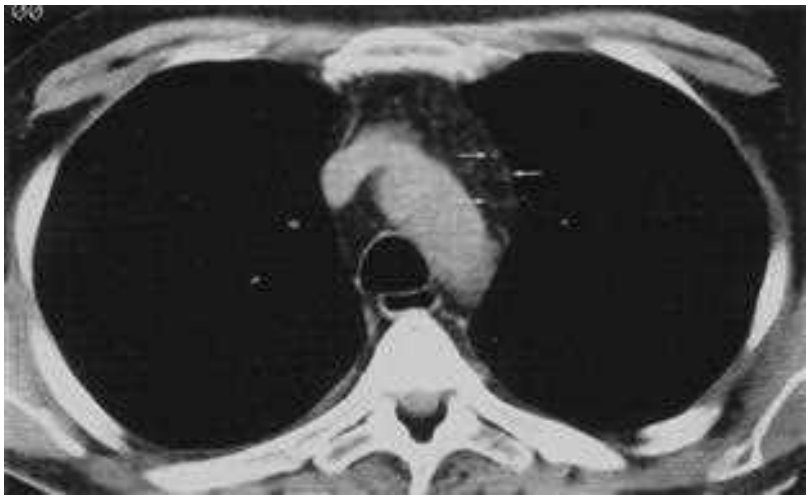

Figure 19-45. Computed tomography scan showing the normal appearance of an involuted thymus gland in an adult. Note the near-total fatty appearance of the gland with only tiny islands of soft tissue scattered within it (*small arrows*).

If an endocrine origin is suspected, several other imaging modalities are available (Table 19-29). Single-photon emission CT (SPECT) technology may be used to improve image contrast and give information on three-dimensional localization, largely replacing conventional two-dimensional nuclear imaging studies. If a thyroid origin is suspected, a thyroid scan using ^{131}I or ^{123}I can identify most intrathoracic goiters and identify the extent of functioning thyroid tissue. If indicated, the thyroid scan should precede other scans requiring iodine-containing contrast agents, because they would subsequently interfere with iodine tracer uptake by thyroid tissue. If a pheochromocytoma or neuroblastoma is suspected, the octreotide scan or ^{123}I-metaiodobenzylguanidine (MIBG) scans are helpful in diagnosis and localization. The sestamibi scan may be useful for diagnosing and localizing a mediastinal parathyroid gland. PET is useful for distinguishing malignant from benign tumors and may help detect distant metastases in some patients. However, the role of routine PET imaging for staging surgically resectable lesions of the mediastinum has not been established.

The use of serum markers to evaluate a mediastinal mass can be invaluable in some patients. For example, nonseminomatous and seminomatous germ cell tumors can frequently be diagnosed and often distinguished from one another by the levels of α-fetoprotein (AFP) and human chorionic gonadotropin (hCG). In over 90% of nonseminomatous germ cell tumors, either the AFP or the hCG level will be elevated. Results are close to 100% specific if the level of either AFP or hCG is greater than 500 ng/mL. Some centers institute chemotherapy based on this result alone, without biopsy confirmation of the diagnosis. In contrast, the AFP level in patients with mediastinal seminoma is always normal; only 10% will have elevated hCG, which is usually less than 100 ng/mL. Other serum markers, such as intact parathyroid hormone level for ectopic parathyroid adenomas, may be useful for diagnosing and also for intraoperatively confirming complete resection. After successful resection of a parathyroid adenoma, this hormone level should rapidly normalize.

Diagnostic Nonsurgical Biopsies of the Mediastinum

The treatment of up to 60% of patients with anterior mediastinal masses is ultimately nonsurgical, so it is essential to

Table 19-25

Usual location of the common primary tumors and cysts of the mediastinum

ANTERIOR COMPARTMENT	VISCERAL COMPARTMENT	PARAVERTEBRAL SULCI

understand all options for obtaining adequate tissue for a definitive diagnosis using the least invasive approach. CT-guided needle biopsy, and EUS-guided FNA, and even core-needle biopsy (either CT-guided EBUS-guided, or EUS-guided) have proven most useful for cytologic and tissue diagnosis of mediastinal masses and lymphadenopathy. When FNA and core-needle biopsy were combined, the accuracy was 98%, compared to 79% for each modality independently. In addition, core-needle biopsy changed the diagnosis in nine cases that had been missed by FNA due to inadequate specimens. Finally, core-needle biopsy was better at diagnosis for benign diseases compared to FNA. Accessible nodal stations include subcarinal (level 7), aortopulmonary (level 5), paraesophageal (level 8), and inferior pulmonary ligament (level 9) as well as paratracheal (level 4).[162] Technical expertise in these modalities should be pursued by thoracic and general surgeons.

Historically, needle biopsies of anterior mediastinal masses were reportedly sensitive and specific for most carcinomatous tumors, but there were questions regarding accuracy for diagnosing lymphomas.[163] However, advances in cytopathology as well as needle biopsy technology have substantially improved diagnostic accuracy such that most centers are reporting yields

ranging from 75% to 80% for the diagnosis of lymphoma as well. To achieve maximal diagnostic yield for mediastinal masses suggestive of a lymphoma, it is necessary to obtain multiple fine-needle aspirates, preferably with immediate onsite rapid cytologic analysis to confirm sampling of the target tissue and adequate cellularity. This also facilitates processing of the sample to ensure that proper studies for lymphoma, including flow cytometry, are obtained. If the needle biopsy is inconclusive, surgical biopsy can be performed.[164,165] If the lesion is accessible by CT-guided or EUS-guided core-needle biopsy, intraoperative frozen section or immediate cytologic smear of a core biopsy can also be performed. Recently, core-needle biopsy with EBUS became possible with release of a EBUS-core needle device. This addition to the surgeon's armamentarium will greatly facilitate tissue sampling for evaluation of mediastinal masses. The authors perform their own endobronchial, endoscopic, and CT-guided transbronchial and transthoracic biopsies and, in our experience, lack of cellularity in the aspirate is readily apparent. In general, plans to proceed with surgical biopsy are made in combination with the image-guided aspiration and, as such, are performed in the same setting. This enables the authors to avoid a more invasive surgical procedure when FNA or core-needle biopsy is sufficient without contributing to delays in diagnosis by having multiple attempts from multiple providers (such as interventional radiology and pulmonology) before involvement of the surgeon in the diagnostic workup.

Surgical Biopsies and Resection of Mediastinal Masses

For tumors of the mediastinum that are not amenable to an endoscopic or CT-guided needle biopsy or that do not yield sufficient tissue for diagnosis, a surgical biopsy is indicated. The definitive approach to a surgical biopsy of the anterior mediastinum is through a median sternotomy. At the time of sternotomy, if the lesion is easily resectable, it should be completely removed. Given the invasiveness of the procedure and the inability in some patients to obtain a definitive diagnosis by frozen section, less invasive procedures are preferable if the lesion is large or if the CT scan or history suggests that surgery is not the best definitive treatment. Masses in the paratracheal region are easily biopsied by mediastinoscopy. For tumors of the anterior or

Table 19-28

Signs and symptoms suggestive of various diagnoses in the setting of a mediastinal mass

DIAGNOSIS	HISTORY AND PHYSICAL FINDINGS	COMPARTMENT LOCATION OF MASS
Lymphoma	Night sweats, weight loss, fatigue, extrathoracic adenopathy, elevated erythrocyte sedimentation rate or C-reactive protein level, leukocytosis	Any compartment
Thymoma with myasthenia gravis	Fluctuating weakness, early fatigue, ptosis, diplopia	Anterior
Mediastinal granuloma	Dyspnea, wheezing, hemoptysis	Visceral (middle)
Germ cell tumor	Male gender, young age, testicular mass, elevated levels of human chorionic gonadotropin and/or α-fetoprotein	Anterior

posterior mediastinum, a left or right VATS approach often allows safe and adequate surgical biopsies. In some patients, an anterior mediastinotomy (i.e., Chamberlain procedure) may be ideal for an anterior tumor or a tumor with significant parasternal extension. Before a surgical biopsy is pursued, a discussion should be held with the pathologist regarding routine histologic assessment, special stains and markers, and requirements for lymphoma workup.

Surgical resection using minimally invasive approaches, including video-assisted and robotic thoracoscopic surgery and transcervical, are now routine for the vast majority of middle and posterior tumors and for moderate sized (<5 to 6 cm) anterior mediastinal tumors.[166-169] Outcomes comparing VATS to open thymectomy in patients with myasthenia gravis without thymoma were prospectively evaluated by Chang and colleagues in 2005, and no differences were seen in terms of response to therapy and recurrence of symptoms. Pain scores were significantly better in the VATS approach.[170] These reports and others support application of VATS for the majority of anterior mediastinal masses.

Other minimally invasive approaches are under study. For example, good results have been reported using a cervical incision with a sternal retractor for thymus removal. The upward lift allows the surgeon reasonable access to the anterior mediastinum and has proven adequate in some centers for definitive resection of the thymus gland for myasthenia gravis.[171]

For larger anterior mediastinal masses or in centers where expertise in thoracoscopy is not available, median sternotomy and thoracotomy remain excellent options for resection of anterior mediastinal masses. Occasionally, a lateral thoracotomy with sternal extension (hemi-clamshell) provides excellent exposure for extensive mediastinal tumors that have a lateral component. Most surgeons would agree that if a larger anterior mediastinal tumor is seen or malignancy is suspected, a median sternotomy with a more radical resection should be performed.

Mediastinal Neoplasms

Thymic Hyperplasia. Diffuse thymic hyperplasia was first described in children after successful chemotherapy for lymphoma. It has now been described in adults and is referred to as

Table 19-29

Nuclear imaging relevant to the mediastinum

RADIOPHARMACEUTICAL, RADIONUCLIDE, OR RADIOCHEMICAL	LABEL	DISEASE OF INTEREST

"rebound thymic hyperplasia."[172] It is most frequently reported after chemotherapy for lymphoma or germ cell tumors. Initially, atrophy of the thymic gland is seen with subsequent thymic gland enlargement, which can be dramatic. The usual time course for thymic hyperplasia is about 9 months after cessation of chemotherapy (range 2 weeks–12 months). Benign hyperplasia must be clearly distinguished from recurrent lymphoma or germ cell tumors, which may be difficult since thymic hyperplasia is dramatic in some patients; careful follow-up with serial CT scans is the minimum requirement. The role of PET scanning is unclear. Thymic hyperplasia is a known cause of false-positive PET scans; in many patients, CT scan will show a triangular soft tissue density in the retrosternal space that has a characteristic bilobed anatomic appearance consistent with thymus gland.[173] In addition, a low standardized uptake value of tracer on PET scan suggests a benign tumor.[174] Biopsies may be required if the clinical index of suspicion is high.

Thymoma. The most frequently encountered neoplasm of the anterior mediastinum in adults (seen most frequently between 40 and 60 years of age), thymoma is rare in children. Between 10% and 50% of patients with thymoma will have symptoms suggestive of myasthenia gravis or have circulating antibodies to acetylcholine receptor, but less than 10% of patients with myasthenia gravis have a thymoma. Most patients with thymoma are asymptomatic. Thymectomy leads to improvement or resolution of symptoms of myasthenia gravis in only about 25% of patients with thymomas. In contrast, in patients with myasthenia gravis and no thymoma, thymectomy results are superior: up to 50% of patients have a complete remission and 90% improve. In 5% of patients with thymomas, other paraneoplastic syndromes, including red cell aplasia, hypogammaglobulinemia, systemic lupus erythematosus, Cushing's syndrome, or SIADH, may be present. Large thymic tumors may present with symptoms related to a mass effect, which may include cough, chest pain, dyspnea, or SVC syndrome.

The diagnosis may be suspected based on CT scan and history, but imaging alone is not diagnostic. In most centers, the diagnosis is made after surgical resection because of the relative difficulty of obtaining a needle biopsy and the likelihood that removal will ultimately be recommended. Biopsy should be avoided in cases where imaging is highly suggestive of thymoma. In most patients, the distinction between lymphomas and thymomas can be made on CT scan, since most lymphomas have marked lymphadenopathy and thymomas most frequently appear as a solitary encapsulated mass. PET scan may have a role in differentiating thymic cancer from thymoma, as thymic cancer tends to be very FDG avid.[174] In addition, PET scan may facilitate identification of low-risk and minimally invasive thymoma; a standardized uptake value (SUV) <5 was associated with Masaoka stage I or II thymoma, whereas invasive thymoma and mediastinal lymphoma were more likely when the SUV was >5.[175] In cases where the diagnosis is unclear, transmediastinal, not transpleural, CT-guided FNA biopsy has a diagnostic sensitivity of 87% and a specificity of 95% in specialized centers.

The most commonly accepted staging system for thymoma is that of Masaoka.[176] It is based on the presence or absence of gross or microscopic invasion of the capsule and of surrounding structures, as well as on the presence or absence of metastases (Table 19-30). Histologically, thymomas are characterized by a mixture of epithelial cells and mature lymphocytes. Grossly, many thymomas remain well encapsulated. Even those with capsular invasion often lack histologic features of malignancy; they appear cytologically benign and identical to early-stage tumors. This lack of classic cellular features of malignancy is why most pathologists use the term "thymoma" or "invasive thymoma" rather than "malignant thymoma." Thymic tumors with malignant cytologic features are classified separately and referred to as "thymic carcinoma."

Table 19-30

Masaoka staging system for thymoma

Stage I	Encapsulated tumor with no gross or microscopic evidence of capsular invasion
Stage II	Gross capsular invasion or invasion into the mediastinal fat or pleura or microscopic capsular invasion
Stage III	Gross invasion into the pericardium, great vessels, or lung
Stage IVA	Pleural or pericardial dissemination
Stage IVB	Lymphogenous or hematogenous metastasis

The definitive treatment for thymoma is complete surgical removal; local recurrence rates and survival vary according to stage (Fig. 19-47). In centers with significant experience with VATS procedures, thymoma is not a contraindication to VATS approach, provided the principles of resection are adhered to, such as a complete resection without disrupting the capsule.[177] Otherwise, resection is generally accomplished by median sternotomy with extension to hemi-clamshell in more advanced cases. Even advanced tumors with local invasion of resectable structures such as the pericardium, SVC, or innominate vessels should be considered for resection with reconstruction.

A multidisciplinary approach to nonresectable and more advanced lesions (stage ≥II) is mandatory to optimize patient care. The goal for surgical resection should be complete excision of the mass with total thymectomy. All contiguous and noncontiguous disease is removed at the same setting; this may include resection of the pericardium or pleura, adjacent adherent lung, phrenic nerve, major vascular structures, and pleural metastasis. Bilateral phrenic nerve resection should be avoided, however, due to the major respiratory morbidity associated with bilateral paralyzed hemidiaphragms.

The role of adjuvant or neoadjuvant therapies for advanced-stage tumors remains unclear. Traditionally, stage II

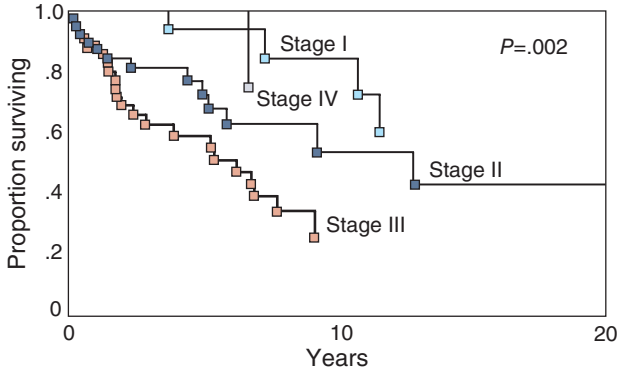

Figure 19-47. Stage-specific survival for thymomas.

thymomas have been treated by complete surgical resection followed by mediastinal radiation, but randomized trials have not been done. A recent retrospective review of a single-institution series of stage II thymoma patients showed no difference in survival or local recurrence after complete surgical resection alone, as compared with surgical resection with radiotherapy. Advanced thymomas have been shown to respond to platinum-based chemotherapy and to corticosteroids.[178] One summary of chemotherapy trials showed an overall response rate of about 70%. Cisplatin/doxorubicin-based regimens appear to yield the best results. The combination radiotherapy and chemotherapy for local progression appears to prolong survival in some small series.[179] Radiation therapy in surgically resected stage III thymoma is likely beneficial in extending disease-specific survival; a recent analysis of the Surveillance, Epidemiology, and End Results (SEER) database identified 476 patients with stage III thymoma treated with primary surgery. Postoperative radiation was given to 322 patients with a significant improvement in survival (127 months compared to 105 months, $P = .038$) despite the fact that these patients were more likely to have had debulking rather than curative resection. In multivariate analysis, disease-specific survival was better in the adjuvant radiation group.[180] Therefore, it is imperative that all patients with thymomas undergo a thorough evaluation for potential resection. Current guidelines recommend radiation for patients with unresectable thymoma who have failed induction chemotherapy or for patients with incompletely resected invasive thymoma or thymic cancer. Planning the radiation ports requires input from the surgeon; it is important for the surgeon to carefully document areas of adherence between the thymoma and adjacent structures during the operation, with clips or other radiopaque markers placed to guide radiation therapy postoperatively. Extracapsular extension and positive surgical margins should be noted by the pathologist and correlated anatomically so that the surgeon and radiation oncologist can ensure appropriate radiation treatment.

Thymic Carcinoma. Thymic carcinomas are unequivocally malignant at the microscopic level. Suster and Rosai classified thymic carcinomas into low-grade and high-grade tumors.[181] Low-grade tumors are well differentiated with squamous cell, mucoepidermoid, or basaloid features. High-grade thymic carcinomas include those with lymphoepithelial, small cell neuroendocrine, sarcomatoid, clear cell, and undifferentiated or anaplastic features. Care must be taken to differentiate thymic carcinoma from lung cancer metastatic to the thymus gland as the histologic features can be similar between the two. Compared with thymomas, they are a more heterogeneous group of malignancies with a propensity for early local invasion and widespread metastases. Malignant pleural and pericardial effusions occur frequently.

Five-year survival rates are between 30% and 50%. Complete resection is occasionally curative and leads to improved survival, but most thymic carcinomas will recur and are refractory to chemotherapy.[178] Management, therefore, depends on the completeness of the resection. Postoperative care includes radiation therapy, guided by residual gross disease or microscopically positive margins from the resection specimen. Chemotherapy may also be given, with carboplatin/paclitaxel recommended based on the best response rates with the least toxicity in clinical trials. The prognosis of patients with thymic cancer remains poor.

Thymolipoma. Thymolipomas are rare benign tumors that may grow to a very large size prior to diagnosis. On CT scan, their appearance can be dramatic, with a characteristic fat density dotted by islands of soft tissue density representing islands of thymic tissue (Fig. 19-48). Thymolipomas are generally well-encapsulated, soft, and pliable masses that do not invade

Figure 19-48. Massive thymolipoma that was asymptomatic in an 18-year-old female.

Table 19-31

Classification of neurogenic tumors of the mediastinum

TUMOR ORIGIN	BENIGN	MALIGNANT
Nerve sheath	Neurilemoma, neurofibroma, melanotic schwannoma, granular cell tumor	Neurofibrosarcoma
Ganglion cell	Ganglioneuroma	Ganglioneuroblastoma, neuroblastoma
Paraganglionic cell	Chemodectoma, pheochromocytoma	Malignant chemodectoma, malignant pheochromocytoma

surrounding structures. Resection is recommended for large masses.

Neurogenic Tumors. Most neurogenic tumors of the mediastinum arise from the cells of the nerve sheath, from ganglion cells, or from the paraganglionic system (Table 19-31). The incidence, cell types, and risk of malignancy strongly correlate with patient age. Tumors of nerve sheath origin predominate in adults. Most present as asymptomatic incidental findings, and most are benign. In children and young adults, tumors of the autonomic ganglia predominate, with up to two thirds being malignant.[182]

Nerve Sheath Tumors. Nerve sheath tumors account for 20% of all mediastinal tumors. More than 95% of nerve sheath tumors are benign neurilemomas or neurofibromas. Malignant neurosarcomas are much less common.

Neurilemoma. Neurilemomas, also called schwannomas, arise from Schwann cells in intercostal nerves. They are firm, well-encapsulated, and generally benign. Two characteristic histologic components are referred to as Antoni type A and Antoni type B regions. Antoni type A regions contain compact spindle cells with twisted nuclei and nuclear palisading. Antoni type B regions contain loose and myxoid connective tissue with haphazard cellular arrangement. These characteristics distinguish neurilemoma from malignant, fibrosarcomatous tumors, which lack encapsulation and have no Antoni features. If routine CT scan suggests extension of a neurilemoma into the intervertebral foramen, MRI is used to evaluate the extent of this "dumbbell" configuration (Fig. 19-49). Such a configuration may lead to cord compression and paralysis and requires a more complex surgical approach. Resection is recommended; VATS has been established as safe and effective for simple and, in experienced centers, even the more complex operations.[183] It is reasonable to follow small, asymptomatic paravertebral tumors in older patients or in patients at high risk for surgery. In children, ganglioneuroblastomas or neuroblastomas are more common; therefore, all neurogenic tumors should be completely resected.

Neurofibroma. Neurofibromas consist of both nerve sheath and nerve cells and account for up to 25% of nerve sheath tumors. Up to 40% of patients with mediastinal fibromas have generalized neurofibromatosis (von Recklinghausen's disease). About 70% of neurofibromas are benign, but malignant degeneration to neurofibrosarcoma occurs in 25% to 30% of patients.[184] The risk of malignant degeneration increases with advancing age,

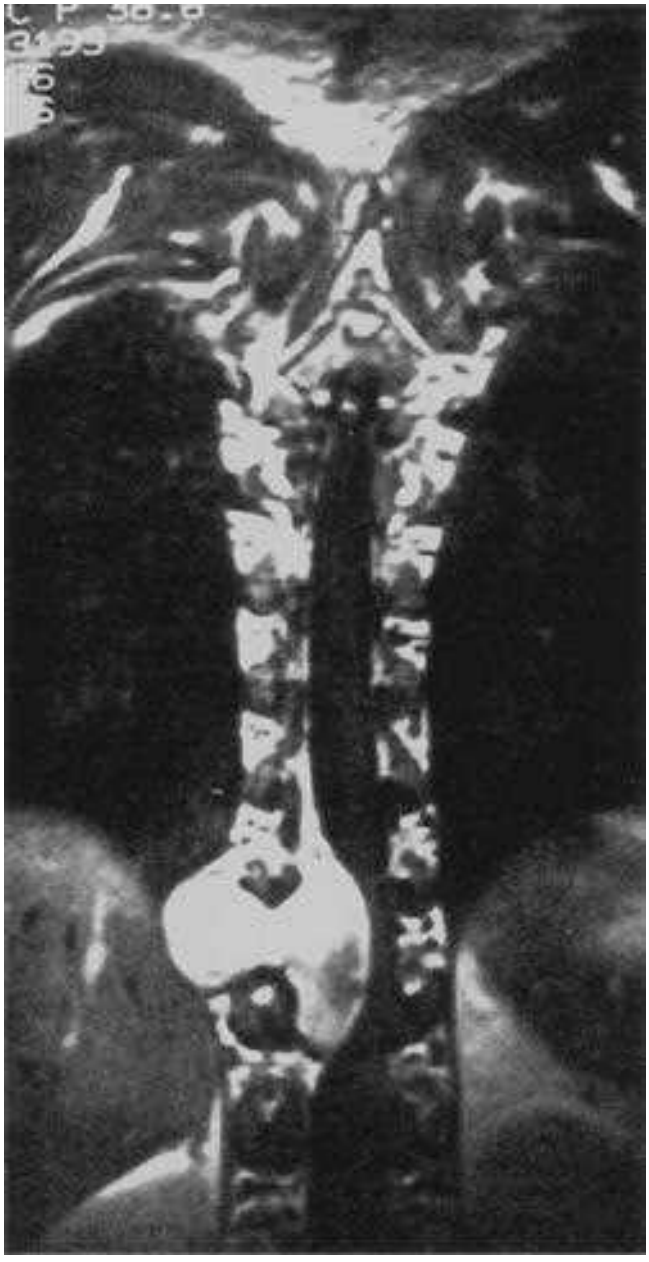

Figure 19-49. Magnetic resonance image of a neurogenic tumor with extension into the spinal canal via the foramen, giving a typical dumbbell appearance.

von Recklinghausen's disease, and exposure to previous radiation. Neurofibrosarcomas carry a poor prognosis because of rapid growth and aggressive local invasion along nerve bundles. Complete surgical resection is the mainstay of treatment. Adjuvant radiotherapy or chemotherapy does not confer a significant benefit, but may be added if complete resection is not possible.[185] The 5-year survival rate is 53%, but drops to 16% in patients with neurofibromatosis or with large tumors (>5 cm).

Ganglion Cell Tumors. Ganglion cell tumors (ganglioneuromas, ganglioneuroblastomas, and neuroblastomas) arise from the sympathetic chain or from the adrenal medulla.

Ganglioneuroma. Well-differentiated, benign tumors characterized histologically by well-differentiated ganglion cells with a background of Schwann cells, these are most often found incidentally in asymptomatic young adults. Diarrhea related to secretion of a vasoactive intestinal peptide has been described in some patients. These tumors have a propensity for intraspinal canal extension, although they remain well-encapsulated; complete resection is curative, with a low risk of local recurrence.

Ganglioneuroblastoma. Ganglioneuroblastomas contain a mixture of benign ganglion cells and malignant neuroblasts. The distribution of these cells within the tumor is predictive of the clinical course. The nodular pattern has a high incidence of metastatic disease, whereas the diffuse pattern rarely metastasizes. Gross examination typically reveals encapsulated tumor; histologically, there are focal calcifications around regions of neuroblasts. Ganglioneuroblastomas arise most frequently in infants and children <3 years old. The majority are resectable, with 80% 5-year survival.

Neuroblastoma. Highly malignant, neuroblastomas are the most common extracranial solid malignancy of childhood. The primary site is intrathoracic malignancy in 14%; extension into the spinal canal and osseous invasion is commonly present. These thoracic tumors are not as recalcitrant to chemotherapy and surgical resection as other chest malignancies; they are more likely to be resectable, with less invasion of surrounding organs. More than half occur in children under 2 years old; 90% arise within the first decade of life, and thus, these malignancies are discussed in more detail in Chapter 39.

Paraganglionic Tumors. Paraganglionic tumors arising in the thoracic cavity include chemodectomas and pheochromocytomas. Only 10% of all pheochromocytomas are located in an extra-adrenal site. Intrathoracic pheochromocytomas are one of the rarest tumors. Approximately 10% of thoracic pheochromocytomas are malignant, a rate similar to that of adrenal tumors. The most common thoracic location is within the costovertebral sulcus, but paraganglionic tumors also arise within the visceral compartment of the mediastinum. These catecholamine-producing lesions can lead to life-threatening hemodynamic problems, so complete removal is important. Diagnosis is generally confirmed by measuring elevated levels of urinary catecholamines and their metabolites. Localization is by CT scan, aided by MIBG scintigraphy. Preoperative care includes α- and β-adrenergic blockade to prevent intraoperative malignant hypertension and arrhythmias. These tumors tend to be highly vascular and should be approached with care. Chemodectomas are rare tumors that may be located around the aortic arch, vagus nerves, or aorticosympathetics. They rarely secrete catecholamines and are malignant in up to 30% of patients.

Lymphoma. Overall, lymphomas are the most common malignancy of the mediastinum. In about 50% of patients who have both Hodgkin's and non-Hodgkin's lymphoma, the mediastinum may be the primary site. The anterior compartment is most commonly involved, with occasional involvement of the middle compartment and hilar nodes. The posterior compartment is rarely involved. Chemotherapy and/or radiation results in a cure rate of up to 90% for patients with early-stage Hodgkin's disease and up to 60% with more advanced stages.

Mediastinal Germ Cell Tumors. Germ cell tumors are uncommon neoplasms, with only about 7000 diagnosed each year. However, they are the most common malignancy in young men 15 to 35 years of age. Most germ cell tumors are gonadal in origin; primary mediastinal germ cell tumors comprise less than 5% of all germ cell tumors and less than 1% of all mediastinal tumors (usually occurring in the anterior compartment). If a malignant mediastinal germ cell tumor is found, it is important to exclude a gonadal primary tumor. Primary mediastinal germ cell tumors (including teratomas, seminomas, and nonseminomatous malignant germ cell tumors) are a heterogeneous group of benign and malignant neoplasms thought to originate from primitive pluripotent germ cells "misplaced" in the mediastinum during embryonic development. Previously, most mediastinal germ cell tumors were thought to be metastatic. However, two lines of evidence suggest that many mediastinal germ cell tumors are primary, developing from pluripotent primordial germ cells in the mediastinum: (a) several autopsy series showed that patients with extragonadal sites of germ cell tumors, presumed previously to have originated from the gonads, had no evidence of an occult primary tumor or of any residual scar of the gonads, even after an exhaustive search; and (b) patients treated by surgery or radiation for their mediastinal germ cell tumors had long-term survival with no late testicular recurrences.[186]

About one third of all primary mediastinal germ cell tumors are seminomatous. Two thirds are nonseminomatous tumors or teratomas. Treatment and prognosis vary considerably within these two groups. Mature teratomas are benign and can generally be diagnosed by the characteristic CT findings of multilocular cystic tumors, encapsulated with combinations of fluid, soft tissue, calcium, and/or fat attenuation in the anterior compartment. FNA biopsy alone may be diagnostic for seminomas, usually with normal serum markers, including hCG and AFP. In 10% of seminomas, hCG levels may be slightly elevated. FNA findings, along with high hCG and AFP levels, can accurately diagnose nonseminomatous tumors. If the diagnosis remains uncertain after assessment of FNA findings and serum marker levels, then core-needle biopsies or surgical biopsies may be required. Thoracoscopy is the most frequent diagnostic surgical approach.

Seminoma. Most patients with seminomas have advanced disease at the time of diagnosis and present with symptoms of local compression, including SVC syndrome, dyspnea, or chest discomfort. With advanced disease, the preferred treatment is combination cisplatin-based chemotherapy regimens with bleomycin and either etoposide or vinblastine. Complete responses have been reported in over 75% of patients treated with these regimens. Surgical resection may be curative for small asymptomatic seminomas that are found incidentally with screening CT scans. Surgical resection of residual masses after chemotherapy may be indicated.

Nonseminomatous germ cell tumors. Nonseminomatous germ cell tumors include embryonal cell carcinomas, choriocarcinomas,

endodermal sinus tumors, and mixed types. They are often bulky, irregular tumors of the anterior mediastinum with areas of low attenuation on CT scan because of necrosis, hemorrhage, or cyst formation. Frequently, adjacent structures have been involved, with metastases to regional lymph nodes, pleura, and lungs. Lactate dehydrogenase (LDH), AFP, and hCG levels are frequently elevated. Chemotherapy is the preferred treatment and includes combination therapy with cisplatin, bleomycin, and etoposide, followed by surgical resection of residual disease. With this regimen, survival is 67% at 2 years and 60% at 5 years. Surgical resection of residual masses is indicated, as it may guide further therapy. Up to 20% of residual masses contain additional tumors; in another 40%, mature teratomas; and the remaining 40%, fibrotic tissue. It is important to note that oxygen toxicity can occur in patients who have been exposed to bleomycin; high levels of oxygen supplementation in the perioperative setting should be avoided in these patients as respiratory failure and death can ensue.[187] Factors independently predictive of survival after induction chemotherapy followed by resection are elevated serum tumor markers after resection, postchemotherapy pathologic findings (complete necrosis vs. teratoma), and persistent germ cell or non-germ cell cancer in the pathologic specimen.[187]

Teratoma. Teratomas are the most common type of mediastinal germ cell tumors, accounting for 60% to 70% of mediastinal germ cell tumors. They contain two or three embryonic layers that may include teeth, skin, and hair (ectodermal), cartilage and bone (mesodermal), or bronchial, intestinal, or pancreatic tissue (endodermal). Therapy for mature, benign teratomas is surgical resection, which confers an excellent prognosis.

Rarely, teratomas may contain a focus of carcinoma; these malignant teratomas (or teratocarcinomas) are locally aggressive. Often diagnosed at an unresectable stage, they respond poorly to chemotherapy and in a limited manner to radiotherapy; prognosis is uniformly poor.

Mediastinal Cysts

Benign cysts account for up to 25% of mediastinal masses and are the most frequently occurring mass in the middle mediastinal compartment. A CT scan showing characteristic features of near water density in a typical location is virtually 100% diagnostic.[188]

Pericardial cyst. Usually asymptomatic and detected incidentally in the right costophrenic angle, pericardial cysts typically contain a clear fluid and are lined with a single layer of mesothelial cells. For most simple, asymptomatic pericardial cysts, observation alone is recommended. Surgical resection or aspiration may be indicated for complex cysts or large symptomatic cysts.

Bronchogenic cyst. Developmental anomalies that occur during embryogenesis and occur as an abnormal budding of the foregut or tracheobronchial tree, bronchogenic cysts arise most often in the mediastinum just posterior to the carina or main stem bronchus. Approximately 15% occur within the pulmonary parenchyma. Thin-walled and lined with respiratory epithelium, they contain a protein-rich mucoid material and varying amounts of seromucous glands, smooth muscle, and cartilage. They may communicate with the tracheobronchial tree. In adults, over half of all bronchogenic cysts are found incidentally during workup for an unrelated problem or during screening. The natural history of an incidentally diagnosed, asymptomatic bronchogenic cyst is unknown, but it is clear that many such cysts do not lead to clinical problems. In one study of young military personnel, 78% of all bronchogenic cysts found on routine CXRs were asymptomatic. However, in other reports with more comprehensive follow-up, up to 67% of adults with incidentally found bronchogenic cysts eventually became symptomatic. Symptoms include chest pain, cough, dyspnea, and fever. If large (>6 cm) or symptomatic, resection is generally recommended since serious complications may occur if the cyst becomes larger or infected. Complications include airway obstruction, infection, rupture, and rarely, malignant transformation.[189,190]

Traditionally, complete removal of the cyst wall has been via posterolateral thoracotomy.[191] Resection of infected cysts may be quite difficult because of dense adhesions; elective removal is often recommended before infection has a chance to occur. Thoracoscopic exploration and resection are possible for small cysts with minimal adhesions. With increasing experience using video-assisted or robotic-assisted thoracoscopy, a greater proportion of these lesions are amenable to minimally invasive resection.

Enteric cyst. Most clinicians agree that in contrast to bronchogenic cysts, esophageal cysts should be removed, regardless of the presence or absence of symptoms. Esophageal cysts have a propensity for serious complications secondary to enlargement, leading to hemorrhage, infection, or perforation. Thus, surgical resection is the treatment of choice in both adults and children. As with bronchogenic cysts, experienced surgeons are approaching enteric cyst resections using minimally invasive techniques with great success.

Thymic cyst. Generally asymptomatic, thymic cysts are often discovered incidentally. Simple cysts are of no consequence; however, the occasional cystic neoplasm must be ruled out. Cystic components occasionally are seen in patients with thymoma and Hodgkin's disease.

Ectopic endocrine glands. Up to 5% of all mediastinal masses are of thyroid origin; most are simple extensions of thyroid masses. Usually nontoxic, over 95% can be completely resected through a cervical approach. True ectopic thyroid tissue of the mediastinum is rare. About 10% to 20% of abnormal parathyroid glands are found in the mediastinum; most can be removed during exploration from a cervical incision. In cases of true mediastinal parathyroid glands, thoracoscopic or open resection may be indicated. Location can generally be pinpointed by a combination of CT scan and Sestamibi scans.

Mediastinitis

Acute Mediastinitis. Acute mediastinitis is a fulminant infectious process that spreads rapidly along the continuous fascial planes connecting the cervical and mediastinal compartments. Infections originate most commonly from esophageal perforations, sternal infections, and oropharyngeal or neck infections, but a number of less common etiologic factors can lead to this deadly process (Table 19-32). Clinical signs and symptoms include fever, chest pain, dysphagia, respiratory distress, and cervical and upper thoracic subcutaneous crepitus. In severe cases, the clinical course can rapidly deteriorate to florid sepsis, hemodynamic instability, and death. Thus, a high index of suspicion is required in the context of any infection with access to the mediastinal compartments.

A chest CT scan illuminates the extent of spread and guides selection of the best approach to surgical drainage. Acute

mediastinitis is a true surgical emergency; treatment must be instituted immediately and aimed at correcting the primary problem, such as the esophageal perforation or oropharyngeal abscess, and debridement and drainage of the spreading infectious process within the mediastinum, neck, pleura, and other tissue planes. Antibiotics, fluid resuscitation, and other supportive measures are also important. Debridement may need to be repeated and other planes and cavities explored depending on the patient's clinical status. Blood cell counts and serial CT scans may also be required. Persistent sepsis or collections on CT scan may require further radical surgical debridement.

Chronic Mediastinitis. Sclerosing or fibrosing mediastinitis results from chronic mediastinal inflammation that originates in the lymph nodes, most frequently from granulomatous infections such as histoplasmosis or tuberculosis. Chronic, low-grade inflammation leads to fibrosis and scarring, which can, in some patients, result in entrapment and compression of the low-pressure veins (including the SVC and innominate and azygos veins), the esophagus, and pulmonary arteries. There is no definitive treatment. Surgery is indicated only for diagnosis or in specific patients to relieve airway or esophageal obstruction or to achieve vascular reconstruction. Reports of palliative success with less invasive procedures (such as dilation and stenting of airways, the esophagus, or the SVC) are promising. In one series of 22 patients, ketoconazole was effective in controlling progression. In another series of 71 patients, 30% died during long-term follow-up. Chronic mediastinitis is similar to retroperitoneal fibrosis, sclerosing cholangitis, and Riedel's thyroiditis.

PLEURA AND PLEURAL SPACE

Anatomy

Each hemithorax has a mesothelial lining that invaginates at the hilum of each lung and continues on to cover each lung. The portion lining the bony rib cage, mediastinum, and diaphragm is called the parietal pleura, whereas the portion encasing the lung is known as the visceral pleura. Between these two surfaces is the potential pleural space, which is normally occupied by a thin layer of lubricating pleural fluid. A network of somatic, sympathetic, and parasympathetic fibers innervates the parietal pleura. Irritation of the parietal surface by inflammation, tumor invasion, trauma, and other processes can lead to a sensation of chest wall pain. The visceral pleura have no somatic innervation.[192,193]

Pleural Effusion

Pleural effusion refers to any significant collection of fluid within the pleural space. Normally, between 5 and 10 L of fluid enters the pleural space each day by filtration through microvessels supplying the parietal pleura (located mainly in the less dependent regions of the cavity). The net balance of pressures in these capillaries leads to fluid flow from the parietal pleural surface into the pleural space, and the net balance of forces in the pulmonary circulation leads to absorption through the visceral pleura. Normally, 15 to 20 mL of pleural fluid is present at any given time. Any disturbance in these forces can lead to imbalance and accumulation of pleural fluid. Common pathologic conditions in North America that lead to pleural effusion include congestive heart failure, bacterial pneumonia, malignancy, and pulmonary emboli (Table 19-33).[194]

Access and Drainage of Pleural Fluid Collections

Most patients with pleural effusions of unknown cause should undergo thoracentesis with only two exceptions: effusions in the setting of congestive heart failure or renal failure or small effusions associated with an improving pneumonia. If the clinical history suggests congestive heart failure as a cause, particularly in the setting of bilateral effusions, a trial of diuresis may be indicated (rather than thoracentesis). Up to 75% of effusions due to congestive heart failure resolve within 48 hours with diuresis alone. Similarly, thoracentesis can be avoided in patients with small effusions associated with resolving pneumonia. These patients typically present with cough, fever, leukocytosis, and unilateral infiltrate, and the effusion is usually a result of a reactive, parapneumonic process. If the effusion is small and the patient responds to antibiotics, a diagnostic thoracentesis may be unnecessary. If the effusion is large and compromising respiratory efforts, or if the patient has a persistent white blood cell count despite improving signs of pneumonia, an empyema of the pleural space must be considered. In these patients, early and aggressive drainage with chest tubes is required, possibly with surgical intervention.

Once the decision is made to access a pleural effusion, the next step is to determine if a sample of the fluid or complete

Table 19-33

Leading causes of pleural effusion in the United States, based on data from patients undergoing thoracentesis

CAUSE	ANNUAL INCIDENCE	TRANSUDATE	EXUDATE
Congestive heart failure	500,000	Yes	No
Pneumonia	300,000	No	Yes
Cancer	200,000	No	Yes
Pulmonary embolus	150,000	Sometimes	Sometimes
Viral disease	100,000	No	Yes
Coronary artery bypass surgery	60,000	No	Yes
Cirrhosis with ascites	50,000	Yes	No

drainage of the pleural space is desired. This step is influenced by the clinical history, the type and amount of fluid present, the nature of the collection (such as free-flowing or loculated), the cause, and the likelihood of recurrence. For small, free-flowing effusions, an outpatient diagnostic and/or therapeutic thoracentesis with a relatively small-bore needle or catheter (14- to 16-gauge) can be performed (Fig. 19-50). The appearance of the fluid is informative: clear straw-colored fluid is often transudative; turbid or bloody fluid is often exudative.

The site of entry for drainage of a pleural effusion or pneumothorax may be based on the CXR alone if the effusion is demonstrated to be free-flowing. For free-flowing effusions, a low approach at the eighth or ninth intercostal space in the posterior midclavicular line facilitates complete drainage. If the effusion is loculated, CT- or ultrasound-guided drainage may be indicated. If the goal is complete drainage of nonbloody and nonviscous fluid, a small-bore pigtail catheter is inserted and connected to a closed drainage system with applied suction (typically –20 cm H_2O). If the fluid is bloody or turbid, a larger-diameter drainage tube (such as a 28F chest tube) may be required. In general, the smallest-bore drainage catheter that will effectively drain the pleural space should be chosen.

Figure 19-50. Techniques for aspiration and drainage of a pleural effusion. **A.** Needle aspiration. With careful appraisal of the x-ray findings, the best interspace is selected, and fluid is aspirated with a needle and syringe. Large volumes of fluid can be removed with a little patience and a large-bore needle. **B.** Chest tube insertion. After careful skin preparation, draping, and administration of local anesthesia, a short skin incision is made over the correct interspace. The incision is deepened into the intercostal muscles, and the pleura is penetrated (usually with a clamp). When any doubt exists about the status of the pleural space at the site of puncture, the wound is enlarged bluntly to admit a finger, which can be swept around the immediately adjacent pleural space to assess the situation and break down any adhesions. The tube is inserted, with the tip directed toward the optimal position suggested by the chest x-rays. In general, a high anterior tube is best for air (pneumothorax), and a low posterior tube is best for fluid. A 28F to 32F tube is adequate for most situations. A 36F tube is preferred for hemothorax or for a viscous empyema. Many surgeons prefer a very small tube (16F–20F) for drainage of simple pneumothorax. **C.** The tube is connected to a water-seal drainage system. Suction is added, if necessary, to expand the lung; it usually will be required in a patient with a substantial air leak (bronchopleural fistula).

Smaller-diameter catheters significantly decrease the pain associated with the placement of chest tubes but are more prone to clogging and twisting.[195,196] For clinical situations requiring biopsy or for potential interventions such as adhesiolysis or pleurodesis, minimally invasive surgery may be indicated, using a VATS approach.

Complications of Pleural Drainage. The most common complications of invasive pleural procedures are inadvertent injury to adjacent organs, including lung, with air leakage and pneumothorax; subdiaphragmatic entry and damage to the liver, spleen, or other intra-abdominal viscera; intercostal vessel injury with subsequent bleeding or larger vessel injury; and even cardiac puncture. Sometimes bleeding may be the result of an underlying coagulopathy or anticoagulant therapy. Other technical complications include loss of a catheter, guidewire, or fragment in the pleural space and infections. Occasionally, rapid drainage of a large effusion can be followed by shortness of breath, clinical instability, and a phenomenon referred to as postexpansion pulmonary edema. For this reason, it is recommended to drain only up to 1500 mL initially. Most complications can be avoided by consulting with a clinician experienced in pleural drainage techniques.

Pleural Fluid Analysis. Pleural fluid collections are generally classified as transudates and exudates (Table 19-34). Transudates are protein-poor ultrafiltrates of plasma that result from alterations in the systemic hydrostatic pressures or colloid osmotic pressures (for example, with congestive heart failure or cirrhosis). On gross visual inspection, a transudative effusion is generally clear or straw-colored. Exudates are protein-rich pleural fluid collections that generally result from inflammation or pleural invasion by tumor. Grossly, they are often turbid, bloody, or purulent. Absent trauma, grossly bloody effusions are frequently malignant, but may also occur in the setting of a pulmonary embolism or pneumonia.

Transudates and exudates can be differentiated using Light's criteria. An effusion is exudative if the pleural fluid-to-serum ratio of protein is greater than 0.5 and the LDH ratio is greater than 0.6 or the absolute pleural LDH level is greater than two thirds of the normal upper limit for serum. If criteria suggest a transudate, a careful evaluation for congestive heart failure, cirrhosis, or conditions associated with transudates is undertaken. If criteria suggest an exudate, further diagnostic studies may be helpful. If total and differential cell counts reveal a predominance of neutrophils (>50% of cells), the effusion is likely associated with an acute inflammatory process (such as a parapneumonic effusion or empyema, pulmonary embolus, or pancreatitis). A predominance of mononuclear cells suggests a more chronic inflammatory process (such as cancer or tuberculosis). Gram stains and cultures should be obtained if possible, with inoculation into culture bottles at the bedside. Pleural fluid glucose levels are frequently decreased (<60 mg/dL) with complex parapneumonic effusions or malignant effusions.

A pleural effusion occurring in association with pleuritic chest pain, hemoptysis, or dyspnea out of proportion to the size of the effusion should raise concern for pulmonary embolism. These effusions may be transudative, but if an associated infarct near the pleural surface occurs, an exudate may be seen. If a pulmonary embolism is suspected in a postoperative patient, most clinicians would obtain a spiral CT scan. Alternatively, duplex ultrasonography of the lower extremities may yield a diagnosis of deep vein thrombosis, thereby indicating anticoagulant therapy and precluding the need for a specific diagnosis of pulmonary embolism. In some patients, a blood test for levels of D-dimer may be helpful; if a sensitive D-dimer blood test is negative, pulmonary embolism may be ruled out.

Malignant Pleural Effusion

Malignant pleural effusions may occur in association with a number of different malignancies, most commonly lung cancer, breast cancer, and lymphomas, depending on the patient's age and gender (Tables 19-35 and 19-36).[197] Cytologic testing should be done on exudative effusions to rule out an associated malignancy; accuracy is 70% when associated with adenocarcinomas, but is less sensitive for mesotheliomas (<10%), squamous cell carcinomas (20%), or lymphomas (25%–50%). If the diagnosis remains uncertain after drainage and fluid analysis, thoracoscopy and direct biopsies are indicated.[198,199] Malignant effusions are exudative and often tinged with blood. An effusion in the setting of a malignancy means a more advanced stage; mean survival ranges from 3 to 11 months, depending on the primary tumor location. Occasionally, effusions associated with a bronchogenic NSCLC are benign, and surgical resection may still be indicated.

Effusion size and degree of associated dyspnea influence management. Symptomatic, moderate to large effusions should be drained by tunneled indwelling pleural catheter, tube thoracostomy (chest tube or pigtail catheter) with subsequent instillation of doxycycline as a sclerosing agent, or VATS with talc instillation. Management is based on patient preference, degree of known or anticipated lung re-expansion, and patient tolerance for operative intervention. Lung entrapment by tumor or adhesions limits re-expansion and generally predicts a poor result with pleurodesis; it is the primary indication for placement of indwelling pleural catheters. Patient preference is also considered, as is their life expectancy. Tunneled indwelling pleural catheters have dramatically changed the management of end-stage cancer treatment because they substantially shorten the amount of time patients spend in the hospital during their final weeks of life.[200] If the lung is expected to fully expand and the patient has a longer life expectancy (e.g., malignant effusions in the setting of breast cancer), drainage with sclerosis is the preferred option. The choice of sclerosant includes mechanical, talc, bleomycin, or doxycycline. Success rates range from 60% to 90% and are highest with talc. Typically, talc is administered as an aerosolized powder during video-assisted thoracoscopy, whereas doxycycline is infused at the bedside through a previously placed pigtail catheter or larger bore chest tube. Figure. 19-51 presents a decision algorithm for the management of malignant pleural effusion.

12▶

Empyema

Thoracic empyema is defined by a purulent pleural effusion. Patients of all ages can develop empyema, but the frequency is increased in older or debilitated patients. Common associated conditions include a pneumonic process in patients with pulmonary disorders and neoplasms, cardiac problems, diabetes mellitus, drug and alcohol abuse, neurologic impairments, postthoracotomy problems, and immunologic impairments. The mortality of empyema frequently depends on the degree of associated comorbid diseases, ranging from as low as 1% to over 40% in immunocompromised patients.

Pathophysiology. The most common causes of empyema are parapneumonic, but postsurgical or posttraumatic empyema

is also common (Table 19-37). The spectrum of organisms involved in pneumonic processes that progress to empyema is changing. Pneumococci and staphylococci continue to be the most frequent causative organisms, but gram-negative aerobic bacteria and anaerobes are becoming more prevalent. Cases involving mycobacteria or fungi are rare. Multiple organisms may be found in up to 50% of patients. Cultures may be sterile, however, if antibiotics were initiated before the culture or if the culture process was not efficient. The choice of antibiotics, therefore, is guided by the clinical scenario and not just the organisms found on culture. Broad-spectrum coverage may be required even when cultures do not grow out an organism or if a single organism is grown when the clinical picture is more consistent with a multiorganism process. Common gram-negative organisms include *Escherichia coli, Klebsiella, Pseudomonas,* and Enterobacteriaceae. Anaerobic organisms may be fastidious and difficult to document by culture and are associated with periodontal diseases, aspiration syndromes, alcoholism, general

anesthesia, drug abuse, or other functional associations with gastroesophageal reflux.

Organisms gain entry into the pleural cavity through contiguous spread from pneumonia, lung abscess, liver abscess, or another, adjacent infectious processes. Organisms may also enter the pleural cavity by direct contamination from thoracentesis, thoracic surgical procedures, esophageal injuries, or trauma. As organisms enter the pleural space, an influx of polymorphonuclear cells and fluid occurs, with subsequent release of inflammatory mediators and toxic oxygen radicals. These mechanisms lead to variable degrees of endothelial injury and capillary instability. This process overwhelms the normal pleural lymphatic drainage. This early effusion is watery and free-flowing in the pleural cavity. Thoracentesis at this stage yields fluid with a pH typically above 7.3, a glucose level greater than 60 mg/dL, and a low LDH level (<500 U/L). At this stage, the decision to use antibiotics alone or perform a repeat thoracentesis, chest tube drainage, thoracoscopy, or open thoracotomy depends on the amount of pleural fluid, its consistency, the clinical status of the patient, the degree of expansion of the lung after drainage, and the presence of loculated fluid in the pleural space (vs. free-flowing purulent fluid). Early in the parapneumonic process, when the purulent fluid is relatively

thin, complete drainage with simple large-bore thoracentesis is possible. If complete lung expansion is obtained and the pneumonic process is responding to antibiotics, no further drainage may be necessary. Pleural fluid with a pH lower than 7.2 and with a glucose level of less than 40 mg/dL means that a more aggressive approach to drainage should be pursued.

The pleural fluid may become thick and loculated over the course of hours to days and may be associated with fibrinous adhesions (the fibrinopurulent stage). At this stage, chest tube insertion with closed-system drainage or drainage with thoracoscopy may be necessary to remove the fluid and adhesions and facilitate complete lung expansion.[201] Further progression of the inflammatory process leads to the formation of a pleural peel, which may be flimsy and easy to remove early on. However, as the process progresses, a thick pleural rind may develop, leaving a trapped lung; complete lung decortication by either thoracoscopy or thoracotomy would then be necessary.

The use of intrapleural fibrinolytic therapy for management of empyema has been investigated in several large prospective trials. Intrapleural infusion of tissue plasminogen activator (t-PA) alone did not improve outcomes, whereas combined intrapleural t-PA and DNase was associated with a reduction in hospital stay of nearly 7 days, 77% fewer referrals for surgical intervention at 3 months, and more than double the reduction in the infected pleural fluid collection by CXR imaging.[202] In this trial, the medications were given twice daily by intrapleural injection; the dose was 5 mg for the DNase and 10 mg for t-PA. The chest drain was clamped for 1 hour after injection and released. This study suggests that the combination of fibrinolysis (t-PA) and cleavage of uncoiled DNA by DNase reduces fluid viscosity and facilitates pleural clearance.

Management. If there is a residual space, persistent pleural infection is likely to occur. A persistent pleural space may be secondary to contracted, but intact, underlying lung; or it may be secondary to surgical lung resection. If the space is small and well-drained by a chest tube, a conservative approach may be possible. This requires leaving the chest tubes in place and attached to closed-system drainage until symphysis of the visceral and parietal surfaces takes place. At this point, the chest tubes can be removed from suction; if the residual pleural space remains stable, the tubes can be cut and advanced out of the chest over the course of several weeks. If the patient is stable, tube removal can frequently be done in the outpatient setting, guided by the degree of drainage and the size of the residual space visualized on serial CT scans. Larger spaces may require open thoracotomy and decortication in an attempt to re-expand the lung to fill this residual space. If re-expansion has failed or appears too high risk, then open drainage, rib resection, and prolonged packing may be required, with delayed closure with muscle flaps or thoracoplasty.[203] Most chronic pleural space problems can be avoided by early specialized thoracic surgical consultation and complete drainage of empyema, allowing space obliteration by the reinflated lung.

Chylothorax

Chylothorax develops most commonly after surgical trauma to the thoracic duct or a major branch, but may be also associated with a number of other conditions (Table 19-38).[204] It is generally unilateral; for example, it may occur after dissection of the distal esophagus where the duct lies in close proximity to the esophagus as it enters the right chest from its origin in the abdomen at the cisterna chyli (Fig. 19-52). If the mediastinal pleura are disrupted on both sides, bilateral chylothoraces may occur. Left-sided chylothoraces may develop after a left-sided neck dissection, especially in the region of the confluence of the subclavian and internal jugular veins. Chylothorax may also follow nonsurgical trauma, including penetrating or blunt injuries to the chest or neck area, central line placements, and other surgical misadventures. It may be seen in association with a variety of benign and malignant diseases that generally involve the lymphatic system of the mediastinum or neck. Given the significant variability of the course of the thoracic duct within the chest, some injuries are inevitable.

Pathophysiology. Most commonly, the thoracic duct originates in the abdomen from the cisterna chyli, which is located in the midline, near the level of the second lumbar vertebra. From this origin, the thoracic duct ascends into the chest through the aortic hiatus at the level of T10 to T12, and courses just to the right of the aorta (see Fig. 19-52). As the thoracic duct courses cephalad above the diaphragm, it most commonly remains in the right chest, lying just behind the esophagus, between the aorta and azygos vein. The duct continues superiorly, lying just to the right of the vertebral column. Then, at the fifth or sixth thoracic vertebra, it crosses behind the aorta and the aortic arch into the left posterior mediastinum and travels superiorly, staying near the esophagus and mediastinal pleura as it exits the thoracic inlet. As it exits the thoracic inlet, it passes to the left, just behind the carotid sheath and anterior to the inferior thyroid and vertebral bodies. Just medial to the anterior scalene muscle, it courses inferiorly and drains into the union of the internal jugular and subclavian veins. Given the extreme variability in the main duct and its branches, accumulation of chyle in the chest or flow from penetrating wounds may be seen after a variety of traumatic and medical conditions.[205]

The main function of the duct is to transport fat absorbed from the digestive system along with variable amounts of protein and lymphatic material (Table 19-39). Given the high volume of chyle that flows through the thoracic duct, significant injuries can cause leaks in excess of 2 L per day; if left untreated, protein, lymphocyte, and volume depletion can lead to serious metabolic effects and death. Thoracentesis is usually grossly suggestive, revealing milky, nonpurulent pleural fluid. However, if the patient is taking nothing by mouth, the pleural

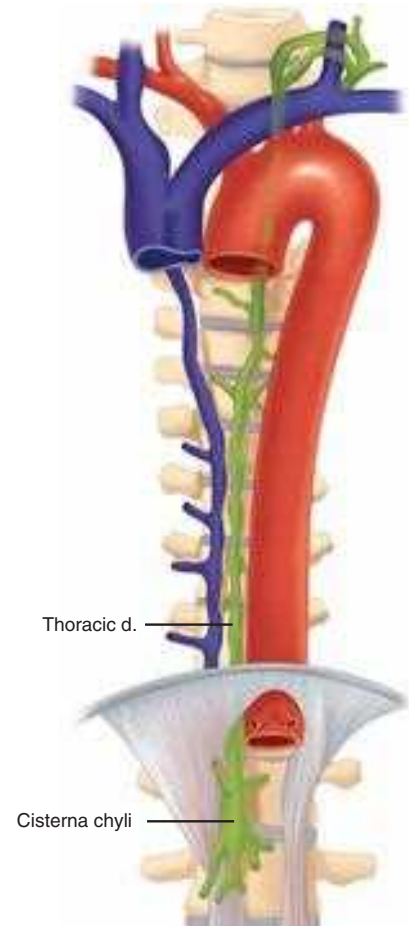

Figure 19-52. Normal thoracic duct anatomy. The esophagus comes into close proximity with the thoracic duct as it enters the chest from its origin in the abdomen at the cisterna chyli.

fluid may not be grossly abnormal. Laboratory analysis of the pleural fluid shows a high lymphocyte count and high triglyceride levels. If the triglyceride level is greater than 110 mg/100 mL, a chylothorax is almost certainly present (a 99% accuracy rate). If the triglyceride level is less than 50 mg/mL, there is only a 5% chance of chylothorax. In many clinical situations, the accumulation of chyle may be slow, because of minimal digestive fat flowing through the gastrointestinal tract after major trauma or surgery, so the diagnosis may be more difficult to establish.

Management. The treatment plan for any chylothorax depends on its cause, the amount of drainage, and the patient's clinical status (Fig. 19-53). In general, most patients are treated with a short period of chest tube drainage, nothing by mouth (NPO) orders, total parenteral nutrition (TPN), and observation.

Table 19-39

Composition of chyle

COMPONENT	AMOUNT (PER 100 ML)
Total fat	0.4–5 g
Total cholesterol	65–220 mg
Total protein	2.21–5.9 g
Albumin	1.1–4.1 g
Globulin	1.1–3.1 g
Fibrinogen	16–24 g
Sugars	48–200 g
Electrolytes	Similar to levels in plasma
Cellular elements	
Lymphocytes	400–6800/mm^3
Erythrocytes	50–600/mm^3
Antithrombin globulin	>25% of plasma concentration
Prothrombin	>25% of plasma concentration
Fibrinogen	>25% of plasma concentration

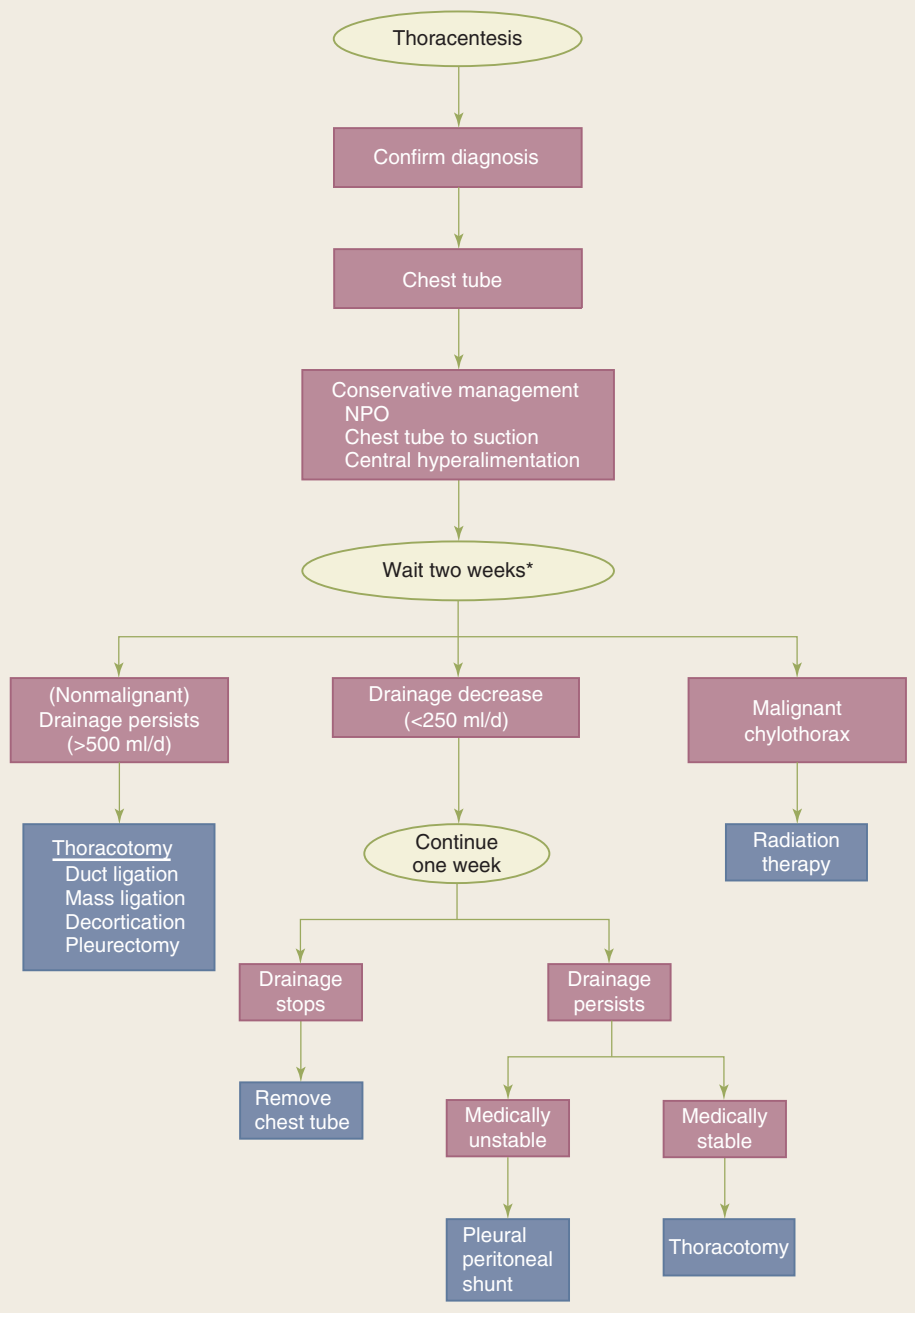

Figure 19-53. Algorithm for the management of chylothorax. *If high output persists (>500 mL/d), early surgical ligation of the thoracic duct may be considered. NPO = nothing by mouth.

Chest cavity drainage must be adequate to allow complete lung re-expansion. Somatostatin has been advocated by some authors, with variable results. If significant chyle drainage (>500 mL per day in an adult, >100 mL in an infant) continues despite TPN and good lung expansion, early surgical duct ligation or embolization is recommended. Ligation can be approached best by right thoracotomy, and in some experienced centers, by right VATS. Chylothoraces due to malignant conditions often respond to radiation and/or chemotherapy and less commonly require surgical ligation. Significant nutritional and immunologic depletion results from untreated chylothorax; associated mortality is in excess of 50%. With early recognition and aggressive medical management as well as early surgical ligation or embolization for persistent leaks, the mortality rate of chylothorax is now less than 10%.

Tumors of the Pleura

Malignant mesothelioma is the most common type of tumor of the pleura, with approximately 3000 cases per year in the United States. Other, less common tumors include benign and malignant fibrous tumors of the pleura, lipomas, and cysts.

Malignant Mesothelioma. The only known risk factor for mesothelioma is exposure to asbestos, identified in over 50% of cases. Exposure is typically work-related in industries using asbestos in the manufacturing process, such as shipbuilding. The risk extends to family members who are exposed to the dust of the clothing or to the work environment. Asbestos exposure and smoking synergistically increase the risk for lung cancer, but smoking does not increase risk for malignant mesotheliomas. Male predominance is 2:1, and it occurs most commonly after the age of 40.

Risk of developing mesothelioma after asbestos exposure differs depending on the physical characteristics of the asbestos and similar fibers (either serpentine or amphibole). The serpentine fibers are large and curly and are generally not able to travel beyond larger airways. However, the narrow, straight

amphibole fibers, in particular the crocidolite fibers, may navigate distally into the pulmonary parenchyma and are most clearly associated with mesotheliomas. The latency period between asbestos exposure and the development of mesothelioma is at least 20 years. The tumor generally is multicentric, with multiple pleural-based nodules coalescing to form sheets of tumor. This process initially involves the parietal pleura, generally with early spread to the visceral surfaces and with a variable degree of invasion of surrounding structures. Autopsy studies have shown that most patients have distant metastases, but the natural history of the disease in untreated patients culminates in death due to local extension. Other risk factors include radiation exposure.

Clinical Presentation. Most patients present with dyspnea and chest pain. Over 90% have a pleural effusion, but thoracentesis is diagnostic in less than 10% of patients. Frequently, a thoracoscopy or open pleural biopsy with special stains is required to differentiate mesotheliomas from adenocarcinomas (Table 19-40). Epithelial subtypes are associated with a more favorable prognosis, and long-term survival may be seen in rare patients with no treatment. Sarcomatous and mixed tumors share a more aggressive course.

Management. The treatment of malignant mesotheliomas remains controversial. Prognosis depends on the stage of the disease (Table 19-41),[206] but most patients present with advanced local or distant disease beyond curative potential. Treatment options include supportive care only, surgical resection, and multimodality approaches (using a combination of surgery, chemotherapy, and radiation therapy).[207] Palliative approaches, such as pleurectomy or talc pleurodesis, may lead to local control and a modest improvement in short-term survival. Several reports of trials of extrapleural pneumonectomy and adjuvant chemotherapy and radiation have shown reasonable improvements in survival for patients with early-stage tumors (as compared with historical controls). In one series of 183 patients, a subset of 31 patients had favorable prognostic features (i.e., epithelial cell type), negative resection margins, and negative extrapleural node status. This favorable subset had a 5-year survival rate of 46%, as compared with 15% for the entire group.[208] In another series, 88 patients with mesotheliomas were studied prospectively. Adjuvant radiation therapy was given to 54 patients after extrapleural pneumonectomy; the median survival was 17 months. However, in patients with stage I and II disease, the median survival was significantly better at 33.0 months.[209]

Intrapleural therapy has been explored to improve the locoregional control of malignant mesotheliomas. In a phase II trial, 37 patients underwent pleurectomy with decortication, followed by intrapleural and systemic therapy with cisplatin and mitomycin C. Their median survival was 17 months, with a locoregional recurrence rate of 80%.[210] According to another study, the addition of hyperthermic intrapleural perfusion seems to be pharmacokinetically advantageous; of seven patients, three underwent pleurectomy with decortication and received hyperthermic cisplatin. Systemic drug concentrations were greater after pleurectomy with decortication than after pleuropneumonectomy. The local tissue:perfusate ratio of platinum concentrations tended to be higher after hyperthermic perfusion rather than normothermic perfusion.[211]

Another promising alternative to enhance the local efficacy of chemotherapy against malignant mesotheliomas is L-NDDP (cis-bis-neodecanoato-trans-R,R-1,2-diaminocyclohexane platinum). A phase II trial of L-NDDP enrolled 33 patients to receive a thoracoscopic biopsy and a thoracoscopic posttreatment pleural biopsy after each cycle. Of those 33 patients, 14 (42%) had a complete pathologic response, with three treatment-related deaths due to infection. Buried residual tumor was found at pleural decortications in another two patients who had pathologic response.[212] These findings are encouraging, but the optimal regimen for intrapleural treatment for mesothelioma remains to be fully defined.

The authors' current approach to malignant mesothelioma is based on tumor stage and patient performance status. Extrapleural pneumonectomy is recommended, especially for epithelial mesotheliomas, early-stage mesotheliomas, and good pulmonary function. For more advanced disease, decortication with intrapleural chemotherapy is administered, using an institutional protocol, for patients who are fit for surgery. Whenever possible, patients are referred for clinical trials of multimodality therapy. For more advanced disease, or if patients have less-than-optimal pulmonary function or performance status, talc pleurodesis or supportive therapy is recommended.

Table 19-40

Differentiation of mesothelioma from adenocarcinoma

	MESOTHELIOMA	ADENOCARCINOMA
Immunohistochemical results		
Carcinoembryonic antigen	Negative	Positive
Vimentin	Positive	Negative
Low molecular weight cytokeratins	Positive	Negative
Electron microscopic features	Long, sinuous villi	Short, straight villi with fuzzy glycocalyx

Fibrous Tumors of the Pleura. Fibrous tumors of the pleura are unrelated to asbestos exposure or malignant mesotheliomas. They generally occur as a single pedunculated mass arising from the visceral pleura but can occasionally arise from the parietal pleura. They can grow to be quite large, with most ranging from 5 to 10 cm and 100 to 400 g in size by the time they are discovered. Architecturally, the most common microscopic feature is the "patternless pattern." This is characterized by randomly situated areas of hypercellularity, containing spindle cells with bland, vesicular, ovoidal nuclei and scarce cytoplasm, and hypocellularity, with fibrous connective tissue, hemorrhage, myxoid, or necrosis. They can also have an hemangiopericytoma-like appearance. The neoplastic cells are immunoreactive for CD34 and CD99 but negative for cytokeratins and desmin. Immunoreactivity for Bcl-2 is variably positive.[213]

They are frequently discovered incidentally on routine CXRs, without an associated pleural effusion. They occur with equal frequency in males and females and are most common in the sixth to seventh decade of life. Fibrous tumors of the pleura may be benign or malignant.[214] Symptoms such as cough, chest pain, and dyspnea occur in 30% to 40% of patients but are found in 75% of patients with malignant tumors. Malignant tumors

Table 19-41

International Mesothelioma Interest Group staging system for diffuse malignant pleural mesothelioma

T Tumor			
T1	T1a	Tumor limited to the ipsilateral parietal ± mediastinal ± diaphragmatic pleura No involvement of the visceral pleura	
	T1b	Tumor involving the ipsilateral parietal ± mediastinal ± diaphragmatic pleura Tumor also involving the visceral pleura	
T2	Tumor involving each of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleurae) with at least one of the following features: Involvement of diaphragmatic muscle Extension of tumor from visceral pleura into the underlying pulmonary parenchyma		
T3	Describes locally advanced but potentially resectable tumor Tumor involving all of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleurae) with at least one of the following features: Involvement of the endothoracic fascia Extension into the mediastinal fat Solitary, completely resectable focus of tumor extending into the soft tissues of the chest wall Nontransmural involvement of the pericardium		
T4	Describes locally advanced technically unresectable tumor Tumor involving all of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleurae) with at least one of the following features: Diffuse extension or multifocal masses of tumor in the chest wall, with or without associated rib destruction Direct transdiaphragmatic extension of tumor to the peritoneum Direct extension of tumor to the contralateral pleura Direct extension of tumor to mediastinal organs Direct extension of tumor into the spine Tumor extending through to the internal surface of the pericardium with or without a pericardial effusion; or tumor involving the myocardium		
N Lymph Nodes			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastases in the ipsilateral bronchopulmonary or hilar lymph nodes		
N2	Metastases in the subcarinal or the ipsilateral mediastinal lymph nodes including the ipsilateral internal mammary nodes		
N3	Metastases in the contralateral mediastinal, contralateral internal mammary, or ipsilateral or contralateral supraclavicular lymph nodes		
M Metastases			
MX	Presence of distant metastases cannot be assessed		
M0	No distant metastases		
M1	Distant metastases present		
Staging			
Stage I			
IA	T1a	N0	M0
IB	T1b	N0	M0
Stage II	T2	N0	M0
Stage III	Any T3	Any N1 Any N2	M0
Stage IV	Any T4	Any N3	Any M1

are differentiated from benign tumors based on high cellularity, more than 4 mitotic figures per 10 high-power fields, nuclear pleomorphism, tumor necrosis, and hemorrhage. They are more likely to arise from the parietal pleura of the chest wall, diaphragm, or mediastinum, or in the fissures or invaginating into the lung parenchyma. Hypoglycemia, associated pleural effusion, and hypertrophic pulmonary osteoarthropathy (clubbed digits, long bone ossifying periostitis, and arthritis) are associated with these lesions in approximately 25% of patients. Less common are fever and hemoptysis.

Symptoms resolve with surgical resection. Given the well-circumscribed and often pedunculated nature of fibrous tumors of the pleura, all benign lesions and approximately 50% of malignant lesions are cured by complete surgical resection.[214] Incompletely resected malignant tumors may recur locally or metastasize, and more than 50% of patients with malignant tumors will die from the disease; frequently, they are fatal within 2 to 5 years.

ACKNOWLEDGEMENT

The authors wish to thank Shannon Wyszomierski for her invaluable help in compiling and editing this chapter. The authors also express appreciation to their spouses, Chris, Lee, and Chris.

chapter 20

Congenital Heart Disease

Tara Karamlou, Yasuhiro Kotani, and Glen A. Van Arsdell

INTRODUCTION

Congenital heart surgery is a dynamic and evolving field. The last 20 years have brought about rapid developments in technology, emphasis on a multidisciplinary approach to treatment, and a more thorough understanding of both the anatomy and pathophysiology of congenital heart disease, leading to the improved care of these challenging patients.

These advancements have created and sustained a paradigm shift in the field of congenital heart surgery. The traditional strategy of initial palliation followed by definitive correction at a later age, which had pervaded the thinking of most surgeons, began to evolve to one emphasizing early repair, even in the tiniest patients. Furthermore, some of the defects that were virtually uniformly fatal (such as hypoplastic left heart syndrome) are now successfully treated with aggressive forms of palliation using cardiopulmonary bypass, resulting in outstanding survival for many of these children.

Because the goal in most cases of congenital heart disease (CHD) is now early repair, as opposed to subdividing lesions into cyanotic or noncyanotic lesions, a more appropriate classification scheme divides particular defects into three categories based on the feasibility of achieving this goal: (a) defects that have no reasonable palliation and for which repair is the only option; (b) defects for which repair is not possible and for which palliation is the only option; and (c) defects that can either be repaired or palliated in infancy. It bears mentioning that all defects in the second category are those in which the appropriate anatomic components either are not present, as in hypoplastic left heart syndrome, or cannot be created from existing structures.

1▶

DEFECTS WHERE REPAIR IS THE ONLY OR BEST OPTION

Atrial Septal Defect

An atrial septal defect (ASD) is defined as an opening in the interatrial septum that enables the mixing of blood from the systemic venous and pulmonary venous circulations.

Embryology. The atrial and ventricular septa form between the third and sixth weeks of fetal development. After the paired heart tubes fuse into a single tube folded onto itself, the distal portion of the tube causes an indentation to form in the roof of the common atrium. Near this portion of the roof, the septum primum arises and extends into a crescentic formation toward the atrioventricular (AV) junction. The gap remaining between the septum primum and the developing tissues of the AV junction is called the ostium primum. Before the septum primum fuses completely with the endocardial cushions, a series of fenestrations appear in the septum primum that coalesce into the ostium secundum. During this coalescence, the septum secundum grows downward from the roof of the atrium, parallel to and to the right of the septum primum. The septum primum does not fuse, but creates an oblique pathway, called the foramen ovale, within the interatrial septum. After birth, the increase in left atrial pressure normally closes this pathway, obliterating the interatrial connection.

Anatomy. ASDs can be classified into three different types: (a) sinus venosus defects, comprising approximately 5% to 10% of all ASDs; (b) ostium primum defects, which are more correctly described as partial AV canal defects; and (c)

Key Points

1. Congenital heart disease comprises a wide morphologic spectrum. In general, lesions can be conceptualized as those that can be completely repaired, those that should be palliated, and those that can be either repaired or palliated depending on particular patient and institutional characteristics.
2. Percutaneous therapies for congenital heart disease are quickly becoming important adjuncts, and in some cases, alternatives, to standard surgical therapy. Important examples include percutaneous closure of atrial and ventricular septal defects, the hybrid approach to hypoplastic left heart syndrome, radiofrequency perforation of the pulmonary valve, and percutaneous pulmonary valve placement. Further studies are necessary to establish criteria and current benchmarks for the safe integration of these novel approaches into the care of patients with congenital heart surgery.
3. Patients with critical left ventricular outflow tract obstruction, such as neonatal critical aortic stenosis, represent a challenging population. It is critical that the correct decision (whether to pursue a univentricular or biventricular) be made at the initial operation, as attrition when the incorrect decision is made is high. There are several published criteria (Congenital Heart Surgeons' Society critical stenosis calculator) to help surgeons decide which strategy to pursue.
4. Optimum strategy for repair of total anomalous pulmonary venous connection (TAPVC) remains a topic of some contention. Sutureless repair, formerly reserved for initial restenosis after conventional repair, has evolved in many centers to be the primary treatment of choice for high-risk patients. Defining whether sutureless repair should be considered in all patients with TAPVC will require further study.
5. A recent prospective, randomized, multi-institutional trial sponsored by the National Institutes of Health, the Systemic Ventricle Reconstruction (SVR) trial, compared the outcomes of neonates with hypoplastic left heart syndrome having either a modified Blalock-Taussig shunt versus a right ventricle-to-pulmonary artery (RV-PA) shunt. The SVR trial demonstrated that transplantation-free survival 12 months after randomization was higher with the RV-PA shunt than with the modified Blalock-Taussig shunt. However, data collected over a mean follow-up period of 32 ± 11 months showed a nonsignificant difference in transplantation-free survival between the two groups.
6. Outcomes have improved substantially over time in congenital heart surgery, and most complex lesions can be operated in early infancy. Neurologic protection, however, remains a key issue in the care of neonates undergoing surgery with cardiopulmonary bypass and deep hypothermic circulatory arrest. New monitoring devices and perioperative strategies are currently under investigation. Attention in the field has shifted currently from analyses of perioperative mortality, which for most lesions is under 10%, to longer-term outcomes, including quality of life and neurologic function.

ostium secundum defects, which are the most prevalent subtype, comprising 80% of all ASDs (Fig. 20-1).[1]

Pathophysiology. ASDs result in an increase in pulmonary blood flow secondary to left-to-right shunting through the defect. The direction of the intracardiac shunt is predominantly determined by the compliance of the respective ventricles. In utero, the distensibility, or compliance, of the right and left ventricles is equal, but postnatally the left ventricle (LV) becomes less compliant than the right ventricle (RV). This shift occurs because the resistance of the downstream vascular beds changes after birth. The pulmonary vascular resistance falls with the infant's first breath, decreasing RV pressure, whereas the systemic vascular resistance rises dramatically, increasing LV pressure. The increased LV pressure creates a thicker muscle mass, which offers a greater resistance to diastolic filling than does the RV; thus, the majority of flow through the ASD occurs from left to right. The greater volume of blood returning to the right atrium causes volume overload in the RV, but because of its lower muscle mass and low-resistance output, it easily distends to accommodate this load.

The long-term consequences of RV volume overload include hypertrophy with elevated RV end-diastolic pressure and a relative pulmonary stenosis across the pulmonary valve, because it cannot accommodate the increased RV flow. The resistance at the level of the pulmonary valve then contributes a further pressure load on the RV, which accelerates RV hypertrophy. Compliance gradually decreases as the right ventricular pressure approaches systemic pressure, and the

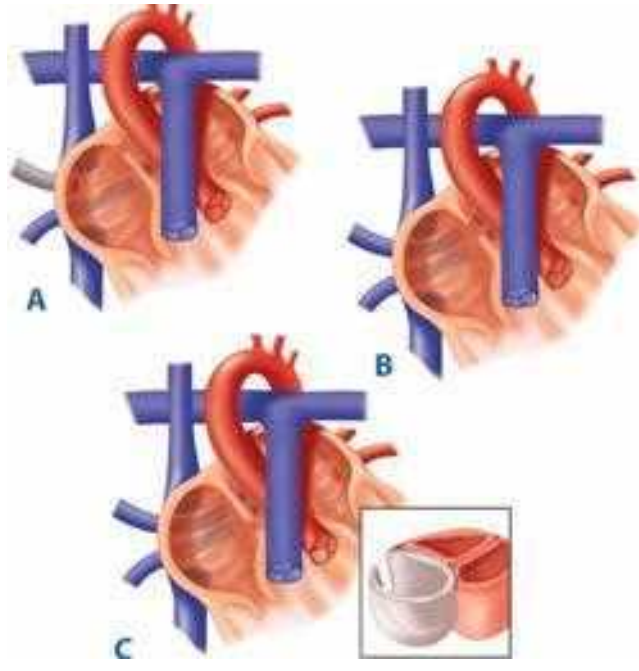

Figure 20-1. The anatomy of atrial septal defects. In the sinus venosus type (**A**), the right upper and middle pulmonary veins frequently drain to the superior vena cava or right atrium. **B.** Secundum defects generally occur as isolated lesions. **C.** Primum defects are part of a more complex lesion and are best considered as incomplete atrioventricular septal defects. *(Reproduced with permission from Greenfield LJ, Mulholland MW, Oldham KT, et al, eds.* Surgery: Scientific Principles and Practice. *3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2001:1444.)*

size of the left-to-right shunt decreases. Patients at this stage have a balanced circulation and may deceptively appear less symptomatic.

A minority of patients with ASDs develop progressive pulmonary vascular changes as a result of chronic overcirculation. The increased pulmonary vascular resistance in these patients leads to an equalization of left and right ventricular pressures, and their ratio of pulmonary (Qp) to systemic flow (Qs), Qp:Qs, will approach 1.[2] This does not mean, however, that there is no intracardiac shunting, only that the ratio between the left-to-right component and the right-to-left component is equal.

The ability of the RV to recover normal function is related to the duration of chronic overload, because those undergoing ASD closure before age 10 years have a better likelihood of achieving normal RV function in the postoperative period.[3]

The physiology of sinus venosus ASDs is similar to that discussed earlier, except that these are frequently accompanied by anomalous pulmonary venous drainage. This often results in significant hemodynamic derangements that accelerate the clinical course of these infants.

The same increase in symptoms is true for those with ostium primum defects because the associated mitral insufficiency from the "cleft" mitral valve can lead to more atrial volume load and increased atrial level shunting.

Diagnosis. Patients with ASDs may present with few physical findings. Auscultation may reveal prominence of the first heart sound with fixed splitting of the second heart sound. This results from the relatively fixed left-to-right shunt throughout all phases of the cardiac cycle. A diastolic flow murmur indicating increased flow across the tricuspid valve may be discerned, and frequently, an ejection flow murmur can be heard across the pulmonary valve. A right ventricular heave and increased intensity of the pulmonary component of the second heart sound indicates pulmonary hypertension and possible unrepairability.

Chest radiographs in the patient with an ASD may show evidence of increased pulmonary vascularity, with prominent hilar markings and cardiomegaly. The electrocardiogram shows right axis deviation with an incomplete bundle-branch block. When right bundle-branch block is associated with a leftward or superior axis, an AV canal defect should be strongly suspected.

Diagnosis is clarified by two-dimensional echocardiography, and use of color-flow mapping facilitates an understanding of the physiologic derangements created by the defects. Older children and adults with unrepaired ASDs may present with stroke or systemic embolism from paradoxical embolism or atrial arrhythmias from dilation of the right atrium.

Echocardiography also enables the clinician to estimate the amount of intracardiac shunting, can demonstrate the degree of mitral regurgitation in patients with ostium primum defects, and with the addition of microcavitation, can assist in the detection of sinus venosus defects.

The advent of two-dimensional echocardiography with color-flow Doppler has largely obviated the need for cardiac catheterization because the exact nature of the ASD can be precisely defined by echocardiography alone. However, in cases where the patient is older than age 40 years, catheterization can quantify the degree of pulmonary hypertension present, because those with a fixed pulmonary vascular resistance greater than 12 U/mL are considered inoperable.[4] Cardiac catheterization also can be useful in that it provides data that enable the calculation of Qp and Qs so that the magnitude of the intracardiac shunt can be determined. The ratio (Qp:Qs) can then be used to determine whether closure is indicated in equivocal cases, because a Qp:Qs greater than 1.5:1 is generally accepted as the threshold for surgical intervention. Finally, in patients older than age 40 years, cardiac catheterization can be important to disclose the presence of coronary artery disease.

In general, ASDs are closed when patients are between 4 and 5 years of age. Children of this size can usually be operated on without the use of blood transfusion and generally have excellent outcomes. Patients who are symptomatic may require repair earlier, even in infancy. Some surgeons, however, advocate routine repair in infants and children, as even smaller defects are associated with the risk of paradoxical embolism. In a recent review by Reddy and colleagues, 116 neonates weighing less than 2500 g who underwent repair of simple and complex cardiac defects with the use of cardiopulmonary bypass were found to have no intracerebral hemorrhages, no long-term neurologic sequelae, and a low operative mortality rate (10%). These results correlated with the length of cardiopulmonary bypass and the complexity of repair.[5] These investigators also found an 80% actuarial survival at 1 year and, more importantly, that growth following complete repair was equivalent to weight-matched neonates free from cardiac defects.[5]

Treatment. ASDs can be repaired in a facile manner using standard cardiopulmonary bypass (CPB) techniques through a midline sternotomy approach. The details of the repair itself are generally straightforward. An oblique atriotomy is made, the position of the coronary sinus and all systemic and pulmonary veins are determined, and the rim of the defect is completely visualized. Closure of ostium secundum defects is accomplished either by primary repair or by insertion of a patch that is sutured to the rim of the defect. The decision of whether patch closure is necessary can be determined by the size and shape of the defect as well as by the quality of the edges.

The type of repair used for sinus venosus ASDs associated with partial anomalous pulmonary venous connection is dictated by the location of the anomalous pulmonary veins. If the anomalous veins connect to the atria or to the superior vena cava caudal to where the cava is crossed by the right pulmonary artery, the ASD can be repaired by inserting a patch, with redirection of the pulmonary veins behind the patch to the left atrium. Care must be taken with this approach to avoid obstruction of the pulmonary veins or the superior vena cava, although usually the superior vena cava is dilated and provides ample room for patch insertion. If the anomalous vein connects to the superior vena cava cranial to the right pulmonary artery, an alternative technique, the Warden procedure, may be necessary. In this operation, the superior vena cava is transected cranial to the connection of the anomalous vein (usually the right superior pulmonary vein). The caudal end of the transected cava is oversewn. The cranial end of the transected cava is anastomosed to the auricle of the right atrium. Inside the atrium, a patch is used to redirect pulmonary venous blood flow to the left atrium. In contrast to the repair for a defect where the pulmonary veins enter the right atrium or the superior vena cava below the right pulmonary artery, the patch covers the superior vena caval right atrial junction so that blood from the anomalous pulmonary vein that enters the cava is directed to the left atrium. Blood returning from the upper body enters the right atrium via the anastomosis between the superior vena cava and the right atrial appendage.

Results and Complications of Surgical ASD Closure. Traditional operative strategies, such as pericardial or synthetic patch closure, have been well established, with a low complication rate and a mortality rate of zero among patients without pulmonary hypertension.[6] The most frequently reported immediate complications include postpericardiotomy syndrome and atrial arrhythmias. Beyond immediate postoperative outcomes, long-term outcomes following surgical closure (up to 20 years) document the low attrition rate and durability of functional status benefit. Importantly, however, atrial arrhythmias are not completely mitigated by closure and can occur in 10% to 40% of patients, especially in older patients (>40 years) or those with pre-existing arrhythmias.[7] Kutty and colleagues[8] followed 300 patients from their institution, 152 of whom had surgical closure. Late mortality at 10 years was 3%, and functional health status had declined in only 15 patients during follow-up. Recently, there have been an increasing number of reports regarding the results following surgical closure among elderly patients (>60 years of age), which demonstrate equivalent survival to younger patients, albeit with slightly higher complication rates.[8-10] Hanninen and colleagues[11] studied 68 patients between 68 and 86 years at their institution undergoing either surgical (n = 13) or device (n = 54) closure. Although the 23% incidence of major complications (including pneumothorax, heart failure, and pneumonia) was higher than that recently reported by Mascio et al[12] using the Society of Thoracic Surgeons' Congenital Database (20%) or a single-institution review by Hopkins et al[13] (12%), there were no operative deaths among the elderly cohort. Moreover, after ASD closure, echocardiographic indices of right ventricular size and function were significantly improved from preoperative values, and functional capacity as measured by standardized survey instruments was also significantly improved.

New and Future Approaches to Traditional Surgical ASD Closure. Because of the uniformly excellent outcomes with traditional surgery, attention has shifted to improving the cosmetic result and minimizing hospital stay and convalescence. Multiple strategies have been described to achieve these aims, including the right submammary incision with anterior thoracotomy, limited bilateral submammary incision with partial sternal split, and limited midline incision with partial sternal split. Some surgeons use either video-assisted thoracic surgery (VATS) in conjunction with the submammary and transxiphoid approaches to facilitate closure within a constricted operative field or totally endoscopic repair in selected patients.[14-16] Use of robotics has also been reported in a small series of 12 adult patients by Argenziano and colleagues.[15] The morbidity and mortality of all of these approaches are comparable to those of the traditional median sternotomy; however, each has technical drawbacks. Operative precision must be maintained with limited exposure in any minimally invasive technique. Extended CPB and aortic cross-clamp times, coupled with increased cost, may limit the utility of totally endoscopic or robotic-assisted ASD closure except at limited centers. Certain approaches have a specific patient population in whom they are applicable. For example, the anterolateral thoracotomy should not be employed in prepubescent girls because it will interfere with breast development. Most totally endoscopic approaches are not feasible in very young patients due to the size of the thoracoscopic ports. Despite these potential drawbacks, however, in carefully selected patients, minimally invasive techniques have demonstrated benefits. Luo and associates performed a prospective randomized study comparing ministernotomy (division of the upper sternum for aortic and pulmonary lesions and the lower sternum for septal lesions) to full sternotomy in 100 consecutive patients undergoing repair of septal lesions.[16] The patients in the ministernotomy group had longer procedure times (by 15 to 20 minutes), but had less bleeding and shorter hospital stays. Consistent with these initiatives, conversion of "low-risk" patients undergoing minimally invasive ASD closure to an ambulatory population (discharge from hospital within 24 hours) has recently been described.[17]

First performed in 1976, transcatheter closure of ASDs with the use of various occlusion devices is gaining widespread acceptance.[18] Certain types of ASDs, including patent foramen ovale, secundum defects, and some fenestrated secundum defects, are amenable to device closure, as long as particular anatomic criteria (e.g., an adequate superior and inferior rim for device seating and distance from the AV valve) are met. Since the introduction of percutaneous closure, there has been a dramatic rise in device closure prevalence to the point where device closure has supplanted surgical therapy as the dominant treatment modality for secundum ASD.[19] A study from Karamlou et al[19] recently found that ASD and patent foramen ovale closures per capita increased dramatically from 1.08 per 100,000 population in 1988 to 2.59 per 100,000 population in 2005, an increase of 139%. When analyzed by closure type, surgical closure increased by only 24% (from 0.86 per 100,000 population in 1988 to 1.07 per 100,000 in 2005), whereas transcatheter closure increased by 3475% (from 0.04 per 100,000 population in 1988 to 1.43 per 100,000 in 2005). Importantly, this study determined that the paradigm shift favoring transcatheter closure has occurred mainly due to increased prevalence of closure in adults over age 40 years rather than an increase in closure in infants or children.

Despite the simplicity of ASD repair, there are a myriad of options for patients and physicians who care for patients with CHD. The patient population that might benefit from closure (whether device or surgical) is likely to increase, challenging current ideas and treatment algorithms that optimize outcomes.

Aortic Stenosis

Anatomy and Classification. The spectrum of aortic valve abnormality represents the most common form of CHD, with the great majority of patients being asymptomatic until midlife. Obstruction of the left ventricular outflow tract (LVOT) occurs at multiple levels: subvalvular, valvular, and supravalvular (Fig. 20-2). The critically stenotic aortic valve in the neonate or infant is commonly unicommissural or bicommissural, with thickened, dysmorphic, and myxomatous leaflet tissue and a reduced cross-sectional area at the valve level. Associated left-sided lesions are often present. In a review of 32 cases from the Children's Hospital in Boston, 59% had unicommissural valves and 40% had bicommissural valves.[20] Associated lesions were frequent, occurring in 88% of patients, most commonly patent ductus arteriosus, mitral regurgitation, and hypoplastic LV. Endocardial fibroelastosis also is common among infants with critical aortic stenosis (AS). In this condition, the LV is largely nonfunctional, and these patients are not candidates for balloon valvotomy, simple valve replacement, or repair, because the LV

is incapable of supporting the systemic circulation. Often, the LV is markedly hypertrophic with a reduced cavity size, but on rare occasion, a dilated LV, reminiscent of overt heart failure, is encountered.[20]

Pathophysiology. The unique intracardiac and extracardiac shunts present in fetal life allow even neonates with critical AS to survive. In utero, left ventricular hypertrophy and ischemia cause left atrial hypertension, which reduces the right-to-left flow across the foramen ovale. In severe cases, a reversal of flow may occur, causing right ventricular volume loading. The RV then provides the entire systemic output via the patent ductus arteriosus (ductal-dependent systemic blood flow). Although cardiac output is maintained, the LV suffers continued damage as the intracavitary pressure precludes adequate coronary perfusion, resulting in LV infarction and subendocardial fibroelastosis. The presentation of the neonate with critical AS is then determined by the morphology of the LV and other left-sided heart structures, the degree of left ventricular dysfunction, and the completeness of the transition from a parallel circulation to an in-series circulation (i.e., on closure of the foramen ovale and the ductus arteriosus). Those infants with mild-to-moderate AS in whom LV function is preserved are asymptomatic at birth. The only abnormalities may be a systolic ejection murmur and electrocardiogram (ECG) evidence of left ventricular hypertrophy. However, those neonates with severe AS and compromised LV function are unable to provide adequate cardiac output at birth and will present in circulatory collapse once the ductus closes, with dyspnea, tachypnea, irritability, narrowed pulse pressure, oliguria, and profound metabolic acidosis.[7,21] If ductal patency is maintained, systemic perfusion will be provided by the RV via ductal flow, and cyanosis may be the only finding.

Diagnosis. Neonates and infants with severe valvular AS may have a relatively nonspecific history of irritability and failure to thrive. Angina, if present, is usually manifested by episodic, inconsolable crying that coincides with feeding. As discussed previously, evidence of poor peripheral perfusion, such as extreme pallor, indicates severe LVOT obstruction. Differential cyanosis is an uncommon finding, but is present when enough antegrade flow occurs only to maintain normal upper body perfusion, while a large patent ductus arteriosus produces blue discoloration of the abdomen and legs.

Physical findings include a systolic ejection murmur, although a quiet murmur may paradoxically indicate a more severe condition with reduced cardiac output. A systolic click correlates with a valvular etiology of obstruction. As LV dysfunction progresses, evidence of congestive heart failure occurs.

The chest radiograph is variable but may show dilatation of the aortic root, and the ECG often demonstrates LV hypertrophy. Echocardiography with Doppler flow is extremely useful in establishing the diagnosis, as well as quantifying the transvalvular gradient.[22] Furthermore, echocardiography can facilitate evaluation for the several associated defects that can be present in critical neonatal AS, including mitral stenosis, LV hypoplasia, LV endocardial fibroelastosis, subaortic stenosis, VSD, or coarctation. The presence of any or several of these defects has important implications related to treatment options for these patients. Although cardiac catheterization is not routinely performed for diagnostic purposes, it can be invaluable as part of the treatment algorithm if the lesion is amenable to balloon valvotomy.

Treatment. The first decision that must be made in the neonate with critical LVOT obstruction is whether the patient is a candidate for biventricular or univentricular repair. Central to this decision is assessment of the degree of hypoplasia of the LV and other left-sided structures. Alsoufi and colleagues[23] recently described a rational approach to the neonate with critical LVOT obstruction (Fig. 20-3). The infant with severe AS requires urgent intervention. Preoperative stabilization, however, has dramatically altered the clinical algorithm and outcomes for this patient population.[19,21] The preoperative strategy begins with endotracheal intubation and inotropic support. Prostaglandin infusion is initiated to maintain ductal patency, and confirmatory studies are performed prior to operative intervention.

3▶

Therapy is generally indicated in the presence of a transvalvular gradient of 50 mmHg with associated symptoms including syncope, CHF, or angina, or if a gradient of 50 to 75 mmHg exists with concomitant ECG evidence of LV strain or ischemia. In the critically ill neonate, there may be little gradient across the aortic valve because of poor LV function. These patients depend on patency of the ductus arteriosus to provide systemic perfusion from the RV, and all ductal-dependent patients with critical AS require treatment. However, the decision regarding treatment options must be based on a complete understanding of associated defects. For example, in the presence of a hypoplastic LV (left ventricular end-diastolic

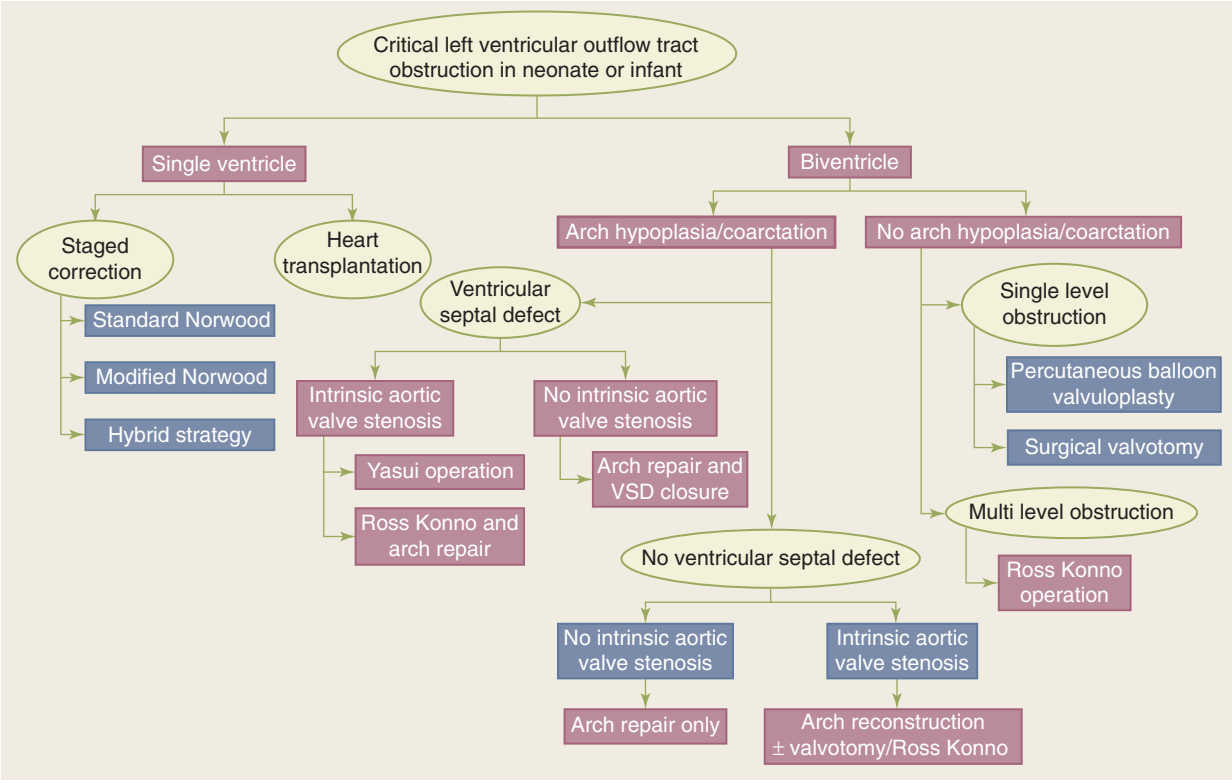

Figure 20-3. Treatment algorithm for neonates and infants with critical left ventricular outflow tract obstruction. Patients can be initially triaged to either a single or a biventricular approach depending on presenting morphologic, demographic, and institutional factors. VSD = ventricular septal defect. *(From Alsoufi B, et al. Management options in neonates and infants with critical left ventricular outflow tract obstruction.* Eur J Cardiothorac Surg. *2007;31:1013. Fig 1. By permission of Oxford University Press.)*

volume <20 mL/m^2) or a markedly abnormal mitral valve, isolated aortic valvotomy should not be performed because studies have demonstrated high mortality in this population following isolated valvotomy.[24]

Patients who have an LV capable of providing systemic output are candidates for intervention to relieve AS, generally through balloon valvotomy. Very rarely, if catheter-based therapy is not an option, relief of valvular AS in infants and children can be accomplished with surgical valvotomy using standard techniques of CPB and direct exposure to the aortic valve. A transverse incision is made in the ascending aorta above the sinus of Valsalva, extending close to, but not into, the noncoronary sinus. Exposure is attained with placement of a retractor into the right coronary sinus. After inspection of the valve, the chosen commissure is incised to within 1 to 2 mm of the aortic wall (Fig. 20-4).

Balloon valvotomy performed in the catheterization lab is the procedure of choice for reduction of transvalvular gradients in symptomatic infants and children. This procedure is an ideal palliative option because mortality from surgical valvotomy can be high due to the critical nature of these patients' condition. Furthermore, balloon valvotomy provides relief of the valvular gradient and allows future surgical intervention (which is generally required in most patients when a larger prosthesis can be implanted) to be performed on an unscarred chest. An important issue when planning aortic valvotomy, whether percutaneously or via open surgical technique, is the risk of inducing hemodynamically significant aortic regurgitation. Induction of more than moderate aortic regurgitation is poorly tolerated in

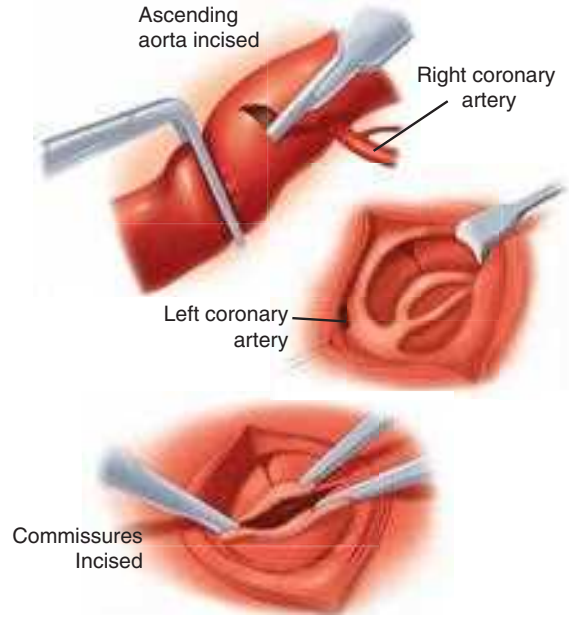

Figure 20-4. Aortic valvotomy with cardiopulmonary bypass. A transverse incision is made in the ascending aorta above the sinuses of Valsalva, extending close to, but not into, the noncoronary sinus. the infant with critical AS and may require an urgent procedure to replace or repair the aortic valve.

In general, catheter-based balloon valvotomy has supplanted open surgical valvotomy. The decision regarding the most appropriate method to use depends on several factors, including the available medical expertise, the patient's overall status and hemodynamics, and the presence of associated cardiac defects requiring repair.[25] Although evidence is emerging to the contrary, simple valvotomy, whether performed using percutaneous or open technique, is generally considered a palliative procedure. The goal is to relieve LVOT obstruction without producing clinically significant regurgitation, in order to allow sufficient annular growth for eventual aortic valve replacement. The majority of infants who undergo aortic valvotomy will require further intervention on the aortic valve within 10 years following initial intervention.[26]

Valvotomy may result in aortic insufficiency that, while not important enough to require intervention in infancy, may alone or in combination with AS result in the need for an aortic valve replacement. Neonates with severely hypoplastic LVs or significant LV endocardial fibroelastosis may not be candidates for two-ventricle repair and are treated the same as infants with the hypoplastic left heart syndrome (HLHS), which is discussed later (see later section, Hypoplastic Left Heart Syndrome).

Many surgeons previously avoided aortic valve replacement for AS in early childhood because the more commonly used mechanical valves would be outgrown and require replacement later and the obligatory anticoagulation for mechanical valves resulted in a substantial risk for complications. In addition, mechanical valves had an important incidence of bacterial endocarditis or perivalvular leak requiring re-intervention.

The use of allografts and the advent of the Ross procedure have largely obviated these issues and made early definitive correction of critical AS a viable option.[19,27,28] Donald Ross first described transposition of the pulmonary valve into the aortic position with allograft reconstruction of the pulmonary outflow tract in 1967.[27] The result of this operation is a normal trileaflet semilunar valve made of a patient's native tissue with the potential for growth to adult size in the aortic position in place of the damaged aortic valve (Fig. 20-5). The Ross procedure has become a useful option for aortic valve replacement in children, because it has improved durability and can be performed with acceptable morbidity and mortality rates. The placement of a pulmonary conduit, which does not grow and becomes calcified

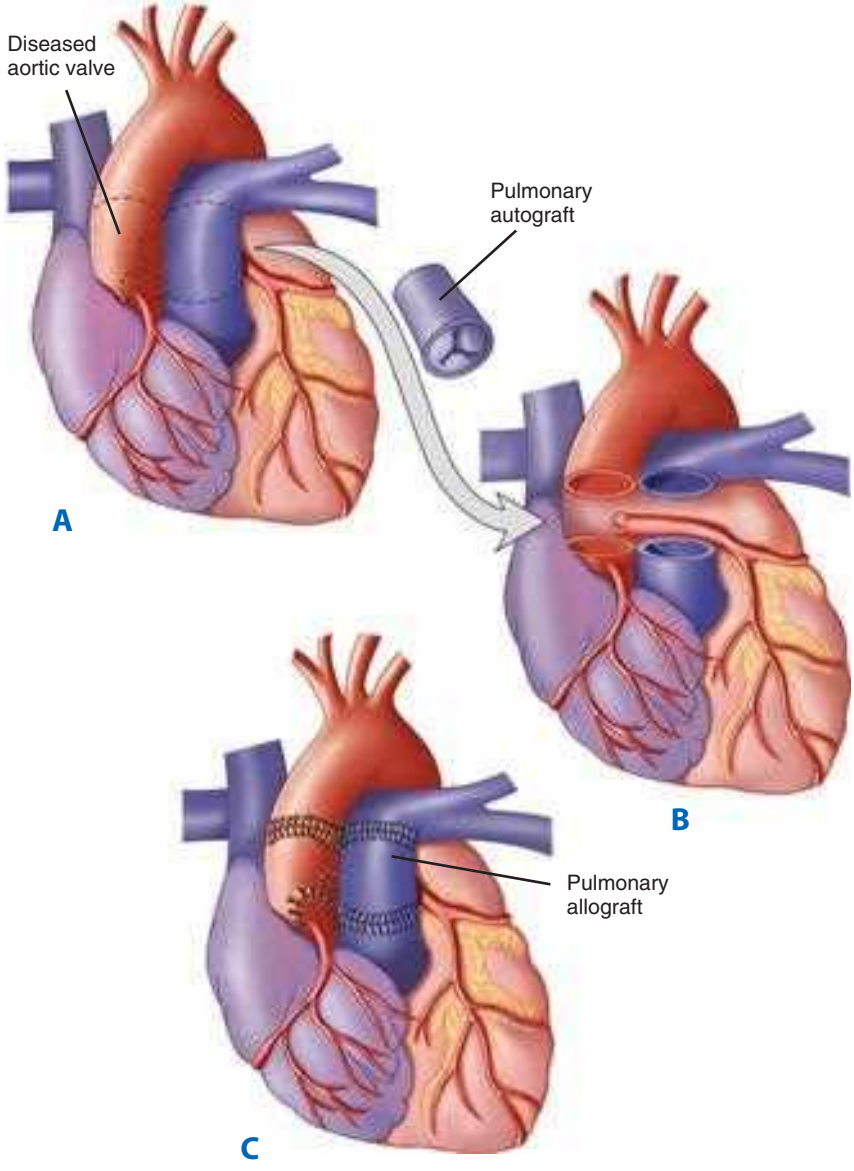

Figure 20-5. **A** through **C.** The pulmonary autograft for aortic valve replacement. The aortic valve and adjacent aorta are excised, preserving buttons of aortic tissue around the coronary ostia. The pulmonary valve and main pulmonary artery are excised and transferred to the aortic position. The coronary buttons are then attached to the neoaortic root. A pulmonary allograft is inserted to re-establish the right ventricular outflow tract. *(From Kouchokos NT, Davila-Roman VG, Spray TL, et al. Replacement of the aortic root with a pulmonary autograft in children and young adults with aortic-valve disease.* N Engl J Med. *1994;330:1.)*

Figure 20-6. Outcomes and associated risk factors for aortic valve replacement in 160 children: A competing risks analysis.* Circulation. *2005;112:3462.)*

and stenotic over time, does obligate the patient to reoperation to replace the RV-to-pulmonary artery conduit. Karamlou and colleagues[29] recently reviewed the outcomes and associated risk factors for aortic valve replacement in 160 children from the Hospital for Sick Children in Toronto. They found that younger age, lower operative weight, concomitant performance of aortic root replacement or reconstruction, and use of prosthesis type other than a pulmonary autograft were significant predictors of death, whereas the use of a bioprosthetic or allograft valve type and earlier year of operation were identified as significant risk factors for repeated aortic valve replacement. Autograft use was associated with a blunted progression of the peak prosthetic valve gradient and a rapid decrease in the left ventricular end-diastolic dimension (Fig. 20-6). In agreement with these findings, Lupinetti and Jones[28] compared allograft aortic valve replacement with the Ross procedure and found a more significant transvalvular gradient reduction and regression of left ventricular hypertrophy in those patients who underwent the Ross procedure. In some cases, the pulmonary valve may not be usable because of associated defects or congenital absence. These children are not candidates for the Ross procedure and are now most frequently treated with cryopreserved allografts (cadaveric human aortic valves). At times, there may be a size discrepancy between the right ventricular outflow tract (RVOT) and the LVOT, especially in cases of severe critical AS in infancy. For these cases, the pulmonary autograft is placed in a manner that also provides enlargement of the aortic annulus (Ross/Konno) (Fig. 20-7).

Subvalvular AS occurs beneath the aortic valve and may be classified as discrete or tunnel-like (diffuse). A thin, fibromuscular diaphragm immediately proximal to the aortic valve characterizes discrete subaortic stenosis. This diaphragm typically extends for 180° or more in a crescentic or circular fashion, often attaching to the mitral valve as well as the interventricular septum.[21] The aortic valve itself is usually normal in this condition, although the turbulence imparted by the subvalvular stenosis may affect leaflet morphology and valve competence.

Diffuse subvalvular AS results in a long, tunnel-like obstruction that may extend to the left ventricular apex. In some individuals, there may be difficulty in distinguishing between hypertrophic cardiomyopathy and diffuse subaortic stenosis. Operation for subvalvular AS is indicated with a gradient exceeding 30 mmHg, in the presence of aortic valve insufficiency, or when symptoms indicating LVOT obstruction are present.[30] Given that repair of isolated discrete subaortic stenosis can be done with low rates of morbidity and mortality, some surgeons advocate repair in all cases of discrete AS to avoid progression of the stenosis and the development of aortic insufficiency, although more recent data demonstrates that subaortic resection should be delayed until the LV gradient exceeds 30 mmHg because most children with an initial LV gradient less than 30 mmHg have quiescent disease.[31] Diffuse AS is a more complex lesion and often requires aortoventriculoplasty as previously described. Results are generally excellent, with operative mortality less than 5%.[32]

Supravalvular AS occurs more rarely and also can be classified into a discrete type, which produces an hourglass deformity of the aorta, and a diffuse form that can involve the entire arch and brachiocephalic arteries. The aortic valve leaflets are usually normal, but in some cases, the leaflets may adhere to the supravalvular stenosis, thereby narrowing the sinuses of Valsalva in diastole and restricting coronary artery perfusion. In addition, accelerated intimal hyperplastic changes in the coronary arteries can be demonstrated in these patients because the proximal position of the coronary arteries subjects them to abnormally high perfusion pressures.

The signs and symptoms of supravalvular AS are similar to other forms of LVOT obstruction. An asymptomatic murmur is the presenting manifestation in approximately half of these patients. Syncope, poor exercise tolerance, and angina may all occur with nearly equal frequency. Supravalvar AS is associated with Williams' syndrome, a constellation of elfin facies, mental retardation, and hypercalcemia.[33] Following routine evaluation, cardiac catheterization should be performed in order to delineate coronary anatomy, as well as to delineate the degree of obstruction. A gradient of 50 mmHg or greater is an indication for operation. However, the clinician must be cognizant of any coexistent lesions, most commonly pulmonic stenosis, which may add complexity to the repair.

The localized form of supravalvular AS is treated by creating an inverted Y-shaped aortotomy across the area of stenosis, straddling the right coronary artery. The obstructing shelf is then excised and a pantaloon-shaped patch is used to close the incision.[21]

The diffuse form of supravalvular stenosis is more variable, and the particular operative approach must be tailored to each specific patient's anatomy. In general, either an aortic endarterectomy with patch augmentation can be performed, or if the narrowing extends past the aorta arch, a prosthetic graft can be placed between the ascending and descending aorta. Operative results for discrete supravalvular AS are generally good, with a hospital mortality of less than 1% and an actuarial survival rate exceeding 90% at 20 years.[34] In contrast, however, the diffuse form is more hazardous to repair and carried a mortality of 15% in a recent series.[34,35]

Patent Ductus Arteriosus

Anatomy. The ductus arteriosus is derived from the sixth aortic arch and normally extends from the main or left pulmonary artery to the upper descending thoracic aorta, distal to the left subclavian artery. In the normal fetal cardiovascular

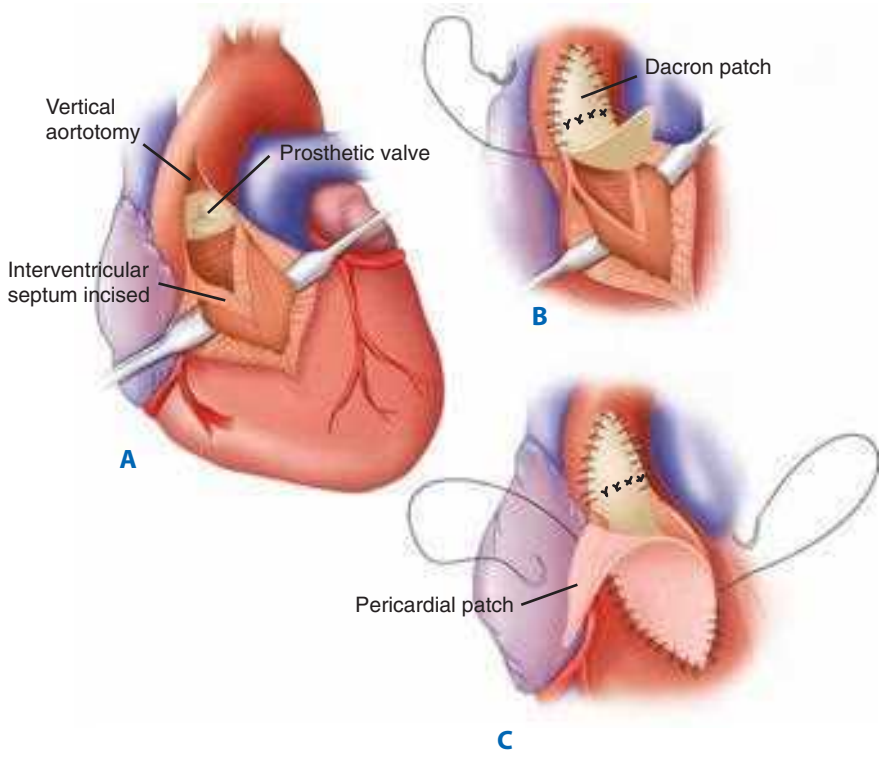

Figure 20-7. The Konno-Rastan aortoventriculoplasty permits significant enlargement of the aortic annulus and subaortic region. **A.** A vertical aortotomy is made to the left of the right coronary artery and extended into the right ventricular outflow tract. After excising the aortic valve, the interventricular septum is incised and an aortic valve prosthesis is secured within the enlarged annulus. **B.** A Dacron patch that is attached to the sewing ring of the prosthesis closes the interventricular septum and the aortotomy. **C.** A separate pericardial patch closes the right ventriculotomy. *(Reproduced with permission from Misbach GA, Turley K, Ullyot DJ, et al. Left ventricular outflow enlargement by the Konno procedure.* J Thorac Cardiovasc Surg. *1982;84:696. Copyright Elsevier.)*

system, ductal flow is considerable (approximately 60% of the combined ventricular output) and is directed exclusively from the pulmonary artery to the aorta.[36] In infancy, the length of the ductus may vary from 2 to 8 mm, with a diameter of 4 to 12 mm.

Locally produced and circulating prostaglandin E_2 (PGE_2) and prostaglandin I_2 (PGI_2) induce active relaxation of the ductal musculature, maintaining maximal patency during the fetal period.[37] At birth, increased pulmonary blood flow metabolizes these prostaglandin products, and absence of the placenta removes an important source of them, resulting in a marked decrease in these ductal-relaxing substances. In addition, release of histamines, catecholamines, bradykinin, and acetylcholine all promote ductal contraction. Despite all of these complex interactions, the rising oxygen tension in the fetal blood is the main stimulus causing smooth muscle contraction and ductal closure within 10 to 15 hours postnatally.[38] Anatomic closure by fibrosis produces the ligamentum arteriosum connecting the pulmonary artery to the aorta.

Delayed closure of the ductus is termed prolonged patency, whereas failure of closure causes persistent patency, which may occur as an isolated lesion or in association with more complex congenital heart defects. In many of these infants with more complex congenital heart defects, either pulmonary or systemic perfusion may depend on ductal flow, and these infants may decompensate if exogenous PGE is not administered to maintain ductal patency.

Natural History. The incidence of patent ductus arteriosus (PDA) is approximately 1 in every 2000 births; however, it increases dramatically with increasing prematurity.[39] In some series, PDAs have been noted in 75% of infants of 28 to 30 weeks gestation. Persistent patency occurs more commonly in females, with a 2:1 ratio.[39]

PDA is not a benign entity, although prolonged survival has been reported. The estimated death rate for infants with isolated, untreated PDA is approximately 30%.[40] The leading cause of death is congestive heart failure, with respiratory infection as a secondary cause. Endocarditis is more likely to occur with a small ductus and is rarely fatal if aggressive antibiotic therapy is initiated early.

Clinical Manifestations and Diagnosis. After birth, in an otherwise normal cardiovascular system, a PDA results in a left-to-right shunt that depends on both the size of the ductal lumen and its total length. As the pulmonary vascular resistance falls 16 to 18 weeks postnatally, the shunt will increase, and its flow will ultimately be determined by the relative resistances of the pulmonary and systemic circulations.

The hemodynamic consequences of an unrestrictive ductal shunt are left ventricular volume overload with increased left atrial and pulmonary artery pressures, and right ventricular strain from the augmented afterload. These changes result in increased sympathetic discharge, tachycardia, tachypnea, and ventricular hypertrophy. The diastolic shunt results in lower aortic diastolic pressure and increases the potential for myocardial ischemia and underperfusion of other systemic organs, while the increased pulmonary flow leads to increased work of breathing and decreased gas exchange. Unrestrictive ductal flow may lead to pulmonary hypertension within the first year of life. These changes will be significantly attenuated if the size of the ductus is only moderate, and completely absent if the ductus is small.

Physical examination of the afflicted infant will reveal evidence of a hyperdynamic circulation with a widened pulse pressure and a hyperactive precordium. Auscultation demonstrates a systolic or continuous murmur, often termed a machinery murmur. Cyanosis is not present in uncomplicated isolated PDA.

The chest radiograph may reveal increased pulmonary vascularity or cardiomegaly, and the ECG may show LV strain, left atrial enlargement, and possibly RV hypertrophy. Echocardiogram with color mapping reliably demonstrates the patency of the ductus as well as estimates the shunt size. Cardiac catheterization is necessary only when pulmonary hypertension is suspected.

Therapy. The presence of a persistent PDA is sufficient indication for closure because of the increased mortality and risk of endocarditis.[2,4] In older patients with pulmonary hypertension, closure may not improve symptoms and is associated with much higher mortality.

In premature infants, aggressive intervention with indomethacin or ibuprofen to achieve early closure of the PDA is beneficial unless contraindications such as necrotizing enterocolitis or renal insufficiency are present.[41] Term infants, however, are generally unresponsive to pharmacologic therapy with indomethacin, so mechanical closure must be undertaken once the diagnosis is established. This can be accomplished either surgically or with catheter-based therapy.[12,42,43] Currently, transluminal placement of various occlusive devices, such as the Rashkind double-umbrella device or embolization with Gianturco coils, is in widespread use.[42] However, there are a number of complications inherent with the use of percutaneous devices, such as thromboembolism, endocarditis, incomplete occlusion, vascular injury, and hemorrhage secondary to perforation.[43] In addition, these techniques may not be applicable in very young infants, because the peripheral vessels do not provide adequate access for the delivery devices.

Surgical closure can be achieved via either open or video-assisted approaches. The open approach employs a posterior lateral thoracotomy in the fourth or fifth intercostal space on the side of the aorta (generally the left). The lung is then retracted anteriorly. In the neonate, the PDA is singly ligated with a surgical clip or permanent suture. In older patients, the PDA is triply ligated. Care must be taken to avoid the recurrent laryngeal nerve, which courses around the PDA. The PDA can also be ligated via a median sternotomy; however, this approach is generally reserved for patients who have additional cardiac or great vessel lesions requiring repair. Occasionally, a short, broad ductus, in which the dimension of its width approaches that of its length, will be encountered. In this case, division between vascular clamps with oversewing of both ends is advisable (Fig. 20-8). In extreme cases, the use of CPB to decompress the large ductus during ligation is an option.

Video-assisted thoracoscopic occlusion, using metal clips, also has been described, although it offers few advantages over the standard surgical approach.[12] Preterm newborns and children may do well with the thoracoscopic technique, while older patients (older than age 5 years) and those with smaller ducts (<3 mm) do well with coil occlusion. In fact, Moore and colleagues recently concluded from their series that coil occlusion is the procedure of choice for ducts smaller than 4 mm.[44] Complete closure rates using catheter-based techniques have steadily improved. Comparative studies of cost and outcome between open surgery and transcatheter duct closure, however, have shown no overwhelming choice between the two modalities. Burke prospectively reviewed coil occlusion and VATS at Miami Children's Hospital and found both options to be effective and less morbid than traditional thoracotomy.[12]

Outcomes. In premature infants, the surgical mortality is very low, although the overall hospital death rate is significant as a

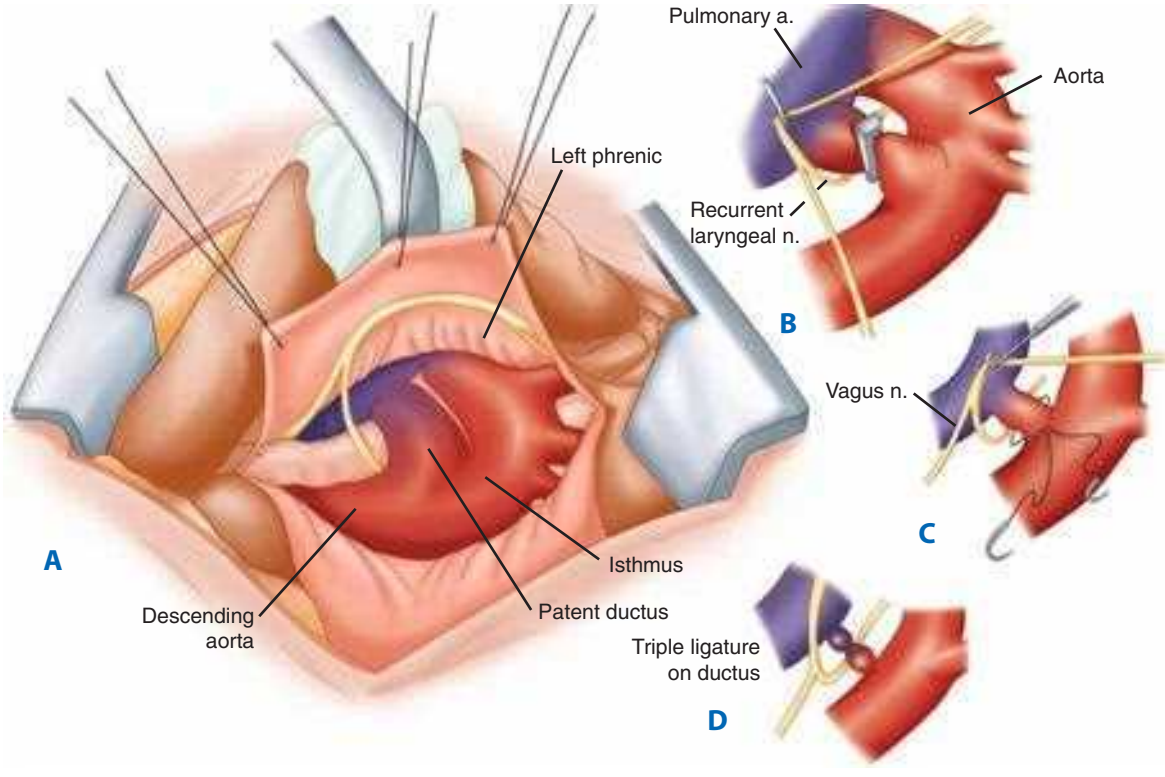

Figure 20-8. **A.** Surgeon's perspective of infant patent ductus arteriosus exposed via a left thoracotomy. **B.** The pleura over the aortic isthmus is incised and mobilized. **C** and **D.** Technique of triple ligation. a. = artery; n. = nerve. *(From Castaneda AR, Jonas RA, Mayer JE, et al.* Cardiac Surgery of the Neonate and Infant. *Philadelphia: W.B. Saunders; 1994:208, with permission. Copyright Elsevier.)*

consequence of other complications of prematurity. In older infants and children, mortality is less than 1%. Bleeding, chylothorax, vocal cord paralysis, and the need for reoperation occur infrequently. With the advent of muscle-sparing thoracotomy, the risk of subsequent arm dysfunction or breast abnormalities is virtually eliminated.[45]

Aortic Coarctation

Anatomy. Coarctation of the aorta (COA) is defined as a luminal narrowing in the aorta that causes an obstruction to blood flow. This narrowing is most commonly located distal to the left subclavian artery. The embryologic origin of COA is a subject of some controversy. One theory holds that the obstructing shelf, which is largely composed of tissue found within the ductus, forms as the ductus involutes.[46] The other theory holds that a diminished aortic isthmus develops secondary to decreased aortic flow in infants with enhanced ductal circulation.

Extensive collateral circulation develops, predominantly involving the intercostals and mammary arteries as a direct result of aortic flow obstruction. This translates into the well-known finding of "rib-notching" on chest radiograph, as well as a prominent pulsation underneath the ribs.

Other associated anomalies, such as ventricular septal defect, PDA, and ASD, may be seen with COA, but the most common is that of a bicuspid aortic valve, which can be demonstrated in 25% to 42% of cases.[47]

Pathophysiology. Infants with COA develop symptoms consistent with left ventricular outflow obstruction, including pulmonary overcirculation and, later, biventricular failure. In addition, proximal systemic hypertension develops as a result of mechanical obstruction to ventricular ejection, as well as hypoperfusion-induced activation of the renin-angiotensin-aldosterone system. Interestingly, hypertension is often persistent after surgical correction despite complete amelioration of the mechanical obstruction and pressure gradient.[48] It has been shown that early surgical correction may prevent the development of long-term hypertension, which undoubtedly contributes to many of the adverse sequelae of COA, including the development of circle of Willis aneurysms, aortic dissection and rupture, and an increased incidence of coronary arteriopathy with resulting myocardial infarction.[49]

Diagnosis. COA is likely to become symptomatic either in the newborn period if other anomalies are present or in the late adolescent period with the onset of left ventricular failure.

Physical examination will demonstrate a hyperdynamic precordium with a harsh murmur localized to the left chest and back. Femoral pulses will be dramatically decreased when compared to upper extremity pulses, and differential cyanosis may be apparent until ductal closure.

Echocardiography will reliably demonstrate the narrowed aortic segment, as well as define the pressure gradient across the stenotic segment. In addition, detailed information regarding other associated anomalies can be gleaned. Aortography is reserved for those cases in which the echocardiographic findings are equivocal.

Therapy. The routine management of hemodynamically significant COA in all age groups has traditionally been surgical. Transcatheter repairs are used with increasing frequency in older patients and those with re-coarctation following surgical repair. Balloon dilatation of native coarctation in neonates has been recently utilized with poor results. The most common surgical techniques in current use are resection with end-to-end anastomosis or extended end-to-end anastomosis, taking care to remove all residual ductal tissue.[50,51] Extended end-to-end anastomosis may also allow the surgeon to treat transverse arch hypoplasia, which is commonly encountered in infants with aortic coarctation.[52,53] The subclavian flap aortoplasty is another repair, although it is used less frequently in the modern era because of the risk of late aneurysm formation and possible underdevlopment of the left upper extremity or ischemia.[51] In this method, the left subclavian artery is transected and brought down over the coarcted segment as a vascularized patch. The main benefit of these techniques is that they do not involve the use of prosthetic materials, and evidence suggests that extended end-to-end anastomosis may promote arch growth, especially in infants with the smallest initial aortic arch diameters.[52]

Despite the benefits, however, extended end-to-end anastomosis may not be feasible when there is a long segment of coarctation or in the presence of previous surgery, because sufficient mobilization of the aorta above and below the lesion may not be possible. In this instance, prosthetic materials, such as a patch aortoplasty, in which a prosthetic patch is used to enlarge the coarcted segment, or an interposition tube graft must be employed.

The most common complications after COA repair are late restenosis and aneurysm formation at the repair site.[54-56] Aneurysm formation is particularly common after patch aortoplasty when using Dacron material. In a large series of 891 patients, aneurysms occurred in 5.4% of the total, with 89% occurring in the group who received Dacron-patch aortoplasty and only 8% occurring in those who received resection with primary end-to-end anastomosis.[54] A further complication, although uncommon, is lower-body paralysis resulting from ischemic spinal cord injury during the repair. This dreaded outcome complicates 0.5% of all surgical repairs, but its incidence can be lessened with the use of some form of distal perfusion, preferably left heart bypass with the use of femoral arterial or distal thoracic aorta for arterial inflow and the femoral vein or left atrium for venous return.[50] These techniques are generally reserved for older patients with complex coarctations that may need prolonged aortic cross clamp times for repair, often in the setting of large collateral vessels and/or previous surgery.

Hypertension is also well recognized following repair of COA. Bouchart and colleagues reported that in a cohort of 35 hypertensive adults (mean age, 28 years) undergoing repair, despite a satisfactory anatomic outcome, only 23 patients were normotensive at a mean follow-up period of 165 months.[55] Likewise, Bhat and associates reported that in a series of 84 patients (mean age at repair, 29 years), 31% remained hypertensive at a mean follow-up of 5 years following surgery.[56]

Although operative repair is still the gold standard, treatment of COA by catheter-based intervention has become more widespread. Both balloon dilatation and primary stent implantation have been used successfully. The most extensive study of the results of balloon angioplasty reported on 970 procedures: 422 native and 548 recurrent COAs. Mean gradient reduction was 74% ± 24% for native and 70% ± 31% for recurrent COA.[57] This demonstrated that catheter-based therapy could produce equally effective results both in

recurrent and in primary COA, a finding with far-reaching implications in the new paradigm of multidisciplinary treatment algorithms for CHD. In the Valvuloplasty and Angioplasty of Congenital Anomalies (VACA) report, higher preangioplasty gradient, earlier procedure date, older patient age, and the presence of recurrent COA were independent risk factors for suboptimal procedural outcome.[57]

The gradient after balloon dilatation in most series is generally acceptable. However, there is a significant minority of patients (0%–26%) for whom the procedural outcome is suboptimal, with a postprocedure gradient of 20 mmHg or greater. These patients may be ideal candidates for primary stent placement. Restenosis is much less common in children, presumably reflecting the influence of vessel wall scarring and growth in the pediatric age group.

Deaths from the procedure also are infrequent (<1% of cases), and the main major complication is aneurysm formation, which occurs in 7% of patients.[50] With stent implantation, many authors have demonstrated improved resolution of stenosis compared with balloon dilatation alone, yet the long-term complications on vessel wall compliance remain largely unknown because only mid-term data are widely available.

In summary, children younger than age 6 months with native COA should be treated with surgical repair, while those requiring intervention at later ages may be ideal candidates for balloon dilatation or primary stent implantation.[50] Additionally, catheter-based therapy should be employed for those cases of restenosis following either surgical or primary endovascular management.

Truncus Arteriosus

Anatomy. Truncus arteriosus is a rare anomaly, comprising between 1% and 4% of all cases of CHD.[58] It is characterized by a single great artery that arises from the heart, overrides the ventricular septum, and supplies the pulmonary, systemic, and coronary circulations.

The two major classification systems are those of Collett and Edwards, described in 1949, and Van Praagh and Van Praagh, described in 1965 (Fig. 20-9).[59,60] The Collett and Edwards classification focuses mainly on the origin of the pulmonary arteries from the common arterial trunk, whereas the Van Praagh system is based on the presence or absence of a VSD, the degree of formation of the aorticopulmonary septum, and the status of the aortic arch.

During embryonic life, the truncus arteriosus normally begins to separate and spiral into a distinguishable anterior pulmonary artery and posterior aorta. Persistent truncus, therefore, represents an arrest in embryologic development at this stage.[61] Other implicated events include twisting of the dividing truncus because of ventricular looping, subinfundibular atresia, and abnormal location of the semilunar valve anlages.[62]

The neural crest may also play a crucial role in the normal formation of the great vessels, as experimental studies in chick embryos have shown that ablation of the neural crest results in persistent truncus arteriosus.[63] The neural crest also develops into the pharyngeal pouches that give rise to the thymus and parathyroids, which likely explains the prevalent association of truncus arteriosus and DiGeorge's syndrome.[64]

The annulus of the truncal valve usually straddles the ventricular septum in a "balanced" fashion; however, it is not unusual for it to be positioned predominantly over the RV, which increases the potential for LVOT obstruction following surgical repair. In the great majority of cases, the leaflets are thickened and deformed, which leads to valvular insufficiency. There are usually three leaflets (60%), but occasionally a bicuspid (50%) or even a quadricuspid valve (25%) is present.[65]

In truncus arteriosus, the pulmonary trunk bifurcates, with the left and right pulmonary arteries forming posteriorly and to the left in most cases. The caliber of the pulmonary arterial branches is usually normal, with stenosis or diffuse hypoplasia occurring in rare instances.

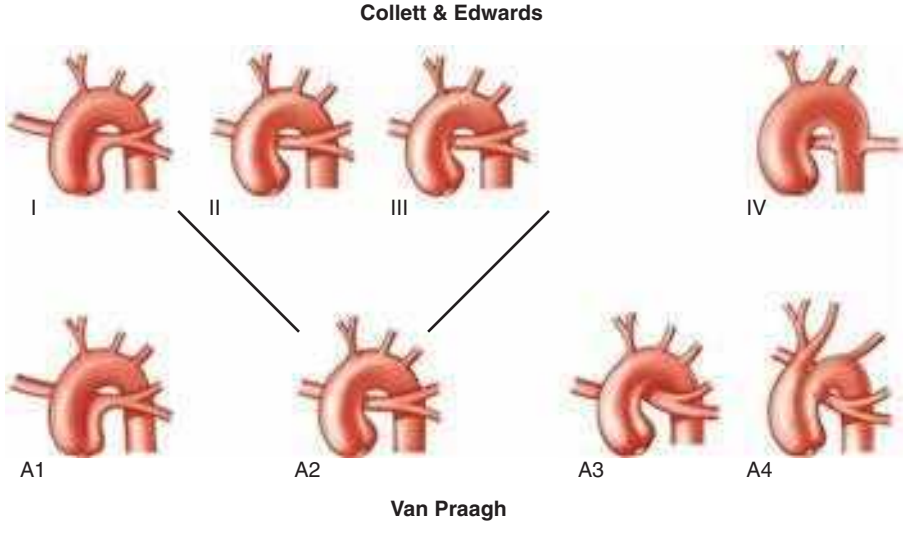

Figure 20-9. There are similarities between the Collett and Edwards and the Van Praagh classifications of truncus arteriosus. Type I is the same as A1. Types II and III are grouped as a single type A2 because they are not significantly distinct embryologically or therapeutically. Type A3 denotes unilateral pulmonary artery with collateral supply to the contralateral lung (hemitruncus). Type A4 is truncus associated with interrupted aortic arch (13% of all cases of truncus arteriosus). *(Reproduced with permission from Fyler DC. Truncus arteriosus. In: Fyler DC, ed.* Nadas' Pediatric Cardiology. *Philadelphia: Hanley & Belfus; 1992:676. Copyright Elsevier. As adapted with permission from Hernanz-Schulman M, Fellows KE. Persistent truncus arteriosus: pathologic, diagnostic and therapeutic considerations.* Semin Roentgenol. *1985;20:121. Copyright Elsevier.)*

The coronary arteries may be normal; however, anomalies are not unusual and occur in 50% of cases.[65,66] Many of these are relatively minor, although two variations are of particular importance, because they have implications in the conduct of operative repair. The first is that the left coronary ostium may arise high in the sinus of Valsalva or even from the truncal tissue at the margin of the pulmonary artery tissue. This coronary artery can be injured during repair when the pulmonary arteries are removed from the trunk or when the resulting truncal defect is closed. The second is that the right coronary artery can give rise to an important accessory anterior descending artery, which often passes across the RV in the exact location where the right ventriculotomy is commonly performed during repair.[65,66]

Physiology and Diagnosis. The main pathophysiologic consequences of truncus arteriosus are (a) the obligatory mixing of systemic and pulmonary venous blood at the level of the ventricular septal defect (VSD) and truncal valve, which leads to arterial saturations near 85%, and (b) the presence of a nonrestrictive left-to-right shunt, which occurs during both systole and diastole, the volume of which is determined by the relative resistances of the pulmonary and systemic circulations.[65] Additionally, truncal valve stenosis or regurgitation, the presence of important LVOT obstruction, and stenosis of pulmonary artery branches can further contribute to both pressure- and volume-loading of the ventricles. The presence of these lesions often results in severe heart failure and cardiovascular instability early in life. Pulmonary vascular resistance may develop as early as 6 months of age, leading to poor results with late surgical correction.

Patients with truncus arteriosus usually present in the neonatal period, with signs and symptoms of congestive heart failure and mild to moderate cyanosis. A pansystolic murmur may be noted at the left sternal border, and occasionally a diastolic murmur may be heard in the presence of truncal regurgitation.

Chest radiography will be consistent with pulmonary overcirculation, and a right aortic arch can be appreciated 35% of the time. The ECG is usually nonspecific, demonstrating normal sinus rhythm with biventricular hypertrophy.

Echocardiography with Doppler color-flow or pulsed Doppler is diagnostic and usually provides sufficient information to determine the type of truncus arteriosus, the origin of the coronary arteries and their proximity to the pulmonary trunk, the character of the truncal valves, and the extent of truncal insufficiency.[65] Cardiac catheterization can be helpful in cases where pulmonary hypertension is suspected or to further delineate coronary artery anomalies prior to repair.

The presence of truncus is an indication for surgery. Repair should be undertaken in the neonatal period or as soon as the diagnosis is established. Eisenmenger's physiology, which is found primarily in older children, is the only absolute contraindication to correction.

Repair. Truncus arteriosus was first managed with pulmonary artery banding as described by Armer and colleagues in 1961.[67] However, this technique led to only marginal improvements in 1-year survival rates because ventricular failure inevitably occurred. In 1967, however, complete repair was accomplished by McGoon and his associates based on the experimental work of Rastelli, who introduced the idea that an extracardiac valved conduit could be used to restore ventricular-to-pulmonary artery continuity.[68] Over the next 20 years, improved survival rates led to uniform adoption of complete repair even in the youngest and smallest infants.[58,65,69]

Surgical correction entails the use of CPB. Repair is completed by separation of the pulmonary arteries from the aorta, closure of the aortic defect (occasionally with a patch) to minimize coronary flow complications, placement of a valved cryopreserved allograft or jugular venous valved conduit (Contegra) to reconstruct the RVOT, and VSD closure. Important branch pulmonary arterial stenosis should be repaired at the time of complete repair and can usually be accomplished with longitudinal allograft patch arterioplasty. Severe truncal valve insufficiency occasionally requires truncal valve replacement, which can be accomplished with a cryopreserved allograft.[70]

Results. The results of complete repair of truncus have steadily improved. Ebert reported a 91% survival rate in his series of 77 patients who were younger than 6 months of age; later reports by others confirmed these findings and demonstrated that excellent results could be achieved in even smaller infants with complex-associated defects.[11,69]

Newer extracardiac conduits also have been developed and used with success, which has widened the repertoire of the modern congenital heart surgeon and improved outcomes.[71] Severe truncal regurgitation, interrupted aortic arch, coexistent coronary anomalies, chromosomal or genetic anomalies, and age younger than 100 days are risk factors associated with perioperative death and poor outcome.

Total Anomalous Pulmonary Venous Connection

Total anomalous pulmonary venous connection (TAPVC) occurs in 1% to 2% of all cardiac malformations and is characterized by abnormal drainage of the pulmonary veins into the right heart, whether through connections into the right atrium or into its tributaries.[72] Accordingly, the only mechanism by which oxygenated blood can return to the left heart is through an ASD, which is almost uniformly present with TAPVC.

Unique to this lesion is the absence of a definitive form of palliation. Thus, TAPVC with concomitant obstruction represents one of the only true surgical emergencies across the entire spectrum of congenital heart surgery.

Anatomy and Embryology. The lungs develop from an outpouching of the foregut, and their venous plexus arises as part of the splanchnic venous system. TAPVC arises when the pulmonary vein evagination from the posterior surface of the left atrium fails to fuse with the pulmonary venous plexus surrounding the lung buds. In place of the usual connection to the left atrium, at least one connection of the pulmonary plexus to the splanchnic plexus persists. Accordingly, the pulmonary veins drain to the heart through a systemic vein (Fig. 20-10).

Darling and colleagues classified TAPVC according to the site or level of connection of the pulmonary veins to the systemic venous system[73]: type I (45%), anomalous connection at the supracardiac level; type II (25%), anomalous connection at the cardiac level; type III (25%), anomalous connection at the infracardiac level; and type IV (5%), anomalous connection at multiple levels.[74] Within each category, further subdivisions can be implemented, depending on whether pulmonary venous obstruction exists. Obstruction to pulmonary venous drainage

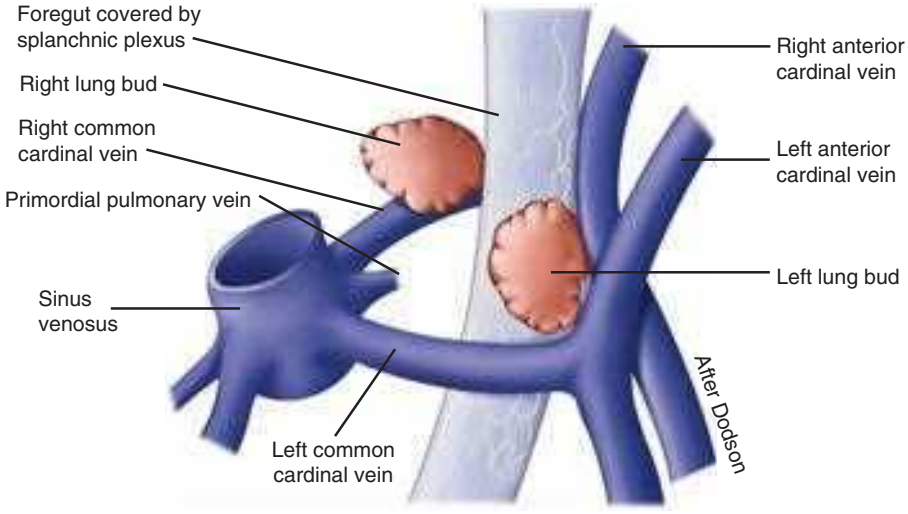

Figure 20-10. Total anomalous pulmonary venous connection results when the primordial pulmonary vein fails to unite with the plexus of veins that surround the lung buds and is derived from the splanchnic venous plexus, including the cardinal veins and umbilicovitelline veins. *(From Castaneda AR, Jonas RA, Mayer JE, et al.* Cardiac Surgery of the Neonate and Infant. *Philadelphia: W.B. Saunders; 1994:158, with permission. Copyright Elsevier.)*

is a powerful predictor of adverse natural outcome and occurs most frequently with the infracardiac type, especially when the pattern of infracardiac connection prevents the ductus venosus from bypassing the liver.[75]

Pathophysiology and Diagnosis. Because both pulmonary and systemic venous blood returns to the right atrium in all forms of TAPVC, a right-to-left intracardiac shunt must be present in order for the afflicted infant to survive. This invariably occurs via a nonrestrictive patent foramen ovale. Because of this obligatory mixing, cyanosis is usually present, and its degree depends on the ratio of pulmonary to systemic blood flow. Decreased pulmonary blood flow is a consequence of pulmonary venous obstruction, the presence of which is unlikely if the right ventricular pressure is less than 85% of systemic pressure.[76]

The child with TAPVC may present with severe cyanosis and respiratory distress, necessitating urgent surgical intervention if a severe degree of pulmonary venous obstruction is present. However, in cases where there is no obstructive component, the clinical picture is usually one of pulmonary overcirculation, hepatomegaly, tachycardia, and tachypnea with feeding. In a child with serious obstruction, arterial blood gas analysis reveals severe hypoxemia (partial pressure of oxygen [Po_2] <20 mmHg), with metabolic acidosis.[77]

Chest radiography will show normal heart size with generalized pulmonary edema. Two-dimensional echocardiography is very useful in establishing the diagnosis and also can assess ventricular septal position, which may be leftward secondary to small left ventricular volumes, as well as estimate the right ventricular pressure based on the height of the tricuspid regurgitant jet. Echocardiography can usually identify the pulmonary venous connections (types I to IV), and it is rarely necessary to perform other diagnostic tests.

Cardiac catheterization is not recommended in these patients because the osmotic load from the intravenous contrast can exacerbate the degree of pulmonary edema.[78] When cardiac catheterization is performed, equalization of oxygen saturations in all four heart chambers is a hallmark finding in this disease since the mixed blood returned to the right atrium gets distributed throughout the heart.

Therapy. Operative correction of TAPVC requires anastomosis of the common pulmonary venous channel to the left atrium, obliteration of the anomalous venous connection, and closure of the ASD.[77,79]

All types of TAPVC are approached through a median sternotomy, and many surgeons use deep hypothermic circulatory arrest in order to achieve an accurate and widely patent anastomosis. The technique for supracardiac TAPVC includes early division of the vertical vein, retraction of the aorta and the superior vena cava laterally to expose the posterior aspect of the left atrium and the pulmonary venous confluence, and a side-to-side anastomosis between a long, horizontal biatrial incision and a longitudinal incision within the pulmonary venous confluence. The ASD can then be closed with an autologous pericardial or synthetic patch.

In patients with TAPVC to the coronary sinus without obstruction, a simple unroofing of the coronary sinus can be performed through a single right atriotomy with concomitant closure of the ASD. If pulmonary venous obstruction is present, the repair should include generous resection of roof of the coronary sinus.[77]

Repair of infracardiac TAPVC entails ligation of the vertical vein at the diaphragm, followed by construction of a proximal, patulous longitudinal venotomy. This repair is usually performed by "rolling" the heart toward the left, thus exposing the left atrium where it usually overlies the descending vertical vein (Fig. 20-11).

As originally described by Lacour-Gayet and colleagues at the Marie-Lannelongue Hospital, Paris, and Coles and colleagues at The Hospital for Sick Children, Toronto, the sutureless technique was developed for patients with anastomotic stenosis occurring after TAPVC repair.[78,79] After determining that favorable outcomes were possible using this technique, it is currently used in selected patients upon initial presentation of TAPVC.[79] Incisions are made in the venous confluence. Based on the surgeon's discretion, the incisions are extended into both upper and lower pulmonary veins separately if judged to be important for an unobstructed pathway. An atriopericardial anastomosis is created using the pericardium adjacent to where the pulmonary veins enter the pericardium (Fig. 20-12). This anastomosis avoids direct contact with the incision site in the wall of the pulmonary veins and allows the free egress of blood from the lungs to the left atrium.

4▶

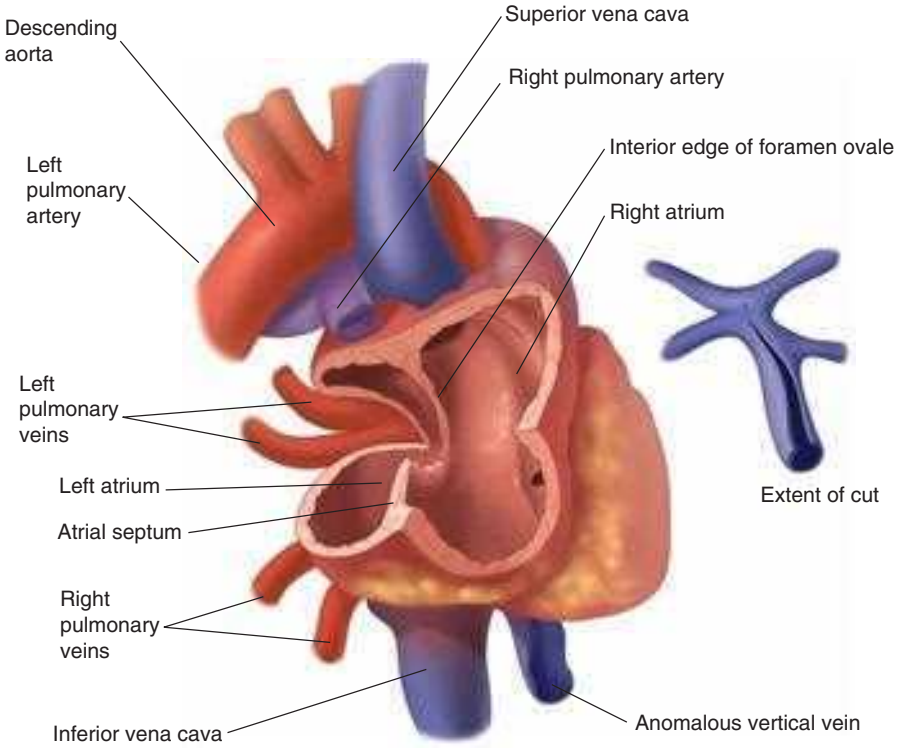

Figure 20-11. Operative exposure obtained with infradiaphragmatic total anomalous pulmonary venous connection, using an approach from the right. *(From Castaneda AR, Jonas RA, Mayer JE, et al.* Cardiac Surgery of the Neonate and Infant. *Philadelphia: W.B. Saunders; 1994:161, with permission. Copyright Elsevier.)*

The perioperative care of these infants is crucial because episodes of pulmonary hypertension can occur within the first 48 hours, which contribute significantly to mortality following repair.[6] Muscle relaxants and narcotics should be administered during this period to maintain a constant state of anesthesia. Arterial partial pressure of carbon dioxide (Pco_2) should be maintained at 30 mmHg with use of a volume ventilator, and the fraction of inspired oxygen (Fio_2) should be increased to keep the pulmonary arterial pressure at less than two thirds of the systemic pressure.

Results. Results of TAPVC in infancy have markedly improved in recent years, with an operative mortality of 5% or less in some series.[77-80] This improvement is probably multifactorial, mainly as a consequence of early noninvasive diagnosis and aggressive perioperative management. The routine use of echocardiography; improvements in myocardial protection with specific attention to the RV; creation of a large, tension-free anastomosis with maximal use of the venous confluence and atrial tissue; use of a sutureless technique in selected cases; and prevention of pulmonary hypertensive events have likely played a major role in reducing operative mortality. The importance of risk factors for early mortality, such as venous obstruction at presentation, urgency of operative repair, and infradiaphragmatic anatomic type, have been debated.[79,81]

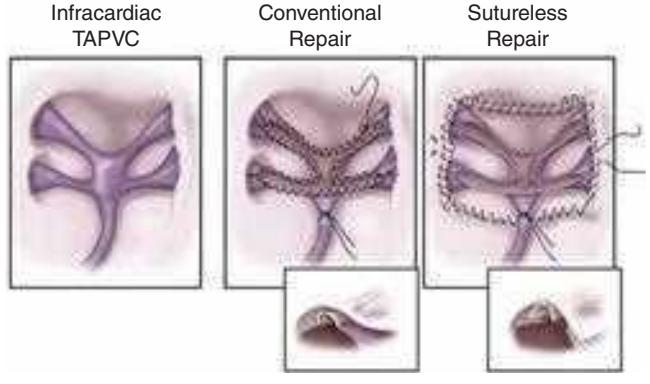

Figure 20-12. Differences between conventional repair of total anomalous pulmonary venous connection (TAPVC) and sutureless repair of TAPVC. In the sutureless techniques, there are no sutures placed in the fragile veins themselves. Rather, the pericardial flaps are used to create a "well" for the pulmonary venous return (*bottom inset*). Early and late extrinsic stenosis are thought to be reduced using this latter technique.

Bando and colleagues[82] made the controversial statement that both preoperative pulmonary venous obstruction and anatomic type had been neutralized as potential risk factors beyond calendar year 1991. Hyde et al[80] similarly reported that connection type was not related to outcome. However, a recent large single-institution report of 377 children with TAPVC by the author from the Hospital for Sick Children in Toronto[83] found that, although outcomes had improved over time, patient anatomic factors were still important determinants of both survival and the need for subsequent reoperation. Risk factors for postrepair death were earlier operation year, younger age at repair, cardiac connection type, and postoperative pulmonary venous obstruction. Risk-adjusted estimated 1-year survival for a patient repaired at birth with unfavorable morphology in 2006 was 37% (95% confidence interval [CI], 8%–80%) compared with 96% (95% CI, 91%–99%) for a patient with favorable morphology repaired at age 1 year. Freedom from reoperation was 82% ± 6% at 11 years after repair, with increased risk associated with mixed connection and postoperative pulmonary venous obstruction (Fig. 20-13). A recent study from the Hospital for Sick Children, Toronto, showed a lower incidence of reoperation in the sutureless technique compared to conventional pulmonary

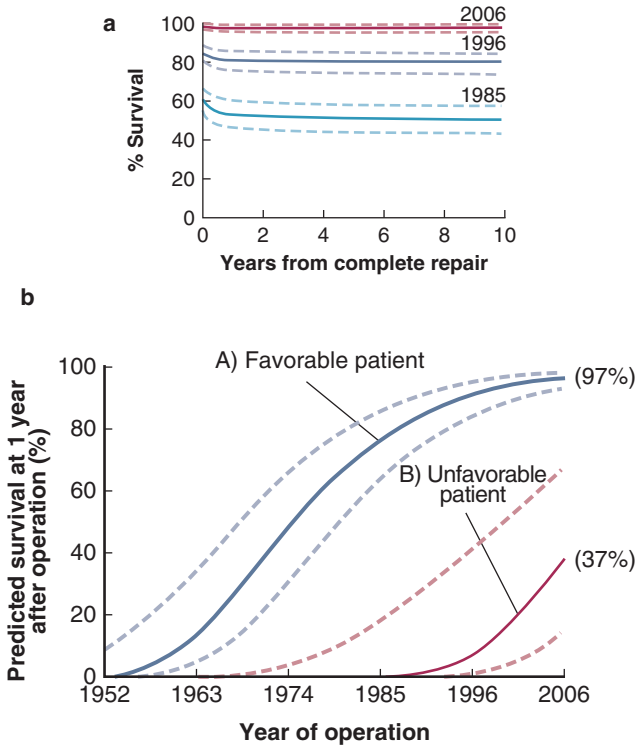

Figure 20-13. **a.** Risk-adjusted survival from repair improved significantly with increasing year of operation, indicating a strong era effect. Solid lines are continuous point estimates enclosed by dashed 95% confidence limits showing three different solutions to the multivariable equation for death after repair. All other predictors have been set to mean values to illustrate the favorable influence of later operation year on survival after repair. **b.** Risk-adjusted nomograms show 1-year survival after repair expressed as a function of increasing year of operation for two different patients. The top line (*A*) shows the multivariable solution for a patient with favorable anatomic characteristics (noncardiac connection without pulmonary venous obstruction) undergoing repair at 1 year of age; the bottom line (*B*) shows the solution for a patient with unfavorable characteristics (cardiac connection with pulmonary venous obstruction) undergoing operation at birth. The nomograms show that the more recent era has improved survival in all patients, especially within the last few decades. However, unfavorable anatomic characteristics have not been neutralized as important determinants of postrepair survival despite improvements in perioperative care. Numbers in parentheses represent parametric estimates of median survival at 1 year after repair in 2005. *(Reproduced with permission from Karamlou T, et al. Factors associated with mortality and reoperation in 377 children with total anomalous pulmonary venous connection.* Circulation. *2007;115:1591.)*

venous confluence–left atrial anastomosis.[84] However, there was no statistically significant difference suggesting similar results between the strategies.[9] Although the sutureless technique appears to have favorable outcomes at primary repair for TAPVC, long-term follow-up is necessary to evaluate the occurrence of arrhythmias, such as complete heart block and atrial tachycardia, since an incision on the atrial septum and atrial wall is more invasive compared to the conventional technique.

The most significant postoperative complication of TAPVC repair is pulmonary venous obstruction, which occurs 9% to 11% of the time, regardless of the surgical technique employed. Mortality varies between 30% and 45%, and alternative catheter interventions do not offer definitive solutions.[78] Recurrent pulmonary venous obstruction can be localized at the site of the pulmonary venous anastomosis (extrinsic), which can usually be cured with patch enlargement or balloon dilatation, or it may be secondary to endocardial thickening of the pulmonary venous ostia frequently resulting in diffuse pulmonary venous sclerosis (intrinsic), which carries a 66% mortality rate because few good solutions exist.[75] More commonly, postrepair left ventricular dysfunction can occur as the noncompliant LV suddenly is required to handle an increased volume load from redirected pulmonary venous return. This can manifest as an increase in pulmonary artery pressure but is distinguishable from primary pulmonary hypertension (another possible postoperative complication following repair of TAPVC) from the elevated left atrial pressure and LV dysfunction along with echocardiographic evidence of poor LV contractility. In pulmonary hypertension, the left atrial pressure may be low, the LV may appear "underfilled" (by echocardiography), and the RV may appear dilated. In either case, postoperative support for a few days with extracorporeal membrane oxygenation may be lifesaving, and TAPVC should be repaired in centers that have this capacity.

Some investigators have speculated that preoperative pulmonary venous obstruction is associated with increased medial thickness within the pulmonary vasculature, which may predispose these infants to intrinsic pulmonary venous stenosis despite adequate pulmonary venous decompression.[80] The majority of studies demonstrating that preoperative pulmonary venous obstruction is a predictor of subsequent need for reoperation to correct recurrent pulmonary venous obstruction lend credence to this notion.

Cor Triatriatum

Anatomy. Cor triatriatum is a rare CHD characterized by the presence of a fibromuscular diaphragm that partitions the left atrium into two chambers: a superior chamber that receives drainage from the pulmonary veins, and an inferior chamber that communicates with the mitral valve and the LV (Fig. 20-14). An ASD frequently exists between the superior chamber and the right atrium, or, more rarely, between the right atrium and the inferior chamber.

Pathophysiology and Diagnosis. Cor triatriatum results in obstruction of pulmonary venous return to the left atrium. The degree of obstruction is variable and depends on the size of fenestrations present in the left atrial membrane, the size of the ASD, and the existence of other associated anomalies. If the communication between the superior and inferior chambers is less than 3 mm, patients usually are symptomatic during the first year of life. The afflicted infant will present with the stigmata of low cardiac output and pulmonary venous hypertension, as well as congestive heart failure and poor feeding.

Physical examination may demonstrate a loud pulmonary S_2 sound and a right ventricular heave, as well as jugular venous distention and hepatomegaly. Chest radiography will show cardiomegaly and pulmonary vascular prominence, and the ECG will suggest right ventricular hypertrophy. Two-dimensional echocardiography provides a definitive diagnosis in most cases,

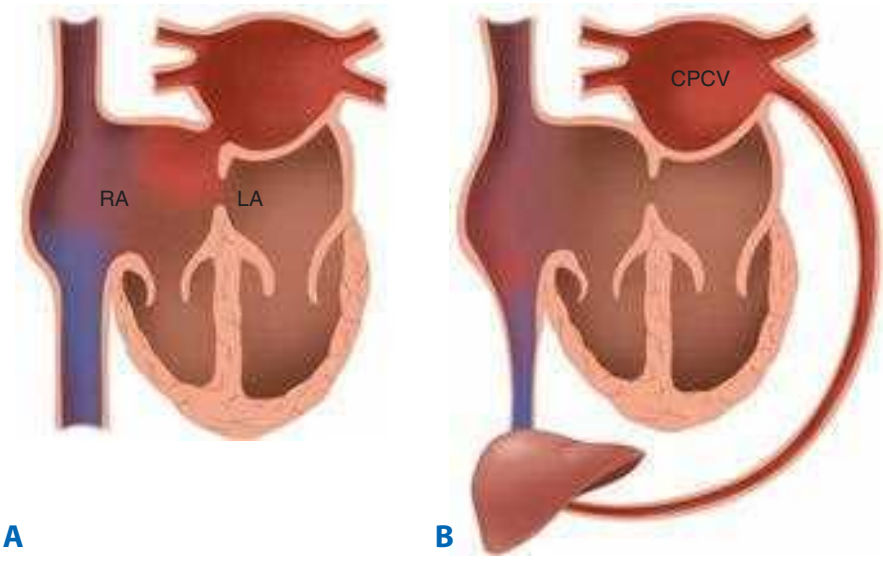

Figure 20-14. Variants of cor triatriatum with imperforate membrane between common pulmonary venous chamber (*CPVC*) and left atrium (*LA*). **A.** Common chamber draining to right atrium directly. **B.** Common chamber draining into systemic venous circulation via anomalous vein. RA = right atrium. *(Adapted with permission from Krabill KA, Lucas RV Jr. Abnormal pulmonary venous connections. with catheterization necessary only when echocardiographic evaluation is equivocal.

Therapy. Operative treatment for cor triatriatum is fairly simple. CPB and cardioplegic arrest are used. A right atriotomy usually allows access to the left atrial membrane through the existing ASD, because it is dilated secondary to communication with the pulmonary venous chamber. The membrane is then excised, taking care not to injure the mitral valve or the interatrial septum, and the ASD is closed with a patch. Alternatively, if the right atrium is small, the membrane can be exposed through an incision directly into the superior left atrial chamber, just anterior to the right pulmonary veins.[7,82] Surgical results are uniformly excellent for this defect, with survival approaching 100%.

The utility of catheter-based intervention for this diagnosis remains controversial, although there have been two recent reports of successful balloon dilatation.[83,85]

Aortopulmonary Window

Embryology and Anatomy. Aortopulmonary window (APW) is a rare congenital lesion, occurring in about 0.2% of patients, characterized by incomplete development of the septum that normally divides the truncus into the aorta and the pulmonary artery.[86]

In the vast majority of cases, APW occurs as a single defect of minimal length, which begins a few millimeters above the semilunar valves on the left lateral wall of the aorta (Fig. 20-15). Coronary artery anomalies, such as aberrant origin of the right or left coronary artery from the main pulmonary artery, are occasionally present.

Pathophysiology and Diagnosis. The dominant pathophysiology of APW is that of a large left-to-right shunt with increased pulmonary flow and the early development of congestive heart failure. Like other lesions with left-to-right flow, the magnitude of the shunt is determined by both the size of the defect and the pulmonary vascular resistance.

Infants with APW present with frequent respiratory tract infections, tachypnea with feeding, and failure to thrive.

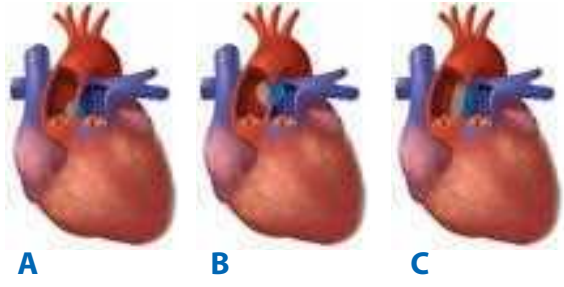

Figure 20-15. **A** through **C.** Classification of aortopulmonary window. *(Reproduced with permission from Mori K, Ando M, Takao A. Distal type of aortopulmonary window: report of 4 cases.* Br Heart J. *1978;40:681. With permission from the BMJ Publishing Group.)*

Cyanosis is usually absent because these infants deteriorate prior to the onset of significant pulmonary hypertension. The rapid decline with this defect occurs because shunt flow continues during both phases of the cardiac cycle, which limits systemic perfusion and increases ventricular work.[86]

The diagnosis of APW begins with the physical examination, which may demonstrate a systolic flow murmur, a hyperdynamic precordium, and bounding peripheral pulses. The chest radiograph will show pulmonary overcirculation and cardiomegaly, and the ECG will usually demonstrate either left ventricular hypertrophy or biventricular hypertrophy. Echocardiography can detect the defect and also provide information about associated anomalies. Retrograde aortography will confirm the diagnosis but is rarely necessary.

Therapy. All infants with APW require surgical correction once the diagnosis is made. Repair is undertaken through a median sternotomy and the use of CPB. The pulmonary arteries are occluded once the distal aorta is cannulated, and a transaortic repair using a prosthetic patch for pulmonary artery closure is then carried out. The coronary ostia must be carefully visualized and included on the aortic side of the patch. Alternatively, a two-patch technique can be used, which may eliminate recurrent fistulas from suture line

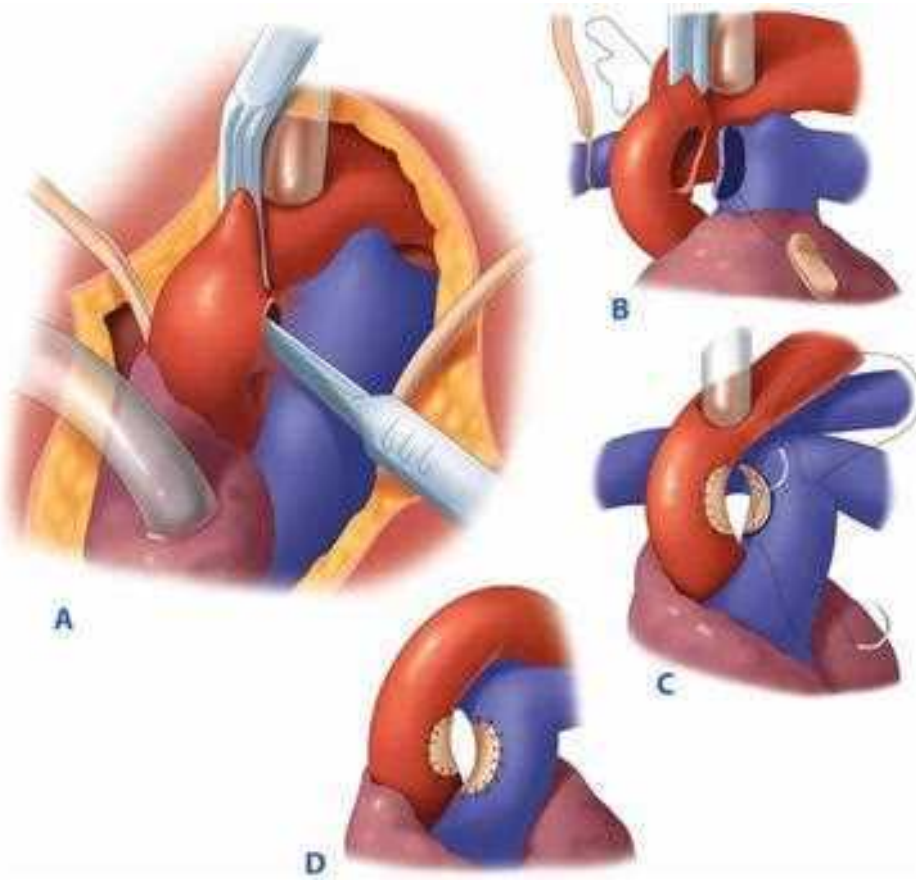

Figure 20-16. Two-patch repair of aortopulmonary window. **A.** The aorta and right atrium are cannulated through a median sternotomy, and once the patient is on cardiopulmonary bypass, the right and left pulmonary arteries are occluded with snares. The ductus arteriosus (when present) can be ligated. The aorta is cross-clamped and the heart arrested with cardioplegia. The aortopulmonary window is then divided, with the left coronary ostia being carefully protected. **B.** A piece of previously prepared pulmonary homograft material is used to patch the aortic defect. In older children, polytetrafluoroethylene material can be safely used. **C.** Once the aortic portion of the defect has been safely repaired, the aortic cross-clamp may be removed to restore perfusion to the heart. During rewarming, the pulmonary portion of the defect is repaired using a similar piece of homograft or polytetrafluoroethylene. **D.** At the completion of repair, the patient is easily weaned from cardiopulmonary bypass, and the cannulas are removed. This type of repair restores normal anatomy, with a reduced likelihood of long-term fistula formation. *(From Gaynor et al,[88] with permission.)*

leaks that occasionally occur with the single-patch method (Fig. 20-16).[86]

Results. Results are generally excellent, with an operative mortality in most large series of less than 5%.[86-88]

DEFECTS REQUIRING PALLIATION

Tricuspid Atresia

Tricuspid atresia occurs in 2% to 3% of patients with CHD and is characterized by atresia of the tricuspid valve. This results in discontinuity between the right atrium and RV. The RV is generally hypoplastic, and left-heart filling is dependent on an ASD. Tricuspid atresia is the most common form of the single-ventricle complex, indicating that there is functionally only one ventricular chamber.

Anatomy. As mentioned, tricuspid atresia results in a lack of communication between the right atrium and the RV, and in the majority of patients, there is no identifiable valve tissue or remnant.[89] The right atrium is generally enlarged and muscular, with a fibrofatty floor. An unrestrictive ASD is usually present. The LV is often enlarged as it receives both systemic and pulmonary blood flow, but the left AV valve is usually normal.

The RV, however, is usually severely hypoplastic, and there is sometimes a VSD in its trabeculated or infundibular portion. In many cases, the interventricular communication is a site of obstruction to pulmonary blood flow, but obstruction may also occur at the level of the outlet valve or in the subvalvular infundibulum.[90] In most cases, pulmonary blood flow is dependent on the presence of a PDA, and there may be no flow into the pulmonary circulation except for this PDA.

Tricuspid atresia is classified according to the relationship of the great vessels and by the degree of obstruction to pulmonary blood flow (Fig. 20-17). Because of the rarity of tricuspid atresia with transposed great arteries, we will restrict our discussion to tricuspid atresia with normally related great vessels.

Pathophysiology. The main pathophysiology in tricuspid atresia is that of a univentricular heart of left ventricular morphology. That is, the LV must receive systemic blood via the interatrial communication and then distribute it to both the pulmonary circulation and the systemic circulation. Unless there is a VSD (as is found in some cases), pulmonary flow is dependent on the presence of a PDA. As the ductus begins to close shortly after birth, infants become intensely cyanotic. Re-establishing ductal patency (with PGE_1) restores pulmonary blood flow and stabilizes patients for surgical intervention. Pulmonary hypertension is unusual in tricuspid atresia. However, occasional patients have a large VSD between the LV and the infundibular portion of the RV (just below the pulmonary valve). If there is no obstruction at the level of this VSD or at the valve, these infants may actually present with heart failure from excessive pulmonary blood flow. Regardless of whether these infants are "ductal-dependent" for pulmonary blood flow or have pulmonary blood flow provided across a VSD, they will be cyanotic since the obligatory right-to-left shunt at the atrial level will provide complete mixing of systemic and pulmonary venous

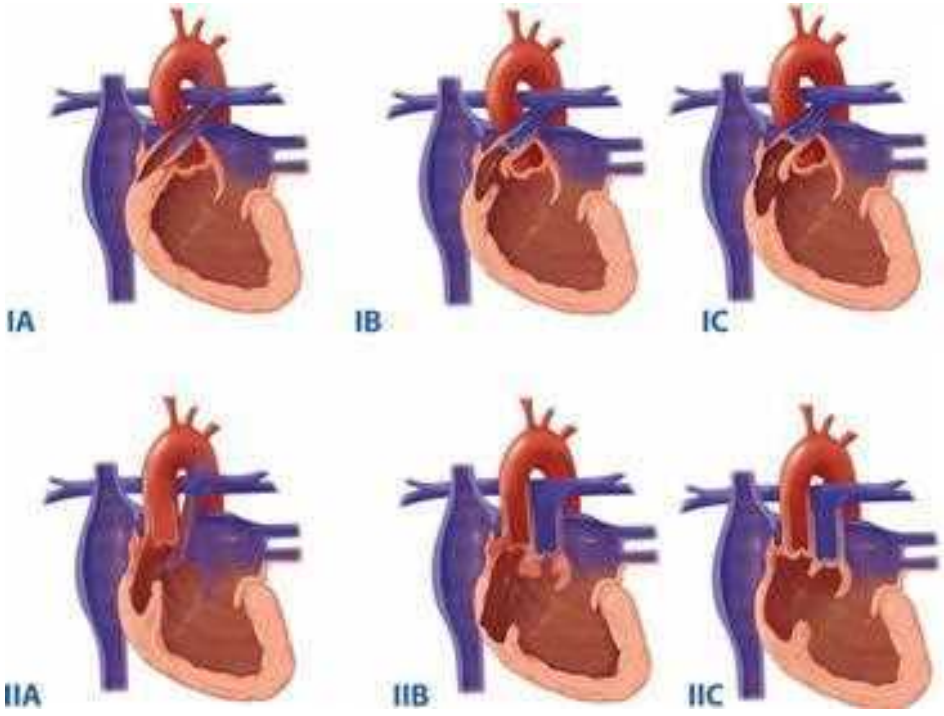

Figure 20-17. Classification of tricuspid atresia. Type I, normally related great arteries with: **IA,** pulmonary atresia with virtual absence of right ventricle; **IB,** pulmonary stenosis with small ventricular septal defect; **IC,** normal pulmonary valve, large ventricular septal defect. Type II, transposed great arteries with: **IIA,** pulmonary atresia; **IIB,** pulmonary or subpulmonary stenosis; **IIC,** normal or enlarged pulmonary valve and artery without subpulmonary stenosis. *(Reproduced with permission from Tricuspid atresia. return so that the LV ejects a hypoxemic mixture into the aorta.

Diagnosis. The signs and symptoms of tricuspid atresia are dependent on the underlying anatomic variant, but most infants are cyanotic and hypoxic as a result of decreased pulmonary blood flow and the complete mixing at the atrial level. When pulmonary blood flow is provided through a VSD, there may be a prominent systolic murmur. Tricuspid atresia with pulmonary blood flow from a PDA may present with the soft, continuous murmur of a PDA in conjunction with cyanosis.

In the minority of patients with tricuspid atresia, symptoms of congestive heart failure will predominate. This is often related to excessive flow across a VSD. The natural history of the muscular VSDs in these infants is that they will close and the congestive heart failure will dissipate and transform into cyanosis with reduced pulmonary blood flow. Chest radiography will show decreased pulmonary vascularity. The ECG is strongly suggestive, because uncharacteristic left axis deviation will be present, due to underdevelopment of the RV. Two-dimensional echocardiography readily confirms the diagnosis and the anatomic subtype.

Treatment. The treatment for tricuspid atresia in the earlier era of palliation was aimed at correcting the defect in the pulmonary circulation. That is, patients with too much pulmonary flow received a pulmonary band, and those with insufficient flow received a systemic-to-pulmonary artery shunt. Systemic-to-pulmonary artery shunts, or Blalock-Taussig (B-T) shunts, were first applied to patients with tricuspid atresia in the 1940s and 1950s.[91] Likewise pulmonary artery banding was applied to patients with tricuspid atresia and congestive failure in 1957. However, despite the initial relief of either cyanosis or congestive heart failure, long-term mortality was high, as the single ventricle was left unprotected from either volume or pressure overload.[92]

Recognizing the inadequacies of the initial repairs, Glenn described the first successful cavopulmonary anastomosis, an end-to-side right pulmonary artery-to-superior vena cava shunt in 1958, and later modified this to allow flow to both pulmonary arteries.[93] This end-to-side right pulmonary artery-to-superior vena cava anastomosis was known as the bidirectional Glenn, and is the first stage to final Fontan repair in widespread use today (Fig. 20-18). The Fontan repair was a major advancement in the treatment of CHD, as it essentially bypassed the right heart and allowed separation of the pulmonary and systemic circulations. It was first performed by Fontan in 1971, and consisted of a classic Glenn anastomosis, ASD closure, and direct connection of the right atrium to the proximal end of the left pulmonary artery using an aortic homograft.[94] The main pulmonary artery was ligated, and a homograft valve was inserted into the orifice of the inferior vena cava.

Multiple modifications of this initial repair were performed over the next 20 years. One of the most important was the description by deLeval and colleagues of the creation of an interatrial lateral tunnel that allowed the inferior vena caval blood to be channeled exclusively to the superior vena cava.[95] A total cavopulmonary connection could then be accomplished by dividing the superior vena cava and suturing the superior portion to the upper side of the right pulmonary artery and the inferior end to the augmented undersurface of the right pulmonary artery. Pulmonary flow then occurs passively, in a laminar fashion, driven by the central venous pressure. This repair became known as the modified Fontan operation.

Another important modification, the fenestrated Fontan repair, was introduced in 1988.[96] In this procedure, a residual 20% to 30% right-to-left shunt is either created or left unrepaired at the time of cavopulmonary connection to help sustain systemic output in the face of transient elevations in the pulmonary vascular resistance postoperatively (Fig. 20-19).[96]

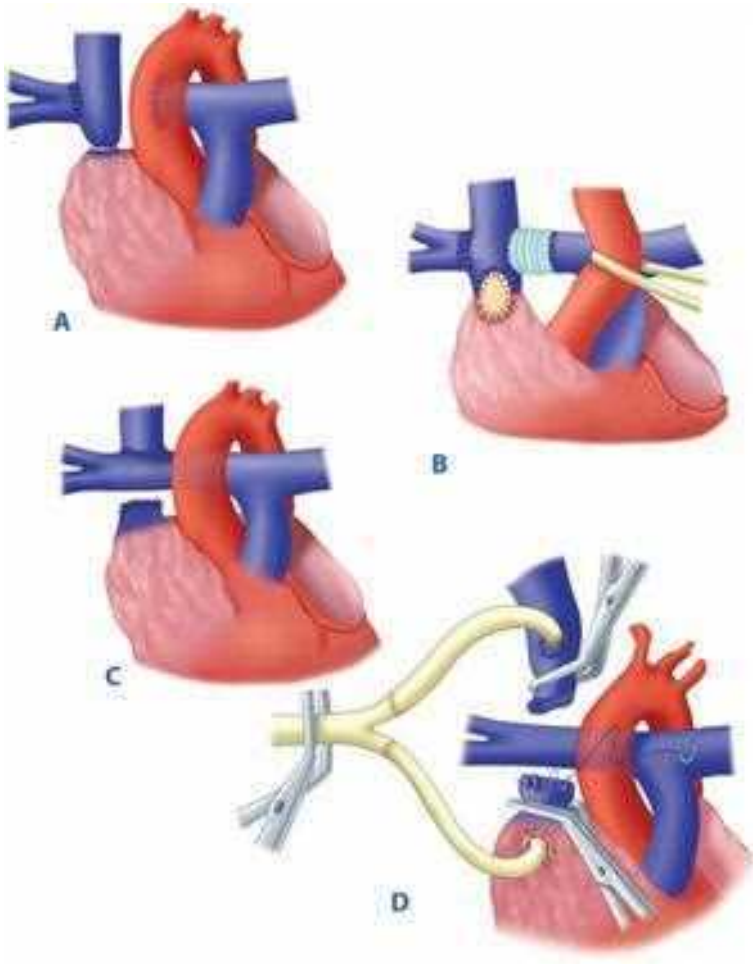

Figure 20-18. Superior vena cava–pulmonary artery shunts. **A.** Classic Glenn shunt. End-to-side right pulmonary artery (RPA)-to-superior vena cava (SVC) anastomosis with ligation of SVC–right atrial junction. **B.** Method of takedown of classic Glenn shunt and creation of total cavopulmonary anastomosis during Fontan operation. **C.** Bidirectional Glenn shunt (bidirectional SVC–pulmonary artery shunt), end-to-side SVC-to-RPA anastomosis. **D.** Method of construction of bidirectional Glenn shunt, one cannula in the high SVC or innominate vein and another cannula in the right atrium connected to a Y-connector. *(Reproduced with permission from Tricuspid atresia. In: Mavroudis C, Backer CL, eds.* Pediatric Cardiac Surgery. *2nd ed. St. Louis: Mosby; 1994:383.)*

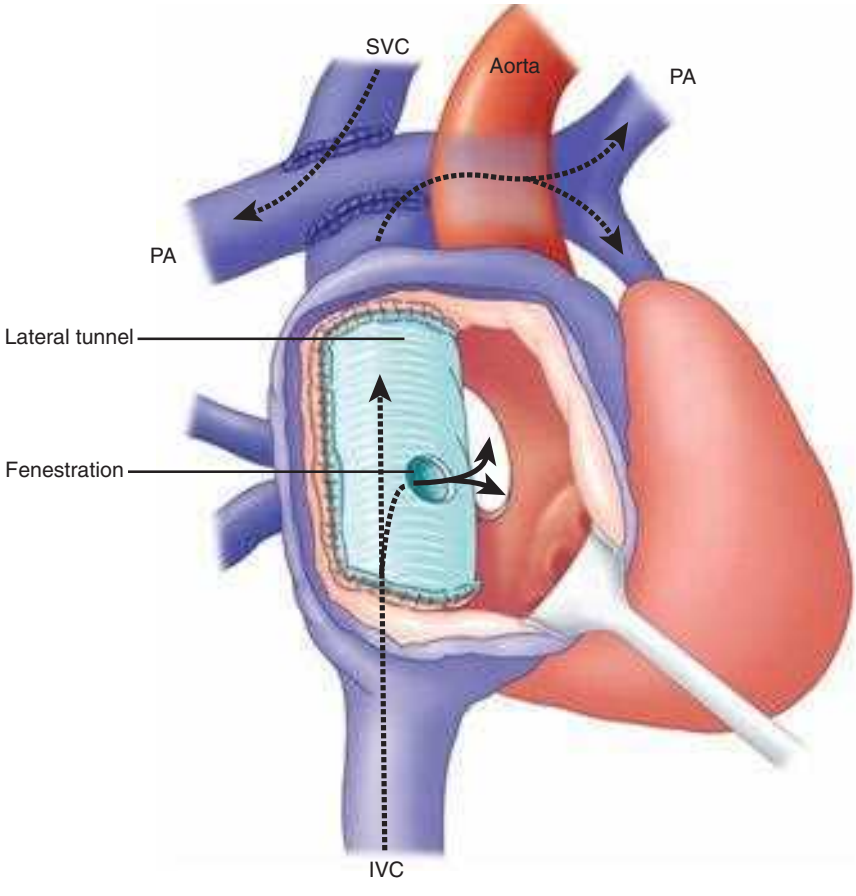

Figure 20-19. The fenestrated Fontan procedure. Using a polytetrafluoroethylene patch, a tunnel is created in the lateral wall of the right atrium to direct inferior vena cava (IVC) flow to the superior vena cava (SVC) that is anastomosed to the pulmonary artery (PA). A 4- to 5-mm fenestration in the baffle diminishes systemic venous pressure and improves cardiac output at the expense of a small decrease in systemic arterial oxygen saturation. *(Reproduced with permission from Kopf GS, Kleinman CS, Hijazi ZM, et al. Fenestrated Fontan operation with delayed transcatheter closure of atrial septal defect: improved results in high-risk patients.* J Thorac Cardiovasc Surg. *1992;103:1039. Copyright Elsevier.)*

The last notable variation on the original Fontan repair uses an extracardiac prosthetic tube graft, usually 20 mm in diameter, as the conduit directing inferior vena cava blood to the pulmonary arteries.[95] This technique has the advantages of decreasing atrial geometric alterations by avoiding intra-atrial suture lines and improving flow dynamics in the systemic venous pathway by maximizing laminar flow. Several investigators have shown a decrease in supraventricular arrhythmias, as well as an improvement in ventricular function, which may be secondary to decreased atrial tension and alleviation of chronic elevations in coronary sinus pressure.[95,96] The extracardiac Fontan operation can be completed without the use of CPB in selected cases, which may further improve outcomes.[97]

One potential disadvantage of the extracardiac Fontan is that it delays performance of the Fontan in order to allow placement of a conduit of sufficient size. Despite these innovative approaches, the current strategy for operative management still relies on the idea of palliation. Patients are approached in a staged manner, to maximize their physiologic state so that they will survive to undergo a Fontan operation. The therapeutic strategy must begin in the neonatal period and should be directed toward reducing the patient's subsequent risk factors for a Fontan procedure. Accordingly, small systemic pulmonary shunts, which are usually performed through a median sternotomy, should be constructed for palliation of ductus-dependent univentricular physiology. This can easily be replaced with a bidirectional Glenn shunt or hemi-Fontan operation at 6 months of life. In non–ductus-dependent univentricular physiology, the infant can be managed medically until primary construction of a bidirectional cavopulmonary anastomosis becomes feasible. This is possible in the majority of cases because the physiologically elevated pulmonary vascular resistance prevents pulmonary overcirculation during the neonatal period.

Occasionally, if a previous B-T shunt was performed, arterioplasty of the right pulmonary artery may be required to ensure adequate size and unobstructed bilateral flow.[2] The bidirectional Glenn shunt or hemi-Fontan operation effectively avoids recirculation of both systemic and pulmonary venous return, thus preventing volume overload of the single ventricle and its attendant sequelae.[95] Pulmonary artery banding is necessary in 10% to 15% of patients with markedly increased pulmonary blood flow and florid congestive heart failure.

The Fontan is usually performed when the child is between 2 and 4 years of age, and it is generally successful if the infant was staged properly, with a protected single ventricle, and there is adequate pulmonary artery growth. The pulmonary vascular resistance should be below 4 Wood units, and the ejection fraction should be more than 45% to ensure success.[98] In patients with high pulmonary artery pressure, fenestration of the atrial baffle may be helpful because their pulmonary vascular resistance may preclude adequate cardiac output postoperatively.[92,96]

Results. Recent reports of the Fontan procedure for tricuspid atresia have been encouraging, with an overall survival of 86% and an operative mortality of 2%.[8] The main complications following repair are atrial arrhythmias, particularly atrial flutter; conduit obstruction requiring reoperation; protein-losing enteropathy; and decreased exercise tolerance.

A recent prospective multi-institutional study from the Congenital Heart Surgeons Society reported the outcomes of 150 neonates with tricuspid atresia and normally related great vessels.[99] Five-year survival was 86%, and by the age of 2 years, 89% had undergone cavopulmonary anastomosis, and 75% of those surviving cavopulmonary anastomosis underwent Fontan operation within 3 years. Competing risks methodology was used in this study to determine the rates of transition to

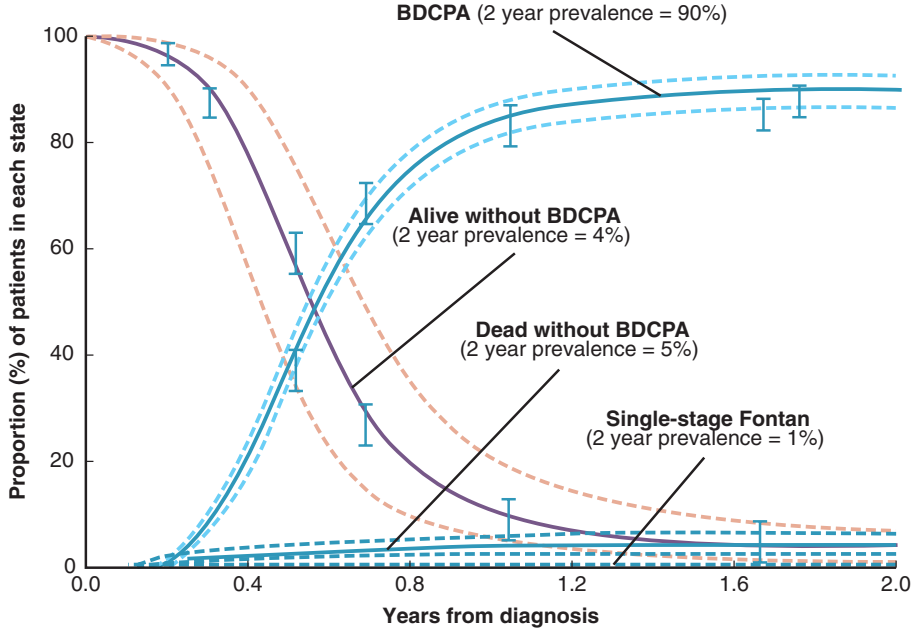

Figure 20-20. Competing risks depiction of events after diagnosis in 150 patients with tricuspid atresia. All patients began alive and thereafter migrated to one of four mutually exclusive end states (death, bidirectional cavopulmonary anastomosis [BDCPA], single-stage Fontan completion, or remaining alive without BDCPA) at time-dependent rates defined by the underlying hazard functions. At any point in time, the sum of proportions of children in each state is 100%. For example, estimated prevalences after 2 years from diagnosis are as follows: 89% BDCPA, 6% dead without BDCPA, 4% alive without BDCPA, and 1% single-stage Fontan completion. Solid lines represent parametric point estimates; dashed lines enclose 70% confidence intervals; circles with error bars represent nonparametric estimates; numbers in parentheses indicate the estimated proportion of patients in each state at 2 years from diagnosis. *(From Karamlou et al,[99] Fig. 1, with permission. Copyright Elsevier.)*

end-states and their associated determinants (Fig. 20-20). Risk factors for death without cavopulmonary anastomosis in this study included the presence of mitral regurgitation and palliation with systemic-to-pulmonary artery shunts not originating from the innominate artery. Factors associated with decreased transition rate to cavopulmonary anastomosis included patient variables (younger age at admission to a participating institution and noncardiac anomalies) and procedural variables (larger systemic-to-pulmonary arterial shunt diameter and previous palliation).[99]

Hypoplastic Left Heart Syndrome

HLHS comprises a wide spectrum of cardiac malformations, including hypoplasia or atresia of the aortic and mitral valves and hypoplasia of the LV and ascending aorta.[100] HLHS has a reported prevalence of 0.2 per 1000 live births and occurs twice as often in boys as in girls. Left untreated, HLHS is invariably fatal and is responsible for 25% of early cardiac deaths in neonates.[101] However, the recent evolution of palliative surgical procedures has dramatically improved the outlook for patients with HLHS, and an improved understanding of anatomic and physiologic alterations has spurred advances in parallel arenas such as intrauterine diagnosis and fetal intervention, echocardiographic imaging, and neonatal critical care.

Anatomy. As implied by its name, HLHS involves varying degrees of underdevelopment of left-sided structures, including the LV and the aortic and mitral valves. Thus, HLHS can be classified into four anatomic subtypes based on the valvular morphology: (a) aortic and mitral stenosis; (b) aortic and mitral atresia; (c) aortic atresia and mitral stenosis; and (d) AS and mitral atresia. Aortic atresia tends to be associated with more severe degrees of hypoplasia of the ascending aorta than does AS.

Even in cases without frank aortic atresia, however, the aortic arch is generally hypoplastic and, in severe cases, may even be interrupted. There is an associated coarctation shelf in 80% of patients with HLHS, and the ductus itself is usually quite large, as is the main pulmonary artery.[7] The segmental pulmonary arteries, however, are small, secondary to reduced intrauterine pulmonary blood flow, which is itself a consequence of the left-sided outflow obstruction. The left atrial cavity is generally smaller than normal and is accentuated because of the leftward displacement of the septum primum. There is almost always an interatrial communication via the foramen ovale, which can be large, but more commonly restricts right-to-left flow. In rare cases, there is no atrial-level communication, which can be lethal for these infants because there is no way for pulmonary venous return to cross over to the RV.

Associated defects can occur with HLHS, and many of them have importance with respect to operative repair. For example, if a VSD is present, the LV can retain its normal size during development even in the presence of mitral atresia. This is because a right-to-left shunt through the defect impels growth of the LV.[102] This introduces the feasibility of biventricular repair for this subset of patients.

Although HLHS undoubtedly results from a complex interplay of developmental errors in the early stages of cardiogenesis, many investigators have hypothesized that the altered blood flow is responsible for the structural underdevelopment that characterizes HLHS. In other words, if the stimulus for normal development of the ascending aorta from the primordial aortic sac is high-pressure systemic blood flow from the LV through the aortic valve, then an atretic or stenotic aortic valve, which impedes flow and leads to only low-pressure diastolic retrograde flow via the ductus, will change the developmental signals and result in hypoplasia of the downstream structures. Normal growth and development of the LV and mitral valve can be secondarily affected, resulting in hypoplasia or atresia of these structures.[100]

Pathophysiology and Diagnosis. In HLHS, pulmonary venous blood enters the left atrium, but atrial systole cannot propel blood across the stenotic or atretic mitral valve into the LV. Thus, the blood is shunted across the foramen ovale into the right atrium, where it contributes to volume loading of the RV. The end result is pulmonary venous hypertension from outflow obstruction at the level of the left atrium, as well as pulmonary overcirculation and right ventricular failure. As the pulmonary vascular resistance falls postnatally, the condition is exacerbated because right ventricular output is preferentially directed away from the systemic circulation, resulting in profound underperfusion of the coronary arteries and the vital organs. Closure of the ductus is incompatible with life in these neonates.

Neonates with severe HLHS receive all pulmonary, systemic, and coronary blood flow from the RV. Generally, a child with HLHS will present with respiratory distress within the first day of life, and mild cyanosis may be noted. These infants must be rapidly triaged to a tertiary center, and echocardiography should be performed to confirm the diagnosis. Prostaglandin E_1 must be administered to maintain ductal patency, and the ventilatory settings must be adjusted to avoid excessive oxygenation and increase carbon dioxide tension. These maneuvers will maintain pulmonary vascular resistance and promote improved systemic perfusion.[2,7,100] Cardiac catheterization should generally be avoided because it is not usually helpful and might result in injury to the ductus and compromised renal function secondary to the osmotic dye load.

Treatment. In 1983, Norwood and colleagues described a two-stage palliative surgical procedure for relief of HLHS[103] that was later modified to the currently used three-stage method of palliation.[104] Stage 1 palliation, also known as the modified Norwood procedure, bypasses the LV by creating a single outflow vessel, the neoaorta, which arises from the RV.

The current technique of arch reconstruction involves completion of a connection between the pulmonary root, the native ascending aorta, and a piece of pulmonary homograft used to augment the diminutive native aorta. There are several modifications of this anastomosis, most notably the Damus-Kaye-Stansel (DKS) anastomosis, which involves dividing both the aorta and the pulmonary artery at the sinotubular junction. The proximal aorta is anastomosed to the proximal pulmonary artery, creating a "double-barreled" outlet from the heart. This outlet is anastomosed to the distal aorta, which can be augmented with homograft material if there is an associated coarctation. At the completion of arch reconstruction, a 3.5- or 4-mm shunt is placed from the innominate artery to the right pulmonary artery. The interatrial septum is then widely excised, thereby creating a large interatrial communication and preventing pulmonary venous hypertension (Fig. 20-21).

The DKS connection, as described earlier, might avoid postoperative distortion of the tripartite connection in the neoaorta, and thus decrease the risk of coronary insufficiency.[105] It can be used when the aorta is 4 mm or larger. Unfortunately, in

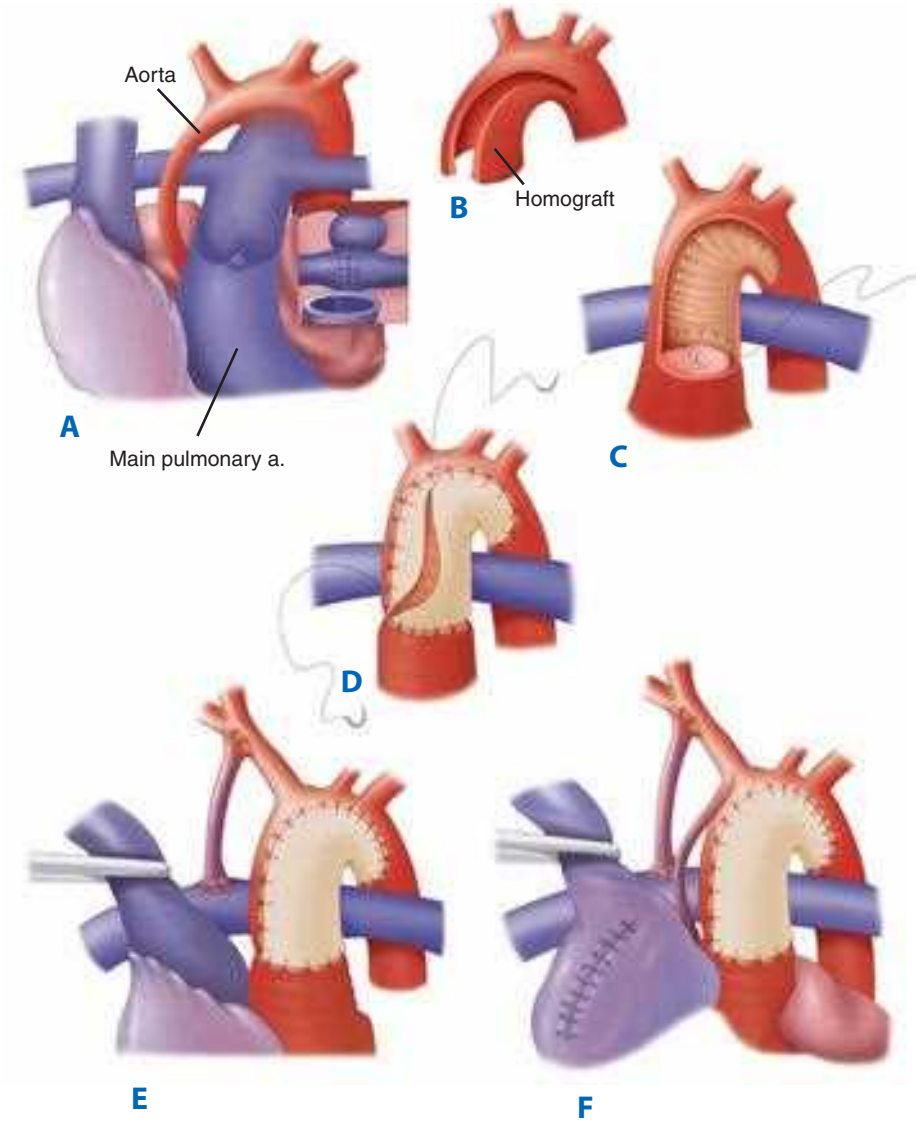

Figure 20-21. Current techniques for first-stage palliation of the hypoplastic left-heart syndrome. **A.** Incisions used for the procedure, incorporating a cuff of arterial wall allograft. The distal divided main pulmonary artery may be closed by direct suture or with a patch. **B.** Dimensions of the cuff of the arterial wall allograft. **C.** The arterial wall allograft is used to supplement the anastomosis between the proximal divided main pulmonary artery and the ascending aorta, aortic arch, and proximal descending aorta. **D** and **E.** The procedure is completed by atrial septectomy and a 3- to 5-mm modified right Blalock shunt. **F.** When the ascending aorta is particularly small, an alternative procedure involves placement of a complete tube of arterial allograft. The tiny ascending aorta may be left in situ, as indicated, or implanted into the side of the neoaorta. a. = artery. *(From Castaneda AR, Jonas RA, Mayer JE, et al.* Cardiac Surgery of the Neonate and Infant. *Philadelphia: W.B. Saunders; 1994:371, with permission. Copyright Elsevier.)*

many infants with HLHS, especially if there is aortic atresia, the aorta is diminutive and often less than 2 mm in diameter.

The postoperative management of infants following stage 1 palliation is complex because favorable outcomes depend on establishing a delicate balance between pulmonary and systemic perfusion. Recent literature suggests that these infants require adequate postoperative cardiac output in order to supply both the pulmonary and the systemic circulations and that the use of oximetric catheters to monitor mixed venous oxygen saturation (Svo_2) aids clinicians in both the selection of inotropic agents and in ventilatory management.[106] Recent introduction of a modification that includes arch reconstruction and placement of the shunt between the RV and the pulmonary artery (Sano shunt) diminishes the diastolic flow created by the classical B-T shunt and may augment coronary perfusion, resulting in improved postoperative cardiac function. A recent prospective, randomized, multi-institutional trial sponsored by the National Institutes of Health, the Systemic Ventricle Reconstruction (SVR) trial, compared the outcomes of neonates having either a modified B-T shunt vs. a Sano shunt.[107] The SVR trial demonstrated that transplantation-free survival 12 months after randomization was higher with the Sano shunt than with the modified B-T shunt (74% vs. 64%, $P = .01$). However, the Sano shunt group had more unintended interventions ($P = .003$) and complications ($P = .002$). Right ventricular size and function at the age of 14 months and the rate of nonfatal serious adverse events at the age of 12 months were similar in the two groups. Data collected over a mean (± standard deviation) follow-up period of 32 ± 11 months showed a nonsignificant difference in transplantation-free survival between the two groups ($P = .06$).[107]

5▶

Although surgical palliation with the Norwood procedure is still the mainstay of therapy for infants with HLHS,

a combined surgical and percutaneous option (hybrid procedure), which consists of bilateral pulmonary artery banding and placement of a ductal stent, has emerged as a promising alternative that obviates the need for CPB in the fragile neonatal period.[108,109] The hybrid procedure is performed in a "hybrid suite," incorporating both advanced fluoroscopic imaging facilities combined with complete operating room capabilities. A 3- or 3.5-mm PTFE tube graft is cut to a width of 3 to 4 mm and used as the bands on the branch pulmonary arteries, placed just distal to the main pulmonary artery. The ductal stent is then positioned in order to cover all ductal tissue and is deployed through a purse-string suture in the main pulmonary artery. A reverse systemic-to-pulmonary shunt is considered in patients with aortic atresia and preductal coarctation to improve coronary perfusion; however, a recent study demonstrated no difference in survival between those with and without the shunt.[110] The hybrid procedure can also be used as a bridge to heart transplantation in those infants with severe AV valve regurgitation or otherwise unsuitable single-ventricle anatomy.

Following stage 1 palliation, the second surgical procedure is the creation of a bidirectional cavopulmonary shunt or hemi-Fontan, generally at 3 to 6 months of life when the pulmonary vascular resistance has decreased to normal levels. This is the first step in separating the pulmonary and systemic circulations, and it decreases the volume load on the single ventricle. The existing innominate artery-to-pulmonary shunt (or RV-to-pulmonary shunt) is eliminated during the same operation (Fig. 20-22).

The third stage of surgical palliation, known as the modified Fontan procedure, completes the separation of the systemic and pulmonary circulations and is performed between 18 months and 3 years of age, or when the patient experiences increased cyanosis (i.e., has outgrown the capacity to perfuse the systemic circulation with adequately oxygenated blood). This has traditionally required a lateral tunnel within the right atrium to direct blood from the inferior vena cava to the pulmonary artery, allowing further relief of the volume load on the RV and providing increased pulmonary blood flow to alleviate cyanosis. More recently, many favor using an extracardiac conduit (e.g., 20-mm tube graft) to connect the inferior vena cava to the pulmonary artery.

Not all patients with HLHS require this three-stage palliative repair. Some infants afflicted with a milder form of HLHS, recently described as hypoplastic left heart complex (HLHC), have aortic or mitral hypoplasia without intrinsic valve stenosis and antegrade flow in the ascending aorta. In this group, a two-ventricle repair can be achieved with reasonable outcome. Tchervenkov recently published the results with 12 patients with HLHC who underwent biventricular repair at a mean age of 7 days.[106] The operative technique consisted of a pulmonary homograft patch aortoplasty of the aortic arch and ascending aorta and closure of the interatrial and interventricular communications. The left heart was capable of sustaining systemic perfusion in 92% of patients, and early mortality was 15.4%. Four patients required reoperations to relieve LVOT obstruction, most commonly between 12 and 39 months following repair.

Although the Norwood procedure is the most widely performed initial operation for HLHS, transplantation can be used as a first-line therapy and may be preferred when anatomic or physiologic considerations exist that preclude a

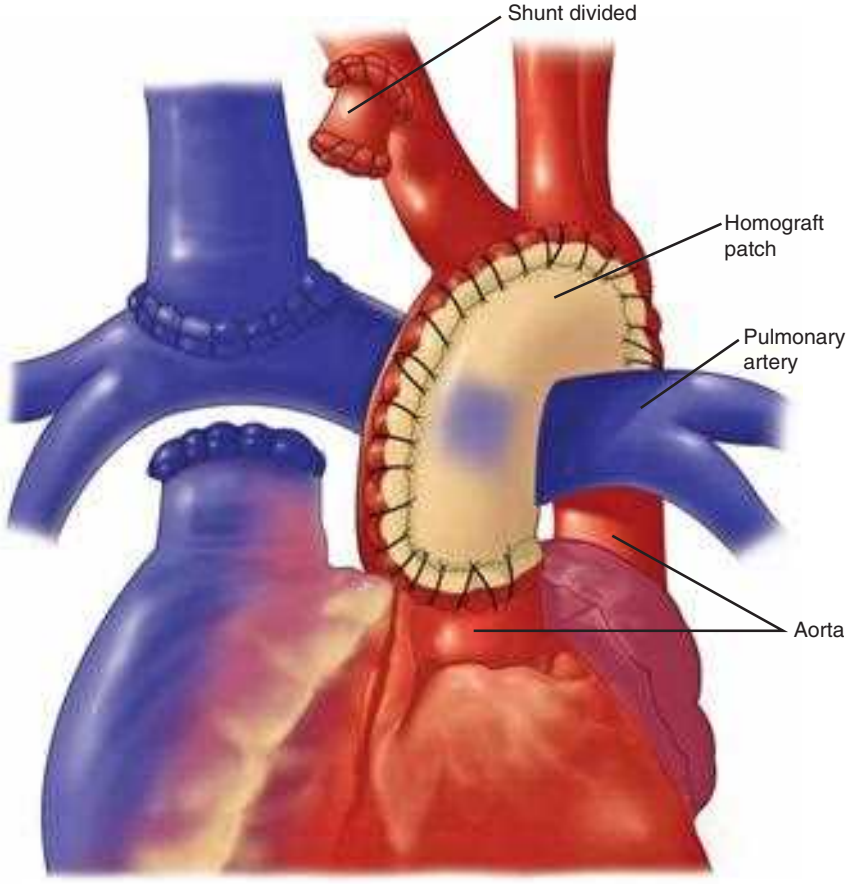

Figure 20-22. Technique of a bidirectional Glenn shunt. The divided right superior vena cava has been anastomosed at the previous site of the distal anastomosis of the modified right Blalock shunt. The cardiac end of the divided superior vena cava may also be anastomosed to the right pulmonary artery, with the internal orifice being closed with a Gore-Tex patch. *(From Castaneda AR, Jonas RA, Mayer JE, et al.* Cardiac Surgery of the Neonate and Infant. *Philadelphia: W.B. Saunders; 1994:376, with permission. Copyright Elsevier.)*

favorable outcome with palliative repair. Significant tricuspid regurgitation, intractable pulmonary artery hypertension, or progressive right ventricular failure are cases where cardiac replacement may be advantageous. Widespread adaptation of transplantation as first-line treatment for HLHS has been limited by improved Norwood survival rates as the operation and pre- and postoperative management of the patient have evolved and by limited organ availability. Organ availability should be considered prior to electing transplantation, as 24% of infants died awaiting transplantation in the largest series to date.[111,112]

Results. Outcomes for HLHS are still significantly worse than those for other complex cardiac defects. However, with improvements in perioperative care and modifications in surgical technique, the survival following the Norwood procedure now exceeds 80% in experienced centers.[100,105,107,109] The outcome for low-birth-weight infants has improved, but low weight still remains a major predictor of adverse survival, especially when accompanied by additional cardiac defects, such as systemic outflow obstruction or extracardiac anomalies.

DEFECTS THAT MAY BE PALLIATED OR REPAIRED

Ebstein's Anomaly

Anatomy. This is a rare defect, occurring in less than 1% of CHD patients. The predominant maldevelopment in this lesion is the inferior displacement of the tricuspid valve into the RV, although Bove[113] and others have emphasized the fact that Ebstein's anomaly is primarily a defect in right ventriclar morphology rather than an isolated defect in the tricuspid valve. The anterior leaflet is usually attached in its normal position to the annulus, but the septal and posterior leaflets are displaced toward the ventricle. This effectively divides the RV into two parts: the inlet portion (atrialized RV) and the outlet portion (true or trabeculated RV). The atrialized RV is usually thin and dilated. Similarly, the tricuspid annulus and the right atrium are extremely dilated, and the tricuspid valve is usually regurgitant with a "sail-like" leaflet. There is commonly an ASD present, which results in a right-to-left shunt at the atrial level. Occasionally, there is true anatomic pulmonary atresia or milder forms of RVOT obstruction.

A Wolff-Parkinson-White syndrome type of accessory pathway with associated pre-excitation is present in 15% of patients.[113]

Pathophysiology. Right ventricular dysfunction occurs in patients with Ebstein's anomaly because of two basic mechanisms: the inflow obstruction at the level of the atrialized ventricle, which produces ineffective RV filling and contractile dysfunction. Inflow obstruction and tricuspid regurgitation, which is exacerbated by progressive annular dilatation, both produce ineffective RV filling. Contractile dysfunction of the RV is a result of a decrease in the number of myocardial fibers, as well as the discordant contraction of the large atrialized portion.

The lack of forward flow at the right ventricular level may lead to physiologic or functional pulmonary atresia, and the infant is dependent on ductal patency for survival. All systemic venous return must be directed through an ASD to the left atrium, where it can be shunted through the ductus for gas exchange. However, the left ventricular function is usually compromised in infants with severe Ebstein's anomaly as well, because the enormous RV and the to-and-fro flow within the atrialized RV prevent adequate intracardiac mixing. Left ventricular function may also be severely compromised in Ebstein's anomaly because the large RV causes left ventricular compression.

Diagnosis. There is a spectrum of clinical presentation in infants with Ebstein's anomaly that mirrors the anatomic spectrum of this anomaly. Some infants with less severe forms may present with a mild degree of cyanosis, whereas the onset of clinical symptoms in patients surviving childhood is gradual, with the average age of diagnosis in the mid-teens.

However, the infant with severe atrialization and pulmonary stenosis will be both cyanotic and acidotic at birth. The chest radiograph may demonstrate the classic appearance, which consists of a globular "wall-to-wall" heart, similar to that seen with pericardial effusion. The ECG may show right bundle-branch block and right axis deviation. Wolff-Parkinson-White (WPW) syndrome, as mentioned earlier, is a common finding in these patients. Echocardiography will confirm the diagnosis and provide critical information including tricuspid valvular function, size of the atrialized portion of the RV, degree of pulmonary stenosis, and the atrial size.[6,113]

The Great Ormond Street Score (GOSE),[114] which consists of the area of the right atrium plus the area of the atrialized portion of the RV divided by the diastolic area of the remaining cardiac chambers, has been proposed as a useful prognostic tool to stratify neonates with Ebstein's anomaly. A score of greater than 1 translates into uniformly fatal outcome. Electrophysiology study with radiofrequency ablation is indicated in patients with evidence of WPW syndrome or in children with a history of supraventricular tachycardia, undefined wide-complex tachycardia, or syncope.

Treatment. Surgery is indicated for symptomatic infants and for older children and adults with arrhythmias, progressive cyanosis, or New York Heart Association class III or IV. However, the operative repair may be different, depending on the patient's age, because older children usually are candidates for a biventricular or one-and-a-half ventricle repair, whereas moderate survival has been reported for neonates, using a procedure that converts the anatomy to a single-ventricle physiology, as described by Starnes and coworkers.[115]

The surgical approach in widespread use today for patients surviving infancy was described by Danielson and colleagues in 1992.[6,113,116] This procedure entails excision of redundant right atrial tissue and patch closure of any associated ASD, plication of the atrialized portion of the ventricle with obliteration of the aneurysmal cavity, posterior tricuspid annuloplasty to narrow the tricuspid annulus, reconstruction of the tricuspid valve if the anterior leaflet is satisfactory, or replacement of the tricuspid valve if necessary.[116] If the tricuspid valve is not amenable to reconstruction, valve replacement should be considered. Care must be taken when performing the posterior annuloplasty, or during the conduct of tricuspid valve replacement, to avoid the conduction system, because complete heart block can complicate this procedure. In addition, patients who demonstrated preoperative evidence of pre-excitation should undergo electrophysiologic mapping and ablation.

Neonatal Ebstein's anomaly is a separate entity. Results with surgical correction have been poor, and many neonates are not candidates for operative repair as previously described. Surgical options for the symptomatic neonate include palliative procedures, the one-and-a-half ventricle repair, or conversion to single-ventricle physiology.[1,7,117] Arguably, the most favorable outcomes in symptomatic neonatal Ebstein's anomaly or repair in slightly older infants have been achieved using the right ventricular exclusion premise. This technique, known as the "Starnes" procedure,[115] uses a fenestrated patch to close the tricuspid valve orifice coupled with systemic-to-pulmonary artery shunt. The patch must be fenestrated to allow decompression of the RV in instances of anatomic pulmonary atresia. Although Knott-Craig and colleagues[117] have described tricuspid valve repair for the full spectrum of neonates and infants with excellent short- and mid-term results, these results have not been reproduced in other institutions.[118] The one-and-a-half ventricle repair was first described by Billingsly and coworkers as an attempt to achieve a more physiologic "pulsatile" pulmonary circulation in patients with a hypoplastic or dysplastic RV.[119] This is accomplished by diverting the superior vena caval blood directly into the pulmonary arterial system by a bidirectional cavopulmonary shunt while recruiting the RV to propel the inferior vena caval blood directly to the pulmonary arteries via the RVOT. Thus the hemodynamics of the one-and-a-half ventricle repair are characterized by separate systemic and pulmonary circulations in series. The systemic circulation is fully supported by a systemic ventricle, and the pulmonary circulation is supported by both the bidirectional Glenn shunt and the hypoplastic (pulmonary) ventricle. Proponents of this approach report a decreased right atrial pressure and a decrease in inferior vena cava hypertension, which is theorized to be responsible for many of the dreaded complications of the Fontan circulation, including protein-losing encephalopathy, hepatic congestion, atrial arrhythmias, and systemic ventricular failure. In addition, the maintenance of pulsatile pulmonary blood flow, as opposed to continuous laminar flow as in the Fontan circulation, may be advantageous to the pulmonary microcirculation, although it has not been proven in any studies thus far.[119,120] Certain criteria, most notably an adequate tricuspid valve Z score, as well as the absence of severe pulmonary hypertension or concomitant defects requiring intricate intracardiac repair, should be satisfied prior to electing the one-and-a-half ventricle approach.[121] Patients who do not fulfill these criteria may be approached with a two-ventricle repair and atrial fenestration or a Fontan repair.

In the infant with severe Ebstein's anomaly, initial stabilization with prostaglandin to maintain ductal patency, mechanical ventilation, and correction of cyanosis is mandatory. Metabolic acidosis, if present from compromised systemic perfusion, must be aggressively treated with afterload reduction. Many of these infants will improve over 1 to 2 weeks as pulmonary vascular resistance falls and they are able to improve antegrade flow into the pulmonary circulation through their abnormal RV and tricuspid valve. When stabilization and medical palliation fail, surgical management remains an option, although its success depends on numerous anatomic factors (e.g., adequacy of the tricuspid valve, RV and pulmonary outflow tract), and surgery for symptomatic neonates with Ebstein's anomaly carries a high risk. Recently, Knott-Craig and associates reported three cases where two-ventricle repair was undertaken by subtotal closure of the ASD, extensive resection of the right atrium, and vertical plication of the atrialized chamber.[117] Five-year follow-up revealed all patients to be asymptomatic and in sinus rhythm without medications.

Results. In the neonatal period, the most common postoperative problem, whether after a simple palliative procedure such as a B-T shunt or following a more extensive procedure such as attempted exclusion of the RV, has been low cardiac output. Supraventricular tachycardia also has been problematic postoperatively. Complete heart blockage necessitating pacemaker implantation should be uncommon if the techniques described to avoid suturing between the coronary sinus and the tricuspid annulus are used.

There are few published reports of outcomes, due to the rarity of this defect. However, based on the natural history of this condition, which is remarkably benign for the majority of older patients, the outlook should be excellent for patients who have survived ASD closure, plication, and tricuspid annuloplasty.[7,112,116,117]

Transposition of the Great Arteries

Anatomy. Complete transposition is characterized by connection of the atria to their appropriate ventricles with inappropriate ventriculoarterial connections. Thus, the aorta arises anteriorly from the RV, while the pulmonary artery arises posteriorly from the LV. Van Praagh and coworkers introduced the term D-transposition of the great arteries (D-TGA) to describe this defect, whereas L-TGA describes a form of corrected transposition where there is concomitant AV discordance.[122,123]

D-TGA requires an obligatory intracardiac mixing of blood, which usually occurs at both the atrial and the ventricular levels or via a patent ductus. Significant coronary anomalies occur frequently in patients with D-TGA.[7] The most common pattern, occurring in 68% of cases, is characterized by the left main coronary artery arising from the leftward coronary sinus, giving rise to the left anterior descending and circumflex arteries. The most common variant is for the circumflex coronary artery to arise as a branch from the right coronary artery instead of from the left coronary artery.

Pathophysiology. D-TGA results in parallel pulmonary and systemic circulations, with patient survival dependent on intracardiac mixing of blood. After birth, both ventricles are relatively noncompliant, and thus, infants initially have higher pulmonary flow due to the decreased downstream resistance. This causes left atrial enlargement and a left-to-right shunt via the patent foramen ovale.

Postnatally, the LV does not hypertrophy because it is not subjected to systemic afterload. The lack of normal extrauterine left ventricular maturation has important implications for the timing of surgical repair because the LV must be converted to the systemic ventricle and be able to function against systemic vascular resistance. If complete repair is done within the first few weeks of life, the LV usually adapts easily to systemic resistance since it is conditioned to high intrauterine pulmonary vascular resistance. After a few weeks of life, the LV that is conditioned to the decrease in pulmonary resistance that occurs when the lungs inflate after birth may have difficulty adapting to systemic vascular resistance without preoperative preparation or postoperative support. Novel techniques of LV "preparation" using a pulmonary arterial band have been used in cases where complete repair has been delayed.

Clinical Manifestations and Diagnosis. Infants with D-TGA and an intact ventricular septum are usually cyanotic

at birth, with an arterial Po_2 between 25 and 40 mmHg. If ductal patency is not maintained, deterioration will be rapid with ensuing metabolic acidosis and death. Conversely, those infants with a coexisting VSD may be only mildly hypoxemic and may come to medical attention after 2 to 3 weeks, when the falling pulmonary vascular resistance leads to symptoms of congestive heart failure.

The ECG will reveal right ventricular hypertrophy, and the chest radiograph will reveal the classic egg-shaped configuration. Definitive diagnosis is made by echocardiography, which reliably demonstrates ventriculoarterial discordance and any associated lesions. Cardiac catheterization is rarely necessary, except in infants requiring surgery after the neonatal period to assess the suitability of the LV to support the systemic circulation. Limited catheterization, however, is useful for performance of atrial septostomy in neonates with inadequate intracardiac mixing.

Surgical Repair. Blalock and Hanlon introduced the first operative intervention for D-TGA with the creation of an atrial septectomy to enhance intracardiac mixing.[124] This initial procedure was feasible in the pre-CPB era, but carried a high mortality rate. Later, Rashkind and Causo developed a catheter-based balloon septostomy, which largely obviated the need for open septectomy.[42]

These early palliative maneuvers, however, met with limited success, and it was not until the late 1950s, when Senning and Mustard developed the first "atrial repair," that outcomes improved. The Senning operation consisted of rerouting venous flow at the atrial level by incising and realigning the atrial septum over the pulmonary veins and using the right atrial free wall to create a pulmonary venous baffle (Fig. 20-23).[125]

Although the Mustard repair was similar, it made use of either autologous pericardium or synthetic material to create the interatrial baffle.[126] These atrial switch procedures resulted in a physiologic correction, but not an anatomic one, as the systemic circulation is still based on the RV. Still, survival rose to 95% in most centers by using an early balloon septostomy followed by an atrial switch procedure at 3 to 8 months of age.[125,126]

Despite the improved early survival rates, long-term problems, such as superior vena cava or pulmonary venous obstruction, baffle leak, arrhythmias, tricuspid valve regurgitation, and right ventricular failure, prompted the development of the arterial switch procedure by Jatene in 1975.[127] The arterial switch procedure involves the division of the aorta and the pulmonary artery, posterior translocation of the aorta (LeCompte maneuver), mobilization of the coronary arteries, placement of a pantaloon-shaped pericardial patch, and proper alignment of the coronary arteries on the neoaorta (Fig. 20-24).

The most important consideration is the timing of surgical repair, because arterial switch should be performed within 2 weeks after birth, before the LV loses its ability to pump against systemic afterload.[2,4,7] In patients presenting later than 2 weeks, the LV can be retrained with preliminary pulmonary artery banding and aortopulmonary shunt followed by definitive repair. Alternatively, the unprepared LV can be supported following arterial switch with a mechanical assist device for a few days while it recovers ability to manage systemic pressures. Echocardiography can be used to assess left ventricular performance and guide operative planning in these circumstances.

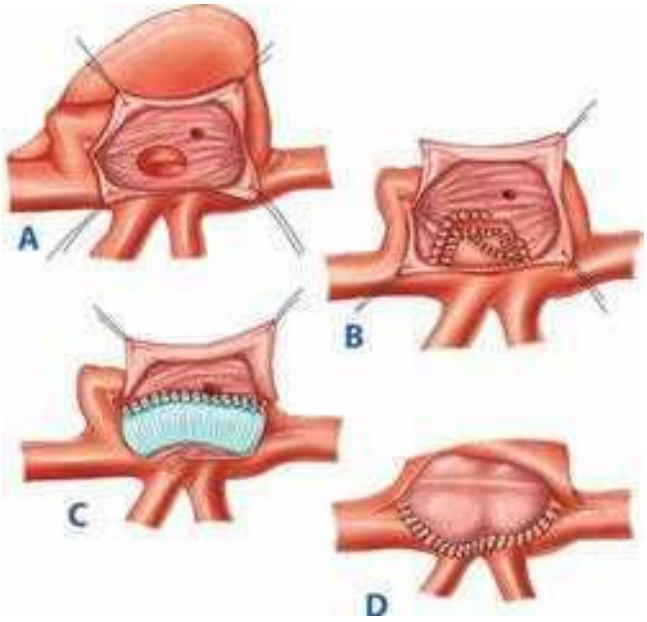

Figure 20-23. The Senning operation. **A.** The atrial septum is cut near the tricuspid valve, creating a flap attached posteriorly between the caval veins. **B.** The flap of atrial septum is sutured to the anterior lip of the orifices of the left pulmonary veins, effectively separating the pulmonary and systemic venous channels. **C.** The posterior edge of the right atrial incision is sutured to the remnant of the atrial septum, diverting the systemic venous channel to the mitral valve. **D.** The anterior edge of the right atrial incision (lengthened by short incisions at each corner) is sutured around the cava above and below to the lateral edge of the LA incision, completing the pulmonary channel and diversion of pulmonary venous blood to the tricuspid valve area. *(Reproduced with permission from D-Transposition of the great arteries. The subset of patients who present with D-TGA complicated by LVOT obstruction and VSD may not be suitable for an arterial switch operation. The Rastelli operation, first performed in 1968, uses placement of an intracardiac baffle to direct left ventricular blood to the aorta and an extracardiac valved conduit to establish continuity between the RV and the pulmonary artery, which has led to successful outcomes in these complex patients.[128]

Results. For patients with D-TGA, intact ventricular septum, and VSD, the arterial switch operation provides excellent long-term results with a mortality rate of less than 5%. Operative risk is increased when unfavorable coronary anatomic configurations are present or when augmentation of the aortic arch is required. The most common complication is supravalvular pulmonary stenosis, occurring 10% of the time, which may require reoperation.[4,7,129]

Results of the Rastelli operation have improved substantially, with an early mortality rate of 5% in a 2001 review.[130] Late mortality rate results were less favorable because conduit failure requiring reoperation, pacemaker insertion, or relief of LVOT obstruction was frequent.

Double-Outlet Right Ventricle

Anatomy. Double-outlet RV (DORV) accounts for 5% of CHD and exists when both the aorta and pulmonary artery arise wholly, or in large part, from the RV. DORV encompasses a spectrum of malformations, because the incomplete shift of the

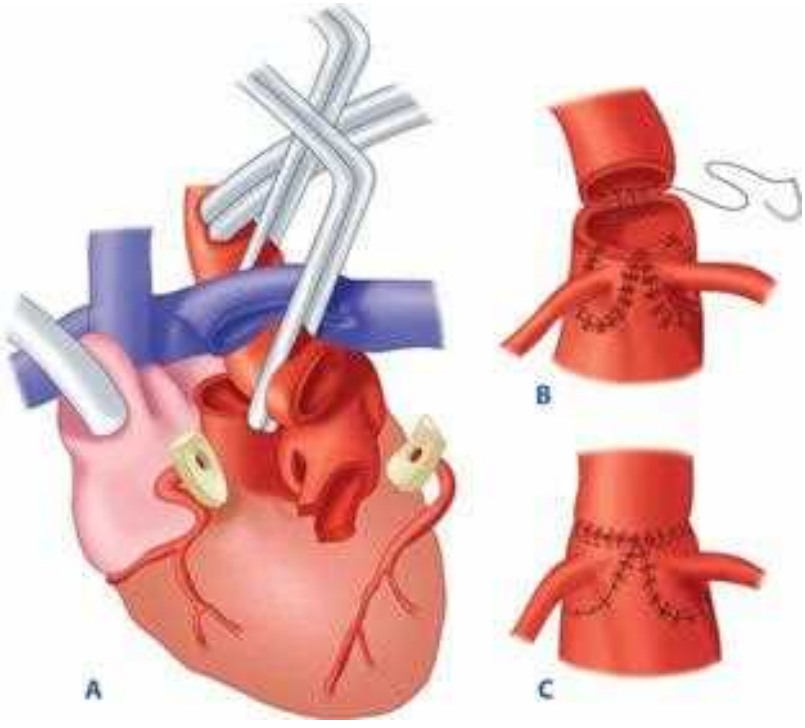

Figure 20-24. **A.** The maneuver of Lecompte (positioning the pulmonary artery anterior to the aorta) is shown with aortic cross-clamp repositioning to retract the pulmonary artery during the neoaortic reconstruction. **A** and **B.** After the coronary patches are rotated for an optimal lie, they are sutured to the linearly incised sinuses of Valsalva at the old pulmonary artery (neoaorta) (**C**). *(Reproduced with permission from Backer CL, Idriss FS, Mavroudis C. Surgical techniques and intraoperative judgments to facilitate the arterial switch operation in transposition with intact ventricular septum. In: Mavroudis C, Backer CL, eds.* Arterial Switch. Cardiac Surgery: State of the Art Review. *Vol. 5, no. 1. Philadelphia: Hanley & Belfus; 1991:108. Copyright Elsevier.)*

aorta toward the LV is often associated with other abnormalities of cardiac development, such as ventricular looping and infundibular-truncal spiraling.[131] The vast majority of hearts exhibiting DORV have a concomitant VSD, which varies in its size and spatial association with the great vessels. The VSD is usually nonrestrictive and represents the only outflow for the LV; its location relative to the great vessels dictates the dominant physiology of DORV, which can be analogous to that of a large isolated VSD, tetralogy of Fallot, or D-TGA. Lev et al, in 1972,[132] suggested considering DORV as a spectrum of hearts that "pass imperceptibly from tetralogy with VSD with overriding aorta into double-outlet right ventricle with subaortic VSD." Thus, Lev and colleagues described a classification scheme for DORV based on the "commitment" of the VSD to either or both great arteries.[7,132] The VSD can be subaortic, doubly committed, noncommitted, or subpulmonic.

The subaortic type is the most common (50%) and occurs when the VSD is located directly beneath the aortic annulus. Doubly committed VSD (10%) is present when the VSD lies beneath both the aorta and the pulmonary artery, which are usually side-by-side in this lesion. The noncommitted VSD (10%–20%) exists when the VSD is remote from the great vessels. The subset of DORV hearts with the VSD located beneath the pulmonary valve also are classified as the Taussig-Bing syndrome.[133] This occurs in 30% of cases of DORV with VSD, and it occurs when the aorta rotates more anteriorly, with the pulmonary artery rotated more posteriorly (Fig. 20-25).

Clinical Manifestations and Diagnosis. Patients with DORV typically present with one of the following three scenarios: (a) those with doubly committed or subaortic VSD present with congestive heart failure and a high propensity for pulmonary hypertension, much like infants with a large single VSD; (b) those with a subaortic VSD and pulmonary stenosis present with cyanosis and hypoxia, much like infants with tetralogy of Fallot; and (c) those with subpulmonic VSD present with cyanosis, much like those with D-TGA, because streaming directs desaturated systemic venous blood to the aorta and oxygenated blood to the pulmonary artery.[131] Thus, the three critical factors influencing the clinical presentation and subsequent management of infants with DORV are the size and loactaion of the VSD, the presence or absence of important RVOT obstruction, and the presence of other anomalies (especially associated hypoplasia of left-sided structures sometimes seen with subpulmonary VSD).

Echocardiography is the mainstay of diagnosis and can also provide valuable information regarding the feasibility of biventricular repair. Specific anatomic questions that should be resolved to assist in surgical planning in addition to those mentioned earlier include the coronary anatomy (presence of a conal branch or left anterior descending from the right coronary coursing across the conus), the presence of additional muscular VSDs remote from either great vessel, and the distance between the tricuspid and pulmonary valve. Cardiac catheterization is rarely necessary in neonates or infants, except to determine the degree of pulmonary hypertension and to determine the effects of previous palliative procedures on the pulmonary arterial anatomy.

Therapy. The goals of corrective surgery are to relieve pulmonary stenosis, to provide separate and unobstructed outflow pathways from each ventricle to the correct great vessel, and to achieve separation of the systemic and pulmonary circulations.

Double-Outlet Right Ventricle with Noncommitted Ventricular Septal Defect

The repair of hearts with DORV and noncommitted VSD can be accomplished by constructing an intraventricular tunnel connecting the VSD to the aorta, closing the pulmonary artery, and placing a valved extracardiac conduit from the RV to the pulmonary artery. In patients without pulmonary stenosis who

Double-outlet right ventricle.* Chest. *1975;68:672.)*

have intractable congestive failure, a pulmonary artery band can be placed in the first 6 months to control pulmonary artery overcirculation and prevent the development of pulmonary hypertension.

Infants with pulmonary stenosis can be managed with a systemic-to-pulmonary shunt followed by biventricular repair as described by Belli and colleagues in 1999, or with a modified Fontan.[134] There is no consensus on the timing of repair, but recent literature suggests that repair within the first 6 months is associated with better outcome. However, in cases where an extracardiac valved conduit is necessary, it is better to delay definitive repair until the child is 2 to 3 years of age, because this allows placement of a larger conduit and possibly reduces the number of future obligatory conduit replacements.[7,131]

Double-Outlet Right Ventricle with Subaortic or Doubly Committed Ventricular Septal Defect Without Pulmonary Stenosis

This group of patients can be treated by creating an intracardiac baffle that directs blood from the LV into the aorta. Enlargement of the VSD may be necessary to allow ample room for the baffle; this should be done anterosuperiorly to avoid injury to the conduction system that normally lies inferoposteriorly along the border of the VSD. In addition, other important considerations in constructing the LV outflow tunnel include the prominence of the conal septum, the attachments of the tricuspid valve to the conal septum, and the distance between the tricuspid and pulmonary valves. In some instances, unfavorable anatomy may preclude placement of an adequate intracardiac baffle, necessitating single ventricle repair.

Double-Outlet Right Ventricle with Subaortic or Doubly Committed Ventricular Septal Defect with Pulmonary Stenosis

Repair of this defect is similar to the above except that concomitant RVOT reconstruction must be performed in addition to the intracardiac tunnel. The RVOT augmentation can be accomplished with the placement of a transannular patch or with placement of an extracardiac valved conduit when an anomalous left anterior descending artery precludes use of a patch.

Taussig-Bing Syndrome without Pulmonary Stenosis

These infants are best treated with a balloon septostomy during the neonatal period to improve mixing, followed by VSD closure baffling LV egress to the pulmonary artery and an arterial switch operation. The Kawashima procedure,[135] in which an intraventricular tunnel is used to baffle LV egress directly to the aorta, may alternatively be used when the aorta is more posterior or when there is associated pulmonary stenosis.

Taussig-Bing Syndrome with Pulmonary Stenosis

This defect may be treated with a variety of techniques, depending on the specific anatomic details and the expertise of the treatment team. A Rastelli-type repair, which involves construction of an intraventricular tunnel through the existing VSD that connects the LV to both great vessels, followed by division of the pulmonary artery at its origin and insertion of a valved conduit from the RV to the distal pulmonary artery, can be performed.[136] Alternatively, a Yasui procedure, which involves baffling the VSD to the pulmonary artery and creation of a DKS anastomosis between the pulmonary artery and the aorta with patch augmentation, can be accomplished concomitant with placement of a RV-pulmonary artery conduit.[137]

Results. The results of DORV repairs are generally favorable, especially for the tetralogy-type DORV with subaortic VSD.[138,139] However, more complex types of DORV, including noncommitted VSD and Taussig-Bing type, still carry important morbidity and mortality.[134,138,139] Furthermore, repeated interventions for RVOT reconstruction or staged operations for patients triaged to single-ventricle pathways pose late hazards for patients surviving initial repair. A recent single-institution series evaluated 393 patients with DORV.[138] The authors found that the need for reintervention approached 37% at 15 years following repair. Arterial switch operation, as opposed

to Rastelli-type repair, was associated with an increased risk of early postrepair mortality, but mitigated against the risk of late death. Patients with hypoplastic left-sided structures and a nonsubaortic VSD may fare better with a single-ventricle repair.

Tetralogy of Fallot

Anatomy. The original description of tetralogy of Fallot (TOF) by Ettienne Louis Fallot,[140] as the name implies, included four abnormalities: a large perimembranous VSD adjacent to the tricuspid valve; an overriding aorta; a variable degree of RVOT obstruction, which might include hypoplasia and dysplasia of the pulmonary valve as well as obstruction at the subvalvar and pulmonary artery level; and right ventricular hypertrophy. More recently, the Van Praagh et al[141] pointed out that TOF could be more correctly termed monology of Fallot, since the four components are explained by the malposition of the infundibular septum. When the infundibular septum is displaced anteriorly and leftward, the RVOT is narrowed and its anterior displacement results in failure of fusion of the ventricular septum between the arms of the trabeculo-septo-marginalis (Fig. 20-26).

The morphology of TOF is markedly heterogeneous and includes an absent pulmonary valve, concomitant AV septal defects, and pulmonary atresia with major aortopulmonary collaterals. The present discussion will focus only on the so-called classic presentation of TOF without coexisting intracardiac defects.

Anomalous coronary artery patterns, related to either origin or distribution, have been described in TOF.[142] However, the most surgically important coronary anomaly occurs when the left anterior descending artery arises as a branch of the right coronary artery. This occurs in approximately 3% of cases of TOF and may preclude placement of a transannular patch, as the left anterior descending coronary artery crosses the RVOT at varying distances from the pulmonary valve annulus.[143]

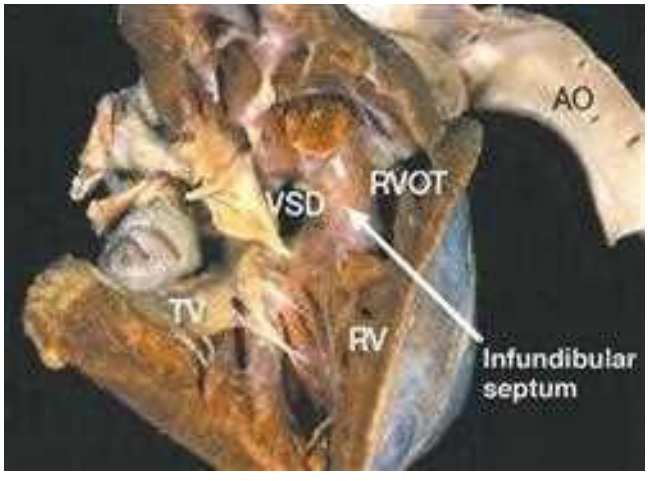

Figure 20-26. Pathologic specimen of the heart in a patient with tetralogy of Fallot. The four anatomic components comprising tetralogy of Fallot can be conceptualized as a monology of Fallot, because they can be explained by malposition of the interventricular septum. AO = aorta; RV = right ventricle; RVOT = right ventricular outflow tract; TV = tricuspid valve; VSD = ventricular septal defect. *(From Van Praagh et al,[141] with permission. © Elsevier Ltd.)*

Pathophysiology and Clinical Presentation. The initial presentation of a child afflicted with TOF depends on the degree of RVOT obstruction. Children with cyanosis at birth usually have severe pulmonary annular hypoplasia with concomitant hypoplasia of the peripheral pulmonary arteries. Most children, however, present with mild cyanosis at birth, which then progresses as the right ventricular hypertrophy further compromises the RVOT. Cyanosis usually becomes significant within the first 6 to 12 months of life, and the child may develop characteristic "tet" spells, which are periods of extreme hypoxemia. These spells are characterized by decreased pulmonary blood flow and an increase in systemic blood flow. They can be triggered by any stimulus that decreases systemic vascular resistance, such as fever, agitation, or vigorous physical activity. Cyanotic spells increase in severity and frequency as the child grows, and older patients with uncorrected TOF may often squat, which increases peripheral vascular resistance and relieves the cyanosis.

Evaluation in the older patient with TOF may demonstrate clubbing, polycythemia, hemoptysis, or brain abscesses. Chest radiography will demonstrate a boot-shaped heart, and ECG will show the normal pattern of right ventricular hypertrophy. Echocardiography confirms the diagnosis because it demonstrates the position and nature of the VSD, defines the character of the RVOT obstruction, and often visualizes the branch pulmonary arteries and the proximal coronary arteries. Cardiac catheterization is rarely necessary and is actually risky in TOF since it can create spasm of the RVOT muscle and result in a hypercyanotic episode (tet spell). Occasionally, aortography is necessary to delineate the coronary artery anatomy.

Treatment. John Deanfield[144] stated "…long follow-up inevitably means surgery in an earlier era: More recent surgery, at a younger age, with better preoperative, operative, and postoperative care, will improve long-term results. Data from the former (earlier) era will be overly pessimistic." This statement is particularly pertinent as surgical correction of TOF has evolved from a staged approach of antecedent palliation in infancy followed by intracardiac repair to primary repair during the first few months of life without prior palliative surgery.

However, systemic-to-pulmonary shunts, generally a B-T shunt, may still be preferred with an unstable neonate younger than 3 months of age, when an extracardiac conduit is required because of an anomalous left anterior descending coronary artery, or when pulmonary atresia, significant branch pulmonary artery hypoplasia, or severe noncardiac anomalies coexist with TOF.

Traditionally, TOF was repaired through a right ventriculotomy, providing excellent exposure for closure of the VSD and relief of the RVOT obstruction, but concerns that the resultant scar would significantly impair right ventricular function or lead to lethal arrhythmias led to the development of a transatrial approach. Transatrial repair, except in cases when the presence of diffuse RVOT hypoplasia requires insertion of a transannular patch, is now being increasingly advocated by many, although its superiority has not been conclusively demonstrated.[145]

The operative technique involves the use of CPB. All existing systemic-to-pulmonary arterial shunts, as well as the ductus arteriosus, are ligated. A right atriotomy is then made, and the anatomy of the VSD and the RVOT are assessed by

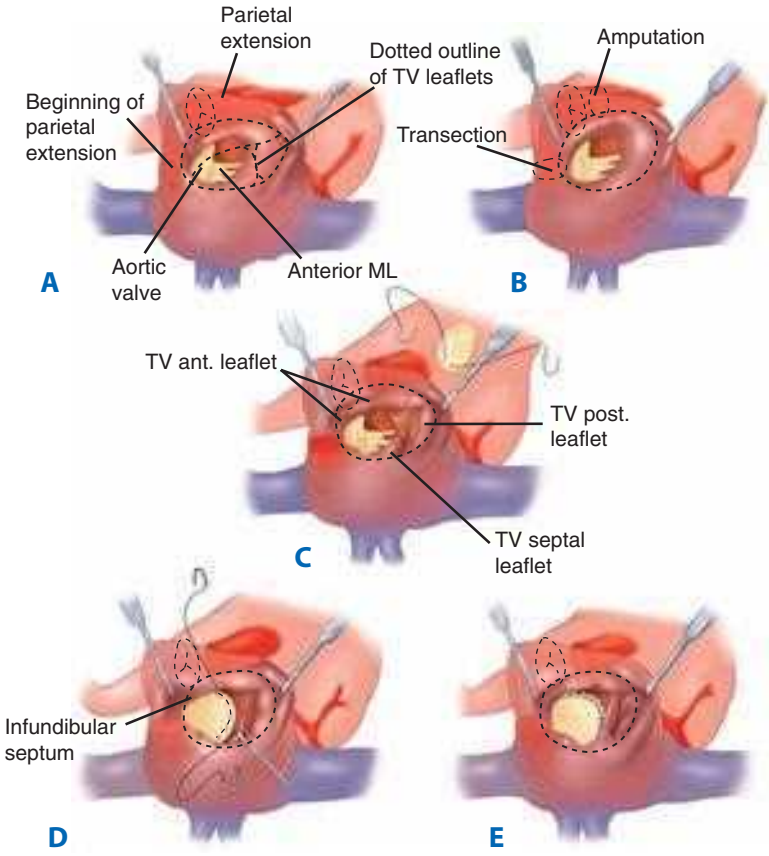

Figure 20-27. The anatomy from the perspective of the right atrial (RA) approach, shown as if the right atrial free wall and tricuspid valve were translucent. The free edge of the tricuspid leaflets is shown by dashed lines. **A.** The difference from the right ventricular (RV) perspective is in the apparent position of the parietal extension. From the RA perspective, the surgeon looks *beneath* this, as the parietal extension arches *over* the right ventricular outflow tract. **B.** The same perspective without the outline of the tricuspid valve leaflets. The parietal extension is transected at its origin from the infundibular septum, dissected up toward the free wall, and amputated at the free wall. **C.** A pledgetted mattress suture is placed from the RA side through the base of the commissural tissue between septal and tricuspid leaflets and through the patch. **D.** The suturing is continued onto the parietal extension and infundibular septum, visualizing and staying close to the aortic valve leaflets to avoid leaving a hole between muscular bands. When working from the RA, it is particularly important to stay close to the aortic valve leaflets in the direction of the septum to avoid narrowing the RV outflow tract. **E.** The repair of the ventricular septal defect is completed. Note that the suture line is away from the bundle of His and its branches, except where it crosses the right bundle branch anteroinferiorly. ant. = anterior; ML = mitral leaflet; post. = posterior; TV = tricuspid valve. *(Reproduced with permission from Kouchoukos NT, Blackstone EH, et al: Kirklin/Barratt-Boyes* Cardiac Surgery. *4th ed. Philadelphia: Elsevier, 2013, p 1384. Copyright Elsevier.)*

retracting the tricuspid valve (Fig. 20-27). The outflow tract obstruction is relieved by resecting the offending portion of the infundibular septum as well as any muscle trabeculations. If necessary, a pulmonary valvotomy or, alternatively, a longitudinal incision in the main pulmonary artery can be performed to improve exposure. The diameter of the pulmonary valve annulus is assessed by inserting Hegar dilators across the outflow tract; if the pulmonary artery/aorta diameter is less than 0.5, or the estimated RV/LV pressure is greater than 0.7, a transannular patch is inserted.[21] Patch closure of the VSD is then accomplished, taking care when placing sutures along the posteroinferior portion to avoid the conduction system.

Results. Operative mortality for primary repair of TOF in infancy is less than 5% in most series.[4,7,145] Previously reported risk factors such as transannular patch insertion or younger age at time of repair have been eliminated secondary to improved intraoperative and postoperative care. According to the Society of Thoracic Surgeons Congenital Heart Surgery Database, discharge mortality from 3059 operations from 2002 to 2007 was 7.5% for initial palliation, 1.3% for primary repair, and 0.9% for staged repair, indicating receiving outcomes for patients getting primary repair compared to staged repair.[146] Nevertheless, for neonatal repair, discharge mortality increased to 6.2% with palliation and 7.8% with primary repair. This may be partly explained by a higher chance of postoperative complications in neonates.

A major complication of repaired TOF is the development of pulmonary insufficiency, which subjects the RV to the adverse effects of acute and chronic volume overload. This is especially problematic if residual lesions such as a VSD or peripheral pulmonary stenosis exist. Pulmonary valve regurgitation after repair of TOF is relatively well tolerated in the short term, partly because the hypertrophied RV usually adapts to the altered hemodynamic load.[147,148] The detrimental effects of chronic pulmonary valve regurgitation are, however, numerous, and include progressive right ventricular dilatation and failure, tricuspid valve regurgitation, exercise intolerance, arrhythmia, and sudden death. Mechanoelectrical interaction, by which a dilatated RV provides the substrate for electrical instability, might underlie the propensity toward ventricular arrhythmia.[149] In support of this contention, Gatzoulis and colleagues[147,149] found that the risk of symptomatic arrhythmia was high in patients with marked right ventricular enlargement and QRS prolongation on resting ECG of more than 180 ms. Karamlou et al have shown that similar structural and hemodynamic abnormalities, including a larger right atrial volume and right ventricular chamber size, are also related to atrial arrhythmias in patients following TOF repair.[150] We found that prolongation of the QRS duration beyond a threshold of 160 ms increased the risk of atrial arrhythmias.[150] Together, these data show that a similar mechanism could be responsible for both atrial and ventricular arrhythmias after repair in TOF patients.

When significant deterioration of ventricular function occurs, insertion of a pulmonary valve may be required, although this is rarely necessary in infants. Unfortunately, there are no universal criteria establishing the timing of pulmonary valve replacement, although dilation of the RV, prolongation of the QRS duration beyond 180 ms, important atrial arrhythmias, and impaired ventricular function are widely used.

Arrhythmias are potentially the most serious late complication following TOF repair. In a multicenter cohort of 793 patients studied by Gatzoulis et al,[149] a steady increase was documented in the prevalence of ventricular and atrial tachyarrhythmia and sudden cardiac death in the first 5 to 10 years after intracardiac repair. Clinical events were reported in 12% of patients at 35 years after repair. Prevalence of atrial arrhythmias from other studies, however, ranges from 1% to 11%,[147,149] which is a reflection of the strong time dependence of arrhythmia onset.

Underlying causes of arrhythmia following repair are complex and multifactorial, resulting in poorly defined optimum screening and treatment algorithms. Older repair age has been associated with an increased frequency of both atrial and ventricular arrhythmias. Impaired ventricular function secondary to a protracted period of cyanosis before repair might contribute to the propensity for arrhythmia in older patients.

Ventricular Septal Defect

Anatomy. VSD refers to a hole between the LV and RV. These defects are common, comprising 20% to 30% of all cases of CHD, and may occur as an isolated lesion or as part of a more complex malformation.[151] VSDs vary in size from 3 to 4 mm to more than 3 cm and are classified into four types based on their location in the ventricular septum: perimembranous, AV canal, outlet or supracristal, and muscular (Fig. 20-28).

Perimembranous VSDs are the most common type requiring surgical intervention, comprising approximately 80% of cases.[151] These defects involve the membranous septum and include the malalignment defects seen in tetralogy of Fallot. In rare instances, the anterior and septal leaflets of the tricuspid valve adhere to the edges of the perimembranous defect, forming a channel between the LV and the right atrium. These defects result in a large left-to-right shunt due to the large pressure differential between the two chambers.

AV canal defects, also known as inlet defects, occur when part or all of the septum of the AV canal is absent. The VSD lies beneath the tricuspid valve and is limited upstream by the tricuspid annulus, without intervening muscle.

The supracristal or outlet VSD results from a defect within the conal septum. Characteristically, these defects are limited upstream by the pulmonary valve and are otherwise surrounded by the muscle of the infundibular septum.

Muscular VSDs are the most common type and may lie in four locations: anterior, midventricular, posterior, or apical. These are surrounded by muscle and can occur anywhere

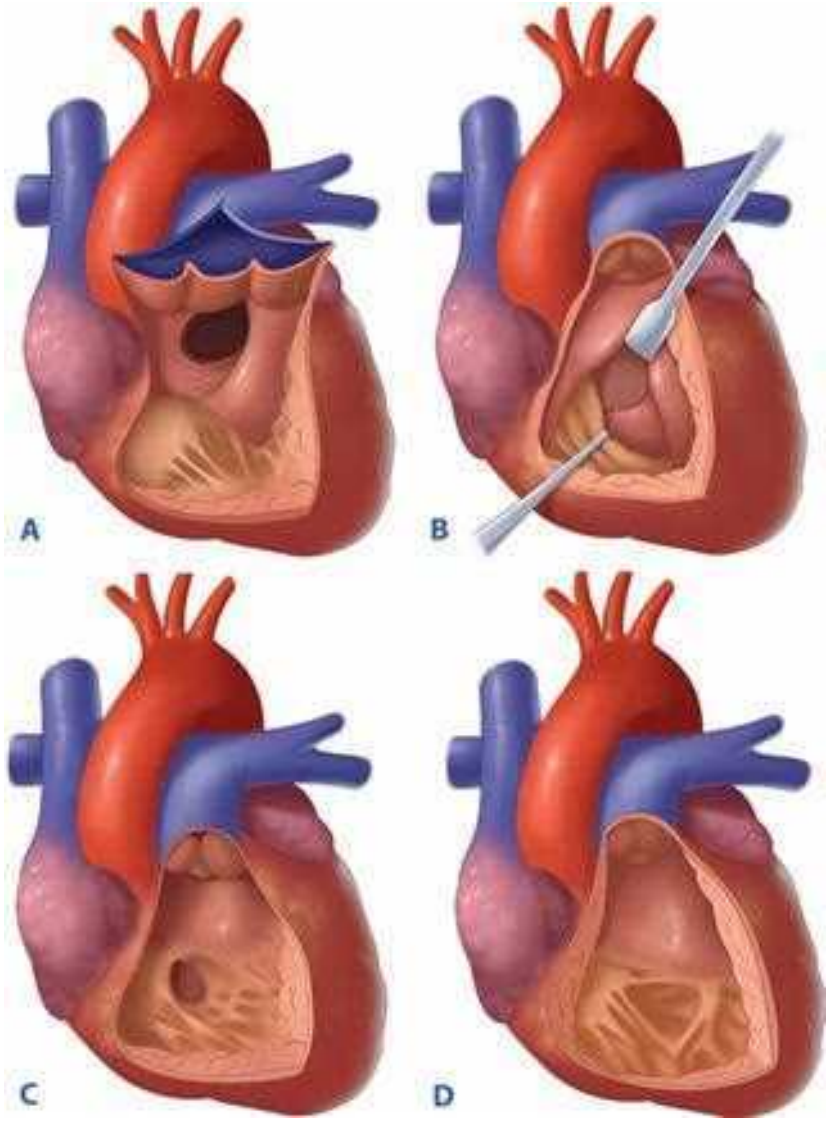

Figure 20-28. Classic anatomic types of ventricular septal defect (VSD). **A.** Type I (conal, infundibular, supracristal, subarterial) VSD. **B.** Type II or perimembranous VSD. **C.** Type III VSD (atrioventricular canal type or inlet septum type). **D.** Type IV VSD (single or multiple). *(Reproduced with permission from Ventricular septal defect. In: Mavroudis C, Backer CL, eds.* Pediatric Cardiac Surgery. *2nd ed. St. Louis: Mosby; 1994:70.)*

along the trabecular portion of the septum. The rare "Swiss-cheese" type of muscular VSD consists of multiple communications between the RV and LV, complicating operative repair.

Pathophysiology and Clinical Presentation. The size of the VSD determines the initial pathophysiology of the disease. Large VSDs are classified as nonrestrictive and are at least equal in diameter to the aortic annulus. These defects allow free flow of blood from the LV to the RV, elevating right ventricular pressures to the same level as systemic pressure. Consequently, the pulmonary-to-systemic flow ratio (Qp:Qs) is inversely dependent on the ratio of pulmonary vascular resistance to systemic vascular resistance. Nonrestrictive VSDs produce a large increase in pulmonary blood flow, and the afflicted infant will present with symptoms of congestive heart failure. However, if untreated, these defects will cause pulmonary hypertension with a corresponding increase in pulmonary vascular resistance. This will lead to a reversal of flow (a right-to-left shunt), which is known as Eisenmenger's syndrome.

Small restrictive VSDs offer significant resistance to the passage of blood across the defect, and therefore right ventricular pressure is either normal or only minimally elevated and Qp:Qs rarely exceeds 1.5.[4,7] These defects are generally asymptomatic because there are few physiologic consequences. However, there is a long-term risk of endocarditis, because endocardial damage from the jet of blood through the defect may serve as a possible nidus for colonization.

Diagnosis. The child with a large VSD will present with severe congestive heart failure and frequent respiratory tract infections. Children with Eisenmenger's syndrome may be deceptively asymptomatic until frank cyanosis develops.

The chest radiograph will show cardiomegaly and pulmonary overcirculation, and the ECG will show signs of left ventricular or biventricular hypertrophy. Echocardiography provides definitive diagnosis and can estimate the degree of shunting as well as pulmonary arterial pressures. Cardiac catheterization has largely been supplanted by echocardiography, except in older children where measurement of pulmonary resistance is necessary prior to recommending closure of the defect.

Treatment. VSDs may close or narrow spontaneously, and the probability of closure is inversely related to the age at which the defect is observed. Thus, infants at 1 month of age have an 80% incidence of spontaneous closure, whereas a child at 12 months of age has only a 25% chance of closure.[152] This has an important impact on operative decision making, because a small or moderate-size VSD may be observed for a period of time in the absence of symptoms. Large defects and those in severely symptomatic neonates should be repaired during infancy to relieve symptoms and because irreversible changes in pulmonary vascular resistance may develop during the first year of life.

Repair of isolated VSDs requires the use of CPB with moderate hypothermia and cardioplegic arrest. The right atrial approach is preferable for most defects, except apical muscular defects, which often require a right ventriculotomy for adequate exposure. Supracristal defects may alternatively be exposed via a transverse or longitudinal incision in the RV immediately beneath the pulmonary valve. Regardless of the type of defect present, a right atrial approach can be used initially to inspect the anatomy, as this may be abandoned should it offer inadequate exposure for repair. After careful inspection of the heart for any associated malformations, a patch repair is employed, taking care to avoid the conduction system (Fig. 20-29). Routine use of intraoperative transesophageal echocardiography should be used to assess for any residual defects.

Successful percutaneous device closure of VSDs using the Amplatzer muscular VSD was recently described.[153] The device has demonstrated a 100% closure rate in a small series of patients with isolated or residual VSDs, or as a collaborative treatment strategy for the VSD component in more complex congenital lesions. Proponents of device closure argue that its use can decrease the complexity of surgical repair, avoid reoperation for a small residual lesion, or avoid the need for a ventriculotomy.

Multiple or "Swiss-cheese" VSDs represent a special case, and many cannot be repaired during infancy. In patients in whom definitive VSD closure cannot be accomplished, temporary placement of a pulmonary artery band can be employed to control pulmonary flow. This allows time for spontaneous closure of many of the smaller defects, thus simplifying surgical repair.

Some centers, however, have advocated early definitive repair of the Swiss-cheese septum, by using oversize patches, fibrin glue, and combined intraoperative device closure, as well as techniques to complete the repair transatrially.[154] At the University of California, San Francisco, 69% of patients with multiple VSDs underwent single-stage correction, and the repaired group had improved outcome compared with the palliated group.[154]

Results. Even in very small infants, closure of VSDs can be safely performed with hospital mortality near 0%.[4,7,155] The main risk factor remains the presence of other associated lesions, especially when present in symptomatic neonates with large VSDs.

Atrioventricular Canal Defects

Anatomy. AV canal defects result from failure of fusion of the endocardial cushions in the central portion of the heart, causing a lesion that involves the atrial and the ventricular septum, as well as the anterior mitral and septal tricuspid valve leaflets. Defects involving primarily the atrial septum are known as partial AV canal defects and frequently occur in conjunction with a cleft anterior mitral leaflet. Complete AV canal defects have a combined deficiency of the atrial and ventricular septum associated with a common AV orifice rather than separate tricuspid and mitral valves. The common AV valve generally has five leaflets, three lateral (free wall) and two bridging (septal) leaflets. The defect in the ventricular septum can lie either between the two bridging leaflets or beneath them. The relationship between the septal defect and the anterior bridging leaflet forms the basis of the Rastelli classification for complete AV canal defects (Fig. 20-30).[156]

Pathophysiology and Diagnosis. Partial AV canal defects, in the absence of AV valvular regurgitation, frequently resemble isolated ASDs. Left-to-right shunting predominates as long as pulmonary vascular resistance remains low. However, 40% of patients with partial AV canal defects have moderate-to-severe valve incompetence, and progressive heart failure

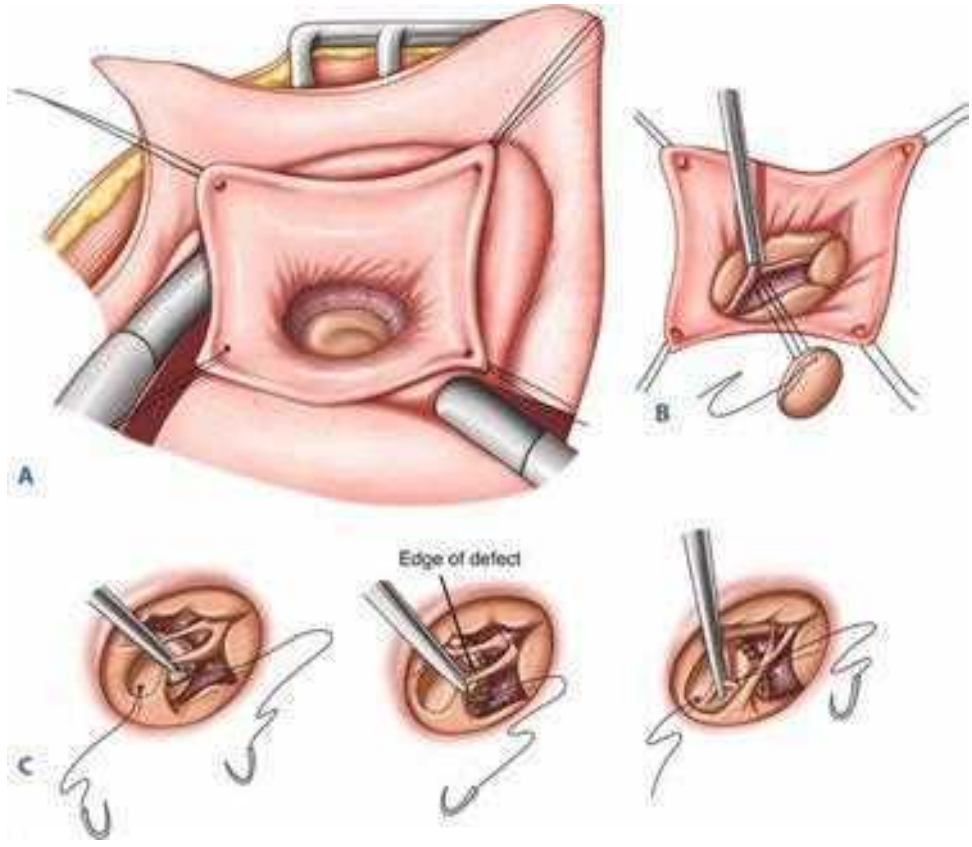

Figure 20-29. **A.** Right atrial incision and exposure of perimembranous ventricular septal defect (VSD) in the region of the tricuspid anteroseptal commissure. Stay sutures have been placed to slightly evert the atrial wall. Note that initially, the superior edge of this typical perimembranous defect is not visible. The atrioventricular node is in the muscular portion of the atrioventricular septum, just on the atrial side of the commissure between the tricuspid septal and anterior leaflets. The bundle of His thus penetrates at the posterior angle of the VSD, where it is vulnerable to injury. **B** and **C.** The repair of the perimembranous VSD is completed with use of a slightly oversized Dacron patch, taking care to place stitches 3 to 5 mm away from the edge of the defect itself to avoid injury to the conduction system. *(Reproduced with permission from Walters HL, Pacifico AD, Kirklin JK: Ventricular septal defects. occurs early in this patient population.[157] Complete AV canal defects produce more severe pathophysiologic changes, because the large intracardiac communication and significant AV valve regurgitation contribute to ventricular volume loading and pulmonary hypertension. Children with complete AV canal defects develop signs of congestive heart failure within the first few months of life.

Physical examination may reveal a right ventricular heave and a systolic murmur. Children may also present with endocarditis or paradoxical emboli as a result of the intracardiac communication. Chest radiography will be consistent with congestive heart failure, and the ECG demonstrates right ventricular hypertrophy with a prolonged PR interval.

Two-dimensional echocardiography with color-flow mapping is confirmatory, but cardiac catheterization can be employed to define the status of the pulmonary vasculature, with a pulmonary vascular resistance greater than 12 Wood units indicating inoperability.[157]

Treatment. The management of patients with AV canal defects can be especially challenging. Timing of operation is individualized. Patients with partial defects can be electively repaired between 2 and 5 years of age, whereas complete AV canal defects should be repaired within the first year of life to prevent irreversible changes in the pulmonary circulation. Complete repair in infancy should be accomplished, with palliative procedures such as pulmonary artery banding reserved for only those infants with other complex lesions or who are too ill to tolerate CPB.

The operative technique requires the use of either continuous hypothermic CPB or, for small infants, deep hypothermic circulatory arrest. The heart is initially approached through an oblique right atriotomy, and the anatomy is carefully observed. In the case of a partial AV canal, the cleft in the mitral valve is repaired with interrupted sutures and the ASD is closed with a pericardial patch.[148] Complete AV canal defects are repaired by patch closure of the VSD, separating the common AV valve into tricuspid and mitral components and suspending the neovalves from the top of the VSD patch and closing the ASD.

Results. Partial AV canal defects have an excellent outcome, with a mortality rate of 0% to 2% in most series.[156] Complete AV canal defects are associated with a poorer prognosis, with an operative mortality of 3% to 13%.

The most frequently encountered postoperative problems are complete heart block (1%–2%), right bundle-branch block (22%), arrhythmias (11%), RVOT obstruction (11%), and severe mitral regurgitation (13%–24%).[156] The increasing use of intraoperative transesophageal echocardiography may positively influence outcomes, as the adequacy of repair can be assessed and treated without need for subsequent reoperation.[156-158]

Interrupted Aortic Arch

Anatomy. Interrupted aortic arch (IAA) is a rare defect, comprising approximately 1% of all cases of CHD.[7,148] It is defined as an absence of luminal continuity between the ascending and descending aorta and does not occur as an isolated defect in most cases, because a VSD or PDA is usually present. IAA is classified based on the location of the interruption (Fig. 20-31).

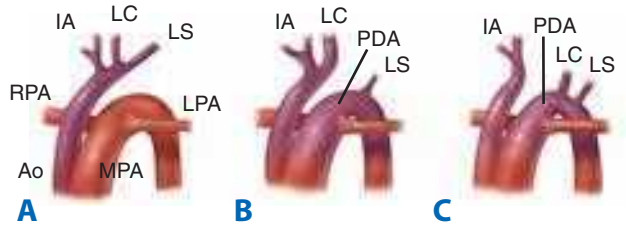

Figure 20-31. Anatomic types of interrupted aortic arch. **A.** Interruption distal to the left subclavian artery. **B.** Interruption between the left subclavian and left carotid arteries. **C.** Interruption between the left carotid and innominate arteries. Ao = aorta; IA = innominate artery; LPA, MPA, RPA = left, main, and right pulmonary arteries; LC = left carotid artery; LS = left subclavian artery; PDA = patent ductus arteriosus. *(Reproduced with permission from Jonas RA. Interrupted aortic arch. In: Mavroudis C, Backer CL, eds.* Pediatric Cardiac Surgery. *2nd ed. St. Louis: Mosby; 1994:184.)*

Clinical Manifestations and Diagnosis. Infants with IAA have ductal-dependent systemic blood flow and will develop profound metabolic acidosis and hemodynamic collapse upon ductal closure. In the rare instance of failed ductal closure, the diagnosis may be missed during infancy, and the child will present with symptoms of congestive heart failure from a persistent left-to-right shunt.

Once definitive diagnosis is made in infants, usually with echocardiography, preparations are made for operative intervention, and prostaglandin E_1 is infused to maintain ductal patency and correct acidosis. The infant's hemodynamic status should be optimized with mechanical ventilation and inotropic support. An effort should be made to increase pulmonary vascular resistance by decreasing the fractional inspired oxygen and avoiding hyperventilation, because this will preferentially direct blood into the systemic circulation.

Treatment. Initial strategies for the management of IAA involved palliation though a left thoracotomy by using one of the arch vessels as a conduit to restore aortic continuity. Pulmonary artery banding can be simultaneously performed to limit left-to-right shunting, because it is not feasible to repair the VSD or other intracardiac communications with this approach.

However, complete surgical repair in infants with IAA is now preferable. The operative technique involves use of a median sternotomy and CPB with short periods of circulatory arrest. Aortic arch reconstruction can be accomplished with either direct anastomosis or patch aortoplasty followed by closure of the VSD.[148]

In certain cases, the defect will involve hypoplasia of the left heart, precluding attempts at definitive repair. These infants should be managed with a Norwood procedure followed by a Fontan repair.

Results. Outcomes in infants with IAA have improved substantially over the last decades as a result of improved perioperative care. Operative mortality is now less than 10% in most series.[157] Some authors advocate the use of patch augmentation of the aorta to ensure adequate relief of LVOT obstruction and to diminish anastomotic tension, thus reducing the subsequent risk of restenosis and tracheobronchial compression.[7,157,159]

chapter 21

Acquired Heart Disease

Shoichi Okada, Jason O. Robertson, Lindsey L. Saint, and Ralph J. Damiano, Jr.

CARDIAC ASSESSMENT

Clinical Evaluation

As with any other field in medicine, history, and physical examination form the foundation for the evaluation of a patient with acquired heart disease requiring surgical intervention. Obtaining a complete history will help identify comorbid conditions and assist in delineating the operative risks and prognosis after surgery. Physical examination not only reveals factors that may increase the complexity of surgery, such as previous surgery or peripheral or cerebral vascular disease. These may influence the operative approach but also help guide the choice and sequencing of diagnostic studies. A complete assessment of the patient allows the surgeon to make educated decisions regarding the optimal treatment strategy for the patient.

History

Symptoms suggestive of heart disease include: chest discomfort, fatigue, edema, dyspnea, palpitations, and syncope. Adequate definition of these symptoms calls for a detailed history-taking paying particular attention to onset, intensity, radiation, duration, and exacerbating/alleviating factors. The demands on the heart are determined by its loading conditions and metabolic state of the body, and symptoms are commonly accentuated with physical exertion or postural changes.

Angina pectoris is the hallmark of coronary artery disease (CAD), but may occur with other cardiac pathologies which results in ischemia from a mismatch between the supply of oxygen by the coronary circulation and the metabolic demand of the myocardium. Typically, angina is described as tightness, heaviness, or dull pain, most frequently substernal in location, lasting for a few minutes. This discomfort may radiate to the left arm, neck, mandible, or epigastrium. It is most often provoked by activities that increase metabolic demand on the heart such as exercise, eating, and states of intense emotion, and is typically alleviated by rest or use of nitroglycerin. It is important to note that a significant number of patients with myocardial ischemia, particularly diabetics, females, and the elderly, may have "silent" angina or angina equivalents (dyspnea, diaphoresis, nausea, or fatigue). The overlap of these features with those

Key Points

1. Although advances have been made in percutaneous coronary intervention techniques for coronary artery disease, survival is superior with coronary artery bypass grafting in patients with left main disease, multivessel disease, and in diabetic patients.
2. Coronary artery bypass grafting has become increasingly safe, and improves late mortality in patients with left main or proximal left anterior descending disease, multivessel disease, and in patients with diabetes.
3. Despite the theoretical advantages, the superiority of off-pump coronary artery bypass to conventional coronary artery bypass grafting has not been clearly established and other factors likely dominate the overall outcome for either technique.
4. Although mechanical valves offer enhanced durability over tissue valve prosthesis, they require permanent systemic anticoagulation therapy to mitigate the risk of valve thrombosis and thromboembolic sequelae, and thus are associated with an increased risk of hemorrhagic complications.
5. Mitral valve repair is recommended over mitral valve replacement in the majority of patients with severe chronic mitral regurgitation. The decision to proceed with mitral valve repair is based on the skill and experience of the surgeon in performing repair, and on the location and type of mitral valve disease encountered at the time of operation.
6. Although open aortic valve replacement has traditionally been the only effective treatment in patients with severe calcific aortic stenosis, transcatheter aortic valve replacement is a developing technology that has proven beneficial for the treatment of aortic stenosis in seriously ill patients that had previously been deemed high risk or inoperable.
7. Mechanical circulatory support with newer generation continuous flow left ventricular assist devices has proven to be durable and effective both in bridging patients to transplant and as a means of "destination therapy" for patients who are not transplant candidates. Recent results for destination therapy have approached those of cardiac transplantation.
8. Performing a biatrial Cox-Maze lesion set results in freedom from atrial fibrillation in approximately 90% of patients and is superior to both catheter-ablation and more limited lesion sets for patients with persistent atrial fibrillation or enlarged left atria. Surgical ablation of atrial fibrillation is recommended for patients referred with concomitant valvular disease and those who have previously failed or are poor candidates for catheter-based approaches.
9. The preferred treatment for pericarditis depends on the underlying cause, although the disease typically follows a self-limited course and is best managed medically. Surgical pericardiectomy may have a role in treating relapsing pericarditis and, more commonly, chronic constrictive pericarditis.
10. Myxomas are the most common cardiac tumors, and, while benign, they should be promptly excised after diagnosis due to the risk of embolization, obstructive complications, and arrhythmias.

of noncardiac etiologies such as costochondritis, biliary colic, gastroesophageal reflux disease, diffuse esophageal spasm, and peptic ulcer disease, to name a few, can lead to misdiagnosis.

Heart failure can occur in the left and/or right heart and respective symptoms arise from congestion of blood flow owing to the inadequacies of the cardiac pump function. Left heart failure manifests as dyspnea, usually with exertion. Orthopnea suggests worsened pulmonary congestion with increased venous return and these patients are not able to lie flat. Ascites, peripheral edema, and hepatomegaly reflect congestion in the systemic venous circulation and are prominent features of right heart failure. Peripheral edema can occur in right heart failure secondary to systemic venous congestion, or in left heart failure due to salt and fluid retention due to impaired renal perfusion. Patients with chronic suboptimal perfusion and oxygenation can also have digital clubbing and cyanosis.

It is difficult to implicate cardiac disease based solely on the presence of fatigue as it is a very nonspecific symptom. However, most cardiac pathologies do result in fatigue or exercise intolerance of some degree. It is important to differentiate fatigue from exertional dyspnea which some patients may describe as "fatigue."

Dyspnea is another common symptom seen in many heart diseases. Although generally a late symptom in patients with valvular heart disease or cardiomyopathy, it may be a relatively early complaint in some patients, particularly those with mitral stenosis. As stated previously, dyspnea is also an anginal equivalent and may signal a myocardial ischemic episode. Many primary pulmonary disorders feature dyspnea as their cardinal symptom and should be evaluated simultaneously as the physiology of the heart and lungs are intimately related, and can have dramatic influences on each other.

Patients typically describe palpitations as a "skipped beat" or "racing heart". Depending on the clinical context, such as occasional premature atrial or ventricular beats in otherwise healthy individuals, these may be benign. Clinically significant arrhythmias, however, require thorough investigation. Atrial fibrillation is the most common arrhythmia and can occur alone or with concomitant cardiac pathologies. It results in an irregular, and at times, rapid heartbeat. Concurrent symptoms such as angina or lightheadedness/syncope are particularly worrisome for life threatening arrhythmias such as ventricular tachycardia or ventricular fibrillation, particularly in those with preexisting heart failure or ischemic heart disease.

Syncope associated with heart disease results from abrupt reduction of cerebral perfusion. Many of the potential etiologies are serious, including sinus node dysfunction, atrioventricular-conduction abnormalities, malignant arrhythmias, aortic stenosis, and hypertrophic obstructive cardiomyopathy. Any episode of syncope warrants a thorough evaluation and search for the root cause. [1]

Table 21-1

New York Heart Association (NYHA) functional classification

CLASS	DESCRIPTION
I	Physical activity not limited by symptoms: fatigue, palpitations, or dyspnea.
II	Comfortable at rest. Slight limitation of physical activity. Fatigue, palpitations, or dyspnea with ordinary physical activity.
III	Comfortable at rest. Marked limitation of physical activity. Fatigue, palpitations, or dyspnea with less than ordinary physical activity.
IV	Inability to carry out any physical activity. Symptoms may be present at rest and increase with activity.

Table 21-2

Canadian Cardiovascular Society (CCS) anginal classification

CLASS	DESCRIPTION
I	Ordinary physical activity (walking, climbing stairs) does not cause angina. Angina occurs with strenuous, rapid, or prolonged exertion during work or recreation.
II	Slight limitation of ordinary activity. Angina occurs with climbing stairs rapidly, walking uphill in the wind, under emotional stress, in the cold, or after meals. Walking more than 2 blocks or climbing one flight of stairs causes angina.
III	Marked limitation of ordinary physical activity (climbing a flight of stairs or walking 1 to 2 blocks at a normal pace).
IV	Inability to carry out any physical activity without discomfort. Angina may be present at rest.

In addition to a thorough inquiry regarding the above symptoms, it is important to obtain details about the patients' medical/surgical history, family history, social habits (with regards to alcohol and tobacco use), current medications, and a focused review of systems, including an assessment of the patients' functional status and frailty. Specific attention should be directed to the patients' comorbidities which not only sheds light on the patients' general health, but also helps delineate the risks if the patient were to undergo surgery. A strong family history of coronary artery disease, myocardial infarction, hypertension, or diabetes is of particular importance as they increase the individuals' risks.

Functional Disability and Angina. With regard to heart failure, functional capacity is strongly correlated with mortality. The New York Heart Association (NYHA) functional classification is the most widely used classification system in categorizing patients based on their functional status (Table 21-1). The NYHA classification has become a basis by which to assess patient characteristics in many studies to compare patient populations. Although less commonly used, the Canadian Cardiovascular Society (CCS) angina classification is also used to incorporate anginal symptoms into the functional assessment for prognostic value (Table 21-2).

Physical Examination

The physical examination is an invaluable tool in directing further diagnostic studies and management of a patient with suspected heart disease. The astute clinician will detect subtle signs that may further characterize the underlying pathologic process.

The general appearance of a patient is important in the clinical assessment. A pale, diaphoretic, and obviously uncomfortable patient is more likely to be in a clinically critical condition than one who is conversing comfortably with an unremarkable demeanor. In addition to basic vital signs, particular attention should be directed to the patients' mental status and skin (color, temperature, diaphoresis) as these may be reflective of the general adequacy of perfusion. Overall frailty and dementia have also been shown to be predictors of operative and late mortality.[2]

Palpation of the precordium may demonstrate deviations in the point of maximal impulse indicative of ventricular hypertrophy or parasternal heaves seen in right ventricular overload. Auscultation should be performed in a quiet environment as critical murmurs, rubs, or gallops may be subtle. Murmurs are characterized by their location, timing, quality, and radiation. They are typically secondary to valvular or other structural pathology and new findings require further investigation. A rub due to pericardial friction is specific and virtually pathognomonic for pericarditis. A third heart sound (S_3) is generated by the rapid filling of a stiff ventricle and can be normal in young patients, but when present in older adults, is indicative of diastolic dysfunction and is pathologic. Increased contribution of the atrial pump function to ventricular filling may manifest as a fourth heart sound (S_4) and is also suggestive of ventricular dysfunction.

Palpation of peripheral pulses is important not only to assess the adequacy of perfusion, but the burden of coronary artery disease often correlates with the degree of peripheral arterial disease. Discovery of carotid stenosis by auscultation for carotid bruits has significant implications for operative planning.

Heart disease will frequently have extracardiac manifestations and examination of the other organ systems should not be neglected. Auscultation of the lung fields may reveal rales in patients with pulmonary edema. The work of breathing may also be assessed simply by observing the patient. Jugular venous distention and hepatosplenomegaly are seen in right heart failure.

Cardiac Risk Assessment in General Surgery Patients

Approximately one half of the mortality in patients undergoing noncardiac surgery is due to complications which are cardiovascular in origin.[3] The American College of Cardiology and American Heart Association have formed a joint task force to publish a consensus statement on guidelines and recommendations which was revised in 2007.[4] The aim of these guidelines is to incorporate surgery-specific risks and patient characteristics to stratify patients in order to guide perioperative decision-making.

Surgical procedures have been categorized based on cardiovascular risk into low and moderate risk, and vascular procedures.

Vascular procedures (aortic, peripheral vascular, and other major vascular surgery), likely due to both the nature of the procedures themselves as well as the associated cardiovascular pathology in many of these patients, carries the highest reported cardiac risk at more than 5%. Low risk procedures, including endoscopic procedures, superficial operations, cataract surgery, breast surgery, and ambulatory surgeries have a risk generally less than 1%. Intermediate risk procedures are: intraperitoneal and intrathoracic surgery, head and neck surgery, orthopedic procedures, and prostate surgery.

Patient characteristics can be classified by the status of the patients' cardiac disease, comorbid conditions, and functional capacity. Patients are considered to be at major perioperative clinical risk if they have one or more of the following active cardiac conditions: unstable coronary syndrome, decompensated heart failure, significant arrhythmias, or severe valvular heart disease. In these patients, intensive evaluation and treatment prior to surgery (unless emergent) is warranted, even if the noncardiac surgery needs to be delayed or cancelled.

If the patient does not have any of the previously mentionedactive conditions, and is scheduled for a low risk surgery or if they have functional capacity greater than or equal to 4 metabolic equivalents (or METs), the official recommendation is to proceed with the planned operation. The previous guidelines contained intermediate and low cardiovascular risk profiles, but this has been replaced by cardiovascular risk factors in the update. These risk factors are: history of ischemic heart disease, history of prior or compensated heart failure, history of cerebrovascular disease, diabetes mellitus, and renal insufficiency. Based on the number of present risk factors and the surgery-specific risk, the guideline recommends pathways for further evaluation and risk management (Table 21-3).

Diagnostic Studies

Electrocardiogram and Chest X-ray. Electrocardiograms (ECGs) and chest X-rays are simple, noninvasive, and inexpensive diagnostic studies that are invaluable in the preoperative assessment of patients with cardiac pathology. ECGs can be useful in detecting old myocardial infarction, dilation or hypertrophy of cardiac chambers, arrhythmias, and conduction abnormalities. A stress ECG requires a patient to exercise to a target heart rate, and is used to help diagnose ischemic pathologies which may not be evident at rest.

A plain film of the chest can detect pulmonary pathology, sequelae of heart failure (e.g., pulmonary edema, cardiac enlargement, pleural effusions) as well as hardware from previous procedures such as, prosthetic valves, sternal wires, pacemakers, and defibrillators.

Echocardiography. Echocardiography utilizes reflected sound waves to image the heart, and is used widely due to its noninvasive nature and low cost. It is the primary diagnostic tool used to evaluate structural diseases of the heart, including: valvular pathology, septal defects, cardiomyopathies, and cardiac masses. Echocardiography is indispensable in assessing surgical prosthetics such as valves, leads, or mechanical circulatory support devices. These examinations can be performed with M-mode imaging (motion along a single line) as well as 2-D and 3-D imaging depending on the graphical information required.

Doppler technology has become a standard addition to assess changes in flow patterns across both stenotic and regurgitant valves. Velocity measurements can be obtained to estimate pressure gradients across structures using the continuity equation. A common example would be the estimation of pulmonary arterial systolic pressure calculated from the regurgitant tricuspid jet profile during right ventricular systole.

Transthoracic echocardiography (TTE) requires no sedation and is generally performed with the patient in a slight left lateral decubitus position. Standardized views are obtained with the ultrasound probe placed in the apical, parasternal, subcostal, and suprasternal positions. The apical four-chamber view is a useful window for visualizing all four cardiac chambers simultaneously as well as the tricuspid and mitral valves. Other windows can be obtained to assess specific structures such as the individual valve anatomy or myocardial wall segments. Dobutamine-stress echocardiography is a study similar in idea to the stress ECG which utilizes a pharmacologic agent to assess the patient for ischemia or stress-induced valvular abnormalities.

A slightly invasive variant of this technology is transesophageal echocardiography (TEE) which takes advantage of the anatomic proximity of the heart to the esophagus. The exam is performed using a special endoscope with an ultrasound probe mounted on its end which is introduced orally into the esophagus under sedation. Posterior structures such as the mitral valve and left atrium are particularly well visualized. TEEs are frequently used intraoperatively during cardiothoracic surgery to assess global cardiac function, integrity of valve repairs and replacements, intracavitary thrombus and/or air, and aortic atherosclerosis or dissections which can have significant influences on operative strategy.

There are some new additions to the echocardiographic armamentarium which capitalize on the strengths of ultrasound imaging. Three dimensional TEE is playing an increasing role in the preoperative and intraoperative evaluation of patients with valvular heart disease and is particularly useful in the valuation of mitral regurgitation. Tissue Doppler imaging is based on principles akin to conventional Doppler echocardiography, but attention is directed to the myocardium itself as opposed to the motion of blood to quantify abnormalities in wall motion. Strain imaging with speckle-tracking echocardiography measures the actual deformation of the myocardium by following

Table 21-3

Algorithm set forth by ACC/AHA guidelines for preoperative cardiovascular evaluation before noncardiac surgery for patients who are scheduled for nonemergent, non-low risk surgery, no active cardiac disease, and less than 3 METs

NUMBER OF RISK FACTORS*	RECOMMENDATION
0	Proceed with planned surgery.
1–2	Control HR and proceed with planned surgery or pursue further testing if it will change management.
3–5	Pursue further testing if it will advance management.

*Risk factors are: history of ischemic heart disease, history of prior or compensated heart failure, history of cerebrovascular disease, diabetes mellitus, and renal insufficiency.

inhomogeneities inherent to the myocardium, and is a useful measure of myocardial function.

Radionuclide Studies. Although ECGs are useful, inexpensive, and safe, baseline abnormalities in the ECG may limit its diagnostic capacity. In particular, ventricular rhythms, bundle-branch blocks, left ventricular hypertrophy, drug effects, and baseline ST-segment depressions can make stress ECGs uninterpretable. In this setting, myocardial perfusion imaging (MPI) using radionuclides can be utilized to assess myocardial ischemia.

Thallium 201 (^{201}Tl) was the initial radionuclide used for MPI, but due to its long half-life and relatively low photopeak, it has largely been replaced by Technetium-99m (sestamibi and tetrofosmin) which has more favorable characteristics. In the past, planar imaging with three separate two-dimensional views of the heart were obtained. Currently, it is more common to have the images acquired by single-photon emission computed tomography (SPECT) technology which detects emitted photons from 180- to 360-degrees around the patients. The signals are then processed to reconstruct multiple slices which together provide a three-dimensional view. The amount of uptake at both rest and stressed states are compared to assess ischemia and viability of the myocardium. The distribution of radionuclides depend on perfusion and therefore areas which show uptake at rest, but not during stress are concerning for ischemia.

Territories that do not show uptake at rest or during stress are likely to be nonviable scar. The sensitivity and specificity of exercise SPECT are 90% and 70%, respectively.[5]

The image acquisition may also be gated to a simultaneously obtained ECG to assess global ventricular function. The endocardial and epicardial borders (as delineated by radionuclide uptake) are detected throughout the cardiac cycle and the ejection fraction, along with end-systolic and end-diastolic volumes, can be calculated. This study is also useful in revealing hypokinetic segments of the myocardium.

One of the most significant weaknesses of SPECT imaging is that it shows regional ischemia well, but does not adequately detect global or "balanced" ischemia which can occur with diffuse CAD. Positron emission tomography (PET) scans have been used due to its ability to obtain absolute quantitative data on both myocardial perfusion and metabolism. Tracers used in PET scans can be divided into those that assess perfusion (Oxygen-15, Nitrogen-13, and Rubidiuim-82) and those that assess metabolism (Carbon-11 and Fluorine-18). The specificity of PET in detecting CAD is better than SPECT at 86% due to its superior spatial resolution.[6]

Magnetic Resonance Imaging. Magnetic resonance imaging (MRI) has a wide variety of uses in cardiac imaging depending on the pulse sequence and signal weighting. Cine-loop of the heart throughout the cardiac cycles can yield information on global chamber function and valvular pathologies. The differential response of normal and ischemic myocardium to certain pulse sequences allows imaging of myocardial perfusion using MRI. Use of contrast agents such as gadolinium can enhance scar tissue and are very useful in viability assessment. Myocardial strain imaging can also be performed using newer technologies taking advantage of radio-frequency tagging of the myocardium which deforms with the tissue and can be followed throughout the cardiac cycle.

Cardiac Catheterization. Cardiac catheterization involves access to the cardiac chambers and great vessels with a peripherally inserted catheter under fluoroscopic guidance. It is a versatile tool used for diagnostic purposes of: cardiac chamber pressures, valvular abnormalities, wall motion assessment, and coronary artery anatomy. While some of these roles are being replaced by less invasive techniques mentioned previously, cardiac catheterization studies continue to be widely performed and is the gold standard for the assessment of coronary artery disease.

A left-heart catheterization is performed by percutaneous access of the femoral, or less commonly, the radial artery. Under fluoroscopic guidance, the catheter is threaded into the aorta where a contrast aortogram may be performed. Coronary angiography requires manipulation of this catheter into the coronary ostia where contrast is directly injected. With advancement of the catheter retrograde past the aortic valve, left ventricular pressures can be obtained. This pressure is used to calculate pressure gradients across the aortic valve which becomes particularly important in the evaluation of aortic stenosis. Again, contrast injection will result in a ventriculogram used to estimate ejection fraction and visualize hypokinetic segments of the walls. Inappropriate retrograde leakage of contrast may indicate insufficiency of the aortic and/or mitral valves.

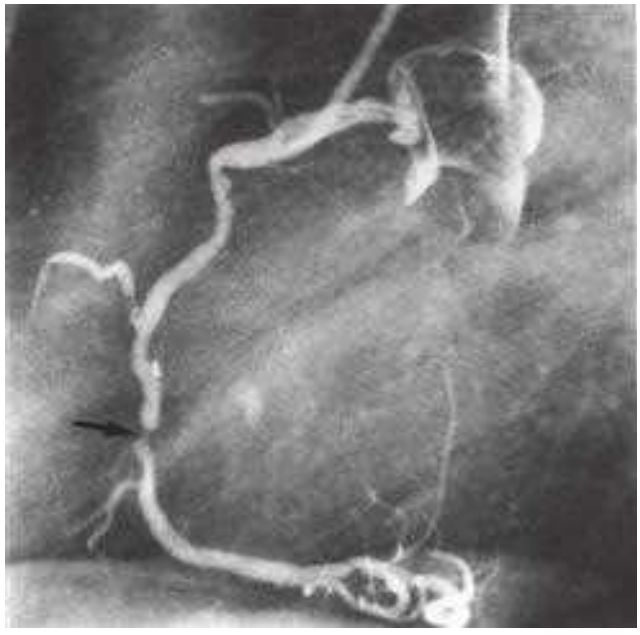
Right heart catheterization is performed through a peripheral vein and the catheter is threaded into the right atrium. Right-sided pressures and structures are assessed in a similar fashion as in the left heart. Extension of the catheter into the pulmonary artery allows measurement of the pulmonary artery pressures as well as the pulmonary capillary wedge pressure (reflecting left ventricular end diastolic pressure) with an occlusive balloon.

In addition to these measurements, cardiac output can be measured using thermodilution or by the Fick method using oxygen saturations of blood sampled from the various locations during the procedure.

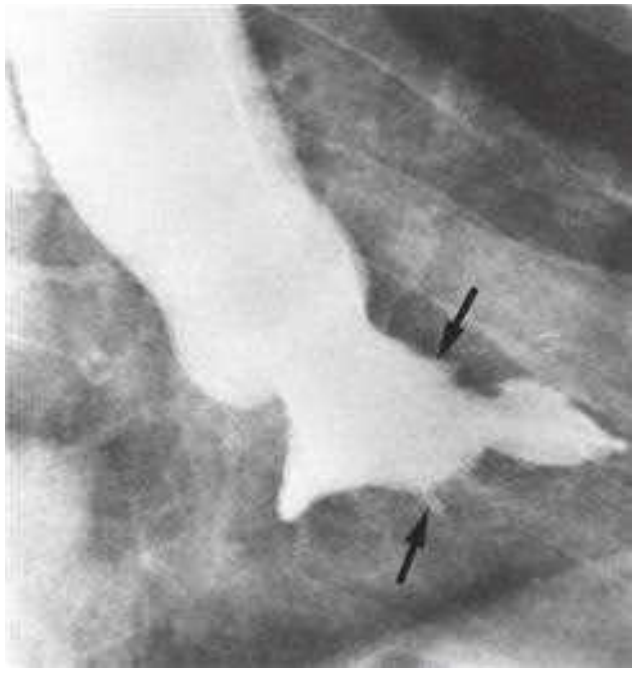
Coronary angiography provides information on hemodynamically significant stenoses in the coronary circulation as well as an anatomical roadmap for surgeons to planning revascularization. (Fig. 21-1A & B) A stenosis is considered to be significant if it narrows the lumen of the artery by 70% (or 50% in the case of left main coronary artery). There is some variability in the coronary arterial anatomy with the posterior descending artery being supplied by the right coronary artery in approximately 80% of patients (right dominant), or the left coronary artery in approximately 15% of patients (left dominant). The remaining patients have a codominant circulation where the posterior descending artery is supplied by both the right and left coronaries.

An advantage of catheterization is that it offers an opportunity for interventional therapy of coronary artery disease, arrhythmias, valvular abnormalities, and other structural defects of the heart. Cardiac catheterization is generally safe, but being an invasive procedure, it is associated with complications. Overall mortality is 0.11%, and total rate of major complications, including: MI, stroke, arrhythmia, vascular injury, contrast reaction, hemodynamic instability, and cardiac perforation is usually <2%.[7]

Cardiac Computed Tomography. Multislice computed tomography (CT) imaging can be used to assess the coronary vasculature. The coronary calcium score is an index developed to quantify the degree of coronary atherosclerotic burden by measuring Hounsfield units in a noncontrast cardiac CT. Although this technique is quite sensitive for angiographic stenoses >50%, it remains fairly nonspecific as calcification often precedes significant luminal narrowing.[8] CT coronary angiography using intravenous contrast is also utilized clinically to assess coronary pathology and is particularly useful in the emergency room to perform a "triple rule-out" for acute coronary events,



A



B

Figure 21-1. Cardiac catheterization angiography. **A.** Stenosis of right coronary artery indicated by the arrow. **B.** Still image of a normal left ventriculogram.

pulmonary embolism, and aortic dissection in patients who present with undifferentiated chest pain. LV ejection fraction may be measured by this technique, and together with the degree of coronary stenoses, incremental prognostic value has been demonstrated in addition to routine clinical predictors.[9]

EXTRACORPOREAL PERFUSION

History

Prior to the development of extracorporeal perfusion, heart surgery was rarely performed and was limited to brief periods of asystole and hypothermia. The need for a bloodless operating field, while maintaining perfusion of heart and other organs, was evident.

John Gibbon's motivation to develop a means for extracorporeal perfusion came from a desire to safely open the pulmonary artery in a patient who suffered from a pulmonary embolus following cholecystectomy. After numerous experimental iterations, Gibbon's cardiopulmonary bypass machine was first used clinically in 1953 to repair a large atrial septal defect in an 18-year-old female.[10]

Although Gibbon is credited for its invention, the development of modern cardiopulmonary bypass (CPB) is a culmination of the work of many investigators throughout the world. The early bubble oxygenators have evolved into the modern membrane oxygenators. The search for an ideal biocompatible material which minimizes the inflammatory cascade initiated by the contact of blood with the circuit components continues to this day.

Technique

The basic CPB circuit consists of the venous cannulae, a venous reservoir, pump, oxygenator, filter, and the arterial cannula.

Anticoagulation is required during CPB, and 300 to 400 units/kg of heparin is given to increase the activated clotting time (ACT) to greater than 450 seconds. Once adequate anticoagulation is achieved, arterial cannulation is performed through a purse-string suture, or through a side graft which is sewn on to the native artery. The distal ascending aorta is the most common site of cannulation, but there may be concern for atheroembolization when the aorta is atherosclerotic. Other sites of cannulation include the femoral artery, axillary artery, or the distal aortic arch. Venous cannulation is performed through purse-string sutures placed on the right atrium either for a single cannula or for two separate cannulae extending into the superior and inferior vena cava, respectively. Alternatively, the venous cannula may be inserted from the femoral vein and advanced into the right atrium.

Effective communication between the surgeon, the anesthesiologist, and the perfusionist is mandatory for effective cardiopulmonary bypass. Once the appropriate cannulations and connections are complete, CPB is commenced. Venous return is initiated followed by arterial flow while monitoring systemic blood pressures. At normothermia, the flow required is approximately 2.4 L/min/m^2, but with hypothermia, oxygen consumption is reduced by 50% for every 10°C drop in temperature, and a flow of only 1L/min/m^2 is required at 18°C. Once the heart is decompressed and hemodynamics are acceptable, ventilation is stopped. The oxygenator is adjusted to maintain a PaO_2 of 150 mm Hg and normocarbia. Blood can also be filtered and returned through vents that are placed in the heart or through the cardiotomy suction used to aspirate blood from the surgical field.

When the cardiac procedure is complete, the patient is rewarmed, the lungs ventilated, and the heart defibrillated if needed. The venous return to the CPB machine is gradually reduced allowing the heart to fill. The pump is also slowed while hemodynamics and global cardiac function are assessed with a TEE probe. Inotropic and vasopressor support may be used to augment cardiac function and treat hypotension. Once CPB has been stopped and stable hemodynamics achieved, the cannulae are removed. The heparin anticoagulation is reversed with protamine and hemostasis is achieved.[11]

Adverse Effects

Cardiopulmonary bypass has a number of deleterious effects as various intertwining processes result in derangements in hemostasis, systemic inflammatory response, and end-organ function.

Anticoagulation prior to the commencement of CPB is required as contact of blood with the artificial surfaces of the circuit can initiate a thrombogenic cascade. Generation of thrombin plays a major role in both thrombotic and bleeding phenomena during CPB. The endothelium which normally regulates the fine balance between procoagulant and anticoagulant pathways is perturbed. Fibrinogen is consumed rapidly as thrombin converts fibrinogen to fibrin while fibrinolytic mechanisms (initiated by the activated endothelium) degrade the fibrin macromolecules. Platelets are activated by the converging hemostatic pathways and are consumed.

The response of the humoral and cellular immune systems partly overlap with the hemostatic pathways. The classic and alternative complement pathways are activated by CPB generating powerful chemotaxic molecules and anaphylatoxins. Monocytes, platelets, and neutrophils are activated releasing acute inflammatory mediators and cytokines which persist even after conclusion of CPB.[12] These inflammatory cells also produce reactive oxidants which may have cytotoxic effects.

The large quantity of unfractionated heparin used during cardiac surgery predisposes patients to developing heparin induced thrombocytopenia (HIT) with an incidence of 1% to 2%. Platelet factor-4 (PF4) is produced by platelets and avidly binds to heparin to form a heparin-PF4 complex which can be antigenic in some patients binding IgG. The IgG-heparin-PF4 complex can bind to platelets which causes release of more PF4, perpetuating the process. The earliest sign is a sudden drop of more than 50% of the platelet count, and HIT can be confirmed with an ELISA or serotonin release assay. Of the patients with HIT, 20% to 50% of patients develop thromboses in arterial or venous beds, designated as heparin induced thrombocytopenia and thrombosis (HITT), which can be life-threatening.[13]

The etiology of end-organ dysfunction resulting from extracorporeal circulation can mostly be categorized into one of three mechanisms. Although cardiac output and blood pressure are monitored carefully during CPB, they are surrogates for regional perfusion and cannot detect end-organ hypoperfusion directly. This can be a problem particularly with the cerebral, renal, and mesenteric circulations. With manipulation of diseased vessels and dysregulation of the native coagulation system, macroscopic and microscopic emboli are a concern despite various strategies to minimize this problem. Activated cells and circulating cytotoxic products of the immune response may cause microvascular injury and edema of other organs manifesting as neurocognitive deficits, respiratory failure, and renal injury.[14]

Myocardial Protection

During CPB, pharmacologic agents in cardioplegic solutions may be delivered into the coronary circulation to arrest the heart allowing for a still operating target and improved myocardial protection. The most common cardioplegia consists of potassium-rich solutions that can be mixed with autologous blood and are delivered into the coronary circulation. Antegrade cardioplegia is delivered into the root of a cross-clamped aorta or directly into the individual coronary ostial via specialized catheters. A retrograde cardioplegia catheter is a balloon-cuffed catheter that is placed through the right atrium into the coronary sinus and is used to perfuse the coronary circulation in the opposite direction through the venous circulation. This has the advantage of more uniform distribution in patients with diffuse coronary artery disease and is not dependent on a competent aortic valve for delivery.

There are controversies regarding the method (antegrade retrograde vs. both), type (crystalloid vs. blood), temperature (cold vs. warm vs. tepid), and interval (continuous vs. intermittent) of cardioplegia delivery. The optimal combination is beyond the scope of this text. However, most surgeons in the United States favor cold blood potassium cardioplegia.

CORONARY ARTERY DISEASE

History

The Vineberg operation, one of the initial attempts at surgical revascularization of the myocardium, was first performed in 1950s. This procedure involved implantation of the internal thoracic artery directly into the myocardium itself. While some patients were relieved of their anginal symptoms, this resulted in very little increase in coronary flow and was supplanted by methods to restore flow directly. Coronary endarterectomy was introduced by Longmire during this time period, but was met with high rates of restenosis and occlusion. The use of vein patches to repair the arteriotomy sites was described by Senning in 1961. The first saphenous vein coronary artery bypass grafting (CABG) was performed by Sabiston in 1962, but was popularized by Favalaro in 1967. In 1968, the internal thoracic artery was introduced as a bypass conduit by Green who used it to bypass the left anterior descending coronary artery.[15]

Etiology and Pathogenesis

Atherosclerotic stenoses are the primary mechanism of coronary artery disease (CAD). The pathophysiologic process is initiated with vascular endothelial injury and is potentiated by inflammatory mechanisms, circulating lipids, toxins, and other vasoactive agents in the blood. Macrophages and platelets are attracted to this area of endothelial dysfunction inciting a local inflammatory response. During this process, macrophages infiltrate into the intimal layers and accumulate cholesterol-containing low-density lipoproteins. The growth factors secreted promote proliferation of smooth muscle cells within the intima and media of the arteries. Together with the accumulation of the lipid-laden macrophages, the smooth muscle hyperplasia results in an atheroma and subsequently stenosis of the vessel. These atheromas have a fibrous cap which may rupture, exposing the underlying cells and extracellular matrix which are very prothrombotic. Acute plaque rupture and thrombus formation is thought to be the main pathophysiologic mechanism responsible for acute coronary syndromes.[16-18]

Risk Factors and Prevention

Prior to the establishment of modern management strategies, the annual mortality rated from ischemic heart disease was quoted to be around 4% by the Framingham study. Since then, risk factor modification along with use of medications, such as aspirin and β-blockers, has dramatically improved survival.

The major risk factors of atherosclerosis include: age, cigarette smoking, hypertension, dyslipidemias, sedentary lifestyles, obesity, and diabetes. Likely due to increased public awareness and aggressive medical management, these risk factors (with the

exception of glucose intolerance and obesity) have recently been on the decline.

Current guidelines outlined in the AHA/ACC consensus statement summarizes secondary prevention recommendations. Class I recommendations are: smoking cessation and avoidance of environmental tobacco exposure, blood pressure control to under 140/90 mm Hg (under 130/80 mm Hg in those with diabetes or chronic kidney disease), LDL cholesterol levels less than 100 mg/dL, aspirin therapy in all patients without contraindications, BMI target of less than 25 kg/m^2, diabetes management with target HbA1c <7%, and encouragement of daily aerobic exercise routines. Beta-blockers are to be considered in patients with LV dysfunction and following MI or ACS. Renin-angiogensin-aldosterone system blockade in patients with hypertension, LV dysfunction, diabetes, or chronic kidney disease should also be considered.[19]

Clinical Manifestations

Patients with CAD may have a spectrum of presentations, including angina pectoris, myocardial infarction, ischemic heart failure, arrhythmias, and sudden death.

Angina pectoris is the pain or discomfort caused by myocardial ischemia and is typically substernal and may radiate to the left upper extremity, left neck, or epigastrium. The variety of presentations can make myocardial ischemia difficult to diagnose. Characteristics of chest pain that make myocardial ischemia less likely include: pleuritic chest pain, pain reproducible by movement or palpation, or brief episodes lasting only seconds. Typical angina is relieved by rest and/or use of sublingual nitroglycerin. Differential diagnoses to be considered include, but are not limited to: musculoskeletal pain, pulmonary disorders, esophageal spasm, pericarditis, aortic dissection, gastroesophageal reflux, neuropathic pain, and anxiety.

Myocardial infarction is a serious consequence of CAD occurring when ischemia results in myocardial necrosis. This may be silent and need not be preceded by angina. Necrosis may result in disruption of the myocardial integrity leading to devastating conditions such as intracardiac shunts from ventricular septal defects, acute valvular regurgitation from rupture of necrotic papillary muscles, and cardiac aneurysms which have the catastrophic potential to rupture.

The ischemic insults from CAD may lead to congestive heart failure. The initial myocardial damage sets off a cascade of responses, both local and systemic. Over time, these changes can cause deleterious myocardial loading and abnormal neurohumoral responses that result in pathologic remodeling of the heart. Heart failure should be suspected in patients who present dyspnea, orthopnea, fatigue, and edema.

Arrhythmias may also be a sequela of CAD. Ischemic etiologies should be investigated in patients who present with new arrhythmias. CAD may result in arrhythmias following an acute MI or as the result of ultrastructural and electrophysiologic remodeling secondary to chronic ischemic heart disease. Ischemia of the electrical conduction system may be seen as the new onset complete or partial atrioventricular conduction blocks.

Preoperative Evaluation

A focused history and physical examination is essential with particular attention directed to the signs, symptoms, and clinical manifestations mentioned previously. The patient's functional status is of importance not only because it is a component of preoperative risk assessment, but also because quality of life improvement and symptomatic relief are both goals of surgical therapy.

Coronary angiography is the primary diagnostic tool. The coronary anatomy and degrees of stenoses are delineated allowing for planning of surgical revascularization.

Noninvasive diagnostic studies, in combination with provocative maneuvers (exercise or pharmacologic agents) offer information regarding the functional significance of ischemic disease. A stress ECG is frequently used as a screening tool with a high sensitivity. The positive predict value is 90% in patients with ST-segment depression >1mm. This test however, requires patients to achieve a certain elevation in their heart rate, and is therefore not suitable for those that cannot achieve this goal. Furthermore, baseline ECG abnormalities may render it impossible to detect typical ischemic changes with stress.

Echocardiography and nuclear imaging may be performed under pharmacologic stress (with dobutamine or dipyridamole) to assess reversible ischemia and myocardial viability. Technetium-99m or thallium-201 perfusion scans have an average sensitivity and specificity of 90% and 75%, respectively. Stress echocardiography has a similar sensitivity and specificity of approximately 85%.[20] These studies also have the ability to assess global ventricular function in terms of LV ejection fraction which can be used to determine operative risk.

CORONARY ARTERY BYPASS GRAFTING

Indications

A joint committee established by the American College of Cardiology and the American Heart Association have published guidelines for surgical revascularization (CABG) in CAD. The indications, categorized by presentation and angiographic disease burden as well as by treatment intention (survival improvement and symptom relief), are summarized later (Tables 21-4,5,6).[21]

Percutaneous Coronary Intervention vs. Coronary Artery Bypass Grafting

In recent years, there have been multiple prospective randomized, controlled trials as well as retrospective studies looking at the comparative effectiveness of percutaneous coronary interventions (PCI) and CABG. Some of the representative studies are summarized here.

The New York State Study (2005). A retrospective review of 59,314 patients in two of New York's registry with multivessel (2 or more) coronary disease was performed. Of these, 37,212 patients received a CABG and the others underwent a PCI. After adjusting by means of proportional-hazards methods, CABG was associated with higher adjusted rates of long-term survival than PCI.[22]

Stent or Surgery Trial (2008). An international multicenter randomized controlled trial of 988 patients (n = 488 PCI, n = 500 CABG) with multivessel CAD was performed to compare revascularization strategies. At 2-year median follow-up, the PCI group had significantly higher rates of repeat revascularizations and mortality compared to the CABG group (incidence of nonfatal Q-wave myocardial infarctions were similar in both groups). The median follow-up was extended to 6-years, and a survival advantage persisted in the CABG group over the PCI group.[23]

Table 21-4

Data from ACC/AHA guidelines for CABG in CAD to improve survival

ANATOMY	CLASS OF RECOMMENDATION	LEVEL OF EVIDENCE
• LM	I	B
• 3-vessel +/– proximal LAD	I	B
• 2-vessel + proximal LAD	I	B
• 2-vessel – proximal LAD	IIa – with extensive ischemia IIb – without extensive ischemia	B C
• Multivessel disease with DM	IIa (CABG preferred over PCI)	B
• Proximal LAD only	IIa – with LITA for long-term benefit	B
• 1-vessel – proximal LAD	III – Harm	B
• LV dysfunction	IIa – LVEF 35%–50% IIb – LVEF <35% without LM disease	B B
• Survivor of ischemia-mediated VT	I	B

DM = Diabetes mellitus; LITA = Left internal thoracic/mammary artery; LM = Left main coronary artery; LV = left ventricle; VT = ventricular tachycardia. Class of recommendation: I – Benefit far outweighs risks and procedure should be performed; IIa – Benefit outweighs risks and procedure is considered to be reasonable; IIb – Potential benefits may exceed risks and procedure may be considered; III – Procedure not helpful and may cause harm. Level of evidence: A – Strong; multiple supporting randomized controlled trials or meta-analyses, B – Limited; data based on a single randomized trial or non-randomized trials, C – Very limited; based on expert consensus, case studies or standards of care.

Synergy between Percutaneous Coronary Intervention with Taxus and Cardiac Surgery (SYNTAX Trial, 2009). Revascularization strategies, CABG vs. PCI, were compared in a 1:1 randomized prospective trial of 1800 patients with high risk coronary artery disease (left-main or triple-vessel disease). Rates of requirement for repeat revascularization and major adverse cardiac or cerebrovascular events at 12-months were lower in the CABG patients (5.9% and 12.4%, respectively) compared to PCI patients (13.5% and 17.8%, respectively). No difference in mortality was seen between the groups at 12-months.[24]

The ACCF and STS Database Collaboration on the Comparative Effectiveness of Revascularization Strategies (ASCERT Study, 2012). This study, performed by collaboration of the American College of Cardiology Foundation and the Society of Thoracic Surgeons, reviewed their respective national databases of patients over the age of 65 who had multivessel coronary disease (excluding those with left main disease). CABG was performed on 86,244 patients and 103,549 underwent PCI. There was no difference in adjusted mortality at 1 year, but there was a significantly lower mortality with CABG than PCI at 4 years.[25]

Summary

PCI technology has improved over time and rates of periprocedural adverse events have decreased significantly. Management strategies must be tailored to the individual patient's clinical status and context, but CABG maintains improved long-term outcome and remains the standard of care for left-main and multivessel coronary artery disease.

Operative Techniques and Results

Bypass Conduit Selection. The most important criterion in conduit selection is graft patency. The conduit with the highest patency rate (98% at 5 years and 85%–90% at 10 years) is the internal thoracic artery which is most commonly left attached proximally to the subclavian artery (although occasionally used as a free graft) and anastomosed distally to the

Table 21-5

Data from ACC/AHA guidelines for CABG in CAD to improve symptoms

ANATOMY ASSOCIATED SYMPTOMS	CLASS OF RECOMMENDATION	LEVEL OF EVIDENCE
• Unacceptable angina with presence of ≥1 stenoses amenable to revascularization despite medical treatment	I	A
• Complex 3-vessel CAD +/– proximal LAD involvement	IIa (CABG preferred over PCI)	B
• Unacceptable angina with presence of ≥1 stenoses amenable to revascularization but medical treatment is not possible	IIa	C
• Previous CABG with ≥1 stenoses associated with ischemia and angina despite medical treatment	IIb	C

Table 21-6

Data from ACC/AHA guidelines for CABG in CAD in specific clinical contexts

CLINICAL SETTING	CLASS OF RECOMMENDATION	LEVEL OF EVIDENCE
EMERGENT CABG FOLLOWING ACUTE MI		
• Failure or inability to perform PCI, anatomy suitable for CABG, persistent ischemia/ hemodynamic instability refractory to nonsurgical therapy	I	B
• Patients undergoing surgical repair of postinfarction complication (e.g.,VSD, papillary or free wall rupture)	I	B
• Cardiogenic shock with anatomy suitable for CABG	I	B
• Life-threatening ventricular arrhythmia, ischemic in origin, with 3-vessel disease or >50% LM stenosis	I	C
• Multivessel disease, recurrent angina or MI within 48 hrs of STEMI (instead of a more delayed strategy)	IIa	B
• Age >75 with ST-elevation or new left bundle branch block who are suitable for revascularization, regardless of time between MI and cardiogenic shock.	IIa	B
• Persistent angina with only small area of viable myocardium	III – Harm	C
SURVIVAL FROM SUDDEN CARDIAC DEATH OR SUSTAINED VT		
• If thought to be due to significant CAD (amenable to revascularization).	I	B
• If only scar present, and no evidence of ischemia	III- Harm	C
PATIENTS UNDERGOING CONCOMITANT NON-CORONARY CARDIAC SURGERY		
• In presence of significant CAD (>50% LM stenosis or >70% stenosis of another major coronary artery.	I	C
• LITA graft to significantly narrowed LAD or CABG of moderately diseased (>50% stenosis) coronary artery.	IIa	C
EMERGENT CABG AFTER FAILED PCI		
• Ongoing ischemia, threatened occlusion with substantial myocardium at risk, or hemodynamic compromise (without coagulopathy or previous sternotomy).	I	B
• Retrieval of foreign bodies (from PCI) or hemodynamic compromise with coagulopathy and without previous sternotomy.	IIa	C
• Absence of ischemia or threatened occlusion	III – Harm	C

LM = Left Main; VT = ventricular tachycardia.

target coronary artery.[26,27] The use of both internal thoracic arteries has been shown to increase event-free survival in a number of studies.[28,29]

The greater saphenous vein can be harvested using an open or endoscopic technique. In the open technique, the initial incision is made along the course of the vein on the medial aspect of the lower extremity. The vein is harvested with meticulous attention directed towards minimizing manipulation of the vein itself. The incision may be continuous or bridged in an attempt to decrease the size of the incision, but multiple bridged incisions may have the potential risk of increased conduit manipulation during harvest. Endoscopic harvest is performed by making a small incision just above and medial to the knee where the endoscope is inserted. Side branches are cauterized under endoscopic visualization using bipolar electrocautery until dissection is carried proximally until the required length of vein is mobilized. A proximal counterincision is then made to extract the venous conduit which is prepared in the standard fashion.

The radial artery is another frequently used conduit. After confirmation of ulnar collateral flow to the hand by the clinical Allen's test or a duplex ultrasound study, an incision is made from a point just proximal to the radial styloid process ending just medial and distal to the biceps tendon on the nondominant hand. With lateral retraction of the brachioradialis muscle, the radial artery is dissected sharply with care to avoid injury to the cutaneous nerves in this area and minimize manipulation of the artery itself. This artery can also be harvested using an endoscopic technique.

Many studies have looked at the patency rates of the radial artery graft in comparison to the saphenous vein graft. Although some studies have resulted in equivocal data, general consensus favors the use of radial arterial grafts over vein grafts with 5 year patency rates of 98% and 86%, respectively.[30,31]

From a historical perspective, the anterior circulation (left main or left anterior descending artery) is generally bypassed using the internal thoracic artery and the lateral (circumflex artery) or inferior (right coronary artery) territories are bypassed using a saphenous vein or radial artery graft. These conduits may be combined to form a composite T- or Y-graft, or sewn to multiple targets as sequential grafts. Since patency is best with arterial grafts, recent data havesuggested that the best long term results are achieved with multiple or all-arterial revascularization, particularly in patients >70 years of age.[32,33] Other conduits such as the gastroepiploic arteries, lesser saphenous veins, and cephalic veins have been described, but are not widely used and will not be discussed here.

Conventional Coronary Artery Bypass Grafting. Traditionally, CABGs are performed with the patient lying supine through a median sternotomy. After the patient is heparinized, cardiopulmonary bypass is initiated. The aorta is cross-clamped and cardioplegia is delivered. Once adequate myocardial protection has been achieved, coronary arteriotomies are made and distal anastomoses are performed using Prolene suture. (Fig. 21-2A & B) The proximal anastomoses are then performed directly onto the ascending aorta or onto preexisting grafts. It is important to note that significant coronary stenoses can cause differential distribution of cardioplegia and myocardial protection. It is therefore recommended to use retrograde cardioplegia or to revascularize the area with the most concern for ischemia first, and give cardioplegia down the completed graft. The left internal thoracic artery to left anterior descending (LAD) graft is frequently performed last to avoid kinking or disruption of this important bypass. Once all grafts are in place, the patient is weaned from bypass. During this time, the heart is monitored closely by direct visual inspection, and transesophageal echocardiography to detect abnormalities which may signify inadequate revascularization or technical problems with the bypasses. Upon confirmation of hemostasis, chest tubes are placed, the sternum is approximated with sternal wires, and the incisions are closed.

Coronary artery bypass grafting. **A.** Intraoperative photograph of the distal anastomoses performed between the left internal thoracic artery and left anterior descending coronary artery with a continuous 8-0 suture. **B.** Fifteen-year follow-up coronary angiogram of a left internal thoracic artery to left anterior descending coronary artery bypass demonstrating a widely patent free of any significant atherosclerotic stenosis. Anastomotic site is shown by the arrow.

Conventional CABG Results 2▶ Several early randomized trials have shown improved survival in patients who receive a CABG as opposed to medical therapy.[34-36] A propensity-matched study identified that CABG greatly benefited patients with LV dysfunction and left main stenosis >50% compared to medical management.[37] The Bypass Angioplasty Revascularization Investigation (BARI) trial demonstrated impressively superior results with CABG compared to PCI in terms of 5-year cardiac mortality (5.8% vs. 20.6%) in patients with diabetes in addition to CAD.[38] In a study examining the benefits of CABG over medical management for specific CAD distributions, survival was better in patients with proximal LAD stenoses, regardless of the number of diseased vessels.[39] In general, these studies show survival rates of over 90% at 5 years and approximately 75% at 10 years following CABG.

The mortality and morbidity of the procedure itself has changed over time. Data from the Society of Thoracic Surgeons (STS) database accounts for 1,497,254 patients who underwent a solitary CABG from 2000 to 2009. The mortality rate of CABGs have improved significantly from 2.4% in 2000 to 1.9% in 2009 despite the relatively constant predicted mortality rate of around 2.3%. In parallel with this, postoperative complication rates have decreased as: stroke (1.6%–1.2%), bleeding requiring reoperation (2.4%–2.2%), and deep sternal wound infection (0.59%–0.37%).[40]

There are marked improvements in the functional status of patients receiving CABG. Patients' 6-minute walk test distances were significantly increased 2 years postoperatively compared to their preoperative assessment.[41] After 10 years, 54% of patients were free of chest pain and 31% were free of dyspnea.[42]

Off-pump Coronary Artery Bypass. To avoid the adverse consequences of cardiopulmonary bypass, off-pump coronary artery bypass (OPCAB) was developed and has been adopted in some centers over the past two decades.

With OPCAB the heart is left beating. Performing anastomoses on the beating heart requires the use of myocardial stabilization devices which help portions of the epicardial surface to remain relatively immobile while the anastomoses are being performed. (Fig. 21-3) Carbon dioxide blower-misters are also used to clear blood from the operative site and improve visualization.

Apical suction devices are used to aid in exposure, particularly of the lateral and inferior vessels. Many creative maneuvers have been developed, including patient repositioning, opening the right pleural space to allow for cardiac displacement, and creation of a pericardial cradle to minimize compromise of cardiac function while exposing the various surfaces of the heart.

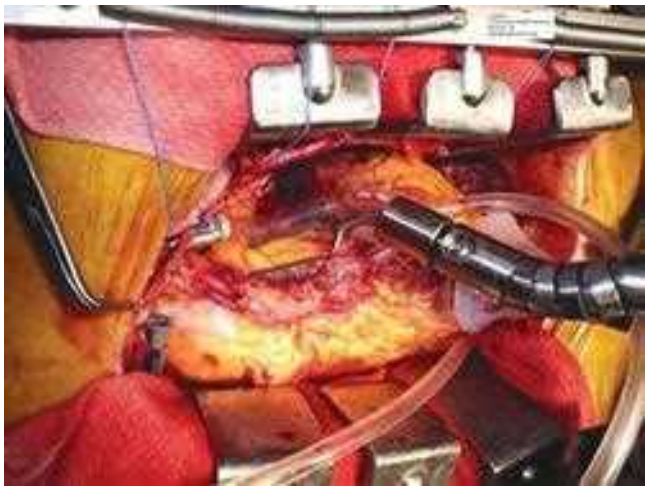

Figure 21-3. Epicardial stabilizing device used during off-pump coronary anastomosis. (Reproduced with permission from Estech.)

Temporary proximal occlusion of the coronary artery being grafted is necessary to provide a bloodless target. This occlusion causes temporary ischemia, and if not tolerated, coronary shunts can be employed.

OPCAB Results The superiority of OPCAB over on-pump CABG remains a controversy despite the large body of literature on this topic. A pooled analysis of two randomized trials, the Beating Heart Against Cardioplegic Arrest Studies (BHACAS 1 & 2), is one of several studies that have touted lower short term mortality rates with the off-pump compared to the on-pump technique.[43-45] Other studies, however, have demonstrated equivocal or contrary results.[46,47] Furthermore, the recent prospective and much larger ROOBY (Randomized On/Off Bypass) trial showed increased rates of adverse cardiac events with OPCAB compared to conventional CABG.[48] Despite the initial enthusiasm for the theoretical advantages of avoiding cardiopulmonary bypass, consistent benefits in clinical outcome have not been observed. There does seem to be a more or less uniform trend towards decreased perioperative blood product transfusions with OPCAB compared to on-pump CABG. In terms of other measures of early outcome, postoperative renal failure, stroke, and acute MI, the superiority of OPCAB has been unclear.[47,49,50]

3▶

There have been questions whether the technical challenge of sewing on a beating heart leads to increased rates of graft occlusion following an OPCAB. The higher cardiac morbidity in the ROOBY trial was associated with decreased 1-year angiographic patency rates.[48] However, studies with contrasting findings exist, quoting equivalent rates of graft patency for OPCAB usage.[51,52] The broad variety in results may be suggestive that other factors (e.g.,surgeon skill, technical difficulty, patient factors) may be dominating the outcome rather than the use or avoidance of cardiopulmonary bypass.[53] After almost two decades, OPCAB has not been widely adopted and remains less than 2% of all CABG procedures in the United States.

Minimally Invasive Direct Coronary Artery Bypass. As an extension of the off-pump coronary revascularization technique, minimally invasive direct coronary artery bypass (MIDCAB) has been described. MIDCAB is performed using a left anterior mini-thoracotomy through which mobilization of the left internal thoracic and direct in situ anastomosis to the left anterior descending artery (or its diagonal branches) is performed. This technique is primarily applicable to single-vessel disease, although reports of multivessel revascularizations do exist.

MIDCAB Results A review of 411 patients undergoing MIDCAB quotes an operative mortality >1%. In this study, all patients received revascularization of the LAD only, regardless of the number of diseased vessels. The 3-year mortality in patients with single-vessel disease following a MIDCAB was 3.1%, which was, not surprisingly, lower than those with multivessel disease (8.7%).[54]

There is an inherent selection bias in retrospective reviews comparing MIDCAB to OPCAB or conventional CABG as MIDCAB patients tend to have less extensive disease. Because of this, there have been multiple randomized controlled trials looking at the efficacy of MIDCAB compared to PCI. A meta-analysis of 5 randomized prospective trials comparing PCI to MIDCAB revascularization of isolated proximal left anterior descending artery demonstrated comparable results in terms of mortality, MI, and repeat revascularization requirement. It is worth noting however, that only one of these trials used drug-eluting stents (DES) in the PCI arm.[55] Hong et al showed similar efficacy with MIDCAB and DES PCI, and when this study was excluded from the meta-analysis, superiority of MIDCAB to PCI in regards to mortality, MI, and repeat revascularizations was seen.[56] Although no further prospective trials have been performed to compare DES PCI and MIDCAB in this patient cohort, a retrospective review of 186 patients has demonstrated significantly higher rates of angina recurrence and major adverse cardiac events in the DES PCI group.[57]

Total Endoscopic Coronary Artery Bypass. With the advent of robotic surgical technology allowing stereoscopic visualization and increased instrument dexterity, total endoscopic coronary artery bypass (TECAB) has become possible. In July of 2004, the da Vinci robotic surgical system received FDA approval for use in coronary anastomoses. Extracorporeal circulation with peripheral cannulation has been used in earlier reports, but the development of mechanical stabilizers has provided the ability to perform the internal thoracic artery harvest and coronary anastomosis off-pump with use of the robotic arms only. Several studies have looked at the feasibility of TECAB, and have shown acceptable results, but this procedure has not been adopted by most surgeons due to its steep learning curve, longer operative times, and lack of demonstrable clinical benefit.[58-60]

Hybrid Coronary Revascularization. With the continually increasing collaboration between cardiothoracic surgeons and interventional cardiologists, hybrid coronary revascularization (HCR) combining a minimally invasive surgical technique (MIDCAB or TECAB) with PCI has become a reality. This capitalizes on a major advantage of both treatments, utilizing the durable left internal thoracic artery to left anterior descending coronary artery bypass while treating other stenoses with PCI obviating the need for a large surgical incision or cardiopulmonary bypass. HCR is not without its downsides as there are some concerns with this approach since aggressive anti-platelet therapy is required with PCI and may increase the hemorrhagic complications of surgical revascularization. A small study comparing HCR to OPCAB showed comparable graft patency and decreased hospital stay with HCR without an increase in complication rates.[61] There are, however, some studies that have reported increased rates of requirement for re-intervention

in patients undergoing HCR, and this aspect requires further study.[62,63] These procedures have not gained widespread acceptance and their clinical value remains a matter of debate.

Transmyocardial Laser Revascularization. Despite the advancement of technology and revascularization strategies, patients with end-stage coronary artery disease may not be amenable to complete revascularization. Transmyocardial laser revascularization (TMR) relies on a CO_2 or holmium:yttrium-aluminum-garnet (Ho:YAG) laser to create multiple transmural channels (1mm in diameter) through the myocardium. The initial concept was that these channels would serve as conduits for direct perfusion from the ventricle, but evidence suggests that the resultant angiogenesis is primarily responsible for the improved perfusion. A meta-analysis of seven randomized controlled trials comparing TMR to medical therapy for chronic angina have shown higher rates of angina improvement in the TMR but was not able to show a difference in mortality between the two groups.[64]

TMR is also being used as an adjunct to CABG in the treatment of extensive CAD that is not amenable to surgical revascularization alone. In a study looking at the benefits of TMR in addition to CABG, Allen et al concluded that TMR decreases angina burden when added to CABG in patients who cannot be revascularized by CABG alone.[65] The current STS guidelines support the consideration of TMR in patients with ischemic myocardial territories that cannot be revascularized by PCI or CABG.[66] Because of equivocal late results at most centers, this therapeutic strategy has not gained widespread acceptance.

New Developments

Regenerative Medicine and Tissue Engineering. Provocative investigations are being performed on the level of signaling molecules, gene therapy, stem cells, and tissue engineering to regenerate or replace damaged tissue in patients with ischemic heart disease. Growth factors, such as FGF and VEGF, are receiving focused attention due their ability to induce ingrowth of new vessels. Although concerns regarding systemic administration of these pleiotropic signaling molecules exist, early placebo-controlled clinical trials have shown some promising results with administration of these agents.[67,68] Adenoviral transfection of diseased tissue with transgenes for these same growth factors has also been attempted with variable results.

Research in tissue engineering has been directed at creation of vascular conduits that are resistant to atherosclerosis. Stem cells have also been infused directly into the site of injury or in the generation of new tissue around a biodegradable scaffold. Despite their potential, these technologies are still in their infancy and significant progress will be needed before more widespread clinical adoption.

VALVULAR HEART DISEASE

General Principles

The number of patients referred for the surgical management of valvular heart disease has increased substantially in recent years, with the percentage of isolated valve procedures performed in the United States increasing from 14% of all cardiac operations in 1996, to 22% in 2006.[69] In 2012, valve procedures represented over 50% of the cases performed at our institution. Although congenital and inherited etiologies represent important clinical entities, age-associated and acquired conditions still represent the primary causes of valvular heart disease, and are the focus of this section.

The most common screening method for valvular heart disease is cardiac auscultation, with murmurs classified based primarily on their timing in the cardiac cycle, but also on their configuration, location and radiation, pitch, intensity and duration (Table 21-7).[70] Although some systolic murmurs are related to normal physiologic increases in blood flow, some may indicate cardiac disease, such as valvular aortic stenosis (AS), that are important to diagnose, even when asymptomatic. Diastolic and continuous murmurs, on the other hand, are frequently pathologic in nature. Dynamic cardiac auscultation provides further evidence as to the significance and origin of many murmurs (Table 21-8).[70]

Although auscultation may provide initial evidence to the existence of valvular disease, associated signs and symptoms may help narrow the diagnosis. Abnormalities in the splitting of the heart sounds and additional heart sounds should be noted, as should the presence of pulmonary rales. Peripheral pulses should be checked for abnormal intensity or timing, and the presence of a jugular venous wave should be documented. Additionally, symptoms of syncope, angina pectoris, heart failure, and peripheral thromboembolism are important and may help guide diagnosis and management.

Several imaging examinations are also available to aid in the diagnosis and classification of various valvular disorders. Electrocardiograms (EKGs) are widely available, and may provide information regarding ventricular hypertrophy, atrial enlargement, arrhythmias, conduction abnormalities, prior myocardial infarction, and evidence of active ischemia that would prompt further workup. Posteroanterior and lateral chest X-rays are also easy to obtain, and may yield information regarding cardiac chamber size, pulmonary blood flow, pulmonary and systemic venous pressure, and cardiac calcifications. The gold standard for the evaluation of valvular heart disease is transthoracic echocardiography (TTE).

Although helpful in the noninvasive evaluation of valve morphology and function, chamber size, wall thickness, ventricular function, pulmonary and hepatic vein flow, and pulmonary artery pressures, TTE may be unnecessary for some patients with asymptomatic cardiac murmurs. Current recommendations for evaluation via TTE are listed in Table 21-9.[70] Specialized examinations based on the specific findings of TTE examinations are discussed as appropriate in the following sections.

Regardless of the etiology, valvular heart disease can produce a myriad of hemodynamic derangements. Left untreated, valvular stenosis and insufficiency can produce significant pressure and volume overload on the affected cardiac chamber, respectively, with mixed disease consequently causing mixed pathology. Although the heart can initially compensate for alterations in cardiac physiology, cardiac function eventually deteriorates, leading to heart failure, decreasing patient functional status, ventricular dysfunction, and eventually death. In order to optimize long-term survival, surgery is recommended in various forms of valvular heart disease, and in an increasing number of elderly and high-risk patients.

Surgical Options

Although valve repair is increasingly indicated, especially in patients with aortic, mitral or tricuspid insufficiency, valve replacement may be necessary in certain patient populations.

Table 21-7

Classification of cardiac murmurs.

MURMUR	CONDITION	MECHANISM/ETIOLOGY
	SYSTOLIC MURMURS	
Holosystolic (pansystolic)	VSD	Flow between chambers that have widely different pressures throughout systole
Mid-systolic (systolic ejection)	High flow rate, MS, MR, TS, TI	Often crescendo-decrescendo in configuration; occur as blood is ejected into the left and right ventricular outflow tracts
Early systolic	Early TI, acute MR	Less common
Mid to late systolic	MR, MVP	Soft to moderate high-pitched murmurs at the LV apex; often due to apical tethering and malcoaptation of MV leaflets; an associated click indicates prolapse of the MV leaflets
	DIASTOLIC MURMURS	
Early high-pitched	AI, PR	Generally decrescendo in configuration; occur when the associated ventricular pressure drops sufficiently below that of the outflow tract
Mid-diastolic	MS, TS, PDA*, VSD*, ASD*	Due to a relative disproportion between valve orifice size and diastolic blood flow volume; seen in normal MV and TV with increased diastolic blood flow associated with these conditions*
Presystolic	MS, TS	Occur during the period of ventricular filling that follows atrial contraction (i.e.,only occur in sinus rhythm)
	CONTINUOUS MURMURS	
Systolic and diastolic	PDA	Uncommon, due to shunts that persist through the end of systole and the some or all of diastole

AI = aortic insufficiency; ASD = atrial septal defect; MR = mitral regurgitation; MS = mitral stenosis. MVP = mitral valve prolapse; PDA = patent ductus-sarteriosus; PR = pulmonic regurgitation; TI = tricuspid insufficiency; TS = tricuspid stenosis; VSD = ventricular septal defect.

Table 21-8

Hemodynamic alterations in cardiac murmur intensity.

INTERVENTION	EFFECT
Respiration	Right-sided murmurs increase with inspiration. Left-sided murmurs increase with expiration.
Valsalva maneuver	Most murmurs decrease in length and intensity. The murmur of HCM becomes louder, and the murmur of MVP becomes louder and longer.
Exercise	Benign flow murmurs and murmurs caused by stenotic valves become louder with isotonic and isometric exercise. The murmurs of MR, VSD, and AI also increase with isometric exercise.
Positional changes	Most murmurs decrease with standing; the murmur of HCM becomes louder, and the murmur of MVP becomes louder and longer. Brisk squatting and passive leg raising increases most murmurs; the murmurs of HCM and MVP diminish.
Postventricular premature beat or atrial fibrillation	Benign flow murmurs and stenosis at the semilunar valves increase in intensity following a ventricular premature beat or a long cycle length in atrial fibrillation. Systolic murmurs of atrioventricular valve regurgitation do not change.
Pharmacologic interventions	The initial hypotensive phase following inhalation of amyl nitrate decreases the murmurs of MR, VSD, and AI, and increases the murmur of AS. The later tachycardic phase following inhalation of amyl nitrate increases right-sided murmurs and the murmur of MS. The response in MVP is biphasic (softer then louder than control).
Transient arterial occlusion	Transient external compression of the upper extremity increases the murmurs of MR, VSD, and AI.

AI = aortic insufficiency; AS = aortic stenosis; HCM = hypertrophic cardiomyopathy; MR = mitral regurgitation; MS = mitral stenosis; MVP = mitral valve prolapse; VSD = ventricular septal defect.

Table 21-9

Data from ACC/AHA guidelines for echocardiographic examination in patients with cardiac murmurs.

CLINICAL SETTING	CLASS OF RECOMMENDATION	LEVEL OF EVIDENCE
• Echocardiography is recommended for asymptomatic patients with diastolic murmurs, continuous murmurs, holosystolic murmurs, late systolic murmurs, murmurs associated with ejection clicks, or murmurs that radiate to the neck or back.	I	C
• Echocardiography is recommended for patients with heart murmurs and symptoms or signs of heart failure, myocardial ischemia or infarction, syncope, thromboembolism, infective endocarditis, or other clinical evidence of structural heart disease.	I	C
• Echocardiography is recommended for asymptomatic patients who have grade 3 or louder midpeaking systolic murmurs.	I	C
• Echocardiography can be useful for the evaluation of asymptomatic patients with murmurs associated with other abnormal cardiac physical findings or murmurs associated with an abnormal electrocardiogram or chest x-ray.	IIa	C
• Echocardiography can be useful for patients whose symptoms and/or signs are likely noncardiac in origin but in whom a cardiac basis cannot be excluded by standard evaluation.	IIa	C
• Echocardiography is not recommended for patients who have a grade 2 or softer midsystolic murmur identified as innocent or functional by an experienced observer.	III – Harm	C

In some cases valve replacement can be accomplished with either mechanical or biological prostheses, and the choice of valve depends on many patient-specific factors such as age, health status, and desire for future pregnancy. Preexisting indications or contraindications to anticoagulation therapy also influence the choice of mechanical vs. tissue valve prosthesis.

4▶ Current options for mechanical valve replacement include tilting disc valves and bileaflet valves. Although mechanical valves are highly durable, they require permanent anticoagulation therapy to mitigate the otherwise high risk of valve thrombosis and thromboembolic sequelae.[71] Due to the concordant risk of hemorrhagic complications, patient characteristics such as debility, lifestyle, and contraindications to systemic anticoagulation therapy may preclude mechanical valve replacement. Moreover, young women who are planning future pregnancies cannot take warfarin due to its teratogenic potential. Conversely, patients with other indications for systemic anticoagulation, such as other risk factors for thromboembolism (i.e., atrial fibrillation), or the existence of a mechanical prosthetic valve already in place in another position, may benefit from mechanical valve replacement. Additionally, patients with renal failure, on hemodialysis, or with hypercalcemia experience accelerated degeneration of bioprosthetic valves, and are thus, recommended to receive mechanical prostheses.[72] In general, mechanical valve replacement is preferred in patients with expected long life spans who are acceptable candidates for anticoagulation therapy, in order to minimize reoperation and bleeding risks.

The potential to avoid the hazards of serious bleeding complications spurred the development of valve prostheses using biological materials, which obviate the need for systemic anticoagulation therapy. As tissue valves are naturally less thrombogenic, the attendant yearly risks of both thromboembolic and anticoagulation-related complications are considerably less than with mechanical valves.[73] Consequently, tissue valve replacement is generally recommended for patients averse to systemic anticoagulation therapy, with potential concerns regarding compliance or follow-up while taking anticoagulant medications, and in the case of reoperation for a thrombosed mechanical valve. However, biological valves are more prone to degeneration, especially when implanted in the mitral position, in younger patients, and in patients in renal failure, on hemodialysis, or with hypercalcemia.[73] Improved manufacturing methods have made currently available tissue valves more durable than previous versions, and valve replacement with a biological prosthesis is generally preferred in patients without other indications for anticoagulation therapy, who are >60 years of age for the aortic position, and >70 years of age for the mitral position.

Mechanical Valves. The first bileaflet valve was introduced in 1977. Bileaflet valves are comprised of two semicircular leaflets which open and close, creating one central and two peripheral orifices (Fig. 21-4). Bileaflet mechanical valves have demonstrated excellent flow characteristics, low risks of late valve-related complications, including valve failure, and are currently the most commonly implanted type of mechanical valve prosthesis in the world.[72]

Although mechanical valves necessitate systemic anticoagulation, careful monitoring of the International Normalized Ratio (INR) reduces the risk of thromboembolic events and hemorrhagic complications, and improves overall survival.[74] Patients undergoing mechanical aortic valve replacement generally have a target INR of 2 to 3 times normal. Patients undergoing mechanical mitral valve replacement frequently have increased left atrial size, concomitant atrial fibrillation, and are at higher risk for thromboembolism that those undergoing mechanical aortic valve replacement, and are thus recommended to have a target INR 2.5 to 3.5 times normal. When managed appropriately, the yearly thromboembolic and bleeding risks in these patients are 1% to 2%, and 0.5% to 2%, respectively.

Tissue Valves. A xenograft valve is one implanted from another species, such as porcine xenograft valves, or manufactured from tissue such as bovine pericardium. A variety of

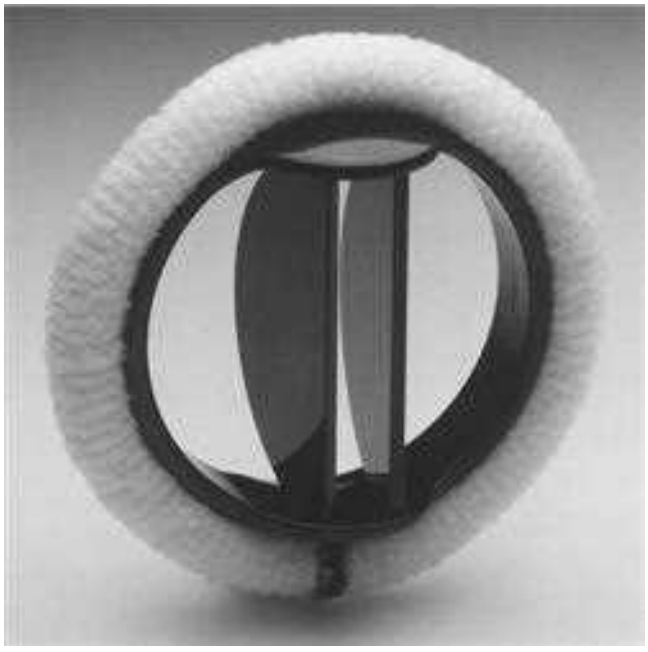

Figure 21-4. St. Jude bileaflet mechanical valve. (Photo reproduced with permission of St. Jude Medical, Inc., St. Paul, MN. All rights reserved.)

xenograft tissue valves exist, and are primarily differentiated by the presence or absence of a mounting stent. Stented valves are the most commonly implanted, and the most popular valve in the United States is a stented bovine pericardial valve.

The more traditional stented valves are attached to a sewing ring, which decreases the technical complexity of valve replacement compared with stentless valves (Fig. 21-5). The chief disadvantage of stented tissue valves is a smaller effective orifice area, which increases the transvalvular gradient. This effect is most pronounced in patients with small prosthetic valve areas, specifically <0.85cm^2 valve area per square meter body surface area, and may affect symptomatic improvement and the hemodynamic response to exercise following surgery.[75]

Stentless porcine xenograft valves were developed in order to minimize the limitations in flow characteristics seen in patients with small prosthetic valve areas, and have demonstrated an increase in effective valve area of approximately 10% over stented xenografts of equivalent size.[72] They can result in improved hemodynamics, both at rest and with exercise.[76] The absence of a stent and sewing ring both increases the technical complexity of valve replacement, and takes advantage of the biologic mobility of the aortic valve apparatus. Though results with stentless valves seem promising, long-term durability remains to be shown, and they have not been widely adopted due to the technical complexity associated with implantation.

Homografts. Homograft valves from human cadavers, also known as *allografts*, have been used for aortic valve replacement since the technique was originally described over 50 years ago.[77] Since that time, homografts have typically been used for aortic and pulmonary valve replacements, and have been successfully harvested from brain dead organ donors and the explanted hearts of heart transplant patients. Following harvest, these valves are sterilized using an antibiotic solution, and subsequently stored in fixative or cryopreserved.

Like other types of tissue valves, the risk of thromboembolic complications with homograft valves is low, and systemic anticoagulation therapy is not required. Additionally, the structure of homograft valves is naturally low-profile, allowing for larger effective valve orifices and lower postoperative transvalvular gradients compared with stented xenograft valves. Additionally, they have been shown to have some advantages in patients with endocarditis.[78]

The major shortcoming of homograft valves is their uncertain long-term durability in the face of significant tissue degeneration. Within one year of implantation, these valves undergo substantial loss of cellular components and subsequent

Figure 21-5. Edwards' Magna Ease stented porcine bioprosthesis. (Image reproduced with permission of Edwards Lifesciences, LLC, Irvine, CA.)

structural compromise, which may ultimately lead to valve failure.[79] Although enhanced preservation techniques significantly improve cellular viability, which approach the 15-year viability of xenograft valves, the availability of these techniques has limited the use of homograft tissue valves.

Autografts. In 1967, Donald Ross described a procedure in which the diseased aortic valve is replaced using the patient's native pulmonary valve as an autograft, which is in turn replaced with a homograft in the pulmonic position.[80] The procedure results in minimal transvalvular gradients, and favorable left ventricular mechanics, both at rest and during exercise. Known as the *Ross procedure*, this operation is particularly beneficial in children, as the pulmonary trunk grows with the child and long-term anticoagulation is not required.[81]

The late results of the Ross procedure are discussed later in this chapter. In addition to potential concerns with durability, performance of the Ross procedure has also been limited by its technical complexity, and the increased surgical risk associated with double valve replacement.

Valve Repair. Valve repair offers several advantages over valve replacement, due in large part to the preservation of the patient's native valve and subvalvular apparatus. In the case of mitral valve (MV) surgery, preservation of the mitral apparatus has been shown to lead to better postoperative left ventricular function and survival.[82,83] Additionally, as there is no implanted prosthesis, the patient avoids the risks of chronic anticoagulation, infection, thromboembolic complications, and prosthetic valve failure after surgery.

In the case of MV repair, freedom from reoperation and valve-related complications has been excellent in certain patient populations, even at 20-year follow-up.[84] It has also been demonstrated that patients undergoing MV surgery with moderate functional tricuspid regurgitation (TR) do not experience increased perioperative complication rates when a concomitant tricuspid valve (TV) repair is performed.[85] Midterm results in this group are encouraging, with greater than 98% freedom from reoperation reported by some groups at 5 years, suggesting further indications for valve repair.

Despite its advantages for the patient, valve repair is generally more technically demanding than valve replacement, and may occasionally fail. Both the suitability of the patient for valve repair and the skill and expertise of the surgeon performing the operation are important when considering valve repair in the individual patient.

MITRAL VALVE DISEASE

Mitral Stenosis

Etiology. Acquired mitral stenosis (MS) is most often caused by rheumatic fever, with approximately 60% of patients with pure MS presenting with a positive clinical history of rheumatic heart disease.[70] Rarely, other conditions can cause obstruction to filling of the left ventricle (LV), mimicking MS. Acquired causes of MV obstruction include left atrial myxoma, ball valve thrombus, mucopolysaccharidosis, previous chest radiation, and severe annular calcification.

Pathology. Although rheumatic heart disease is associated with a transmural pancarditis, pathological fibrosis of the valves results primarily from the endocarditic process. The damage caused by endocardial inflammation and fibrosis is progressive, causing commissural fusion, subvalvular shortening of the chordae tendineae, and calcification of the valve and subvalvular apparatus.[86] The resulting stenotic MV has a funnel-shaped apparatus, with a significantly narrowed orifice obliterated by interchordal and commissural fusion (Fig. 21-6). The degree of mitral stenosis should be determined preoperatively, as these pathological features may help determine the timing and type of intervention to perform.[70]

Figure 21-6. Mitral stenosis. The thickened, fused leaflets of the diseased mitral valve are viewed through a left atriotomy. (Image courtesy of the Centers for Disease Control and Prevention, Edwin P. Ewing, Jr.)

Pathophysiology. As the normal MV area of 4.0 to 5.0 cm^2 is reduced by the rheumatic process, blood can flow from the left atrium to the left ventricle only if it is propelled by an ever-increasing pressure gradient. The diastolic transmitral gradient, which is a function of the square of the transvalvular flow rate and the diastolic filling period, is a fundamental expression of the severity of MS. When the valve area is reduced to <2.5 cm^2, patients may begin to experience symptoms when the transmitral gradient is exacerbated by conditions that either increase transmitral flow or decrease diastolic filling time, such as exercise, emotional stress, infection, pregnancy, or atrial fibrillation with a rapid ventricular response.[87] Symptoms may begin to occur at rest with the onset of moderate stenosis, defined as a cross-sectional area of 1.0 to 1.5 cm^2, and any physical exertion is typically limited by the time the MV area is <0.8 to 1.0 cm^2 (Table 21-10).[70]

The progression of symptoms is due to the evolution of pathophysiological processes, beginning with an elevation in left atrial pressure. The increased left atrial pressure is subsequently transmitted to the pulmonary venous system, causing pulmonary edema as the hydrostatic pressure in the vessels exceeds the plasma oncotic pressure. Decreased pulmonary venous compliance exacerbates the pulmonary venous hypertension, though a concomitant decrease in microvascular permeability may preclude pulmonary edema in the chronic setting.[88] Patients may also develop pulmonary arterial hypertension, owing to vasoconstriction, intimal hyperplasia, and medial hypertrophy of the pulmonary arterioles in response to the increased pulmonary venous pressure. The secondary obstruction to flow caused by reactive pulmonary arterial hypertension may serve to protect against pulmonary edema, but also exacerbates the intractable decrease in cardiac output that develops as stenosis worsens.[89]

Throughout the process, the left atrium becomes dilated and hypertrophied due to increased work in filling the ventricle

Table 21-10

Data from ACC/AHA guidelines for the classification of the severity of mitral valve disease in adults

MITRAL STENOSIS			
INDICATOR	MILD	MODERATE	SEVERE
Mean gradient (mm Hg)*	<5	5–10	>10
Pulmonary artery systolic pressure (mm Hg)	<30	30–50	>50
Valve area (cm^2)	>1.5	1.0–1.5	<1.0
MITRAL REGURGITATION			
QUALITATIVE	MILD	MODERATE	SEVERE
Angiographic grade	1+	2+	3+
Color Doppler jet area	Small, central jet (<4 cm^2 or <20% left atrial area)	More than mild criteria, but no severe criteria present	Vena contracta width >0.7 cm with large central jet (area >40% of left atrial area) or with a wall-impinging jet of any size, swirling in left atrium
Doppler vena contracta width (cm)	<0.3	0.3–0.69	≥0.7
QUANTITATIVE (CATH OR ECHO)			
Regurgitant volume (ml per beat)	<30	30–59	≥60
Regurgitant fraction (%)	<30	30–49	≥50
Regurgitant orifice area (cm^2)	0.2	0.2–0.39	≥0.4
ADDITIONAL ESSENTIAL CRITERIA			
Left atrial size			Enlarged
Left ventricular size			Enlarged

*Valve gradients are flow dependent and when used as estimates of severity of valve stenosis should be assessed with knowledge of cardiac output or forward flow across the valve.

against a fixed obstruction. Atrial fibrillation may develop, exacerbating the patient's symptoms and increasing the risk of atrial thrombus and subsequent embolization. Left ventricular structure and function are typically preserved, however, owing to the protective effect of the stenotic valve.

Clinical Manifestations. The sudden opening of the thickened, nonpliable valve with left atrial contraction produces an opening snap, followed by a diastolic rumble caused by rapid entry of blood into the left ventricle. When diastole is complete, the MV subsequently closes very rapidly, causing an increased first heart sound. The murmur, classically known as the *auscultatory triad*, is best heard at the apex. Associated mitral and tricuspid insufficiencies are heard as a pansystolic murmur radiating to the axilla, and a systolic murmur at the xiphoid process, respectively.

The first clinical signs of MS are those associated with pulmonary venous congestion, namely exertional dyspnea, decreased exercise capacity, orthopnea, and paroxysmal nocturnal dyspnea. Hemoptysis, and pulmonary edema may develop as the venous hypertension worsens. Advanced MS can also cause pulmonary arterial hypertension and subsequent right heart failure, manifested as jugular venous distention, hepatomegaly, ascites, and lower extremity edema.[1]

As mentioned previously, atrial fibrillation may develop as left atrial pathology worsens, causing atrial stasis and subsequent thromboembolism. Patients with MS may initially present with signs of arterial embolization, even rarely with angina from coronary occlusion.[1]

Diagnostic Studies. All patients with a clinical history and physical exam suggestive of MS should undergo EKG and chest X-ray. Abnormalities in the EKG may include atrial fibrillation, left atrial enlargement, or right-axis deviation. Chest X-ray findings may include enlargement of the left atrium and pulmonary artery, creating a double contour behind the right atrial shadow, and obliterating the normal concavity between the aorta and left ventricle. Findings consistent with pulmonary congestion may also be present.[1]

The diagnostic tool of choice is TTE, which not only confirms the diagnosis of MS, but also rules out other causes of stenosis and other concomitant myocardial or valvular heart disease.[90] Two-dimensional TTE can be used to calculate the MV orifice area and to determine the morphology of the MV apparatus, including leaflet mobility and flexibility, leaflet thickness and calcification, subvalvular fusion, and the appearance of the commissures. Doppler TTE can also be used in combination with various equations to estimate the hemodynamic severity of MS in terms of the mean transmitral gradient, the MV area, and the pulmonary artery systolic pressure.

In most cases further examinations are not necessary. A preoperative TEE is usually unnecessary, unless there is a need to rule out left atrial appendage thrombus, the patient is being considered for percutaneous mitral balloon valvotomy, or the preoperative TTE is insufficient for diagnosis. Exercise TTE is indicated when resting TTE parameters are discordant with symptom severity.[91] Routine cardiac angiography should be performed prior to valve surgery in patients with evidence of

ischemia, decreased LV systolic function, a history of coronary artery disease or coronary risk factors, including postmenopausal status and age ≥35 in men and premenopausal women.[70]

Indications for Operation. Depending on the severity and the morphology of the diseased MV (Table 21-10), balloon valvuloplasty, surgical commissurotomy or repair, or MV replacement may be indicated for the treatment of MS (Table 21-11).[70]

Mitral Regurgitation

Etiology. The most important cause of MR in the United States is myxomatous degenerative disease of the MV, which occurs in approximately 2.4% of the population.[1] Other important causes of MR include rheumatic heart disease, infective endocarditis, ischemic heart disease, and dilated cardiomyopathy. Less frequently, MR can be caused by collagen vascular diseases, trauma, previous chest radiation, the hypereosinophilic syndrome, carcinoid disease, and exposure to certain drugs.[70]

Pathology. The MV apparatus consists of the mitral leaflets, chordae tendineae, papillary muscles, and mitral annulus, and abnormalities in any one of these components has the potential to cause MR.[92] The system for classifying MR proposed by Carpentier focuses on the functional anatomic and physiologic characteristics of the MV pathology, and proposes three basic types of diseased valves based on the motion of the free edge of the leaflet relative to the plane of the mitral annulus.[93]

In Type I MR, valvular insufficiency occurs secondary to annular dilatation or leaflet perforation, and normal leaflet motion is maintained. Type II MR is seen in patients with mitral valve prolapse, and is due to prolapse of often thickened excessive leaflet tissue that gives the valve a "billowing" appearance, frequently in addition to ruptured or elongated chordae tendineae causing increased leaflet motion. Type III insufficiency, as seen in patients with rheumatic and ischemic heart disease, occurs from restricted leaflet motion, either during systole and diastole (Type IIIA) or during systole alone (Type IIIB).

Pathophysiology. The basic pathophysiologic abnormality of MR is the retrograde flow of a portion of the LV stroke volume into the left atrium during systole due to an incompetent MV or dilated MV annulus.

Acute severe MR can result from ruptured chordae tendineae, a ruptured papillary muscle, or infective endocarditis, and causes a sudden volume overload on both the left atrium and ventricle.[70] Although an acute increase in preload provides a modest increase in overall stroke volume, the left atrium and ventricle are unable to fully accommodate the regurgitant volume or maintain forward stroke volume in the acute setting due to a lack of remodeling.

Chronic MR generally has a more indolent course, with increasing volume overload of the left atrium and ventricle as the effective valve orifice size becomes larger. The resulting increase in left atrial and ventricular volume initially allows for an increase in the total stroke volume by Starling's law and accommodation of the regurgitant volume, thus maintaining forward cardiac output and alleviating pulmonary congestion during the compensatory phase of chronic MR.[94] However, as the left atrium becomes more dilated, the development of AF becomes more likely, disrupting atrioventricular synchrony and predisposing to thrombus formation. Additionally, chronic volume overload may lead to LV contractile dysfunction, resulting in impaired ejection and end-systolic volume increases. LV dilatation and filling pressure may also worsen throughout the progression of MR, reducing cardiac output and causing congestion of the pulmonary vasculature. These changes herald LV decompensation and heart failure, and often indicate significant irreversible injury to the ventricular myocardium.

Clinical Manifestations. In cases of acute severe MR, patients are often very symptomatic and present with pulmonary congestion and reduced forward stroke volume. In very severe cases, patients may present with cardiogenic shock.[1] Because the LV has not remodeled in the acute setting, a hyperdynamic apical impulse may not be present in the precordium. The typical systolic murmur of MR may be holosystolic or absent, with a third heart sound and/or diastolic flow murmur being the only auscultatory findings.

In cases of chronic MR, patients may remain asymptomatic for long periods of time due to the compensatory mechanisms of the remodeled LV. However, once the LV begins to fail, patients become increasingly symptomatic from exertional dyspnea, decreased exercise capacity, orthopnea, and eventually pulmonary hypertension and right heart failure.[1] Physical examination may demonstrate displacement of the LV apical impulse due to cardiac enlargement from chronic volume overload, and a third heart sound or early diastolic flow rumble. The characteristic auscultatory findings also include an apical systolic murmur which is variably transmitted to the axilla or the left sternal border, depending on the location of the pathology. As mentioned previously, patients may present with AF due to dilatation of the left atrium. Findings consistent with pulmonary hypertension frequently indicate late-stage disease.

Diagnostic Studies. In the setting of acute heart failure, TTE should be performed and may demonstrate the anatomical location and severity of the MV pathology. However, TTE may underestimate lesion severity due to inadequate views of the color flow jet. In this case, severe MR should be suspected if hyperdynamic systolic function of the LV is visualized, and TEE may be used to confirm the diagnosis and direct repair strategies. [95] In the hemodynamically stable patient, coronary angiography should be performed preoperatively in the majority of patients so that myocardial revascularization may be performed in combination with MV surgery if necessary.[70]

In cases of chronic MR, EKG and chest X-ray are performed to assess rhythm status and the degree of pulmonary vascular congestion.[70] An initial two-dimensional and Doppler TTE should be performed for a baseline estimation of LV and left atrial size, LV systolic function, pulmonary artery pressure, MV morphology, and MR severity.[96] A central color flow jet in the setting of a structurally normal MV on TTE suggests functional MR, which may be due to LV dilatation or tethering of the posterior leaflet in patients with coronary artery disease. In the setting of organic MR, which is suggested by the presence of an eccentric color flow jet and morphological abnormalities in the MV apparatus on TTE, the presence of calcium in the annulus or leaflets, the redundancy of the leaflets, and the anatomy of the MV pathology should be assessed. Follow-up TTE is indicated on an annual or semiannual basis in patients with asymptomatic moderate to severe MR in order to assess changes from baseline parameters and direct the timing of surgery. Any abrupt change in signs or symptoms in a patient with chronic MR is also an indication for TTE examination.[70]

Additional preoperative studies are variably indicated in certain patient populations. Preoperative TEE is indicated in patients with poor diagnostic windows on TTE in order to
